Granuloma annulare

Granuloma annulare (GA) is a relatively common idiopathic disorder of the dermis and subcutaneous tissue. It occurs in all races and at all ages, but much more frequently affects women (2:1). GA may exhibit the isomorphic response of Koebner, affect healed areas of herpes zoster, and may be restricted to sun-exposed areas. While most cases spontaneously resolve, leaving entirely normal skin, loss of elastic tissue may occur, leaving atrophic lesions resembling mid-dermal elastolysis or anetoderma. GA lesions will sometimes spontaneously resolve when biopsied. Long-term follow-up of at least 20 years in patients with GA reveals that lesions usually heal, and that the patients remain healthy and do not develop unusual diseases. Case reports of associations as described below demonstrate that GA can be a reactive condition associated with a variety of underlying disorders and medications. In most patients, however, it is a benign, self-limited (although not soon enough for the dermatologist or patient) condition affecting only the skin.

Many clinical morphologies of GA exist. Usually, patients exhibit primarily one clinical type during the course of their illness, except in the subcutaneous form, in which typical papular or localized GA may also occur.

Localized granuloma annulare

This form of GA tends to affect children and young to middle-aged adults. Usually only one or a few lesions are present at any one time. Localized GA usually appears on the lateral or dorsal surfaces of the fingers or hands, elbows, dorsal feet, and ankles (Figs 31-1 to 31-3). Rarely, the eyelid or even a Becker

nevus may be affected. Lesions are erythematous, fawn-colored or violaceous, thinly bordered plaques or papules, which slowly spread peripherally, at the same time undergoing central involution, so that roughly annular lesions are formed. The overlying skin usually remains completely normal. Lesions may coalesce and sometimes form scalloped patterns or firm plaques. The lesions never ulcerate and on resolving virtually always leave no residua. They develop slowly and often involute spontaneously. Although more than

Fig. 31-4 Granuloma annulare, macular lesion of the medial thigh.

50% of patients clear within 2 years, lesions will recur in 40%. Autoimmune thyroiditis may be present in women with localized GA.

Generalized granuloma annulare

This form of GA affects mostly women in the fifth and sixth decades, adolescents and children. The association of generalized GA with diabetes mellitus has been questioned. The eruption presents as a diffuse but symmetrical, papular or annular eruption of more than 10 lesions, and often hundreds. Lesions favor the nape of the neck, upper trunk, and proximal upper extremities, and rarely exceed 5 cm in diameter. The palms, soles, and eyelids may be affected. The face and genital area are usually spared. In some cases sun exposure seems to be a trigger (see section on actinic granuloma below). Some patients are completely asymptomatic, whereas others complain of severe pruritus. Spontaneous clearing usually occurs but at variable times. The average duration is 3–4 years but may be as short as 4 months or longer than a decade.

Patch-type or macular granuloma annulare

This form of GA is significantly more common in women, usually between 30 and 70 years of age. Flat or only slightly palpable erythematous or red-brown lesions occur (Fig. 31-4), especially on the upper medial thighs and in bathing-trunk distribution. Lesions may closely simulate cutaneous T-cell lymphoma or morphea. Individual lesions average at least several centimeters in diameter but may be much larger. On careful palpation, small papules can be felt in some cases and on stretching the skin the papules or small annular lesions can be seen. Such papules are the most fruitful sites for biopsies. Both well-formed necrobiotic granulomas and the interstitial pattern of GA may be seen on biopsy.

Subcutaneous granuloma annulare (deep granuloma annulare, pseudorheumatoid nodule)

Subcutaneous GA is most common in children, with boys affected twice as frequently as girls. Childhood cases appear at any age from 1 year to adolescence, with one congenital case reported. Lesions tend to occur on the lower legs, especially the dorsal foot, but may also occur on the distal upper extremity or scalp. Multiple lesions are usually present. There is often a history of trauma to the affected area preceding the appearance of a lesion. Typically, lesions are skin-colored, deep dermal or subcutaneous nodules, up to several centimeters in diameter (Fig. 31-5). Superficial papular lesions are present in about one-quarter of patients with subcutaneous GA. Lesions in general are asymptomatic and resolve over a few years. The

Fig. 31-5 Granuloma annulare, subcutaneous and dermal lesion.

major clinical problem occurs when the initial pathologic interpretation is rheumatoid nodule and an unnecessary extensive rheumatologic work-up is performed. An unusual variant is one that remains localized to the penis or scrotum, an atypical location for GA in general. Adult women without rheumatoid arthritis may develop similar lesions around the joints.

Perforating granuloma annulare

Perforating GA usually appears on the dorsal hands and presents as papules with a central keratotic core. This core represents transepidermal elimination of the degenerated material in the center of GA lesions and clinically can resemble a pustule.

Acute-onset painful acral granuloma annulare

This recently described clinical variant of GA does not resemble other forms of the disease. Female patients present with the sudden onset of painful lesions on the hands and feet, and a scattering of lesions at other sites. The lateral, dorsal, and marginal hands and, to less extent, the feet are affected. Palm and sole lesions are characteristic. Lesions are tender to palpation and, when present on the palms, are dusky and may vaguely resemble erythema multiforme. Patients may have associated arthralgias and diarrhea, and feel feverish, features of a “cytokine storm.” The erythrocyte sedimentation rate (ESR) may be elevated, even above 50 mm/hr. Lesions resolve over months, at times after having been treated with systemic corticosteroids or hydroxychloroquine. The authors have seen one such case associated with Hodgkin disease.

Granuloma annulare in human immunodeficiency (HIV) disease

GA may occur in persons with HIV infection at all stages of disease. Lesions are typically papular and generalized GA is more common (60%) than localized GA (40%). Photodistributed and perforating lesions may also occur. The histology is identical to GA in the normal host. The natural history of GA in HIV is unknown.

Granuloma annulare and malignant neoplasms

The occurrence of GA and a cancer in the same patient is rare, but has been reported many times. Most of these patients are between 35 and 75, older than the typical GA patient. Half the cases occur in lymphoma/leukemia patients and half in solid tumor patients. The diagnosis of the neoplasm usually precedes the diagnosis of GA, but may precede it. In some cases, lesions are described as “atypical” in that they may be painful (see above).

Other conditions associated with granuloma annulare

Since these reports are anecdotal, causality cannot be ascribed in every case. However, these cases do show trends that parallel our concept of the pathogenesis of GA. Numerous medications have been reported to cause GA. Many of these medications are immunomodulatory—interferon (IFN)- α , IFN- β , and tumor necrosis factor (TNF) inhibitors. GA may follow a bee sting, waxing in a patient with pseudofolliculitis, and injections at a medispa for mesotherapy. Two groups of infectious diseases have been described as having GA-like lesions either histologically or clinically: borreliosis and tuberculosis. Both Lyme disease in the USA and *Borrelia* infections in Europe have been described rarely as demonstrating interstitial granulomatous inflammation; clinically, however, at least in Europe, the lesions resemble morphea rather than GA. Despite laboratory evidence of infection, treatment of the patient with appropriate antibiotics may not lead to resolution of the skin lesions. A tuberculid can closely resemble disseminated GA, although histologically caseous necrosis may be seen in the center of the granulomas. Treatment for tuberculosis leads to resolution of the skin lesions. In the appropriate patient evaluation for tuberculosis and anti-tuberculous treatment may be indicated.

Granuloma annulare and eye disease

Anterior and chronic intermediate uveitis has been described in patients with localized GA. The uveitis can be unilateral or bilateral, may be mild and respond to topical therapy, or may be aggressive, resulting in visual impairment. The frequency of uveitis in patients with GA seems to be too low to recommend that all patients with GA be screened by an ophthalmologist. However, GA patients should be questioned about visual symptoms, including reduced visual acuity. If these are present, ophthalmologic evaluation would be appropriate.

Histology

Because there are many clinical patterns of GA, skin biopsies are often performed to confirm the diagnosis. In general, there are two histopathologic patterns that often coexist in the same patient. The classic pattern of GA is a palisading granuloma characterized by histiocytes and epithelioid cells surrounding a central zone of altered collagen. In well-developed lesions, there is mucin deposition within the foci of altered collagen. Fibrin and nuclear dust may also be present in the degenerated foci. Lesions are most typically located in the upper and mid-reticular dermis, but may involve the deep dermis or subcutaneous tissue. At the periphery of lesions a leukocytoclastic vasculitis may rarely be found. IgM and C3 in the blood vessels of the skin lesions are found in about half of patients.

The second pattern of GA is the interstitial pattern. Lesions may be entirely interstitial, or an interstitial pattern may be seen adjacent to well-formed palisaded lesions. A patchy dermal infiltrate of histiocytes and other mononuclear cells with occasional neutrophils is interspersed between collagen bundles. The patchy distribution within the dermis is best appreciated at scanning magnification. Interstitial mucin is often present in the affected areas, and is best demonstrated with a colloidal iron stain. Although these features are sufficient to confirm the diagnosis of GA, further sectioning may reveal typical palisaded granulomas. If the number of histiocytes in the infiltrate is small and lymphocytes predominate, the diagnosis of interstitial cutaneous T-cell lymphoma should be considered.

Treatment

Patients regularly report that a biopsy of the lesion will cause its involution. Because the lesions are often asymptomatic and

spontaneous involution occurs, no treatment is required in many mild cases. Numerous modalities have been reported to improve GA, suggesting that no one treatment is uniformly efficacious and the “treatment of choice.” It is best to develop a therapeutic ladder for both localized and generalized cases of GA. For localized cases, the intralesional injection of triamcinolone suspension is effective and is a reasonable initial treatment. Most cases relapse within 3–7 months. Superpotent topical steroids or topical calcineurin inhibitors, or imiquimod, may be effective in some patients, especially those with more macular lesions. Localized phototherapy in the form of pulsed dye laser, high-intensity UV therapy with a laser designed to treat psoriasis, PUVA, photodynamic therapy, or even fractional photothermolysis could be considered.

Generalized cases represent a major therapeutic challenge. Although systemic steroids may be very effective, the high doses required and the usual immediate relapse as the steroids are tapered make this approach untenable in most situations. In addition, because diabetes may be present, systemic steroids may complicate the management of the diabetes. Many systemic agents have been reported as effective, but few have been tested in large numbers of cases or in blinded or controlled fashion. For any treatment, 3–6 months of therapy appear to be necessary for efficacy or failure to be demonstrated. With all treatments, the GA may clear, only to recur when the treatment is stopped. Antibiotics such as doxycycline; the combination of rifampin, ofloxacin, and minocycline, once monthly; pentoxifylline, 400 mg three times daily; or high-dose nicotinamide, potassium iodide, or dapsone, 100 mg per day, can be effective. Fumaric acid esters over 1–18 months have also shown efficacy. Oral retinoids, especially isotretinoin, can be considered at a dose of 0.5 mg/kg or slightly more. Hydroxychloroquine in very high doses (9 mg/kg initially) reportedly cleared all nine patients so treated. Phototherapy in the form of NB-UVB, PUVA, or UVA-1 can be effective in selected patients. With UVA-1 about half of treated patients have a “satisfactory response”; however, stopping treatment led to relapse. Photodynamic therapy will clear or “almost clear” some lesions and can be used for multiple lesions in a localized area. For patients with severe or disabling disease, TNF inhibitors can be considered. Etanercept, infliximab, and adalimumab have all been reported to be effective. It is of interest that these medications can also cause GA. Systemic agents, such as cyclosporine, IFN- γ , and hydroxyurea, have been reported to be effective in small series of patients. The potential toxicity of these medications limits their use to patients with significant GA.

Annular elastolytic giant cell granuloma (Meischer's) and actinic granuloma (O'Brien)

Annular elastolytic giant cell granuloma (AEGCG) and actinic granuloma are unified by their histopathologic appearance. Non-diabetes-associated necrobiosis lipoidica of the face has been included in this category. It is currently unclear whether they simply represent variants of GA occurring on sun-damaged skin or are distinct diseases.

AEGCG have been reported in two patterns. One is a single, asymptomatic, atrophic-appearing, yellow, thin plaque on the forehead (Meischer's Granuloma) (Fig. 31-6). Fine wrinkling and loss of elasticity characterize the skin within the ring. Clinically, this pattern resembles facial necrobiosis lipoidica more than GA. The second variant is of multiple extensor upper extremity and sometimes trunk lesions, and occurs more frequently in women and largely in sun-exposed areas. In these cases the lesions have an active erythematous border with central clearing. A papular variant has been described. While the vast majority of cases occur in adults, children and even an infant have been affected. Except for temporal arteritis as described below, most patients are otherwise well. However, AEGCG has been described in association with acute myelogenous leukemia (which resolved with remission and recurred with relapse of the leukemia) and pleomorphic cutaneous T-cell lymphoma. At times, as in GA, the lesions may heal with loss of elastic tissue and clinical features of skin laxity and anetoderma. The condition is chronic.

Actinic granuloma, as described by O'Brien, may represent the same disorder as AEGCG. It presents as papules and plaques on sun-exposed skin (Fig. 31-7). Lesions are frequently numerous and may coalesce to cover much of the exposed

Fig. 31-7 Granuloma annulare, generalized papular lesions localized to sun-exposed sites.

skin. A history of onset after significant sun exposure and the distribution on physical examination should lead to suspicion of the diagnosis. A few lesions may occur on sun-protected sites or spill over from affected areas to more photoprotected sites. Rarely, open comedones, scarring, and milia formation may be present clinically. This may be associated with transepidermal elimination of damaged connective tissue or loss of elastic tissue surrounding the follicular ostia, leading to a Favre-Racouchot-like appearance. This condition affects older adults (usually over age 50) and can be intensely pruritic. It is not associated with diabetes mellitus, but there are numerous reports of it occurring in patients with temporal arteritis. It is speculated that the vasculitis is also due to actinic injury to the connective tissue surrounding the temporal artery.

Histologically, all these conditions show a characteristic histology. The dermal infiltrate of macrophages is largely interstitial and well-formed palisaded granulomas are uncommon. Multinucleated giant cells, often quite large, are numerous. Mucin is scant or lacking. The macrophages characteristically contain fragments of actinically damaged elastic tissue (elastophagocytosis). When this typical histology is seen in concert with the classic clinical features noted above, it may be reasonable to make these specific diagnoses. These conditions cannot, however, be diagnosed on clinical or histologic grounds alone. Some cases with the clinical features of AEGCG or actinic granuloma will show a histology more characteristic of typical GA, suggesting that there is a spectrum of both clinical and histologic features in these patients.

Treatment of these conditions has been difficult. Cases with an active erythematous border tend to respond to systemic steroids, but relapse immediately when the steroids are tapered or discontinued. Tranilast, 300 mg/day, and chloroquine, 250 mg/day, have been reported as effective. Insulin improved diabetic control and the actinic granuloma in one case. Other anecdotal treatments include oral retinoids, fumaric acid, PUVA, pentoxifylline, cyclosporine, and methotrexate.

Interstitial granulomatous drug reaction

Interstitial granulomatous drug reaction (IGDR) is an uncommon, and increasingly recognized, pattern of adverse reactions to medication. While it may occur within a few days of starting the medication, most patients with IGDR have been on the offending medication for months to years. A wide variety of medications have been implicated, including calcium channel-blockers (most common cause reported), lipid-lowering agents, angiotensin-converting enzyme (ACE) inhibitors, diuretics, nonsteroidal anti-inflammatory drugs (NSAIDs), antihistamines, anticonvulsants, antidepressants, allopurinol, thalidomide, lenalidomide, darifenacin, anakinra, ganciclovir, strontium ranelate, sennoside (a common over-the-counter laxative), Chinese herbs, and even soy. The TNF inhibitors have been implicated as causal in IGDR in many cases, mostly in patients being treated for rheumatoid arthritis. Since rheumatoid arthritis patients may develop similar lesions independent of medication exposure, it suggests that rheumatoid arthritis patients may be predisposed to developing this reaction pattern. In cases of IGDR from TNF inhibitors, stopping the medication led to resolution of the eruption over several months, strongly supporting the association.

Clinically, the lesions are erythematous annular plaques with an indurated border and sometimes a tendency to central clearing. Lesions favor the creases (groin, axillae, popliteal fossae), but may also affect the trunk, proximal extremities, palms, and soles. Lesions may be photodistributed, affecting the face and dorsal extensor forearm and hands. Pruritus is minimal or absent. Mucous membranes are spared. Histologically, there is a diffuse deep dermal infiltrate that is perivascular but has a prominent interstitial component. The inflammatory infiltrate is centered in the lower two-thirds of the dermis; it contains neutrophils, eosinophils, histiocytes, and multinucleated giant cells. Degenerated collagen bundles may be surrounded by histiocytes, neutrophils, and eosinophils, forming "Churg-Strauss" granulomas, and mucin is usually scant or absent. Necrobiotic granulomas are usually incomplete, but have at times been reported to resemble those seen in GA. Unique features that should suggest IGDR over GA include an interface component and "atypical" lymphocytes in the infiltrate. The histologic differential diagnosis includes interstitial granulomatous dermatitis associated with arthritis, palisaded neutrophilic granulomatous dermatitis, papular eruption of methotrexate, and interstitial GA. Lesions resolve over months once the offending ingested is stopped.

Granuloma multiforme (Leiker)

Granuloma multiforme is seen most commonly in central Africa, where it is a common disorder, and rarely elsewhere. It affects adults aged over 40 and is more common in females. Lesions are most frequently found on the upper trunk and arms, and in sun-exposed areas. It begins as small papules that evolve within a year into round or oval plaques up to 15 cm in diameter. The active edge of lesions may be elevated to as much as 4 mm in height and the center may be slightly depressed and hypopigmented. Pruritus can occur and coalescing lesions may form unusual polycyclic shapes. The course is chronic. It is, most importantly, separated from tuberculoid leprosy. Histologically, it resembles GA, but multinucleated giant cells are prominent. Giant cells typically contain phagocytosed connective tissue and elastic tissue is decreased in the areas affected by the granulomas. GM shares many features with AEGCG and actinic granuloma/GA of sun-exposed skin, and in fact may be considered identical to those disorders.

Kumari R, et al: Granuloma multiforme: a report from India. *Indian J Dermatol Venereol Leprol* 2009; 75:296.

Necrobiotic xanthogranuloma

Necrobiotic xanthogranuloma is an uncommon multisystem disease with prominent skin findings. The cause is unknown. Disease is gradually progressive, affecting men and women equally, and beginning on average at around age 50 (range 25–80 years or more). The most common site affected is the periorbital area (65–80% of cases). Multicentric involvement is typical. The characteristic skin lesions are yellow (xanthomatous) plaques and nodules. Periorbitally, they may be mistaken for xanthelasma, but they are deep, firm, and indurated, and may extend into the orbit. The trunk and proximal extremities may have orange-red plaques that have an active red border and an atrophic center with superficial telangiectasias (Fig. 31-8). These plaques may grow to 25 cm in diameter. The skin lesions ulcerate in 50% of cases, leading to atrophic scarring. Acral nodules may also occur, some localized solely to the subcutaneous tissue. Extracutaneous involvement most commonly affects the eyes. Patients may complain of burning, itching, or pain around or in the eyes. Diplopia and inflammation in various compartments of the eye can occur, including

Fig. 31-8 Necrobiotic xanthogranuloma.

conjunctivitis, keratitis, scleritis, uveitis, iritis, ectropion, or proptosis. Ulceration and scarring of the plaques and distortion of the eye may lead to visual occlusion. Blindness may result. Lymphadenopathy, hepatosplenomegaly, and mucosal, myocardial, and pulmonary lesions may occur. There is a monoclonal IgG (usually κ) paraproteinemia in 80% of cases, and rarely an IgA paraproteinemia (one patient had both). Thrombocytopenia, neutrophilia, neutropenia, and eosinophilia may be present. The bone marrow may show leukopenia, plasmacytosis (25–50% of patients), or frank myeloma (10–20% of patients). In some cases a myelodysplastic syndrome may be present or develop (chronic lymphocytic lymphoma, Hodgkin or non-Hodgkin lymphoma). The necrobiotic xanthogranuloma predates the development of the myeloma or myelodysplastic syndrome by an average of 2.5 years.

Histologically, there are extensive zones of degenerated collagen surrounded by palisaded macrophages. These macrophages are of various forms—foamy, Touton cells, epithelioid, and giant cells, sometimes with more than 50 nuclei. Atypical multinucleated giant cells with multiple nuclei clustered at one end of the cell (polarized nuclei) are seen in 80% or more of cases. The process extends into the fat, obliterating fat lobules. Cholesterol clefts and extracellular lipid deposits are prominent. Within this process is a perivascular and interstitial infiltrate of lymphocytes and plasma cells. Lymphoid follicles are present. In the skin, the lymphoid aggregates are polytypic. The histologic differential diagnosis includes necrobiosis lipoidica and other histiocytoses. Necrobiotic xanthogranuloma has more atypical and Touton giant cells, lymphoid nodules, and cholesterol clefts.

The treatment is usually directed at the paraprotein or underlying malignancy and consists of systemic corticosteroids, alkylating agents (including chlorambucil, cyclophosphamide, and melphalan), plasmapheresis, or local radiation therapy (for eye lesions). Anecdotally, high dose intravenous immunoglobulin (0.5 g/kg/d for 4 consecutive days 2 g/kg total) at 4 week intervals, IFN- α 2b, 3–6 MU three times a week, in combination with systemic corticosteroids, and pulse cyclophosphamide with dexamethasone both led to improvement. Simple excision is an option, but lesions may recur.

Sarcoidosis

Sarcoidosis is a systemic granulomatous disease that involves the skin and many of the internal organs with an acute or persistent course. In addition to the skin, which is involved in approximately 25% of cases, other sites of involvement are the lungs, mediastinal and peripheral lymph nodes, eyes, phalangeal bones, myocardium, central nervous system (CNS), kidneys, spleen, liver, and parotid glands.

Sarcoidosis occurs worldwide. In Europe it is most prevalent in Scandinavia, especially in Sweden, with a prevalence of 64 in 100 000. In the UK, the rate is 20 in 100 000, and in France and Germany about 10 in 100 000, with lower rates in Spain and Japan of 1.4 in 100 000. In the US the southeastern states and certain urban centers (New York City, Detroit, and Washington DC) show the highest prevalence. In the US there is a marked racial variation with a rate of 10–14 in 100 000 for white persons and 35–64 in 100 000 for African Americans. The highest annual incidence is in African American women between the ages of 30 and 39, who have an annual incidence of 107 in 100 000. The lifetime risk for the development of sarcoidosis is 0.85% for white US residents, and 2.4% for African Americans. The disease begins most frequently between the ages of 20 and 40, and is slightly more common in women. Children may also develop sarcoidosis. There are two distinct forms of pediatric sarcoidosis. Early-onset disease, usually before the age of 4, is unique and characterized by the triad of skin lesions, uveitis, and arthritis. It is due to a defined genetic deficiency. It may be confused with juvenile rheumatoid arthritis. Older children, aged 8–14, present similarly to adults, with lymphadenopathy and pulmonary disease.

Several genetic associations have been made with sarcoidosis, but the underlying cause still remains a mystery. *HLA-DQB1*0201* and *HLA-DRB1*0301* are strongly associated with acute disease and a good prognosis. The butyrophilin-like 2 (*BTNL2*) gene is associated with sarcoidosis, but the mechanism of this association is unknown. Mutations in the promoter region of TNF are associated with erythema nodosum in sarcoidosis in white Caucasians, and a variant in intron 1 of the lymphotoxin alpha (*LTA*) gene is associated with erythema nodosum in Caucasian female sarcoidosis patients.

Cutaneous involvement in sarcoidosis may be classified as specific, which reveals granulomas on biopsy, or nonspecific, which is mainly reactive, such as erythema nodosum. In about 20% of cases the skin lesions appear before the systemic disease, in 50% there is simultaneous appearance of the skin and systemic lesions, and in 30% the skin lesions appear up to 10 years after the systemic disease has occurred. This is often coincidental with the tapering of systemic steroids for pulmonary sarcoidosis. The cutaneous manifestations of sarcoidosis are quite varied and numerous morphologic lesion types have been described. The morphology of the lesions in sarcoidosis might include papules, nodules, plaques, subcutaneous nodules, scar sarcoidosis, erythroderma, and ulcerations. The lesions may be verrucous, ichthyosiform, hypomelanotic, psoriasisiform, or alopecic. They are usually multiple, firm, and

Fig. 31-9 Sarcoidosis, characteristic papules on the nares.

elastic when palpated. They extend to involve the entire thickness of the dermis. The overlying epidermis may be slightly thinned, discolored, telangiectatic, or scaly. The color is faint, showing dull tints of red, purple, brown, or yellow according to the stage of development. Usually the lesions are asymptomatic, but approximately 10-15% of patients itch. There is a racial difference in the frequency of cutaneous lesions in sarcoidosis. Among white patients erythema nodosum is as frequent as the specific cutaneous manifestations and both types of cutaneous involvement occur in about 10% of white patients with sarcoidosis. In black patients, erythema nodosum is much less common; however, specific cutaneous manifestations occur in 50% or more of patients. The skin lesions in general do not correlate with the extent or nature of systemic involvement or with prognosis. The exceptions are erythema nodosum, which is associated with a good prognosis, and subcutaneous sarcoidosis and lupus pernio. The morphologic types of sarcoidosis are discussed below, and when possible, the relationship to systemic sarcoidosis is discussed.

Erythema nodosum in sarcoidosis

Erythema nodosum is the most common nonspecific cutaneous finding in sarcoidosis. Sarcoidosis may first appear with fever, polyarthralgias, uveitis, bilateral hilar adenopathy, fatigue, and erythema nodosum. This combination, known as Löfgren syndrome, occurs frequently in Scandinavian white persons and is uncommon in American blacks. The typical red, warm, and tender subcutaneous nodules of the anterior shins are distinctive and are most frequently seen in young women. The face, upper back, and extensor surfaces of the upper extremities may less commonly be involved. There is a strikingly elevated ESR, frequently above 50 mm/hr. Erythema nodosum is associated with a good prognosis, with the sarcoidosis involuting within 2 years of onset in 80% of cases. Conversely, the absence of erythema nodosum is a risk factor for persistent disease activity. Sweet's syndrome may also rarely be seen in association with sarcoidosis as a non-specific finding.

Papular sarcoid

Papules are the most common morphology of cutaneous sarcoidosis and are usually less than 1 cm in diameter. Lesions may be localized or generalized, in which case small papules predominate (Fig. 31-9). This is also known as miliary sarcoid.

Fig. 31-10 Sarcoidosis, annular plaque.

The papules are especially numerous over the face, eyelids, neck, and shoulders. Plaques may occur by the expansion or coalescence of papules. In time the lesions involute to faint macules. Hyperkeratosis may rarely be prominent, giving the lesions a verrucous appearance. "Papular sarcoidosis of the knee" is distinctive, in that disease is often limited to this site. In this region the sarcoidal granulomas often contain foreign bodies. In Caucasians it often occurs in the context of Löfgren syndrome (see above) and has a good prognosis. Papular lesions along the alar rim in African Americans, in contrast, may be the first evidence of lupus pernio (see below) and portend a bad prognosis.

Annular sarcoidosis

Papular lesions may coalesce or be arranged in annular patterns, usually with a red-brown hue (Fig. 31-10). On palpation the lesions are indurated. Central clearing with hypopigmentation, atrophy, and scarring may occur. Lesions favor the head and neck, and are usually associated with chronic sarcoidosis. Alopecia may result in the center of the lesion. Annular plaques of sarcoidosis can preferentially develop in sun-exposed areas.

Hypopigmented sarcoidosis

Hypopigmentation may be the earliest sign of sarcoidosis and is usually diagnosed in darkly pigmented races. Lesions vary from a few millimeters to more than a centimeter in diameter and favor the extremities. Although they appear macular by visual inspection, on palpation a dermal or subcutaneous component is often palpable in the center of the lesion.

Lupus pernio

Lesions typically are brown to violaceous, smooth, shiny plaques on the head and neck, especially the nose (Fig. 31-11), cheeks, lips, forehead, and ears. They can be very disfiguring. Involvement of the nasal mucosa and underlying bone may occur and lead to nasal perforation and collapse of the nasal bridge. Upper aerodigestive tract involvement is also common. Ear, nose, and throat (ENT) evaluation is recommended. In three-quarters of cases of lupus pernio, chronic fibrotic respiratory tract involvement is found. In 43% of cases, lupus pernio is associated with granulomas in the bones (punched-out cysts), most commonly of the fingers. Chronic ocular lesions occur in 37% of cases. Sarcoid involving the sinus is

Fig. 31-11 Sarcoidosis, lupus pernio with rhinophymatous nasal changes.

associated with lupus pernio 50% of the time. Lupus pernio is typically seen in women in their fourth or fifth decade of life. The skin lesions rarely involute spontaneously. At times, lupus pernio may resemble rhinophyma. It is important to make the correct diagnosis, as ulceration of sarcoidal lesions may occur with laser treatment, even with pulsed dye laser.

Ulcerative sarcoidosis

Ulcerative sarcoidosis is very rare, affecting about 0.5% of patients with sarcoidosis. It affects primarily blacks, but it is also well recognized in Japanese. It is 2–3 times more common in women than men. In one-third of cases it is the presenting finding of sarcoidosis, except in Japan where it is commonly a late finding in patients with known sarcoidosis. The ulcerations may occur *de novo* or in sarcoidal plaques. Lesions favor the lower extremities, but most patients have lesions in more than one anatomic region. Trauma may be the inciting event. The clinical appearance may not be specific, but skin biopsies are diagnostic. Lupus pernio may also be present. Many patients have multisystem sarcoidosis, although uncommonly no other evidence of sarcoidosis is found. Biopsies may show necrosis in the center of sarcoidal granulomas. Methotrexate, which can be therapeutic in sarcoidosis, may also lead to ulceration in sarcoidosis patients.

Subcutaneous sarcoidosis

About 10% of patients with cutaneous sarcoidosis will have subcutaneous lesions. They may also have other types of specific lesion, along with subcutaneous lesions. Subcutaneous sarcoidosis is also known as Darier-Roussy sarcoidal and consists of a few to numerous 0.5–3 cm, deep-seated nodules on the trunk and extremities; only rarely do they appear on the face. The overlying epidermis may be normal (30%), erythematous (50%), or slightly violaceous (10%). The lesions are usually asymptomatic. Ninety percent of patients will have multiple lesions, and the upper extremity is most frequently affected (virtually 100% of patients). Lesions on the upper

extremity have a tendency to form indurated linear bands from the elbow to the hand on the cubital side of the forearm. The amount of subcutaneous involvement in the upper extremity may be so extensive as to simulate chronic cellulitis. A biopsy is usually required to confirm the diagnosis. About 90% of patients will have systemic involvement, usually bilateral hilar adenopathy, but the overall prognosis is good.

Plaques

These distinctive lesions are flat-surfaced, slightly elevated plaques that appear with greatest frequency on the cheeks, limbs, and trunk symmetrically. Superficial nodules may be superimposed and coalescence of plaques may lead to serpiginous lesions. Involvement of the scalp may lead to permanent alopecia. The finding of alopecia in an annular plaque with a raised border should raise the diagnostic consideration of sarcoidosis.

Erythrodermic sarcoidosis

Erythrodermic sarcoidosis is an extremely rare form of sarcoidosis. A diffuse infiltrative erythroderma of the skin usually begins as erythematous, scaling patches that merge to involve large portions of the body. A biopsy is confirmatory, but the diagnosis can be clinically suspected if small apple jelly papules are seen on diascopy throughout the erythroderma.

Ichthyosiform sarcoidosis

Ichthyosiform sarcoidosis resembles ichthyosis vulgaris or acquired ichthyosis, with fine scaling usually on the distal extremities (Fig. 31-12). It is virtually always seen in non-white persons, especially African Americans. Nearly all patients have or will develop systemic disease. In 75% of patients, the skin lesions follow or occur at the same time as the diagnosis of systemic sarcoidosis. Although the lesions have no palpable component, a biopsy will reveal dermal noncaseating granulomas.

Alopecia

Alopecia on the scalp due to sarcoidosis can have multiple morphologies. Plaques may extend into and involve the scalp, leading to scarring hair loss (Fig. 31-13). More rarely, macular lesions from one to several centimeters in diameter appear on the scalp and closely resemble alopecia areata. This form may be permanent or reversible. Diffuse alopecia, scaly plaques resembling seborrheic dermatitis, and cicatricial lesions resembling discoid lupus erythematosus or pseudopelade may also occur. A biopsy of all forms of alopecic sarcoidal will reveal dermal granulomas and sometimes loss of follicular structures. Scalp sarcoidosis is virtually always seen in African or African American women. In cases where sarcoidosis affects the scalp, causing alopecia, the patient virtually always has other cutaneous lesions and the vast majority of cases will demonstrate systemic involvement.

Morpheaform sarcoidosis

Very rarely, specific cutaneous lesions of sarcoidosis may be accompanied by substantial fibrosis and simulate morphea. Less than 10 cases have been described to date. Most typically, the lesions are localized and resemble linear morphea. Skin biopsy will demonstrate noncaseating granulomas. African American women are most commonly affected. This form of sarcoidosis responds favorably to antimalarial therapy.

Fig. 31-12 Sarcoidosis, ichthyosiform type; biopsy showed noncaseating granuloma, although there was no palpable dermal component to the lesions.

Sarcoidosis in scars (scar sarcoid)

Infiltration and elevation of tattoos and old flat scars are two variants of scar sarcoid. Previously flat scars become raised and may become erythematous or violaceous. These lesions may be confused with hypertrophic scars. Infiltration of tattoos may be the first manifestation of sarcoidosis and can be confused with a granulomatous hypersensitivity reaction to the tattoo pigment (Fig. 31-14). Cosmetic tattooing, as may be performed in a dermatology office, may result in sarcoidal granulomas in patients with pulmonary sarcoidosis. Hyaluronic acid injections can also be complicated by the development of sarcoidal lesions in patients with sarcoidosis. As noted below, patients with hepatitis C virus (HCV) infection receiving IFN therapy are at high risk for developing sarcoidosis and can develop disfiguring sarcoidal reactions following cosmetic filler injections. Similar granulomatous reactions may occur in the earlobe following ear piercing, and represent granulomatous dermatitis to metals introduced by the procedure or the earring. Titanium, nickel, cobalt, zinc, gold, and palladium can all be the allergen.

From 22 to 77% of biopsies from patients with cutaneous sarcoidosis will contain polarizable foreign material, suggesting that scar sarcoidosis is very common. The foreign material seems to be a nidus that favors the development of sarcoidal granulomas when sarcoidosis develops. Scar sarcoid may sometimes occur in patients with acute disease and erythema nodosum, especially if the lesions are small papules on the knees. It may also occur in patients with chronic sarcoidosis. The presence of polarizable material in a granulomatous

Fig. 31-13 Sarcoidosis, scarring alopecia of the scalp.

Fig. 31-14 Sarcoidosis, papules and plaques arising in a tattoo.

process does not confirm the diagnosis of “foreign body granuloma,” but rather should result in evaluation of the patient for evidence of systemic sarcoidosis. When foreign material is found, infection must be carefully excluded if no other features of sarcoidosis are found.

Mucosal sarcoidosis

The lesions in the mouth are characterized by pinhead-size papules that may be grouped and fused together to form a flat plaque. The hard palate, tongue, buccal mucosa, or posterior pharynx may be involved. They may simulate Fordyce spots. In lupus pernio the nasal mucosa is frequently involved. Rarely, in ulcerative sarcoidosis, the oral mucosa may be involved. Sarcoidosis may also infiltrate the gingiva, causing “strawberry gums” that simulate Wegener’s granulomatosis.

Systemic sarcoidosis

Sarcoidosis may involve virtually every internal organ and its presentations are protean. Many instances of sarcoidosis are asymptomatic and it is only when routine radiographs of the chest reveal some abnormality that sarcoidosis is suspected. Fever may be the only symptom of the disease or be accompanied by weight loss, fatigue, and malaise.

Intrathoracic lesions, including parenchymal lung lesions and hilar adenopathy, are the most common manifestation of

the disease, occurring in 90% of cases of sarcoidosis. Pulmonary changes are staged as follows:

Stage 0: normal

Stage I: bilateral hilar and/or paratracheal adenopathy

Stage II: adenopathy with pulmonary infiltrates

Stage III: pulmonary infiltrates only

Stage IV: pulmonary fibrosis.

Transbronchial lung biopsy and needle aspiration have a high yield in confirming the diagnosis of sarcoidosis, even in patients with only stage I changes on chest x-ray. Gallium-67 scanning is useful in the diagnosis of sarcoidosis since typical patterns of uptake are seen. The panda sign correlates with gallium uptake in the nasopharynx and lacrimal and parotid glands; the lambda sign correlates with uptake in the paratracheal lymph nodes. These characteristic findings, plus a skin biopsy demonstrating typical sarcoidal granulomas, can be used as presumptive evidence for sarcoidosis.

Lymphadenopathy, especially of the mediastinal and hilar nodes, and generalized adenopathy, or adenopathy confined to the cervical or axillary areas, may be an initial sign of sarcoidosis or may occur during the course of the disease.

Polyarthralgias may be seen with acute sarcoidosis or as a component of chronic disease. Chronic arthritis may occur (Fig. 31-15). Osseous involvement is often present in chronic disease. The most characteristic changes are found radiographically in the bones of the hands and feet, particularly in the phalanges. They consist of round, punched-out, lytic, cystic lesions. These are seen frequently in patients with lupus pernio. The bone lesions represent epithelioid granulomas.

Ocular involvement is present in 30–50% of patients, with granulomatous uveitis the most characteristic lesion. The lacrimal gland may be involved unilaterally or bilaterally by painless nodular swellings. Lesions of the iris are nodular and painless. There may also be lesions of the retina, choroid, sclera, and optic nerve. Ophthalmic disease is highly correlated with systemic involvement. All patients, even those who have no ocular symptoms, should be seen by an ophthalmologist. Sarcoidal involvement of the eye can progress to blind-

ness. Conjunctival biopsy is positive in about 50% of patients with sarcoidosis, making it an easy site to sample and confirm the diagnosis.

Parotid gland and lacrimal gland enlargement with uveitis and fever may occur in sarcoidosis; this is known as uveoparotid fever or Heerfordt syndrome, and usually lasts 2–6 months if not treated. Facial nerve palsy and CNS disease are frequently seen in this syndrome. Mikulicz syndrome is bilateral sarcoidosis of the parotid, submandibular, sublingual, and lacrimal glands.

Clinically apparent hepatic involvement occurs in about 20% of patients; however, a blind liver biopsy will reveal granulomas in 60% of cases. Hepatomegaly with elevation of serum alkaline phosphatase, biliary cirrhosis with hypercholesterolemia, and portal hypertension with esophageal varices are some of the manifestations. Liver biopsy showing hepatic granulomas is an excellent means of confirming the diagnosis of sarcoidosis.

Renal disease may be due to direct involvement with granulomas or secondary to hypercalcemia. Hypercalcemia is due to the macrophage in the granulomas having large amounts of 25-hydroxyvitamin D-1 α -hydroxylase, which converts 25-hydroxyvitamin D to the more active 1,25 dihydroxyvitamin D. Nephrolithiasis may result. Cardiac involvement occurs in 5% of cases, but in a higher percentage of autopsy cases.

Neurosarcoidosis occurs in 5–10% of patients. It can present in numerous ways, from focal cranial nerve involvement (most commonly facial nerve palsy) to aseptic meningitis, seizures, psychiatric changes, stroke, and space-occupying lesions. Neurosarcoidosis tends to be chronic and relapsing, with a higher mortality rate. Vision loss in sarcoidosis after heat exposure is called the Uhthoff phenomenon. Magnetic resonance imaging (MRI) with gadolinium is useful for detecting CNS lesions of sarcoidosis and following therapy. Treatment is recommended with corticosteroids and an immunosuppressive agent until all MRI-visible lesions are eradicated.

Measuring ACE levels in sarcoidosis patients has little utility. ACE levels may be elevated in all granulomatous diseases, including infectious granulomatous disorders. An elevated ACE level is suggestive of, but not diagnostic for granulomatous inflammation. A normal ACE level cannot be used to rule out sarcoidosis and an elevated level does not necessarily indicate the presence of multisystem involvement. The use of 18FDG positron emission tomography (PET) is more accurate in identifying extent of involvement and monitoring response to treatment.

Pediatric sarcoidosis

Childhood sarcoidosis is rare. The clinical features are very age-dependent. In children under 4 years, the triad of skin, joint, and eye involvement is characteristic, and often confused with juvenile rheumatoid arthritis. In older children, lung, lymph node, and eye involvement is typical. Calcium abnormalities are present in 30% of children with sarcoidosis. Older children develop specific sarcoidal skin lesions at the same rate as adults, about 30% of the time. One presentation resembles granulomatous peri-orificial dermatitis.

Blau syndrome is due to mutations in the *NOD2* gene and is associated with early-onset sarcoidosis (age <4 years). It is more common in white patients. Skin lesions are typically small papules and are the first clinical feature in more than half of patients, starting at a median age of 1 year. The skin lesions are often generalized and may be flat-topped, giving them a lichenoid appearance. They are red-brown to tan and can occur in clusters or linear arrays. The face may have confluent lesions. Infliximab can be beneficial in early-onset sarcoidosis/Blau syndrome.

Fig. 31-15 Sarcoidosis, fusiform swelling of the digits.

Histopathology

The histology of sarcoidosis in all affected tissues is identical. The characteristic finding is that of the “naked tubercle,” composed of collections of large, pale-staining, epithelioid histiocytes. There may be small foci of necrosis in the center of the granulomas, and multinucleate giant cells, sometimes with inclusions (asteroid bodies and Schaumann bodies), may be present. Although classically there are few lymphocytes around the granulomas, they may be numerous. The granulomas may be nodular, diffuse, or tubular along neurovascular structures. Perifollicular and other periadnexal involvement can be seen in sarcoidosis.

The histologic differential diagnosis is broad and the diagnosis of sarcoidosis cannot be definitely made histologically. Allergic granulomas caused by metals are histologically identical to sarcoidosis. Other foreign body granulomas (especially as a result of silica), granulomatous rosacea, granulomatous secondary syphilis, tuberculoid leprosy, atypical mycobacterial infections, and leishmaniasis may closely simulate sarcoidosis.

The diagnosis of sarcoidosis is established by the demonstration of involvement consistent with sarcoidosis in two different organ systems. This is usually done histologically, or by characteristic findings with radiological techniques (including gallium scans, PET scans, and MRI). If cutaneous sarcoidal granulomas are identified in a patient with no prior history of sarcoidosis, the first diagnostic test to be performed should be a chest radiograph. If this is abnormal, further pulmonary evaluation is indicated. Ophthalmologic evaluation and conjunctival biopsy may be useful. Since many patients with sarcoidosis may develop ocular involvement that may be asymptomatic, every patient should see an ophthalmologist. Blind biopsy of the minor salivary glands may demonstrate sarcoidal granulomas in about 50% of patients with systemic sarcoidosis. Otherwise, histologic evaluation of any involved tissue may be considered. The site for biopsy may be guided by PET scans, which, if characteristic, can be used to support the diagnosis.

Sarcoidosis in the setting of immunologic abnormalities

Numerous reports document sarcoidosis occurring in patients with various forms of spontaneous or iatrogenic immunological aberrations. Sarcoidosis may be associated with lymphoma, especially Hodgkin disease (“sarcoidosis-lymphoma syndrome”). B-cell lymphoma, chronic myeloid and lymphoid leukemia, and MALT lymphoma have all been described in patients with sarcoidosis. Sarcoidosis patients are about 40–60% more likely to develop malignancy, including solid tumors such as non-melanoma skin cancers (three-fold risk), renal cancer, and nonthyroid endocrine tumors. In addition, adenopathy in patients with lymphoma or solid tumors may demonstrate sarcoidal granulomas without tumor. This is important to know when a patient with a cancer develops an enlarged node, and makes sampling of the node important to avoid unnecessary therapy. Sézary syndrome with extensive cutaneous granulomas has been described.

Alteration of the immune system with medications can lead to the development of systemic sarcoidosis. These typically cause a constellation of pulmonary and cutaneous disease. Etanercept, adalimumab, and infliximab (the TNF inhibitors) have all been reported to trigger sarcoidosis. This is ironic, since they are also often therapeutic in sarcoidosis (analogous to the situation with TNF inhibitors and psoriasis). There are numerous reports documenting the appearance of sarcoidosis

in association with IFN- α therapy, usually for the treatment of HCV infection. HCV alone may also trigger sarcoidosis. Cutaneous lesions (60% of patients), pulmonary findings (75% of patients), or both, as well as other features of sarcoidosis, occur in 5% of patients treated with IFN- α for HCV. The addition of ribavirin may increase the risk. In more than 80% of cases the sarcoidosis resolves after the treatment is discontinued. Treatment of HIV infection with highly active antiretroviral therapy (HAART) has led to the appearance of sarcoidosis or tattoo granulomas, apparently by enhancing the number and function of helper T cells. Sarcoidosis is now well recognized as a feature of immune reconstitution syndrome (IRIS). Hematopoietic stem cell transplantation, both allogenic or autologous, has been associated with the appearance of pulmonary sarcoidosis. If the transplantation is performed for malignant disease, the presence of hilar adenopathy may be interpreted as recurrent or metastatic disease, and inappropriate treatment may be given. Other medications causing sarcoidosis include alemtuzumab (anti-CD52 monoclonal antibody for CTCL) and ipilimumab (anti CTLA4 monoclonal antibody for malignant melanoma).

Differential diagnosis

Granulomatous secondary syphilis may closely simulate sarcoidosis both clinically and histologically. Blau syndrome, an autosomal-dominant granulomatous disease, is similar to childhood sarcoidosis. It can be distinguished from sarcoidosis by the lack of pulmonary involvement. Granulomatous cutaneous T-cell lymphoma can usually be distinguished histologically and by the presence of pulmonary involvement in sarcoidosis.

Treatment

Numerous therapies have been reported as beneficial in cutaneous sarcoidosis, usually after anecdotal observation. There is virtually no information regarding what types of therapy are best for which of the various cutaneous manifestations. The cutaneous disease may spontaneously remit without treatment. Because most skin lesions are asymptomatic, the major indication for treatment is cosmetic.

Systemic corticosteroids are virtually always beneficial in cutaneous sarcoidosis. Unfortunately, the doses required to control cutaneous disease may be too high (usually in excess of 15 mg/day) to be ideal for long-term use. For limited skin disease, intralesional injection of 2.5–5.0 mg/mL of triamcinolone acetonide suspension is very effective. For thinner lesions, superpotent topical steroids, topical tacrolimus, and UVA1 phototherapy may be effective. A trial of minocycline or doxycycline, up to 100 mg twice a day, may be considered in patients with skin lesions in whom systemic disease does not require treatment. Maximum response is reported to occur at 3 months of therapy.

Local surgical procedures can be beneficial for some forms of sarcoidosis. Pulsed dye laser, used repeatedly, photodynamic therapy, and even CO₂ laser remodeling may be effective in the appropriate cases. In severe lupus pernio, nasal skin excision followed by flap reconstruction can lead to dramatic improvement.

Systemic corticosteroid therapy is indicated when there is acute systemic involvement with fever and weight loss, in active eye disease, in sarcoidal involvement of the myocardium, in active pulmonary disease with functional disability, in hypersplenism, in hypercalcemia, and in symptomatic CNS involvement.

Antimalarials, both chloroquine and hydroxychloroquine, have been used to treat extensive cutaneous sarcoidosis, in doses of 250 mg/day or 200–400 mg/day, respectively. About three-quarters of patients appear to respond partially or completely. In some cases the associated CNS disease or hypercalcemia also improves. These agents may also be used to reduce the dose of systemic steroids required.

Methotrexate, in doses of 15–25 mg/week, is also efficacious and seems to help patients with severe lupus pernio or ulcerative sarcoidosis who are otherwise very difficult to treat. Methotrexate-induced hepatitis occurs in 15% of patients with sarcoidosis treated with methotrexate. Leflunomide may be given in analogous fashion to methotrexate and may be used in patients with gastrointestinal intolerance for methotrexate. Response rates are about 75%. The retinoids, principally isotretinoin, have been reported as beneficial in some patients, usually at doses of 0.5–1.0 mg/kg. Response is only seen after 6 weeks or more. Thalidomide, 50–200 mg/day, has led to improvement of the skin lesions after several months. It should not be used to treat pregnant patients, however, because of possible teratogenic effects on the fetus. Venous thrombosis may complicate thalidomide therapy, especially if doses above 100 mg/day are used. While azathioprine and cyclophosphamide had been used for refractory disease, mycophenolate mofetil has shown efficacy in mucocutaneous disease and may be considered as an effective form of rescue and steroid-sparing therapy. The combination of thalidomide, an immunosuppressive agent, with an antimalarial may be effective when these agents fail individually. Such combination therapy in addition to anti-TNF agents may be necessary in severe sarcoidosis. TNF is an important cytokine in the formation of granulomas. Not surprisingly, TNF inhibitors, including infliximab, etanercept, and adalimumab, can be effective in refractory cutaneous and systemic sarcoidosis. Infliximab appears to be particularly beneficial in controlling severe lupus pernio.

Histiocytoses

These disorders are characterized by infiltrates which contain either Langerhans cells (the X-type histiocytoses) or infiltrates of non-Langerhans cell histiocytes (the non-X histiocytoses).

Non-X histiocytoses

Zelger and Burgdorf proposed classifying this group of disorders as the “xanthogranuloma family.” Their classification scheme relies on the morphology of the monocyte/macrophage composing the lesion. Weitzman and Jaffe refined this concept and outlined the immunohistochemical features of the cells involved. These classification schemas are useful for this

uncommon group of disorders. However, since the histiocytes within any disorder can change their appearance, no one specific morphological cell type absolutely characterizes these disorders. There are three large families of histiocytoses based on these classification schema—X-type histiocytosis or Langerhans cell histiocytosis (LCH); non-LCH histiocytoses of the juvenile xanthogranuloma (JXG) family (which have the phenotype of dermal dendritic cells, being positive for factor XIIIa, fascin, MS-1, and CD68); and multicentric reticulohistiocytosis and sinus histiocytosis with massive lymphadenopathy (SHML; Rosai-Dorfman disease), which are felt to not be in the JXG family of non-X histiocytoses. In the end, the final diagnosis is established by typical clinical features, a compatible histology, and an evolution typical for that disorder (Fig. 31.16).

The non-X histiocytoses are divided clinically into three groups: those involving primarily or only the skin (JXG); those that affect the skin but have a major systemic component (Erdheim-Chester disease); and those that are primarily a systemic disease with occasional skin lesions as a part of the disease (SHML). At any level of differentiation or appearance of the histiocyte there may be a disease in any category. Conceptually, this allows one to think of the JXG group of non-X histiocytoses as lying along a spectrum: benign cephalic histiocytosis, JXG, Erdheim-Chester disease, generalized eruptive histiocytosis, xanthoma disseminatum, and progressive nodular histiocytosis. Most diseases at the beginning of the spectrum are localized benign disorders; as one progresses through the diseases they tend to become more generalized but are still benign; at the end of the spectrum lie diseases that are less likely to involute and may have visceral involvement. This parallels the histological appearance of the infiltrating histiocyte, which progresses from scalloped to vacuolated to xanthomatized and finally spindled. In any disease, however, many morphologies of the histiocyte may be seen.

Juvenile xanthogranuloma

Juvenile xanthogranuloma (JXG) is the most common non-LCH. Between 20 and 35% of lesions are congenital. The vast majority of lesions (70%) are diagnosed within the first year of life. The mean age of onset is 22 months, and the median 5 months (demonstrating the proclivity for early onset). Eighty percent of cases are solitary (Fig. 31-17). Boys are slightly more commonly affected than girls (1.5:1). In adults, lesions tend to occur in the late twenties to early thirties, and the gender distribution is equal. JXG is 10 times more common in white than black persons, but occurs in all races. Multiple cutaneous lesions affect male children much more commonly (12:1).

JXGs begin as well-demarcated, firm, rubbery, round to oval dermal papules or nodules from 5 to 10 mm in diameter. Early lesions are pink to red with a yellow tinge and become tan-brown over time. By dermoscopy, the lesions have an orange-yellow background, a subtle erythematous border with branched and linear vessels running from the edge to the center of the lesion, and “clouds” of paler yellow areas representing areas of xanthomatized histiocytes. Most lesions are asymptomatic. The head and neck are the most common locations, followed by the upper trunk and upper extremities. Lesions have been divided into three forms: small nodular (2–5 mm; Fig. 31-18); large nodular (5–20 mm; Fig. 31-19); and giant xanthogranuloma (>20 mm) types. The small-type lesions are more numerous than the large type. However, often one patient will have both types of lesion, and the proposed increased risk for ocular involvement in the

Fig. 31-16 Schematic drawing of unifying concept of non-X histiocytoses.

Fig. 31-17 Juvenile xanthogranuloma, solitary.

miconodular type and other internal involvement in the macronodular type has been refuted. Skin lesions regress spontaneously within 3–6 years in children. In adults, lesions are usually persistent. Hyperpigmentation, atrophy, or anetoderma may remain after lesions resolve.

Multiple atypical presentations have been described. These include hyperkeratotic nodules; macronodular tumors from 2 to 10 cm in diameter; clustered (agminated) forms; linear lesions; flat, plaque-like lesions; and pedunculated or cylindrical exophytic lesions. Atypical sites of involvement include the genitalia, lips, palms, soles, earlobes, and fingers. The most common location for JXGs after the dermis is the subcutaneous tissue, again most commonly on the head and neck. About 15% of JXGs present in this manner, usually as a solitary

Fig. 31-18 Juvenile xanthogranuloma, multiple small papules.

Fig. 31-19 Juvenile xanthogranuloma, multiple nodules.

mobile mass up to 3 cm in diameter. Subcutaneous JXG most commonly appears before age 1 and often before age 3 months. Oral JXG may develop in infancy or childhood, and is most frequently a solitary lesion of the tongue, lip, or palate.

Extracutaneous JXG is uncommon and occurs as visceral involvement, in association with either multiple cutaneous lesions or a solitary extracutaneous lesion. Visceral disease of both types accounts for only 4% of childhood JXGs, and for 5–10% of all JXG cases. Ocular involvement occurs in about 0.3–0.4% of children with multiple JXGs, and 41% of children with ocular JXGs have skin lesions. Skin lesions appear after eye lesions in 45% of cases. In 92% of cases, eye lesions occur during the first 2 years of life. The most common location is the iris, where JXG can present as a tumor, unilateral glaucoma, unilateral uveitis with spontaneous hyphema, or as heterochromia iridis. The eyelid or posterior eye may also be involved. Ocular screening is recommended for all children with multiple cutaneous lesions before the age of 2 years.

Mass lesions of the nasal, orbital, and paranasal sinus region can occur and can cause erosion of the orbit and extend to the skull. Other extracutaneous sites and their presentations, in order of frequency, include the lung (respiratory distress and nodular opacities on chest radiograph), liver (hepatomegaly and, rarely, fatal giant cell hepatitis), testis (mass), and rarely, the CNS, kidney, spleen, and retroperitoneum. Other evaluations for extracutaneous JXGs are not indicated unless there are symptoms or findings suggesting their presence. Extracutaneous lesions also spontaneously regress. If surgical intervention is required, extracutaneous lesions tend not to recur, even if they are incompletely excised. Rarely, the burden of visceral JXGs may be so great that the patient's life is threatened. These cases have been called "disseminated JXG," "systemic JXG," or "systemic xanthogranuloma." In 25% of these cases, no skin lesions are found. Progressive CNS, liver, or bone marrow involvement usually mandates aggressive therapy. These cases may simulate hemophagocytic lymphohistiocytosis syndrome. Locally aggressive tumors may be radiated. Systemic steroids, chemotherapy, and even liver or bone marrow transplantation may be required. Even more rarely, a visceral lesion may behave malignantly, spreading to previously unaffected organs and killing the patient.

JXGs have been reported in association with neurofibromatosis (NF-1) and juvenile myelomonocytic leukemia (JMML). Patients with NF-1 and JXG are 20–32 times more likely to develop JMML. JMML and NF-1 are known to be linked, but since JMML occurs in infancy or early childhood, often café-au-lait macules are the only findings of NF-1 at the time. Sometimes all three conditions affect the same patient, with males having a 3:1 predominance and commonly a maternal history of NF-1. Children with JXG should be examined for stigmata of NF-1. If these stigmata are found, especially in a boy with a maternal history of NF-1, the pediatrician should be alert to the possible, although uncommon, occurrence of JMML. Rarely, JXG in childhood may be associated with mastocytosis or childhood acute lymphoblastic leukemia. Multiple xanthogranulomas are rare in adults and it is quite unusual for them to occur in an eruptive manner. At least six cases have been associated with hematologic malignancy (chronic lymphocytic leukemia, essential thrombocytosis, large B-cell lymphoma, adult T-cell lymphoma/leukemia, and monoclonal gammopathy).

Lesions appear histologically as nonencapsulated but circumscribed proliferations in the upper and mid-reticular dermis, and may extend more deeply into the subcutaneous tissue or abut directly on the epidermis with no Grenz zone. Epidermotropism does not occur. Classically, it has been proposed that the histopathology varies in accordance with the age of the lesion. Very early lesions are composed of mono-

nuclear cells with abundant amphophilic cytoplasm that is poorly lipidized or vacuolated. Later, the cells become more vacuolated and multinucleated forms appear. In mature lesions, foam cells, multinucleated foam cells (Touton giant cells), and foreign-body giant cells are present. Touton giant cells are characteristic of JXG but not specific for it. The inflammatory infiltrate consists of lymphocytes, eosinophils, and neutrophils, and lacks plasma cells. Fibrosis occurs in the older lesions. The histology described above is characteristic of cutaneous JXGs. Soft-tissue and visceral JXGs present with more monomorphous cytology, may have very few of the characteristic Touton giant cells, and can have a prominent spindle cell appearance. Immunohistochemistry is especially valuable in confirming the diagnosis of extracutaneous JXG. The cells of JXG of all anatomic locations stain with factor XIIIa, vimentin, fascin, MS-1, and CD68, not with CD1, S-100, or other specific markers for Langerhans cells.

The treatment for most cases of JXG is observation. By age 6 most lesions have resolved, often leaving normal or only slightly hyperpigmented skin. In adults spontaneous involution is slower, and local removal with surgery or CO₂ laser could be considered.

It is noteworthy that the patterns of involvement by JXG and LCH are similar, with childhood onset and primary cutaneous involvement; when visceral disease occurs, the liver, bone, and lungs are commonly involved. Without histologic confirmation, isolated JXG of the bone would be most likely diagnosed as isolated LCH, a much more common condition. These clinical similarities between JXG and LCH may be explained by the fact that both diseases are caused by antigen-presenting dendritic cells. JXG is a proliferation of dermal dendrocytes and LCH is a proliferation of Langerhans cells. The clinical features favoring JXG include lack of crusting or scale and the distribution and uniformity of size of lesions. Histologic evaluation is definitive in difficult cases, since JXGs are negative for the Langerhans cell marker CD1. Unlike LCH, JXGs are usually negative for S-100, although a few S-100-positive JXGs have been reported. Benign cephalic histiocytosis (BCH) may be difficult to distinguish both clinically and histologically, but in BCH lesions tend to be flatter and are mainly on the head and neck. Papular xanthoma can be distinguished histologically. Clinically, mastocytosis will urticate when scratched (Darier's sign) and can be distinguished histologically. Solitary JXG appearing in a child must be distinguished from a Spitz nevus, usually requiring a biopsy.

Benign cephalic histiocytosis

BCH is a rare condition affecting boys and girls of all races equally. The onset is between 2 and 34 months of age (rarely up to 5 years), with 50% of cases beginning between ages 5 and 12 months. The disease begins initially on the head in virtually all cases, often the cheeks, eyelids, forehead, and ears. Lesions may later appear on the neck and upper trunk, and less commonly more caudad. There are always multiple lesions, but often few in number (5–20), although they can number more than 100. Individual lesions are slightly raised, reddish-yellow papules, 2–4 mm in diameter. Lesions may coalesce to give a reticulate appearance. The lesions cause no symptoms. The mucosa and viscera are not involved. Lesions spontaneously involute over 2–8 years, leaving behind hyperpigmented macules. Some cases of BCH have evolved to become JXGs, and one patient later developed generalized eruptive histiocytoma many years after the involution of BCH. This supports the concept outlined above that these conditions lie along a spectrum and all derive from the same cell type, a dermal dendritic cell. Histologically, there is a diffuse dermal infiltration of monomorphous macrophages, which stain positively for CD68 and factor XIIIa and negatively with S-100 and CD1a.

Generalized eruptive histiocytoma (generalized eruptive histiocytosis)

Generalized eruptive histiocytosis (GEH) is a rare disease, usually presenting in young adulthood. The diagnostic criteria are:

1. widespread, erythematous, essentially symmetrical papules, particularly involving the trunk and proximal extremities, sparing the flexors, and rarely involving the mucous membranes (there is no visceral involvement)
2. progressive development of new lesions, often in crops, over several years with eventual spontaneous involution to hyperpigmented macules
3. a benign histologic picture of monomorphous, vacuolated macrophages.

Lesions appear in crops, and may be grouped or clustered. (Since Winkelmann's initial report of this entity, several cases with grouped lesions have been reported, so finding grouped lesions does not exclude the diagnosis of GEH.) They are skin-colored, brown, or violaceous. GEH is rare in childhood. It may be difficult to distinguish from widespread BCH in childhood, if indeed it is a separate condition. In adults and children, GEH may suddenly appear several weeks following a bacterial or viral illness; in adults it may be associated with underlying malignancy, usually leukemia or lymphoma. GEH is distinguished from xanthoma disseminatum by the lack of visceral disease, the benign course, and by the scalloped appearance of the macrophages in xanthoma disseminatum. Histologically, there is a dermal infiltrate of monomorphous vacuolated macrophages and mononuclear histiocytes. The GEH cells stain positively for vimentin, CD68, and usually factor XIIIa, and negatively for S-100, and CD1a. The natural history of GEH is unpredictable, with complete resolution in some cases and persistence in others. Some cases have progressed to widespread xanthogranulomas, xanthoma

disseminatum, or progressive nodular histiocytosis, again supporting the concept that these diseases all fall along a spectrum and derive from the same cell type. In childhood, no treatment may be required. In adulthood, treatment with PUVA or isotretinoin could be considered.

Xanthoma disseminatum (Montgomery syndrome)

Xanthoma disseminatum (XD) is a very rare, potentially progressive non-LCH that preferentially affects males in childhood or young adulthood. It is characterized by the insidious onset of small, yellowish-red to brown papules and nodules that are discrete and disseminated. They characteristically involve the eyelids and flexural areas of the axillary and inguinal folds, and the antecubital and popliteal fossae. Over years the lesions increase in number, forming coalescent xanthomatous plaques and nodules. About 30–50% of cases have mucous membrane involvement, most commonly of the oropharynx (causing dysphagia), larynx (causing dysphonia and airway obstruction), and conjunctiva and cornea (causing blindness). Diabetes insipidus, usually transient, occurs in 40%. CNS involvement, with epilepsy, hydrocephalus, and ataxia, can occur. Synovitis and osteolytic bone lesions have been described. In some cases, the disease may spontaneously involute.

The serum lipids are abnormal in 20% of cases, which may lead to confusion with hyperlipidemic xanthomatosis. Histologic examination of early lesions shows surprisingly nonfoamy, scalloped macrophages. Later lesions show xanthoma cells, Touton giant cells, and frequently, a mild inflammatory cell infiltrate of lymphocytes, plasma cells, and neutrophils. The macrophages stain with CD68 and factor XIIIa.

Disseminated xanthosiderohistiocytosis is a variant of XD in which there is a keloidal consistency to the lesions; they have annular borders, a cephalad distribution, and extensive iron and lipid deposition in the macrophages and connective tissue.

Progressive XD can produce considerable morbidity and can even be fatal. Therefore, aggressive therapy may be indicated. Systemic steroids have led to improvement in one case. In a patient with XD and dyslipidemia, the combination of rosiglitazone, simvastatin, and acipimox led to partial remission and stabilization of mucosal and osseous disease. Cyclophosphamide has led to dramatic improvement in two of three patients so treated.

Progressive nodular histiocytosis

Progressive nodular histiocytosis (PNH) is a very rare disorder that affects men and women equally and usually begins between the ages of 40 and 60 years. The characteristic clinical feature is the development of two types of lesion: superficial papules and deeper, larger, subcutaneous nodules. The superficial lesions are small xanthomatous papules up to 5 mm in diameter. They are diffusely distributed on the body, but spare the flexors. The larger deep lesions can be up to 5 cm in diameter and are associated with pain, ulceration, and disfigurement. On the face, lesions may coalesce, giving the patient a leonine facies and creating ectropion. New lesions progressively appear and spontaneous resolution does not occur. Most patients have no mucosal or visceral lesions, although one patient had a hypothalamic lesion leading to precocious puberty and growth hormone deficiency. Histologically, the superficial lesions show foamy macrophages and the deeper lesions a densely cellular proliferation of spindle-shaped histiocytes with multinucleated giant cells. It is the development of these deep lesions composed of primarily spindled histiocytes that is the diagnostic feature of PNH. Local excision may be used for symptomatic lesions.

Papular xanthoma

Papular xanthoma (PX) is a rare form of non-LCH that is poorly defined. The disease can occur at any age, but usually appears in early childhood or after adolescence. PX usually presents as a solitary lesion favoring men 4:1 over women. The primary lesion is a small, yellow papule from 1 to 10 mm in diameter. If there are multiple lesions they are generalized, not grouped, and do not favor the flexors. There is no visceral involvement and no abnormalities are found on lipid profile examination. Histologically, there are aggregates of xanthomatized foamy macrophages in the dermis, with Touton giant cells. Inflammatory cells are scant or absent. Cells stain positively for markers of monocytes/macrophages such as CD68, but are negative for factor XIIIa. The differential diagnosis includes normolipemic plane xanthomas and normolipemic papuloeruptive xanthomatosis. In infants the natural history is for spontaneous involution. In one adult patient, treatment with doxycycline was effective.

Erdheim–Chester disease

This rare non-LCH is primarily a visceral disorder with cutaneous manifestations. It can begin at any age from childhood to the ninth decade. The characteristic feature is bilateral and symmetrical sclerosis of the metaphyseal and diaphyseal

regions of the long bones. These radiologic findings are considered pathognomonic. Diabetes insipidus from involvement of the pituitary and retroperitoneal fibrosis affecting the kidneys may occur. Despite a normal gross appearance, many internal organs are affected. The course is progressive with infiltration of many visceral organs, followed by fibrosis. This is often fatal, usually from pulmonary fibrosis and cardiac failure. In one series, 60% of patients had died, 36% within 6 months of diagnosis, with a mean survival of less than 3 years. Skin lesions occur in 25% of patients, typically presenting as red-brown or xanthomatous 2–15 mm papules or nodules. Lesions favor the eyelids, axilla, groin, neck, trunk (inframammary areas), and face. As opposed to plane xanthomas and xanthelasmas, the lesions can be elevated or tubelike, resembling sausages or keloids.

Progressive mucinous histiocytosis in women

Progressive mucinous histiocytosis is an autosomal-dominant or X-linked hereditary disorder described only in women. The skin lesions consist of a few to numerous skin-colored to red-brown papules, ranging from pinhead- to pea-sized, which tend to appear on the face, arms, forearms, hands, and legs. Onset is in the second decade of life, with slow progression and no tendency to spontaneous involution. Visceral and mucosal lesions have not been reported. Histologically, in the mid-dermis there is a proliferation of spindle-shaped and epithelioid monocytes. Superficial telangiectatic vessels and increased mast cells are found. Abundant mucin is demonstrated by alcian blue staining, indicating the presence of acid mucopolysaccharides. This condition can be distinguished from the other non-LCHs by its familial pattern, lack of lipidized and multinucleated cells, and presence of mucin. Immunoperoxidase studies have been conflicting, but most consistently show positivity for factor XIIIa and CD68, and negativity for CD1a, S-100, and CD34.

Young A, et al: Two sporadic cases of adult-onset progressive mucinous histiocytosis. *J Cutan Pathol* 2006; 33:166.

Reticulohistiocytosis

Two distinct forms of reticulohistiocytosis occur: reticulohistiocytoma and multicentric reticulohistiocytosis. The two forms have identical histology but distinct clinical manifestations.

Reticulohistiocytoma

Reticulohistiocytoma usually occurs as a solitary, firm dermal lesion of less than 1 cm in diameter. Lesions favor the trunk and extremities. Multiple lesions may rarely occur and can be quite extensive and diffuse. Solitary lesions and multiple lesions without systemic involvement, in contrast to multicentric reticulohistiocytosis, have been described, mainly in adult men and rarely in children.

Multicentric reticulohistiocytosis

Multicentric reticulohistiocytosis (MRH) is a multisystem disease beginning usually around age 50 (range 6–86). It is twice as common in women as in men and affects all races. The primary manifestations are skin lesions and a potentially

Fig. 31-20 Multicentric reticulohistiocytosis.

destructive arthritis. In 40% of cases the joint disease occurs first, in 30% the skin lesions precede the joint symptoms, and in 40% the joint and skin disease appear simultaneously.

Clinically, there may be a few to a few hundred firm, skin-colored to red-brown papules and nodules, mostly 2–10 mm in diameter, but some reaching several centimeters in size (Fig. 31-20). These occur most frequently on the fingers and hands, with a tendency to cause paronychia lesions. In about half the cases, lesions will be arranged about nailfolds, giving a so-called “coral bead” appearance, which may be associated with nail dystrophy. The upper half of the body, including the arms, scalp, face, ears, and neck, are also common sites. Ninety percent of patients have lesions on the face and hands. Nodular and papular involvement of the pinnae and a symmetrical distribution of the lesions, especially over joints, are characteristic. The nodules on the arms, elbows, and knees may resemble rheumatoid nodules. Diffuse erythematous lesions can occur, at times simulating erythroderma. Lesions may ulcerate. Xanthelasma occurs in 30% of patients. Atypical patchy areas of hypopigmentation over the face and upper limbs have been noted. About 10% of MRH patients may complain of pruritus. The itching is not localized to the lesions and may precede the appearance of the skin lesions.

Mucous membrane involvement is seen in one-third of cases and is most common on the lips and tongue; other sites are the gingiva, palate, buccal mucosa, nasopharynx, larynx, and sclera. Lesions of the esophagus can lead to dysphagia. One-third of cases have hypercholesterolemia and xanthelasma. Rheumatoid factor is usually negative.

Osteoarticular changes are the most important aspect of MRH. There is no association between the extent, size, or severity of the skin eruption and the course of the joint disease. The associated arthropathy is an inflammatory, symmetrical, polyarticular arthritis that can affect many joints, including the hands, knees, shoulders, wrists, hips, ankles, elbows, feet, and spine. The arthritis can be rapidly destructive and mutilating, with absorption and telescopic shortening of the phalanges and digits—doigts en lorgnette (opera-glass fingers). In older reports at least 50% of cases developed arthritis mutilans, but this has been reduced to about 11%. The infiltrating cells in the skin and joints are identical on microscopic examination and immunophenotypic evaluation. The clinical course varies. In many instances there is complete involution after about 8 years. The joint destruction is permanent, however, and is a cause of severe disability. The joint involvement may resemble

rheumatoid arthritis and psoriatic arthritis. Weight loss and fever occur in one-third of patients.

About 15% of patients with MRH have associated autoimmune disorders. Thyroiditis, Sjögren's, ulcerative colitis, and vitiligo have all been reported. At least six patients have been described with myopathy closely simulating dermatomyositis.

About 25% of reported cases have had an associated malignancy. Given this high rate of malignancy, every patient with MRH should have a complete age-appropriate cancer screening, repeated at regular intervals (similar to the protocol followed for patients with dermatomyositis). No specific tumor type has been associated. There are reports involving breast, colon, cervix, stomach, melanoma, and ovary, as well as leukemia and lymphoma. The skin lesions usually appear before the diagnosis of the malignancy, but synchronous behavior of the skin lesions and the underlying malignancy is only occasionally reported. In one case, tuberculosis was identified, and treatment of the tuberculosis led to resolution of the MRH.

Other organs and tissues may be involved, such as bone, muscle, lymph nodes, liver, myocardium, pericardium, lungs, pleura, and stomach. Myocardial involvement may be fatal. Gallium is a method to screen for extent of disease.

Histologically, the skin lesions are usually centered in the mid-dermis and tend to occupy much or all of the dermis. The infiltrating cells are mononuclear and multinucleate monocyte/macrophages. The giant cells are most characteristic, with an abundant smooth or slightly granular, eosinophilic or amphophilic, "ground-glass" cytoplasm. Their cytoplasm is darker in the center than at the periphery. These cells stain positive for periodic-acid Schiff (PAS) after diastase digestion. The overlying epidermis may be thinned but is usually separated from the dermal process by a narrow zone of collagen (Grenz zone). Characteristically, there is a polymorphous infiltrate of lymphocytes, neutrophils, eosinophils, and plasma cells within the lesions. By immunohistochemistry the monocyte/macrophage cells stain positively for CD68, vimentin, and CD163. In MRH the cells in the skin and joints stain positively for acid phosphatase that is tartrate-resistant (TRAP) and cathepsin K, markers for osteoclasts. This may explain the response of MRH to bisphosphonates, which cause apoptosis of osteoclasts and are taken up by cells in the reticuloendothelial system.

Given the aggressive nature of the arthritis, early and adequate treatment should be considered. However, associated malignancy is frequent and can be worsened by immunosuppressive therapy. The same would be true if there were underlying asymptomatic tuberculosis. Initially, the patient should be screened for these two conditions and they should be adequately treated if found. In patients free of neoplasia and tuberculosis, the treatment is individualized. Spontaneous remissions are common, making efficacy of treatment hard to determine. The major goal of treatment is to prevent the destruction of the joints that are the cause of disability. If systemic therapy is considered, two approaches can be taken. One is the use of the combination of systemic steroids, methotrexate, and a TNF inhibitor. In the case of TNF inhibitors, infliximab has proven more effective than etanercept and should probably be the initial agent used. The other approach is to use a combination of immunosuppressives and a bisphosphonate. Since the infiltrating cells in MRH seem phenotypically to be osteoclastic in behavior, this therapy is logical and appears to be joint-sparing. In refractory cases, the use of a bisphosphonate and TNF inhibitor with methotrexate and systemic steroids could be considered. For patients with skin lesions only, therapy is not required. PUVA, antimalarials, topical nitrogen mustard, and low-dose methotrexate, a

bisphosphonate, or a TNF inhibitor could be considered if symptoms are severe.

Indeterminate cell histiocytosis

Indeterminate cells are felt to represent dermal precursors of Langerhans cells. They are positive for S-100 and CD1a but do

not contain Birbeck granules. Indeterminate cell histiocytosis (ICH) is the term used to describe disorders that are composed of cells that immunophenotypically stain as Langerhans cells but lack Birbeck granules. Since electron microscopy is rarely employed, it is difficult to use this criterion to establish the diagnosis of a disorder. Langerin immunostaining might be substituted.

ICH cases are quite rare, and there is little homogeneity among the reports to reassure one that all these cases actually describe a single disease. In addition, S-100 staining is variable in the various non-Langerhans cell histiocytoses (NLCH), making S-100 positivity a soft criterion to use. In addition, reactive conditions are associated with tissue infiltration by S-100-positive cells. Indeterminate cells may be found as a minor component of the dermal infiltrate in nodular scabies and rarely following pityriasis rosea. Some authors favor classifying ICH as a generalized eruptive histiocytosis. This being said, it appears that both children and adults are affected by ICH, with males outnumbering females. Solitary and multiple lesions may occur, and the color of lesions varies from yellow to red-brown. Lesions may be papules, plaques, or nodules from 3 mm to 10 cm in size. These clinical features are not specific, and resemble the papular lesions seen in many forms of NLCH. Conjunctival involvement has been reported. Solitary malignant tumors with similar immunohistochemistry have been described, clinically resembling atypical fibroxanthoma. Histologically, while the cells in these cases do stain with S-100 and at times with CD1a, the staining is never as intense as in Langerhans cells. ICH seems to have a benign course in the vast majority of cases, and no therapy is required. Broad-band UVB, PUVA, and total skin electron beam have each been effective in limited number(s) of cases with severe skin involvement. Many cases have been treated with numerous chemotherapeutic agents similar to those used for LCH, including cyclophosphamide, etoposide, vinblastine, systemic corticosteroids, and 2-chlorodeoxyadenosine, but therapeutic response has been equivocal. Acute myelogenous leukemia has followed some of these courses of chemotherapy. Solitary lesions with malignant histology should be managed with surgical excision ensuring adequate margins. The utility of adjunctive therapy and sentinel lymph node sampling is not known.

Sea-blue histiocytosis

Sea-blue histiocytosis may occur as a familial inherited syndrome or as an acquired secondary or systemic infiltrative process. The characteristic and diagnostic cell is a histiocytic cell containing cytoplasmic granules that stain blue-green with Giemsa stain and blue with May-Gruenwald stain. The disorder is characterized by infiltration of these cells into the marrow, spleen, liver, lymph nodes, and lungs, as well as the skin in some cases. Skin lesions include papules or nodules, facial waxy plaques, eyelid swelling, and patchy gray pigmentation of the face and upper trunk. Similar histologic findings have occurred in patients with myelogenous leukemia, light chain deposition disease, adult Niemann-Pick disease (type B), sphingomyelinase deficiency, or mutations in the apolipoprotein E gene, and following the prolonged use of intravenous fat supplementation. The unifying feature in all these conditions is an abnormal lipid metabolism by the infiltrating histiocytes. This condition has been seen in the infiltrate of a case of cutaneous T-cell lymphoma.

X-type histiocytoses (Langerhans cell histiocytosis—LCH)

This group of disorders is caused by infiltration of the skin, and in some cases other organs, by Langerhans cells. The spectrum of disease is broad, with solitary, usually benign and autoinvolving lesions at one end, and multicentric, multi-organ visceral and skin disease at the other. While not completely worked out, it appears that most cases of LCH demonstrate clonality. In addition, the Langerhans cells in LCH demonstrate telomere shortening. Clonality and telomere shortening are features of preneoplastic conditions and cancer.

Histologically, in all cases of LCH in the skin, there is a dense dermal infiltrate of Langerhans cells. This can be superficial and immediately below the epidermis (usually corresponding to small papules or scaly patches clinically), folliculocentric, or deep and diffuse (in papular and nodular lesions). The Langerhans cells are recognized by their abundant, amphophilic cytoplasm and eccentric round or kidney bean-shaped nucleus. There is frequently exocytosis of the abnormal cells into the overlying epidermis. If this is extensive, macroscopic vesicles can be seen, and erosion can occur secondarily. The dermal infiltrate is accompanied by many other inflammatory cells, including neutrophils, eosinophils, lymphocytes, and plasma cells. Dermal edema and hemorrhage are characteristically present. In larger and older lesions the infiltrating histiocytic cells become foamy and fibrosis may be present.

The histologic features of the Langerhans cells, such as nuclear atypia and mitotic indices, do not predict prognosis and are not reproducible. Histology is not predictive of biological behavior. Immunohistochemistry is useful in confirming the diagnosis. The infiltrating cells in LCH are positive for S-100 and CD1a. Langerin is a protein expressed in the Birbeck granule and stained with CD207. Electron microscopy is rarely required to diagnose LCH due to this panel of Langerhans cell "characteristic" markers.

Congenital self-healing reticulohistiocytosis (Hashimoto–Pritzker disease)

Congenital self-healing reticulohistiocytosis (CSHR) is an autoinvoluting, self-limited form of LCH. It can be considered as one end of the spectrum of LCH, and although cases continue to be described, it is best approached as a variant of LCH, not a separate entity. CSHR is usually present at birth or appears very soon thereafter, although a case in an 8-year-old has been reported. It has been described in two forms: a solitary and a multinodular variant. Solitary or generalized lesions can affect any part of the cutaneous surface. Lesions range from 0.2 to 2.5 cm in diameter (Fig. 31-21). Lesions may grow postnatally. Exceptionally large tumors up to 8 cm in diameter can occur. At presentation the lesions can be papules or nodules, with or without erosion or ulceration. Individual lesions are red, brown, pink, or dusky. Lesions may rarely appear as hemorrhagic bullae. Lesions greater than 1 cm characteristically ulcerate as they resolve. Lesions are asymptomatic and spontaneously involute over 8–24 weeks, leaving atrophic scarring from the ulcerated nodules. Internal involvement is not found. Histologically, the skin lesions are composed of Langerhans cells and no histological features identify this variant of LCH. Because LCH with systemic involvement may present in identical fashion, systemic evaluation is recommended, including a physical examination, complete blood count, liver function tests, and radiological evaluation of the bones. The affected child must be followed regularly because, as in other forms of LCH, late recurrences can occur.

Langerhans cell histiocytosis (LCH)

LCH is a rare disease characterized by proliferation of Langerhans cells in many organs. The rarity of the disease and a lack of understanding of how to manage patients appropriately have inspired the formation of the "Histiocyte Society." Many patients throughout the world are entered in large standardized treatment protocols (LCH-I to IV). This has led not only to standardized approaches to management, but also to standardized terminology and classification of patients. It is clear that age of onset is an important determinant of the nature of the disease, and childhood and adult forms of LCH are considered separately. It is also quite clear that patients may begin with any pattern of disease and evolve or relapse to another pattern. This is especially true of younger children. Up to 50% of children under the age of 1 year diagnosed with skin-limited LCH progress to have multisystem disease. Repeated evaluation and close follow-up are required.

Childhood LCH

In childhood LCH, boys are slightly more commonly affected than girls. The incidence in children is about 2.6 cases per million, with a greater rate in children under 1 year of age (9 cases per million), 5 cases per million in 1–4-year-olds, and about 1 per million in 5–14-year-olds. Neonatal disease occurs in 6% of cases but at times is unrecognized, especially if it were to involve an internal organ asymptotically but not affect its function. Thus many of the neonatal cases have predominantly cutaneous lesions. Overall, in childhood LCH bone lesions represent about two-thirds of cases and skin disease about one-third. Only 10% of cases have neither skin nor bone involvement. In children under 1 year of age, the skin is involved in three-quarters of cases, with ear and bone being involved in about one-third of cases. Two-thirds of children under 1 year of age have multisystem disease, with half having involvement of liver, lungs, or bone marrow. In children aged 1–4, bone disease is most common, but two-thirds or more have multisystem disease. In children aged 5–14, bone disease is almost always seen, and multisystem disease is seen in less than 20%.

Skin lesions About 10% of children have single-organ disease involving only the skin and 50% of children with multisystem LCH have skin involvement, making skin the second most commonly involved organ in childhood LCH. Almost 90% of children less than 1 year old with multisystem LCH have skin lesions. The pattern of skin disease does not predict the presence or extent of systemic disease. The most common form of skin disease in children is that described in Abt–Letterer–Siwe disease. The skin lesions are tiny red,

Fig. 31-25 Langerhans cell histiocytosis, xanthomatous nodule in a patient with diabetes insipidus.

red-brown, or yellow papules that are widespread but favor the intertriginous areas, behind the ears, and the scalp (Figs 31-22 and 31-23). There is a superficial resemblance to seborrheic dermatitis, but on careful inspection the lesions are individual papules and there is focal hemorrhage in the lesions. The papules are often folliculocentric. Lesions may erode or weep. In children this pattern is frequently associated with multisystem disease. A rare variant of this pattern of LCH is one in which vesicles appear (Fig. 31-24), usually in infants. The vesicles rupture easily, resulting in widespread erosions. This presentation may be confused with other bullous diseases, especially congenital candidiasis, herpes virus infections, bullous impetigo, bullous mastocytosis, primary immunobullous diseases, and epidermolysis bullosa. The vesicles are due to large intraepidermal collections of Langerhans cells, and a Tzanck smear may lead to suspicion of the diagnosis. A less common presentation is with slightly larger papules up to 1 cm in diameter. These lesions tend to be yellow-red and resemble xanthomas or xanthogranulomas (Fig. 31-25). They can be numerous and widespread. A rare variant resembling lichen planopilaris has been reported. Congenital lesions with hemorrhage have been reported as resembling “blueberry muffin” babies, but the biopsies show typical LCH.

Nail changes can occur, but are uncommon and can include longitudinal grooving, purpuric striae, hyperkeratosis, sub-

ungual thinning, deformities, loss of nail plate, and paronychia. Both fingernails and toenails may be affected. Most patients with nail involvement have multisystem disease. LCH restricted to the genitalia is rare, but vulvar, inguinal, and perianal disease may be the initial manifestation of LCH. It tends to be painful and ulcerative, and may simulate hidradenitis suppurativa, since axillary and scalp involvement may also be present.

Oral mucosa lesions The oral mucosa may be involved. Lesions may be mucosal ulcerations that are painful and inflamed. They affect primarily the buccal mucosa. Most oral disease is due to alveolar bone lesions. These osteolytic lesions can lead to significant periodontitis. Gingival ulceration can result (Fig. 31-26). Teeth detach from the underlying bone and on x-ray appear to be “floating.” Palpable masses and gingival lesions should be looked for and a dental evaluation completed in all patients. Cervical adenopathy is common. Bilateral parotid swelling may occur.

Visceral involvement The most commonly involved organ is the bone (Fig. 31-27). The lesions may be asymptomatic or cause pain. The skull is most commonly involved, followed by the long bones, then the flat bones. Bony lesions tend to occur in older children and young adults. Lesions are treated with curettage, intralesional corticosteroids, or radiation. Endocrine dysfunction occurs, usually in the form of diabetes insipidus, which is more common in patients with bone disease of the

Fig. 31-26 Langerhans cell histiocytosis, gingival lesions.

Fig. 31-27 Langerhans cell histiocytosis, eosinophilic granuloma of rib that eroded through to the skin.

skull and in patients with extensive disease. Diabetes insipidus is one of the common long-term sequelae of children recovering from LCH.

Lymph nodes are characteristically involved, especially the cervical nodes. The bone marrow may be affected, resulting in cytopenias. This may present as purpura in the skin. The liver may be involved directly by infiltration with Langerhans cells, or may be affected indirectly by enlarged nodes in the porta hepatis, leading to obstructive disease. Either pattern can lead to biliary cirrhosis. Pulmonary disease with diffuse micronodular infiltrates and cysts occurs less commonly in childhood LCH than in adults with LCH.

Adult LCH

In adults the peak age of presentation is between 20 and 35 years, with multisystem disease in between one-third and two-thirds of adults with LCH. Bones are the most common organ involved in adults with LCH, and 12% of adult LCH patients have disease limited to one or several bones. Skin and mucosal involvement is the second most common manifestation in adults. In the skin, lesions can be papular or diffuse, sometimes with both forms of lesion present at different sites. Acneiform lesions of the chest and back, identical clinically to acne vulgaris, can occur. Xanthomatous lesions may be found. A pattern that has been repeatedly reported in the skin of adults with LCH is a red, erosive, intertriginous eruption, with a close resemblance to deficiency dermatitis. It favors the groin and inframammary areas, especially in elderly women.

Box 31-1 Classification system for Langerhans cell histiocytosis (LCH)

1. Monosystem disease
 - a. Focal disease of bone, skin, or lymph node
 - b. Multifocal disease of skeleton or lymph nodes
2. Multisystem disease
 - a. Low risk—age over 2, without involvement of lungs, liver, spleen, or hematopoietic system
 - b. High risk—age under 2 and involvement of multiple organs, or age over 2 years and involvement of lungs, liver, spleen, or hematopoietic system

Pulmonary LCH occurs on average at age 33 years. A diffuse micronodular pattern on chest radiograph may progress to cyst formation (honeycomb lung), large bullae, and pneumothorax. More than 90% of adults with pulmonary LCH are tobacco or marijuana smokers. Pneumothorax occurs in 25% of cases. High-resolution CT is useful for diagnosis. Five-year survival is 88%. Lung transplantation may be required. It is unclear if isolated pulmonary LCH is a reactive process or a variant of LCH.

Treatment/prognosis

In childhood LCH, outcome is determined by the extent of involvement and, more importantly, the function of affected organs. Children younger than 1 year with multisystem disease have the worst prognosis, with mortality approaching 50%, children aged 1–4 have a 30% or lower mortality, and mortality is only 6% in children 5 years or older. Not only is the organ system involved important, but also the extent of involvement. Liver function tests greater than five times normal are associated with a 5-year survival of only 25%, with most deaths occurring within 1 year. Without liver involvement, the 5-year survival is more than 75%. Involvement of the ear and lung is also a poor prognostic finding in patients with multisystem disease. Early initial response to multidrug chemotherapy in childhood multisystem LCH is an important predictor of survival, with survival of 92% of responders and 11% of nonresponders after 6 weeks of treatment. Baseline and repeated evaluation is important. Lesions in one organ system may resolve while disease progresses in another organ. Skin lesions may spontaneously resolve, only for the disease to recur, even years later, so patients must be followed regularly.

For treatment children with LCH are classified into four groups (Box 31.1). Monosystem disease 1a and 1b involves local therapies to the skin, and surgery alone for bone lesions. These patients may be observed, as spontaneous resolution may occur. Treatment is not required. Low-risk patients are treated with a combination of vinblastine and prednisone over months. High-risk patients receive prednisone and vinblastine as initial treatment, followed by maintenance therapy with methotrexate and 6-mercaptopurine. Multisystem LCH in adults has a 5-year survival of more than 90%. Pulmonary LCH in adults can be progressive and fatal, especially in smokers. Adults with multisystem disease who require treatment are given a combination of vinblastine and prednisone induction, followed by maintenance treatment with 6-mercaptopurine and methotrexate. Relapses or progression may be treated with 2-chlorodeoxyadenosine. Imatinib mesylate, thalidomide, cyclosporine, and anti-TNF agents can be considered experimental approaches. Rarely, hematopoietic stem cell transplantation and solid organ (liver, lung)

transplantation have been performed as life-saving measures in refractory or progressing patients.

Various skin-directed treatments have been reported for children and adults with skin-predominant disease, who do not require systemic therapy. These include topical nitrogen mustard, topical steroids, imiquimod, systemic steroids, PUVA, narrow-band UVB, excimer laser, isotretinoin, thalidomide, low-dose methotrexate, and IFN- α . Associated lymphomas, solid tumors, and myelodysplasias have occurred in patients with LCH, with acute lymphoblastic leukemia and myelodysplastic syndrome preceding the appearance of LCH, and acute myelogenous leukemia and acute lymphoblastic leukemia following it. The role of the preceding lymphoma or myelodysplasia in the appearance of LCH in adults is unknown. The appearance of acute leukemia and possibly solid tumors following the diagnosis of LCH is felt to be a complication of the chemotherapeutic regimens and is seen predominantly in LCH patients so treated. In some cases of cutaneous and systemic lymphomas, aggregates of polyclonal Langerhans cells are seen in the tissue affected by the lymphoma. Whether this represents the coexistence of LCH and lymphoma (unlikely) or a reactive proliferation of Langerhans cells within the tissue affected by the lymphoma (more likely) is unknown. Reactive proliferations of histiocytes resembling sarcoidosis can also be seen in lymphoma, suggesting this is a reactive phenomenon.

Differential diagnosis

The diffuse small papular form is frequently misdiagnosed as seborrheic dermatitis. The yellow color of the lesions and the presence of hemorrhage in the small papules, if present, should suggest the diagnosis of LCH. Nodular lesions of scabies can closely simulate LCH. This includes the finding of Langerhans or indeterminate cells in the dermal infiltrate by electron microscopy and S-100 and CD1a staining. The larger papules resemble juvenile xanthogranulomas and xanthomas. Erosive genital disease may simulate deficiency dermatitis.

Cutaneous Lymphoid Hyperplasia, Cutaneous T-cell Lymphoma, Other Malignant Lymphomas, and Allied Diseases

Cutaneous lymphoid hyperplasia (lymphocytoma cutis, lymphadenosis benigna cutis, pseudolymphoma)

The term cutaneous lymphoid hyperplasia refers to a group of benign disorders characterized by collections of lymphocytes, macrophages, and dendritic cells in the skin. These processes can be caused by known stimuli (such as medications, injected foreign substances, infections, or the bites of arthropods) or they may be idiopathic. They may have a purely benign histologic appearance or resemble cutaneous lymphoma. If there is a histologic resemblance to lymphoma, the term pseudolymphoma is sometimes used. Most cases contain a mixed population of T and B cells, but they may contain mostly T cells. By standard techniques, most cases of cutaneous lymphoid hyperplasia will be found to lack clonality. Cases of monoclonal B- and T-cell cutaneous lymphoid hyperplasia do occur. Thus, a finding of monoclonality does not equate to the diagnosis of malignancy or lymphoma, nor does it predict biologic behavior. A subset of polyclonal or monoclonal (T- or B-cell) cutaneous lymphoid hyperplasias does progress to cutaneous B-cell and, less commonly, T-cell lymphoma. Even when the initial evaluation detects a T-cell rich infiltrate (>90%), which may be monoclonal, the lymphoma that eventuates from this form of cutaneous lymphoid hyperplasia may be B-cell. Thus, as in many cancer syndromes, cutaneous lymphoid hyperplasia represents the benign end of a spectrum of cutaneous lymphoid proliferation, with cutaneous lymphoma at the other end, and cases falling everywhere along that spectrum of progression. Unfortunately, current techniques cannot always predict which cases will progress.

Two clinical patterns of cutaneous lymphoid hyperplasia exist. The nodular form consists of nodular and diffuse dermal aggregates of lymphocytes, macrophages, and dendritic cells. The clinical and histologic differential diagnosis is cutaneous B-cell lymphoma. The diffuse type is usually associated with drug exposure or photosensitivity (actinic reticuloid). Histologically, it is to be distinguished from cutaneous T-cell lymphoma.

Cutaneous lymphoid hyperplasias—nodular B-cell pattern

The nodular pattern of cutaneous lymphoid hyperplasia is the most common pattern. It usually presents in adults and is 2–3 times more common in women. It favors the face (cheek, nose, or earlobe), and the majority of cases present as a solitary or localized cluster of asymptomatic, erythematous to violaceous papules or nodules (Fig. 32-1). Less commonly, lesions may affect the trunk (36%) or extremities (25%). At times, the lesions may coalesce into a plaque or be widespread in one region, in which case they present as miliary papules. Systemic

symptoms are absent and, except for rare cases with regional lymphadenopathy, there are no other physical or laboratory abnormalities. It is usually idiopathic, but can be caused by tattoos, *Borrelia* infections, herpes zoster scars, antigen injections, acupuncture, and, in rare cases, drug reactions, tumor necrosis factor (TNF)- α inhibitors, and persistent insect bite reactions. Lesions that result from a known stimulus tend to be localized to the site of the original process—tattoo, injection, or insect bite.

Borrelia-induced cutaneous lymphoid hyperplasia is an uncommon manifestation of this infection, occurring in 0.6–1.3% of cases reported from Europe. The lack of borrelial pseudolymphoma in the US compared with Europe may relate to the fact that there are different borrelial species in Europe, specifically *Borrelia afzelii*, that cause borreliosis. Lesions occur at the site of the tick bite or close to the edge of a lesion of erythema migrans. They may appear up to 10 months after infection. Lesions may be multiple and favor the earlobes, nipple and areola, nose, and scrotal area, and vary from 1 to 5 cm in diameter. Usually, there are no symptoms, but associated regional lymphadenopathy may be present. Late manifestations of *Borrelia* infection are uncommon. The diagnosis is suspected from a history of a tick bite or erythema migrans, the location (earlobe or nipple), and the histologic picture. The diagnosis is confirmed by an elevated anti-*Borrelia* antibody (present in 50% of cases) and the finding of borrelial DNA in the affected tissue. The treatment is penicillin. Some cases progress to true lymphoma.

Histologic examination of nodular cutaneous lymphoid hyperplasia reveals a dense, nodular infiltrate that occupies primarily the dermis and lessens in the deeper dermis and subcutaneous fat, i.e. it is “top-heavy.” The process is usually separated from the epidermis by a clear Grenz zone. The infiltrate is composed chiefly of mature small and large lymphocytes, histiocytes, plasma cells, dendritic cells, and eosinophils. In the deeper portions, well-defined germinal centers are usually seen, with central large lymphoid cells with abundant cytoplasm and tingible body macrophages, and a peripheral cuff of small lymphocytes. A plasma cell-predominant variant has been described. Reactive hyperplasia of adnexal epithelium is common and characteristic, but may also occasionally be seen in true lymphomas. Germinal centers are symmetrical and surrounded by a mix of B and T cells. BCL-6 and CD10 expression is limited to the germinal centers, which also have an intact CD21+ network of dendritic cells. Typically, more than 90% of the cells in the germinal center express the proliferative marker Ki-67 (MIB-1). There is no evidence of light chain restriction by in situ hybridization. CD30+ cells may occasionally be prominent, raising concern about the development of a CD30+ lymphoproliferative disorder.

As most lesions are asymptomatic, treatment is often not required. If the process has been induced by a medication, use of the medication should be discontinued. Infection should be

Fig. 32-1 Reactive lymphoid hyperplasia.

treated and localized foci of infection removed. Intralesional steroidal agents are sometimes beneficial, but lesions may recur in a few months. Potent topical steroids may also be tried for superficial lesions. Intralesional corticosteroids, cryosurgery, thalidomide, 100 mg/day for a few months, interferon (IFN)- α , IFN- α 2b, laser ablation, and surgical excision can all produce good results. Low-dose radiation therapy is usually very effective and may be used on refractory facial lesions that cannot be satisfactorily removed surgically. If monoclonality is detected in a localized lesion, complete removal and local radiation have been recommended, but there is no evidence that this improves outcome, and lesions that are not initially monoclonal may also progress to lymphoma.

Cutaneous lymphoid hyperplasias—bandlike T-cell pattern

Cutaneous lymphoid hyperplasias may histologically show a bandlike and perivascular dermal infiltrate, at times with epidermotropism. They may be idiopathic, or caused by photosensitivity (formerly called actinic reticuloid; now called chronic actinic dermatitis), medications (usually anticonvulsants, but also many others), or contact dermatitis (so-called lymphomatoid contact dermatitis).

Clinically, these patients have lesions that clinically resemble mycosis fungoides: widespread erythema with scaling. Thicker plaques may occur as well and these cases are frequently caused by medications. The treatment is to stop any implicated medication. If stopping the medication is ineffective, topical and intralesional steroids, PUVA, and, for persistent localized lesions, radiotherapy may be considered.

Histologically, a T cell-rich band of lymphocytes is present. Epidermotropism, atypia, and even clonality may suggest mycosis fungoides, but the lesions resolve when the drug or other inciting agent is withdrawn.

Jessner lymphocytic infiltrate of the skin

The existence of this entity has recently been challenged. Even the coauthors of the original paper feel their cases would now best be classified as a variant of lupus erythematosus. Clinically, Jessner infiltrate is a persistent papular and plaque-like eruption that is photosensitive and occurs primarily on the face. Histologically, there is a superficial and deep perivascular and periadnexal lymphocytic infiltrate. Interface dermatitis is absent. The infiltrating lymphocytes are suppressor T cells (CD8+). Features that suggest this may be distinct from

other forms of cutaneous lupus erythematosus include the absence of an interface dermatitis, lack of mucin, and negative direct immunofluorescence. Tumid lupus erythematosus also lacks interface dermatitis but has ample mucin. Polymorphous light eruption (PMLE) is distinguished from Jessner infiltrate by having edematous papules and plaques that are more transient, and by the presence of dermal edema. In PMLE the infiltrating cells are CD8+. There may still exist true cases of lymphocytic infiltration of the skin. To distinguish them clearly from lupus erythematosus and PMLE, the lesions must contain predominantly CD8+ suppressor T cells, lack dermal mucin and dermal edema, and be fixed (not transient like PMLE); patients must have negative direct immunofluorescence and serologic testing for lupus erythematosus. Both Jessner and chronic cutaneous lupus erythematosus can respond to antimalarials.

Cutaneous lymphomas

Because cutaneous Hodgkin disease is very rare, the term non-Hodgkin lymphoma has little meaning when speaking of a lymphoma in the skin, because virtually all cutaneous lymphomas are “non-Hodgkin lymphomas.” Cutaneous lymphoma can be considered to be either primary or secondary. Primary cutaneous lymphomas are those that occur in the skin and where no evidence of extracutaneous involvement is found for some period after the appearance of the cutaneous disease. Secondary cutaneous lymphoma includes cases that have simultaneous or preceding evidence of extracutaneous involvement. These cases are best classified and managed as lymph node-based lymphomas with skin involvement. This conceptual separation is not ideal, but it has been important in developing classification schemes and determining prognosis in cutaneous lymphomas.

For many years classification of lymphomas has been based on their histologic appearance, and lesions from all organ systems were classified histomorphologically in an identical manner to lymphomas arising in lymph nodes. It had been recognized that these classification schemes have major shortcomings when applied to extranodal lymphomas. Specifically, they did not uniformly predict clinical behavior. The new World Health Organization (WHO) classification scheme recognizes distinct forms of primary cutaneous lymphoma.

Cutaneous lymphomas are classified based on their cell type. There are B-cell lymphomas and T-cell lymphomas, but B-cell lymphomas can be T cell-rich. In such cases, atypia is restricted to the B-cell population and immunoglobulin gene rearrangements are detected. Histologic features used in the

classification system include cell size (large versus small), nuclear morphology (cleaved or non-cleaved), and immunophenotype. Because appropriate classification may be prognostically important, experienced dermatopathology consultation should be sought in cases of cutaneous lymphoma.

Primary cutaneous T-cell lymphomas

A major insight into cutaneous lymphoma was the finding that the majority of lymphomas in the skin were of T-cell origin. This is logical, since T cells normally traffic through the skin and are important in "skin-associated lymphoid tissue." Unfortunately, dermatologists frequently use the term cutaneous T-cell lymphoma synonymously with mycosis fungoides. Although mycosis fungoides represents the large majority of primary cutaneous T-cell lymphomas, up to 30% of primary cutaneous T-cell lymphomas are not mycosis fungoides. The following discussion is divided into mycosis fungoides and related conditions, Sézary syndrome, lymphomatoid papulosis, and non-mycosis fungoides primary cutaneous T-cell lymphomas.

Mycosis fungoides

Mycosis fungoides is a malignant neoplasm of T-lymphocyte origin, almost always a memory T-helper cell. The incidence has been cited as 1 in 300 000 per year, but has been increasing. Mycosis fungoides affects all races. In the US black persons are relatively more commonly affected than white persons. The condition is twice as common in males as in females.

Natural history

In most cases, mycosis fungoides is a chronic, slowly progressive disorder. It usually begins as flat patches (patch stage), which may or may not be histologically diagnostic of mycosis fungoides. This inability to diagnose early cases has more to do with the limits of diagnostic capabilities, rather than a transformation from some non-neoplastic (premycotic) condition to mycosis fungoides, and these cases are best considered mycosis fungoides from the onset. Pruritus, sometimes severe, is usually present at this stage. Over time, sometimes years, the lesions become more infiltrated, and the diagnosis is usually confirmed with repeated histologic evaluation. Infiltrated plaques occur eventually (plaque stage). In some cases, tumors may eventually appear (tumor stage). Some patients may present with or progress to erythroderma. Most rarely, patients may present with tumors *de novo*, the so-called *d'émblée* form. With immunophenotyping, many of these cases are now recognized as non-mycosis fungoides T-cell lymphomas. Eventually, in some patients, noncutaneous involvement is detected. This is most commonly first identified in lymph nodes. Peripheral blood involvement and visceral organ involvement may also occur.

In general, mycosis fungoides affects elderly patients and has a long evolution. However, once tumors develop or lymph node involvement occurs, the prognosis is guarded and mycosis fungoides can be fatal. In most fatal cases the patient dies of septicemia. Early, aggressive chemotherapy in an attempt to "cure" mycosis fungoides is associated with excessive morbidity and mortality, and is not indicated.

Evaluation and staging

The North American Mycosis Fungoides Cooperative Group has developed a staging system. Because mycosis fungoides is a systemic disease from the onset (as lymphocytes naturally traffic throughout the body), concepts used for solid tumors, such as tumor burden and metastasis, cannot be readily applied. The TNMB system scores involvement in the skin (T), lymph node (N), viscera (M), and peripheral blood (B), and is

in evolution. Skin involvement is divided into less than 10% (T1), more than 10% (T2), tumors (T3), and erythroderma (T4). Node involvement is normal clinically and pathologically (N0), palpable but pathologically not mycosis fungoides (N1), not palpable but pathologically mycosis fungoides (N2), or clinically and pathologically involved (N3). Viscera and blood are either not involved (M0 and B0) or involved (M1 and B1).

- Stage IA is T1,N0,M0.
- Stage IB is T2,N0,M0.
- Stage IIA is T1-2,N1,M0.
- Stage IIB is T3,N0-1,M0.
- Stage IIIA is T4,N0,M0.
- Stage IIIB is T4,N1,M0.
- Stage IVA is T1-4, N2-3,M0.
- Stage IVB is T1-4,N0-3,M1.

The "B" or blood status does not alter staging of the disease.

A staging work-up would include a complete history and physical examination, with careful palpation of lymph nodes and mapping of skin lesions; a complete blood cell count with assays for circulating atypical cells (Sézary cells); serum chemistries, including renal and liver function tests with lactic dehydrogenase; a chest radiograph evaluation; and a skin biopsy. If lymph nodes are palpable, they should be examined histologically. Fine-needle aspiration is not an ideal mode of evaluation, since early lymph node involvement may be localized to certain areas of the affected nodes, and architectural evaluation is often required to detect early lymph node involvement. If any abnormalities are detected through the above evaluations, they should be pursued. Computed tomography (CT) can be performed to assess chest, abdominal, and pelvic lymph nodes, and visceral organs. These are useful in patients with stage II-IV disease, but are not indicated in patients with stage IA disease. Whether patients with stage IB disease should undergo these tests is unknown.

The value of this staging system is confirmed in large series. Stage IA patients have a life expectancy identical to that of a control population; only 8-9% progress to have more advanced disease; and only 2% die of their disease. By contrast, patients with T2 disease have a shorter survival time than control subjects (median survival of 11.7-15.6 years). Twenty-four percent of T2 patients progress to more advanced disease. T3 patients have a median survival of 3.2-8.4 years, and T4 patients 1.8-3.7 years. Palpable adenopathy is associated with a median survival of only 7.7 years, whereas patients without adenopathy have a survival of 21.8 years. Lymphadenopathy, tumors, and cutaneous ulceration are cardinal prognostic factors; no patient dies without having developed one of them and patients with all three (in any order) survive a median of 1 year.

Clinical features

In the early patch/plaque stage, the lesions are macular or slightly infiltrated patches or plaques varying in size from 1 to 5 cm or more. Folliculotropic disease can resemble lichen nitidus. Except for the folliculotropic variant, lesions >5 cm in size are virtually always present in true cases of mycosis fungoides. In contrast, most histologic simulators present with smaller skin lesions. The eruption may be generalized or begin localized to one area and then spread. The lower abdomen, buttocks, upper thighs, and breasts of women are preferentially affected. The lesions may have an atrophic surface, or present as true poikiloderma with atrophy, mottled dyspigmentation, and telangiectasia. Poikiloderma vasculare atrophicum most commonly represents a clinical form of patch-stage mycosis fungoides. Likewise, large-plaque parapsoriasis and cases of small-plaque parapsoriasis with poikilodermatous change are early patch-stage lesions of mycosis fungoides. In

contrast, typical digitate dermatosis probably never evolves into mycosis fungoides. “Invisible” mycosis fungoides is generalized skin involvement that is not visible to the naked eye but can be documented histologically. With current diagnostic methods, this can usually be confirmed. In general, the patch-stage lesions resemble an eczema, being round or ovoid, but annular, polycyclic, or arciform configurations can occur. Less common forms are the verrucous or hyperkeratotic form, the hypopigmented form (Fig. 32-2), lesions resembling a pigmented purpura, and the vesicular, bullous, or pustular form. The hypopigmented form seems to be more common in persons of color and is a common presentation for adolescents and children with mycosis fungoides. Subtle lesions of mycosis fungoides may manifest clinically during anti-TNF therapy.

In the plaque stage, lesions are more infiltrated and may resemble psoriasis (Fig. 32-3), a subacute dermatitis, or a granulomatous dermal process such as granuloma annulare. The palms and soles may be involved, with hyperkeratotic, psoriasiform, and fissuring plaques. The infiltration of the plaques, at first recognized by light palpation, may be present in only a few of the lesions. It is a manifestation of diagnostic importance. Different degrees of infiltration may exist even in the same patch and sometimes it is more pronounced peripherally, the central part of the plaque being depressed to the level of the surrounding skin. The infiltration becomes more marked

and leads to discoid patches or extensive plaques, which may be as wide as 30 cm.

Eventually, through coalescence of the various plaques, the involvement becomes widespread, but there are usually patches of apparently normal skin interspersed. When the involvement is advanced, painful superficial ulcerations may occur. During this phase, enlarged lymph nodes usually develop. They are nontender, firm, and freely movable.

The tumor stage is characterized by large, various-sized and shaped nodules on infiltrated plaques and on apparently normal skin. These nodules have a tendency to break down early and to form deep oval ulcers, whose bases are covered with a necrotic grayish substance and which have rolled edges (Fig. 32-4). The lesions generally have a predilection for the trunk, although they may be seen anywhere on the skin or may involve the mouth and upper respiratory tract. Uncommonly, tumors may be the first sign of mycosis fungoides.

The erythrodermic variety of mycosis fungoides is a generalized exfoliative process, with universal redness. The hair is scanty, nails are dystrophic, palms and soles are hyperkeratotic, and at times there may be generalized hyperpigmentation (Fig. 32-5). Erythroderma may be the presenting feature.

Alopecia mucinosa The infiltrating cells of mycosis fungoides can demonstrate a predilection for involving the hair follicle (Fig. 32-6). This may be observed simply by

Fig. 32-2 Mycosis fungoides, hypopigmented patches.

Fig. 32-5 Erythrodermic mycosis fungoides.

Fig. 32-6 Follicular mycosis fungoides.

Fig. 32-7 Alopecia mucinosa.

folliculotropism of the cells (pilotropic or follicular mycosis fungoides) or by the appearance of follicular mucinosis (Fig. 32-7). In all cases of follicular mucinosis, the histologic specimen should be carefully examined and the diagnosis of mycosis fungoides considered. Among patients older than 40 years of age who have follicular mucinosis, a large percentage will have mycosis fungoides or go on to develop it. However, the finding of a T-cell clone in lesions of follicular mucinosis without mycosis fungoides is not predictive of the development of cutaneous T-cell lymphoma.

Selective tropism of the cutaneous T-cell lymphoma cells to the sweat glands and ducts is termed syringotropic cutaneous T-cell lymphoma (Fig. 32-8). This is often seen in conjunction with follicular involvement. Syringolymphoid hyperplasia may be seen in these cases histologically and may mimic eccrine carcinoma. Cases previously termed "syringolymphoid hyperplasia with alopecia" are now considered to be cutaneous T-cell lymphoma. Clinically, the lesions present as discrete follicular and nonfollicular erythema, along with alopecia, milia, and follicular cysts. The initial clinical diagnosis in such cases is often discoid lupus erythematosus. The prognosis in mycosis fungoides with axillary involvement is as predicted by the staging system for other forms of mycosis fungoides.

Systemic manifestations

Mycosis fungoides as a form of malignant lymphoma may progress to include visceral involvement. Lymph node involvement is most common; it predicts progression of the disease in at least one-quarter of patients and reduces survival to

Fig. 32-8 Syringotropic mycosis fungoides.

about 7 years. Any other evidence of visceral involvement is a grave prognostic sign. An abnormal result on liver-spleen scan, chest radiograph or CT evaluation, abdominal or pelvic CT scans, or bone marrow biopsy is associated with a survival of about 1 year. The prognosis is worse in non-Caucasian patients with early-onset mycosis fungoides, especially African American women.

Pathogenesis

Mycosis fungoides is a neoplasm of memory helper T cells in most cases. Rare cases of suppressor cell (CD8+) mycosis fungoides have been reported. These CD8+ cases may behave indolently, like mycosis fungoides, or aggressively. The latter aggressive subset tends to present with plaques rather than patches. The events leading to the development of the malignant T cells are unknown. It has been speculated that it is caused by chronic exposure to an antigen, but this has yet to be confirmed. Patients with atopic dermatitis appear to be at increased risk for the development of mycosis fungoides, suggesting that persistent stimulation of T cells may lead to development of a malignant clone.

The inflammatory nature of the skin lesions has led to investigation of the interactions of the malignant T cells and both keratinocytes and antigen-presenting cells (including Langerhans cells) in mycosis fungoides. Mycosis fungoides skin lesions have many features of skin that is immunologically "activated." Mycosis fungoides cells express cutaneous lymphocyte antigen (CLA), the ligand for E selectin, which is expressed on the endothelial cells of inflamed skin. This allows the malignant cells to traffic into the skin from the peripheral blood. CCR4, another homing molecule, is expressed on mycosis fungoides cells, and the ligand for this receptor is on basal keratinocytes. Antigen-presenting cells are increased in mycosis fungoides lesions and have increased functional capacity to activate T cells. There is increased expression of major histocompatibility complex (MHC) class II antigens on the surface of the antigen-presenting cells. Through cytokines, infiltration of neoplastic and reactive T cells is increased. The pattern in early mycosis fungoides is more T-helper 1 (Th1)-like and the non-neoplastic infiltrating cells (tumor infiltrating lymphocytes [TILs]) may play a role in downregulating and controlling the neoplastic cells. There are more CD8+ cells in these early lesions and these TILs may control the malignant clone. In fact, mycosis fungoides patients with more than 20% CD8+ cells in their skin survive longer than those with less than 15%. In summary, early mycosis fungoides is a condition in which host immunity is intact and the host immune system effectively limits proliferation of the malignant T-cell clone. In more advanced mycosis fungoides and in Sézary syndrome,

perhaps through interleukin (IL)-4 and 10, a Th2 environment exists. This downregulates suppressor cell function and allows the malignant clone to proliferate. In addition, the Th2-dominant environment reduces effective helper T-cell function, explaining the increased risk of infection and secondary cancer in patients with advanced cutaneous T-cell lymphoma. Correcting the aberrant immune response in advanced cutaneous T-cell lymphoma is the basis of some treatment approaches.

Common chromosomal alterations in mycosis fungoides include gain of 7q36 and 7q21-7q22, and loss of 5q13 and 9p21. This characteristic pattern differs from that seen in Sézary syndrome, suggesting that the two disorders are distinct. Low levels of human herpesvirus (HHV) 8 have been detected in large-plaque parapsoriasis as well as mycosis fungoides, but an etiologic link has not been established.

As mycosis fungoides advances, the number of circulating malignant T cells increases. Standard cytologic evaluation (the Sézary preparation) is expensive and not very accurate, even when enhanced by specific labeling techniques. Use of standard laboratory tests, such as the CD4/CD8 ratio test, which increases as mycosis fungoides progresses, and assessment of the number of CD4+,CD7- or CD4+,CD26- circulating cells, which relatively specifically identify mycosis fungoides cells, yield indicators of tumor burden with advanced disease but are of limited value in early disease.

Histopathology

Perhaps more than in any other situation in dermatopathology, the ability to diagnose mycosis fungoides histologically correlates closely with the skill, training, and experience of the reviewing pathologist. When the clinician is considering a diagnosis of mycosis fungoides, consultation with a skilled dermatopathologist should be strongly considered if original histologic reports are nonconfirmatory or nonspecific.

In patch-stage lesions there is subtle epidermotropism of lymphocytes that resembles a vacuolar interface dermatitis with a lymphocyte in every vacuole. As lesions progress, there is a distinct bandlike distribution of lymphocytes with epidermotropism. At this stage, there is a large dark lymphocyte in every vacuole. The lymphocytes within the epidermis may be numerous or few in number, but are typically larger, darker, and more angulated than those in the dermis. Papillary dermal fibrosis is typically present. The superficial perivascular lymphoid infiltrate that surrounds the postcapillary venule is typically more prominent above the vessel than below the vessel (bare under-belly sign).

Plaques of mycosis fungoides show a more prominent superficial bandlike lymphoid infiltrate and a deeper perivascular dermal component than patch-stage lesions. Papillary dermal fibrosis is more prominent and the subpapillary plexus is shifted downward. Epidermotropism is much more marked and is typically associated with very little spongiosis. This helps distinguish patch-stage mycosis fungoides from spongiotic dermatitis. Vesicular variants are an exception to this rule. In vesicular variants, spongiosis is prominent and results in intraepidermal and subcorneal vesiculation. Eosinophils are common in folliculotropic mycosis fungoides (with or without follicular mucinosis), but are uncommon in other forms of mycosis fungoides.

In thick plaques and tumors, epidermotropism may be substantially diminished. The diagnosis is confirmed by the presence of dense sheets of infiltrating lymphocytes in the dermis and subcutaneous fat. These cells may have cerebriform nuclei.

Cardinal features that should suggest a diagnosis of mycosis fungoides include the following:

- solitary or small groups of lymphocytes in the basal cell layer

- epidermotropism of lymphocytes, with disproportionately scant spongiosis
- more lymphocytes within the epidermis than would normally be seen in an inflammatory dermatosis, with little accompanying acanthosis or spongiosis
- lymphocytes in the epidermis larger than those in the dermis
- papillary dermal fibrosis with bundles of collagen arranged haphazardly
- prominent folliculotropism or syringotropism of the lymphocytes, especially with intrafollicular mucin deposition (follicular mucinosis).

Features that should suggest a diagnosis of inflammatory dermatosis over mycosis fungoides include the following:

- prominent upper dermal and papillary edema
- marked epidermal spongiosis
- accumulation of the intraepidermal inflammatory cells in flask-shaped collections, with the top open to the stratum corneum.

Immunohistochemistry is of some value in assessing mycosis fungoides. Mycosis fungoides cells characteristically are CD4+, but lose the CD7 and CD26 antigens, i.e. they are CD4+,CD7-,CD26-. This phenotype is very unusual for nonmalignant T cells and thus is useful in evaluating biopsy specimens and peripheral blood lymphocytes. Loss of CD7 expression within the large dark lymphocytes in the epidermis, with normal expression in the benign recruited lymphocytes in the infiltrate below, suggests a diagnosis of mycosis fungoides. DNA hybridization or a Southern blot test is frequently performed in equivocal cases to detect clonal rearrangement of the T-cell receptor (TCR). However, these data must be interpreted with caution; clonality does not confirm a diagnosis of malignancy. Benign processes may contain clonal TCR rearrangements. In early lesions of mycosis fungoides, the number of infiltrating cells may be insufficient for a clone to be detected, so a negative test does not exclude the diagnosis of mycosis fungoides. Testing with fresh tissue is somewhat more sensitive than with fixed tissue using current methods. Similar techniques can be used to evaluate lymph nodes in mycosis fungoides patients. Lymph node involvement can be detected by these molecular methods, while the routine histologic evaluation yields normal results. Patients with more advanced disease are more likely to have clones in their lymph nodes, and the presence of clonality is predictive of shorter survival.

Differential diagnosis

In the early patch stage, mycosis fungoides may be difficult to diagnose. The skin lesions usually resemble a nondescript form of eczema with some scale. Interestingly, despite the itching, scratch marks and lichenification are usually absent. Mycosis fungoides presenting as papuloerythroderma of Ofuji is an obvious exception. The multiple morphologies of mycosis fungoides make the differential diagnosis vast. Plaque-like lesions may resemble subacute dermatitis or psoriasis. Tumors must be differentiated from other forms of lymphoreticular malignancy and metastases.

Treatment

Effective therapy that reliably prolongs survival has not yet been documented. Many forms of therapy induce remissions of variable length. The choice between them depends on extent of disease, the patient's overall health and physical status, the physician's experience and preference, and the availability of various options. Topical steroids, topical nitrogen mustard or 1,3-bis (2-chloroethyl)-1-nitrosourea (carmustine) (BCNU),

bexarotene gel 1%, and PUVA (or narrow-band UVB) are generally good choices for stages IA, IB, and IIA disease. Patch-stage mycosis fungoides has responded to alefacept. Total skin electron beam (TSEB) therapy can be used for refractory stage IIA and IIB cases. Single-agent chemotherapy or photophoresis can be employed as initial management for stage III patients. Low-dose methotrexate may control the skin lesions of mycosis fungoides, but has been associated with the development of a secondary aggressive lymphoma in a few patients. Pegylated liposomal doxorubicin and combinations of IFN- α , retinoids (bexarotene or isotretinoin), photophoresis, IFN- γ , skin-directed PUVA, sargramostim (granulocyte macrophage colony-stimulating factor), alemtuzumab, and perhaps IL-2, IL-12, and IFN- α may be effective in stage IV disease, and for patients who have failed the above therapies for stages IIB and III mycosis fungoides. Multiagent systemic chemotherapy is used much less commonly with the advent of immunomodulatory treatments for mycosis fungoides. It should only be considered when all other treatment options have failed. Treatment of early-stage disease is in general restricted to skin-directed treatments. More advanced disease is treated with different modalities at different institutions. Combinations of agents are often used, and those combinations and their order of use vary from one institution to the next. In general, therapies that also enhance the patient's immune system are favored in persons with more advanced disease. Complete remission has been noted following a severe reaction to combined therapy with bexarotene, vorinostat, and high-dose fenofibrate. The reaction included fever, extensive skin necrosis, and granuloma formation.

Topical corticosteroids The availability of superpotent class I topical corticosteroids has led to a reassessment of their possible role in the management of early (patch-stage, T1 and T2) mycosis fungoides. Zackheim reported a 63% complete remission for patients with T1 disease and a total response rate of 94% in T1 patients. In T2 patients, complete responses were only 25% but total responses were 82%. The predominant side effect was a temporary and reversible suppression of the hypothalamic-pituitary axis in about 13% of patients. The responses were short-lived if therapy was stopped, but given the limited toxicity, this is not necessary in many patients. The adjunctive value of topical corticosteroids in T1 mycosis fungoides requires reappraisal because the response rates are similar to other modalities used for early mycosis fungoides and the toxicity is very low.

Topical nitrogen mustard The contents of a 10 mg vial of mechlorethamine hydrochloride (Mustargen-MSD) are dissolved in 60 mL of tap water and applied to the entire skin surface, except the face, axillae, and genitalia, with a 2 inch paint brush or gauze pad. The last milliliter may be diluted to half-strength or greater dilution for application to the face, axillae, and genitalia. Daily applications are made until complete clearing occurs, which usually takes several months or longer, and may be continued indefinitely. Such treatment leads to complete responses in 80% of patients with stage IA disease, 68% in patients with stage IB, 61% in stage IIA, 49% in stage IIB, and 60% in stage III patients. About 10% of patients obtain a durable and long-lasting remission of over 8 years. The major side effects of topical nitrogen mustard (NH₂) therapy are cutaneous intolerance, which occurs in almost 50% of patients, and allergic contact dermatitis, which occurs in 15%. Short (1 h) contact does not reduce this rate of sensitization. This can be reduced by the use of an ointment formulation, but response rates have been reported to be inferior with the ointment form. At least half of patients will relapse when therapy is stopped, but frequently will respond again to NH₂.

The duration of maintenance therapy after achieving remission varies in different centers. Some treat for an additional 6 months and others taper treatment over a year

or more, or continue treatment indefinitely. In many centers, topical nitrogen mustard has been a proven mainstay of therapy for patch- or plaque-stage mycosis fungoides without lymphadenopathy.

Topical BCNU (carmustine) BCNU, 2 mg/mL in 150 mL aliquots, dissolved in ethanol, is dispensed to the patient. From this stock solution the patient takes 5 mL and adds it to 60 mL of water at room temperature. This is applied once a day to the whole body, sparing the folds, genitals, hands, and feet (if they do not have lesions). If the extent of disease is limited, only the affected areas are treated. The average treatment course is 8–12 weeks. If, after 3–6 months, the patient's condition is not responding, the concentration may be doubled and the treatment repeated for 12 weeks. For small or persistent lesions, the straight stock solution may be applied daily. Patients tolerate BCNU better than nitrogen mustard, contact sensitization is uncommon, and responses are more rapid. Complete blood counts should be monitored monthly during treatment, but marrow suppression occurs in less than 10% of patients treated with the low concentrations. Telangiectasia, which may be persistent and severe, can occur after prolonged BCNU therapy or following an adverse cutaneous reaction to the medication.

Ultraviolet therapy Both UVB (narrow- or broad-band) and PUVA (systemic or bath) have been effective in the management of mycosis fungoides. About 75% of patients with patch-stage disease will have a complete clinical remission with UVB therapy. Home therapy is successful. PUVA has been used more extensively and, because of its deeper penetration, is perhaps better suited to the treatment of a disorder with a dermal component. Complete clearing is seen in 88% of patients with limited patch/plaque disease and in 52% of patients with extensive disease. Tumor-stage patients do not clear. Erythrodermic patients have poor tolerance for PUVA. Up to 50% of patients with a complete response to PUVA may have a remission of up to 10 years. Retinoids and IFN- α may be added to PUVA. Retinoids may reduce the total number of PUVA treatments required. Low-dose IFN- α plus PUVA may be used in patch-stage patients in whom topical therapy and PUVA alone are ineffective. The excimer laser may be used once or twice a week to deliver the phototherapy if the patient has a limited number of lesions. On average, 5–6 weeks of treatment are required, and remissions of up to 2 years or more can be achieved.

Extracorporeal photochemotherapy (photophoresis, ECP) is a therapeutic modality in which the circulating cells are extracted and treated with UVA outside the body; the patient ingests psoralen before the treatment. Complete responses are seen in a small percentage of mycosis fungoides patients, about 20%, and a partial response occurs in a similar percentage of patients. In the original reports, the overall response rate for erythrodermic patients was 80%, but many of these patients failed to have at least the 50% clearing required to be considered a partial response. In one comparative trial, standard PUVA was significantly more effective than photophoresis alone, and photophoresis was judged ineffective in plaque-stage (T2) mycosis fungoides. ECP is now used in combination with other agents, especially IFN- α , and appears to have better efficacy. Insulin-dependent diabetics respond poorly.

Radiation TSEB therapy in doses in excess of 3000 Gy is very effective in the management of mycosis fungoides. Stage T1 patients have a 98% complete response; stage T2, 71%; stage T3, 36%; and stage T4, 64%. Long-term remissions occur in about 50% of T1 patients and 20% of T2 patients. Erythrodermic patients tolerate TSEB therapy poorly; other modalities should be attempted initially. Adjuvant therapy with a topical agent or PUVA can be considered if the patient relapses, which is a frequent occurrence. The most common side effects of TSEB therapy are erythema, edema, worsening of lesions, alopecia,

and nail loss. Persistent hyperpigmentation and chronically dry skin are also problems after TSEB therapy. Orthovoltage radiation may be used to control tumors or resistant thick plaques in patients whose conditions have been otherwise controlled with another modality.

Biologic response modifiers (multimodality immunomodulatory therapy) The appearance of circulating malignant T cells in mycosis fungoides may indicate failure of the host immune system to control the disease. Immunomodulatory agents are used in an attempt to enhance host immune function and gain control of the disease. It is often combined with treatments that increase malignant cell apoptosis, so that the “tumor antigens” released will be recognized and immunologically “attacked” by the host immune system. These immunomodulatory agents both activate antigen-presenting cells and enhance Th1 immune function directed against the malignant T-cell clone. IFN- α and IFN- γ have been shown to have efficacy against mycosis fungoides. IFN- α is associated with a positive response in about 60% of patients and a complete response in 19%. If it is used as a single agent, toxicity is high and includes fever, chills, myalgias, neutropenia, and depression. Low-dose IFN- α and IFN- γ treatments and granulocyte macrophage colony-stimulating factor are now used in an adjunctive fashion in combination with retinoid therapy, phototherapy, and other modalities. This is termed multimodality immunomodulatory therapy. IL-2 and 12 may be used in a similar fashion in the future.

Retinoids Both isotretinoin and etretinate have efficacy in the treatment of mycosis fungoides. A clinical response is noted in about 44% of patients. Dosage of isotretinoin is about 1 mg/kg/day to start, and may be increased up to 3 mg/kg/day as tolerated. Retinoids may be effective in stage IB (T2) and stage III patients, and as a palliative treatment in those with stage IVA disease. Bexarotene (Targretin), a synthetic retinoid that is bound preferentially by the retinoid X receptor (RXR), is felt to work by inducing apoptosis in the malignant T cells. It is available as a 1% topical gel and as an oral tablet. Topical therapy is used in patients with stage IA–IIA cutaneous T-cell lymphoma. Patients improve about 50% with this treatment. Oral bexarotene at a dose of 300 mg/m² also has a response rate of about 50% in early-stage cutaneous T-cell lymphoma. This dose is complicated by hypercholesterolemia, marked hypertriglyceridemia (at times complicated by pancreatitis), central hypothyroidism, and leukopenia. It may be combined with PUVA and other forms of treatment at a lower dose.

Systemic chemotherapy For most forms of cancer, combinations of chemotherapeutic agents are given. In mycosis fungoides, however, multidrug chemotherapy often exacerbates the ongoing immune imbalance and may prevent the patient’s immune system from attacking the malignant T cells. For this reason, and due to the enhanced efficacy of combination immunomodulatory treatment regimens, systemic chemotherapy is now very uncommonly used for mycosis fungoides. Methotrexate, in doses from 5 to 125 mg/week, is effective for the management of T3 patients. In these patients, Zackheim et al demonstrated that 41% had a complete response, and an additional 17% a partial response, giving a total response of 58%. The median overall survival was 8.4 years and 69% of patients were alive at 5 years. For advanced mycosis fungoides, higher doses of methotrexate with citrovorum-factor rescue were successful in obtaining a response, which was then maintained with lower doses of methotrexate, not requiring rescue. Similarly, pentostatin, etoposide, fludarabine, and 2-chlorodeoxyadenosine have been used. Systemic chemotherapy beyond methotrexate, especially multiagent chemotherapy, is best managed by an oncologist. Systemic chemotherapy is only indicated in stage III and IVA patients who have failed all the available immunoenhancing treatment

protocols noted above. A number of new agents are being evaluated for the treatment of mycosis fungoides. Histone deacetylase inhibitors including vorinostat demonstrate responses in a subgroup of patients. Forodesine is a novel inhibitor of purine nucleoside phosphorylase and pralatrexate is a novel targeted antifolate agent.

Fusion toxin DAB389IL-2 is the fusion of a portion of the diphtheria toxin to recombinant IL-2. This selectively binds to cells expressing the IL-2 receptor and leads to their death. A series of mycosis fungoides cases that expressed the IL-2 receptor demonstrated a response rate of 37%, including a complete response in 14% of cases. These patients had failed conventional therapies. Patients in stages I–III achieved response, but no patient with stage IV disease did so. Fever, chills, hypotension, nausea, and vomiting were common and at high doses a vascular leak syndrome occurred. This agent is reserved for advanced-stage patients who have failed other modalities.

Pagetoid reticulosis

Localized epidermotropic reticulosis, Pagetoid reticulosis, or Wroinger-Kolopp disease is an uncommon lymphoproliferative disorder considered to be a form of mycosis fungoides. Other terms suggested for these cases have been acral mycosis fungoides or mycosis fungoides palmaris et plantaris. In large mycosis fungoides clinics, such cases represent about 0.6% of all mycosis fungoides cases. Pagetoid reticulosis is divided

into classic Woringer-Kolopp, which usually describes solitary lesions, and cases with multiple lesions (Ketron-Goodman variant). The unique features of Woringer-Kolopp disease are clinical. The disease presents as a solitary lesion that is often located on an extremity and frequently has a keratotic rim. If there is more than a single lesion, there is often a propensity for lesions to involve both the palms and soles. Frequently, over months to years, the lesion gradually enlarges, reaching a size of over 10 cm. In some cases, the lesions spontaneously come and go over many years. Twenty percent of cases occur in patients who are younger than 15 years of age. The long duration without progression has been a clinical hallmark of Woringer-Kolopp disease. Histologically, there is prominent epidermotropism of lymphocytes, with many lining up in the basal cell layer. This histologic pattern correlates with strong $\alpha E-\beta 7$ and $\alpha 4-\beta 7$ integrin expression by the infiltrating cells. This integrin expression is also seen in the epidermotropic cells of classic mycosis fungoides and contact dermatitis. In mycosis fungoides, most cases are CD4+, but in the acral mycosis fungoides cases they may be CD4+, CD8+, or negative for both. TCR gene rearrangements can be detected in many cases of Woringer-Kolopp disease. Therapeutically, local excision and radiation therapy have been “curative” in many cases. Topical and systemic PUVA has also proved effective. Local recurrence is possible.

Sézary syndrome

Sézary syndrome is the leukemic phase of mycosis fungoides. The characteristic features are generalized erythroderma, superficial lymphadenopathy, and atypical cells in the circulating blood. Although patients with classic mycosis fungoides may progress to Sézary syndrome, usually patients with Sézary syndrome are erythrodermic from the onset. The skin shows a generalized or limited erythroderma of a typical fiery red color. Associated features can include leonine facies, eyelid edema, ectropion, diffuse alopecia, hyperkeratosis of the palms and soles, and dystrophic nails. Some patients develop lesions identical to vitiligo, especially on the lower legs. The symptoms are those of severe pruritus and burning, with episodes of chills. Prognosis is poor, with an average survival of about 5 years.

Superficial lymphadenopathy is usually found in the cervical, axillary, and inguinal areas. Leukocytosis up to 30 000/mm³ is usually present. In the peripheral blood, skin infiltrate, and lymph nodes, helper T cells with deeply convoluted nuclei are found—the so-called Sézary cells. Chromosomal aberrations are common, but differ from the typical pattern seen in mycosis fungoides. Resistance to Fas-ligand and TNF-related apoptosis has been demonstrated.

Histologically, and by immunohistochemistry, there are no reproducible differences between cases of mycosis fungoides and Sézary syndrome. In a fair number of cases of the latter, the cutaneous histology may be nonspecific, showing a spongiotic dermatitis. Additional hematologic evaluation may be necessary to confirm the diagnosis in the erythrodermic patient. T-cell gene rearrangement studies are frequently used to confirm the diagnosis of Sézary syndrome. In addition, an increased CD4/CD8 ratio in the blood, with an increase in the number of CD3+/CD4+/CD7-/-CD26- circulating cells, is suggestive of leukemic mycosis fungoides.

The erythroderma of Sézary syndrome must be distinguished from chronic lymphocytic leukemia (CLL), psoriasis, atopic dermatitis, photodermatitis, seborrheic dermatitis, contact dermatitis, drug reaction, and pityriasis rubra pilaris. This is done primarily by histopathologic and immunopathologic examination. In Sézary syndrome, the infiltrating T cells in the skin have a Th2 phenotype, and Th2 cytokines are produced by these cells. This explains the reduced delayed-type

hypersensitivity, elevated IgE, and eosinophilia seen in these patients.

Sézary syndrome is difficult to treat. Low-dose methotrexate has a reasonable response rate of about 50% and an overall survival of 101 months, suggesting a survival benefit with its use. Photopheresis, used in combination with other agents, is effective in some patients, but the median survival time is only between 39 and 60 months (see above). TSEB radiation has produced some complete cutaneous responses, as well as improvement in the blood burden of malignant cells. Zanolimumab has also been used in this setting.

Granulomatous slack skin

Granulomatous slack skin is a rare variant lymphoma that typically presents in middle-aged adults and gradually progresses over years. It occurs more often in men. Lesions are erythematous, atrophic, bulky, infiltrated, pendulous, and redundant plaques in the axillae and groin (Fig. 32-9). Unusual presentations may resemble Hansen’s disease or acquired ichthyosis. Histologically, there is a lymphohistiocytic infiltrate extending through the dermis into the subcutaneous fat. Focal collections of huge, multinucleated cells with 20–30 nuclei arranged in a wreath-like pattern are characteristic. Elastophagocytosis is prominent and elastic tissue is absent in areas of inflammation. Lymphocytes are also found within the multinucleate giant cells and are arranged around them. Epidermotropic lymphocytes are also seen. Immunohistologically, the cells are CD4+. T-cell gene rearrangements can be detected. In most patients, the condition evolves into mycosis fungoides, but about one-third of patients with granulomatous slack skin develop Hodgkin disease after years to decades.

Fig. 32-9 Granulomatous slack skin.

Lymphomatoid papulosis

Lymphomatoid papulosis (LyP) is an uncommon, but not rare disorder. It occurs at any age, including childhood, but is most common in adults with a mean age of 44. In most typical cases, the lesions and course are very similar to that of Mucha-Habermann disease (pityriasis lichenoides et varioliformis acuta), except that the lesions tend to be slightly larger and fewer in number, and have a greater propensity to necrosis. Symptoms are usually minimal. The primary lesion is a red papule up to about 1 cm in diameter (Fig. 32-10). The lesions evolve to papulovesicular, papulopustular, or hemorrhagic, then necrotic papules over days to weeks. They typically heal spontaneously within 8 weeks, somewhat longer in larger lesions. Lesions are usually generalized, although cases limited to one anatomic region have been reported.

There may be crops of lesions or a constant appearance of a few lesions. In most patients, however, the condition tends to be chronic, and lesions are present most of the time if no treatment is given. The average number of lesions present at any one time is usually 10–20, but cases with more than 100 lesions occur. Lesions heal with varioliform, hyperpigmented, or hypopigmented scars. Cases previously reported as solitary, large nodules of lymphomatoid papulosis would now be classified as CD30+ large-cell lymphomas or as overlaps between LyP and lymphoma, termed borderline cases. Localized agminated LyP may be seen in areas typical for mycosis fungoides.

The diagnosis of LyP is confirmed histologically. There is a dermal infiltrate that is wedge-shaped, patchy, and perivascular. In larger lesions, the infiltrate may occupy the whole dermis. It may also be bandlike. The infiltrate may involve the epidermis, with epidermotropism of inflammatory cells. As lesions evolve, epidermal necrosis and ulceration may occur. The dermal vessels may demonstrate fibrin deposition and, more rarely, a lymphocytic “vasculitis.” The dermal infiltrate is composed of lymphoid cells, eosinophils, neutrophils, and larger mononuclear cells. Atypical large or small lymphoid cells are present and may represent up to 50% of the infiltrate. Histologically, lesions have been classified into type A, type B, and type C lesions.

Type A lesions contain atypical large cells with abundant cytoplasm and prominent nuclei, with prominent eosinophilic nucleoli. If these cells contain two nuclei, they closely resemble Reed–Sternberg cells. In type B lesions, the atypical cells are smaller, with a smaller cerebriform, hyperchromatic nucleus. These resemble the atypical cells of mycosis fungoides. In both types of lesion, atypical mitotic figures may be observed.

Fig. 32-10 Lymphomatoid papulosis. (Courtesy of M. Rosenbach, MD)

Immunophenotypically, the large atypical cells mark as T cells, usually of the helper type. The atypical cells, especially those of the type A lesions, stain for the activation marker Ki-1 or CD30. Bcl-2 expression occurs in about 50% of cases. When clonal rearrangement studies are performed, clonal rearrangements may be found in up to 40% of LyP lesions, but this finding is not predictive of the behavior of that lesion or the case in general. Type C lesions overlap with primary cutaneous large-cell lymphoma with no clear distinction between the two. CD8+ LyP is a rare variant in which the Tc2 subset of CD8+ T cells proliferates and attracts eosinophils.

Lymphomatoid papulosis types A and B are associated with lymphoma. In the general literature this number is about 5–10%, but some reports have documented rates as high as 20%, and at the University of California at San Francisco (UCSF) up to 40% of cases of LyP have an associated lymphoma. The lymphoma may occur before, concurrently with, or after the appearance of the LyP. In most cases, the LyP precedes the development of lymphoma, sometimes by a long period—up to 20 years. The associated lymphoma is most commonly mycosis fungoides (40%), a CD30+ T-cell lymphoma (30%), or Hodgkin disease (25%). The lymphoma and LyP may behave quite independently. If the lymphoma is successfully treated and cleared, the LyP typically continues. Despite this independent behavior, the lymphoma and the LyP may contain the same clonal TCR gene rearrangement. Patients with pure type B lesions are much less likely to develop lymphoma than patients with type A lesions. Lesions of LyP may occur on a background of mycosis fungoides and must be distinguished from CD30-positive large-cell transformation of mycosis fungoides. Papular lesions of LyP tend to occur in crops. Even though the LyP lesions may demonstrate the same clonal rearrangements as the mycosis fungoides, they often continue to appear in crops, even when the mycosis fungoides lesions respond to therapy.

Therapy may not be necessary; there is no evidence that treatment of LyP prevents the development of secondary lymphoma. When any therapy is stopped, the LyP invariably returns. Therefore, patients only need to be treated if they are moderately symptomatic and the treatment has fewer potential complications than the benefits gained. Superpotent topical corticosteroids have been beneficial in some childhood cases. Topical bexarotene may abort early lesions, and oral bexarotene may suppress lesion formation. PUVA systemically or topically may be effective, although maintenance treatment is usually required. Both narrow- and broad-band UVB may be successful. Of all the systemic agents, methotrexate gives the most dependable response, with up to 90% of LyP patients improving significantly. It is given in weekly doses similar to those used for rheumatoid arthritis—usually 7.5–15 mg/week. Higher doses may be required in some patients. Response is rapid. Some patients treated with methotrexate may have remissions of the LyP. In most, however, maintenance therapy is required.

Pityriasis lichenoides

Both the acute and chronic forms of pityriasis lichenoides are lymphocytic vasculitides. The lymphoid infiltrate may contain

a clonal proliferation. However, progression to cutaneous lymphoma is rare.

Pityriasis lichenoides et varioliformis acuta (Mucha–Habermann disease)

Pityriasis lichenoides et varioliformis acuta (PLEVA) is a disorder that usually appears suddenly in children or young adults. Individual lesions are erythematous macules, papules, or papulovesicles. Lesions tend to be brownish-red and evolve through stages of crusting, necrosis, and varioliform scarring. Lesions tend to appear in crops, and may number from a few to more than 100 (Fig. 32-11). In general, PLEVA patients have more and smaller lesions than patients with LyP. The trunk is favored, but even the palms and soles may infrequently be involved. The patient feels otherwise well. The natural history is benign, with spontaneous involution occurring over 1–3 years. In children, diffuse cases resolved more quickly than cases that were purely central; cases with primarily peripheral lesions took almost twice as long to resolve.

Histologically, PLEVA is characterized by epidermal necrosis, together with prominent hemorrhage and a dense perivascular infiltrate in the upper and mid-dermis in a wedge-shaped pattern. Lymphocytic vasculitis may be seen. T-cell gene rearrangements may be detected, but the significance of that finding is unclear at this time. Treatment of PLEVA may include oral erythromycin or tetracyclines and phototherapy (broad- or narrow-band UVB, PUVA, or photodynamic therapy). Topical tacrolimus may be effective. Low-dose methotrexate, 5.0–15 mg/week, may be required in severe cases. A rapid response to azithromycin has been reported. Etanercept has been reported as effective, but infliximab has been reported to cause pityriasis lichenoides.

An unusually severe form of PLEVA (febrile ulceronecrotic Mucha–Habermann disease) is characterized by the acute onset of diffuse, coalescent, large, ulceronecrotic skin lesions associated with high fever and constitutional symptoms. The condition may begin as typical PLEVA, but the ulceronecrotic lesions usually begin to appear within a few weeks. Skin necrosis may be extensive, especially in the intertriginous regions. Associated symptoms include gastrointestinal and central nervous system (CNS) symptoms, pneumonitis, myocarditis, and even death (in adult cases). The condition favors boys who are 18 years of age or younger. This severe form of PLEVA usually lasts several months with successive outbreaks, then resolves or converts to more classic PLEVA. Reported triggers include viral infections and radiocontrast injection. Treatment is systemic steroids, and if response is limited, methotrexate. Dapsone may also be useful, for maintenance and as a steroid-sparing agent.

Fig. 32-11 Mucha–Habermann disease.

Pityriasis lichenoides chronica

Pityriasis lichenoides chronica (PLC) is a chronic form of pityriasis lichenoides, related to PLEVA by its common histology. Lesions are erythematous, scaly macules and flat papules with very slow evolution. Lesions each last several months. The eventual resolution of lesions of PLC distinguishes it from guttate parapsoriasis, which it may resemble clinically. Lesions of small-plaque parapsoriasis do not spontaneously resolve. Lesions of PLC favor the lateral trunk and proximal extremities. Patients may have from 10 to hundreds of lesions, but usually fewer than 50. Resolution may leave persistent areas of hypopigmentation, which last for months to years. In many patients, the hypopigmented macules are the most prominent clinical finding. Unlike PLEVA, PLC tends to last for many years. Lesions may occur at any age. The condition commonly affects children, and onset at birth has been described.

Histologically, the changes are similar to PLEVA but much more subtle. A mild interface or perivascular lymphocytic infiltrate with overlying parakeratosis may be present. T-cell gene rearrangement studies may demonstrate monoclonality; however, the meaning of this finding is unclear at this time. Treatment with phototherapy (natural sunlight, UVB, UVA1, or PUVA) is most effective. Topical steroids or tacrolimus may be tried. No treatment is required.

PLC is generally a benign disease. There are rare patients who have progressed to develop cutaneous T-cell lymphoma. The authors recommend that patients with PLC be followed regularly and changes in lesion morphology, including induration, erosion, atrophy, persistent erythema, or poikiloderma, should trigger repeat pathologic evaluation.

Primary cutaneous T-cell lymphomas other than mycosis fungoides

Once a cutaneous lymphoma has been identified as being of T-cell origin and the diagnosis of mycosis fungoides and its variants has been excluded, the most important evaluation is to determine the CD30-staining pattern. CD30 is a marker found on some activated, but not resting T and B cells. It also marks the Reed–Sternberg cells of Hodgkin disease. Monoclonal antibodies Ki-1 and Ber H2 are used to identify CD30 positivity. A cutaneous lymphoma is considered to be CD30+ if there are large clusters of CD30+ cells or more than 75% of the anaplastic T cells are CD30+. Systemic CD30+ lymphoma with cutaneous involvement has a poor prognosis. Those cases that

express anaplastic lymphoma kinase (ALK-1) associated with a 2:5 translocation have a somewhat better prognosis. Primary cutaneous large T-cell lymphomas that are CD30+ are typically ALK-1-negative, have a very good prognosis, and tend to run a relapsing course similar to that of lymphomatoid papulosis. Individual lesions respond to irradiation and the relapsing course may remit with low-dose methotrexate. Large-cell lymphomas of the skin have similar histologic and clinical features, so immunophenotyping is essential for prognosis. Clonal TCR gene rearrangements are present in large-cell T-cell lymphoma. The group of T-cell lymphomas that are not large-cell and CD30+ are classified in the WHO system as peripheral T-cell lymphomas.

CD56 is rapidly becoming the second most important immunophenotypic marker for cutaneous lymphomas. Four important variants of CD56+ cutaneous lymphomas have been identified: a subset of subcutaneous panniculitis-like T-cell lymphoma; natural killer (NK)/T-cell lymphoma; blastic NK cell lymphoma; and CD8+ aggressive epidermotropic cytotoxic T-cell lymphoma.

Peripheral T-cell lymphoma is a heterogeneous grouping that includes primary cutaneous CD30+ nonanaplastic large-cell lymphoma, primary cutaneous CD30- anaplastic and nonanaplastic large-cell lymphoma, and primary cutaneous CD30- pleomorphic small-/medium-cell lymphoma.

CD30+ cutaneous T-cell lymphoma (primary cutaneous anaplastic large-cell lymphoma)

Clinically, these lymphomas present as solitary or localized skin lesions that have a tendency to ulcerate (50%), spontaneously regress (25%), and relapse. They are rare in children and occur with slightly greater frequency in males. Lesions are usually firm, red to violaceous tumors up to 10 cm in diameter (Fig. 32-12). Tumors may grow in a matter of weeks. There is no favored anatomic site. Onset has been reported during glatiramer acetate treatment of multiple sclerosis.

Relapses in the skin are common, but the development of extracutaneous, bone marrow, or lymph node involvement is uncommon. Clonal populations may occasionally be demonstrated in peripheral blood, but differ from those in the skin. Lymph node involvement is associated with a poorer prognosis. The "pyogenic lymphoma" of the skin is a neutrophil-rich CD30+ lymphoma with skin lesions that clinically resemble Sweet syndrome, pyoderma gangrenosum, halogenoderma, leishmaniasis, or deep fungal infection. IL-8 overexpression by the anaplastic CD30+ cells causes the neutrophilic infiltration. The number of neutrophils present may make histologic interpretation difficult. Cases with features of both lymphomatoid

Fig. 32-12 Large-cell anaplastic lymphoma.

papulosis and CD30+ anaplastic T-cell lymphoma have been described, sometimes under the designation type C lymphomatoid papulosis. Histologically, there is a dense dermal non-epidermotropic infiltrate with atypical tumor cells whose large nuclei have one or several prominent nucleoli and abundant cytoplasm. The malignant cells can be further characterized as anaplastic, pleomorphic, and immunoblastic, but this distinction may be difficult and has yet to be determined to be of prognostic or therapeutic value. This form of primary cutaneous T-cell lymphoma has an excellent prognosis, with a 5-year survival of 90%. Lesions are highly responsive to radiotherapy. Early individual lesions can even be surgically excised. Topical imiquimod has been therapeutically successful. Chemotherapy causes regression of lesions, but a rapid relapse usually occurs. Other than low-dose methotrexate, chemotherapy generally has little role in the treatment of this disease. Local hyperthermia has been used successfully, as has inhibition of the mammalian target of rapamycin.

Secondary cutaneous CD30+ large-cell lymphoma

CD30+ large-cell lymphomas may arise in cases of mycosis fungoides, in patients with lymphomatoid papulosis, and in patients who have documented extracutaneous disease (secondary cutaneous anaplastic large-cell lymphoma). Skin lesions of pyogenic lymphoma may be seen secondary to a pyogenic lymphoma of other organs. The prognosis is poor in patients who have extracutaneous disease preceding or near the time of cutaneous involvement. Among those with systemic disease, the expression of Alk-1 associated with a t(2; 5) translocation is a favorable prognostic feature. Kempf et al reported that MUM1 expression is common in secondary anaplastic large-cell lymphoma and in LyP, but uncommon in primary cutaneous anaplastic large-cell lymphoma. Other authors have disputed that MUM1 is a useful marker. Patients with lymphomatoid papulosis, who develop cutaneous CD30+ lymphoma and who do not have systemic lymphoma or mycosis fungoides, typically have an excellent prognosis. The prognosis for patients with mycosis fungoides who develop CD30+ anaplastic large-cell lymphoma is poor.

Non-mycosis fungoides CD30- cutaneous large T-cell lymphoma

Non-mycosis fungoides CD30- cutaneous large T-cell lymphomas usually present as solitary or generalized plaques, nodules, or tumors of short duration. There is no preceding patch stage that distinguishes it from mycosis fungoides. The prognosis is poor, with a 5-year survival rate of 15%. The malignant cells are pleomorphic large or medium cell types or are immunoblastic. The cells may be cerebriform and epidermotropism may be present. Some cases previously called d'emblée mycosis fungoides are better classified in this group. Multiagent chemotherapy is recommended.

Pleomorphic T-cell lymphoma (non-mycosis fungoides CD30- pleomorphic small/medium-sized cutaneous T-cell lymphoma)

This group comprises about 3% of all primary cutaneous lymphomas. Pleomorphic small/medium-sized cutaneous T-cell lymphoma is distinguished from the large-cell type by having less than 30% large pleomorphic cells. It is distinguished from mycosis fungoides by clinical features (lack of patch or plaque lesions). These primary cutaneous lymphomas usually present with one or several red-purple papules, nodules, or tumors (5 mm to 15 cm in size). Immunophenotypically, they are usually of helper T-cell origin and clonal rearrangements of the TCR gene are usually present. A CD4 phenotype, as opposed to a CD8 phenotype, is associated with a more

favorable prognosis, but a CD4/CD56 phenotype has a poorer prognosis. The presence of a mixed population of suppressor cells, B cells, and histiocytes usually favors the diagnosis of reactive lymphoid hyperplasia. The overall prognosis is intermediate, with a 5-year survival rate of 62%. The optimal therapy for this form of lymphoma has not been determined. Therapeutically, localized lesions have been treated with radiation therapy or surgical excision. Chemotherapy, retinoids, interferons, and monoclonal antibodies have been used in widespread or progressive disease.

Lennert lymphoma (lymphoepithelioid lymphoma)

Lennert lymphoma is a rare CD4+ systemic T-cell lymphoma. Cutaneous lesions occur in less than 10% of cases and present as papules, plaques, or nodules. The skin lesions may not represent lymphoma cutis because palisaded granulomatous and nonspecific dermal infiltrates may occur. The clinical and histologic appearance may resemble granuloma annulare very closely. The course is low-grade until the lymphoma transforms to a high-grade, large-cell lymphoma.

Subcutaneous (panniculitis-like) T-cell lymphoma

Clinically, patients are usually young adults who present with subcutaneous nodules (Fig. 32-13), usually on the lower extremities, and are frequently diagnosed as having erythema nodosum or some other form of panniculitis. Weight loss, fever, and fatigue are common and may herald the onset of a rapidly progressive hemophagocytic syndrome, which is often fatal. Extracutaneous involvement is rare, even in fatal cases. An indolent chronic course can also be seen, but even in these cases the prognosis is poor. This variant of lymphoma may also rarely be seen in childhood.

Histologically, there is a lace-like infiltration of the lobules of adipocytes, mimicking panniculitis, especially lupus profundus. A characteristic feature is rimming of neoplastic cells around individual adipocytes. The infiltrate contains primarily small cells with hyperchromatic, irregular nuclei and large anaplastic cells in varying proportions. The small cells are atypical, karyorrhexis is prominent, and mitotic figures are

Fig. 32-13 Subcutaneous T-cell lymphoma.

frequent. Benign histiocytes are present in large or small numbers and demonstrate erythrophagocytosis (bean-bag cells). Immunophenotypically, the neoplastic cells mark as T cells (CD2+, CD3+). Most cases are derived from α/β T cells and are CD56-. They have a less aggressive course. A subset of subcutaneous T-cell lymphomas are derived from γ/δ T cells and are CD56+. These cases have been misdiagnosed as lupus profundus or alopecia areata; histologically prominent dermal and even epidermal (interface) involvement may be seen. They have a more aggressive course and are now classified separately. SPTCL may evolve from the benign variant of cytophagic histiocytic panniculitis, which may also have a hemophagocytic syndrome. Multiagent chemotherapy is recommended, at times with stem-cell support. Denileukin diftitox (Ontak) was reported to produce a favorable response.

Nasal/nasal-type NK/T-cell lymphoma (angiocentric lymphoma)

NK/T-cell lymphoma most frequently presents in extranodal tissue and is characterized by a high incidence of nasal involvement. It is more common in Asia, where it affects primarily women with a mean age of 40. In Korea it is reported to be the most common form of cutaneous lymphoma after mycosis fungoides. It is uncommon in the US. It presents clinically as dermal or subcutaneous papules or nodules that may ulcerate. Lesions are usually widespread and involve the lower extremities. A hydroa vacciniforme-type has been described in children in Mexico and in adults and children in Japan and Korea. Skin lesions are facial and extremity papulovesicles ulcerate and heal with scarring. Skin lesions are exacerbated by sun exposure and are reproduced with UVA irradiation.

Histologically, the dermis and subcutaneous fat are infiltrated with intermediate-sized, atypical lymphocytes, within and around the walls of small and medium-sized vessels. Epidermotropism may be noted. The lymphoma cells express a spectrum of T- and NK-cell immunophenotypic markers, variably expressing CD2, CD3, CD4, CD8, and the NK-cell marker CD56. CD56 is not cell lineage-specific, and a subset of CD56 cutaneous lymphoma cases is classified under the SPTCL category. Epstein-Barr virus is present in the NK variants and variably present in the T-cell variants. T-cell clonality is detected if the T-cell immunophenotype is present. The prognosis is poor.

Blastic plasmacytoid dendritic cell neoplasm (blastic NK-cell lymphoma, CD4, CD56+ hematodermic neoplasm)

The majority of patients are males, with a mean age of about 60 years. All patients present with multiple, rapidly expanding plaques and/or nodules on noncontiguous sites. Lesions are characteristically purple in color. The course is aggressive in most patients, with rapid cutaneous relapse after chemotherapy with systemic involvement. Histologically, the cells infiltrate the dermis or subcutaneous fat, with a tendency for the neoplastic cells to "Indian file" in dermal collagen. There is usually a Grenz zone below the epidermis. The lymphoma cells are small/medium to large blastic lymphocytes. Angiocentricity may be noted, but is not prominent. Immunophenotyping is usually CD4+, CD56+. MIB-1 shows a proliferation activity of over 50%. T-cell gene rearrangements are negative. A response to pralatrexate has been reported, but in general the results with radiation therapy and chemotherapy have been poor. Bone marrow transplantation (BMT) may play an important role in therapy.

Adult T-cell leukemia/lymphoma

Infection with human lymphotropic virus type 1 (HTLV-1) may lead to acute T-cell leukemia/lymphoma (ATL) in 0.01–0.02% of infected persons. This virus is endemic in Japan, Southeast Asia, the Caribbean, Latin America, and equatorial Africa. ATL usually has an acute onset, with leukocytosis, lymphadenopathy, and HOTS (hypercalcemia, osteolytic bone lesions, T-cell leukemia, and skin lesions). Lesions resemble mycosis fungoides, except that patches are uncommon and plaques and nodules predominate. Histologically, the skin lesions contain lichenoid infiltrates of medium-sized lymphocytes with convoluted nuclei. Epidermotropism and involvement around and within adnexa occur. Granuloma formation may occur in the dermis. ATL cells are usually CD4+/CD7– and show T-cell gene rearrangements.

Cutaneous B-cell lymphoma

Primary cutaneous B-cell lymphomas (Fig. 32-14) occur less commonly than cutaneous T-cell lymphomas (25% of cases of primary cutaneous non-Hodgkin lymphomas are B-cell in origin). Although the morphologic appearance of the malignant lymphocytes composing these primary cutaneous lymphomas is identical to lymphomas based in lymph nodes, they have a distinctly different clinical behavior and immunophenotypic profiles. This renders the classification systems based on lymph node histology of limited benefit in the diagnosis of primary cutaneous B-cell lymphomas. More simplified schemes have thus been proposed that apply to primary cutaneous lymphomas only. While most entities classified by the European Organization for Research and Treatment of Cancer (EORTC) have now been accepted in the WHO classification, some remain provisional entities.

The great majority of primary cutaneous B-cell lymphomas are composed of cells with the morphologic characteristics of the B cells normally found in the marginal zone or germinal centers of lymph nodes. Classification schemes used primarily for lymph node-based lymphomas divide these lymphomas into multiple types based on histomorphology. Secondary cutaneous involvement can occur with all forms of B-cell lymphoma based primarily in lymph node or other sites. The clinical features are similar to those of primary cutaneous lymphoma, with violaceous papules or nodules (Fig. 32-15). Typically, the histologic structure of secondary lesions in the skin is similar to that of the lymphoma at the site of origin, usually the lymph nodes. The pattern in the skin may not, however, be sufficient to classify the lymphoma, making lymph node biopsy necessary in most cases. In secondary cutaneous B-cell lymphomas the prognosis is generally poor. It is therefore critical to evaluate any patient suspected of having primary cutaneous B-cell lymphoma to exclude involvement at another site. Radiation is most commonly used for indolent forms of cutaneous B-cell lymphoma, but excision, rituximab, intralesional corticosteroids, and systemic chemotherapy have also been used in selected cases. Higher-grade lymphomas, including leg-type lymphoma, primary cutaneous follicle center lymphoma occurring on the leg, and precursor B-cell lymphoblastic lymphoma, are typically treated with systemic chemotherapy regimens including combinations of anthracycline-containing chemotherapies and rituximab.

Fig. 32-14 Lymphoma, B-cell.

Fig. 32-15 Secondary cutaneous B-cell lymphoma.

Primary cutaneous marginal zone lymphoma (PCMZL, MALT-type lymphoma, including primary cutaneous immunocytoma)

These lymphomas present as solitary or multiple dermal or subcutaneous nodules or tumors primarily on the upper part of the body, trunk, or extremities. Widespread lesions suggest secondary skin involvement by systemic lymphoma. Women are affected more than men. Immunocytomas are associated with European *Borrelia* and occur as tense, shiny, pink to red nodules on the legs of older patients.

Histologically, the infiltrate may be nodular or diffuse. The neoplastic cells are medium-sized gray cells with predominantly cleaved nuclei that proliferate within the space surrounding and between benign germinal centers. Plasma cells are typically present and may be numerous. Light chain restriction is easiest to identify in the plasma cell population by means of in situ hybridization. The lymphoma cells may contain “Dutcher bodies,” intranuclear collections of immunoglobulin. Initially, the malignant cells may represent a very small proportion of the infiltrate and an incorrect diagnosis of pseudolymphoma may be made. Over time, the “marginal zone” cells predominate and the germinal centers are diminished. Immunophenotypically, the cells are CD20+, CD79+, and BCL-2+. Clonal immunoglobulin gene rearrangements can usually be demonstrated. The prognosis is excellent, with 5-year survival close to 100%. Local radiation therapy, or excision if lesions are few, is recommended. In some *Borrelia*-endemic areas in Europe, immunocytomas are common. They present with sheets of plasmacytoid B cells with Dutcher bodies. Treatment is similar to other forms of PCMZL.

Primary cutaneous follicle center cell lymphoma (PCFCCL, diffuse and follicular types)

Clinically, most patients present with single or multiple papules, plaques, or nodules, with surrounding erythema, in one anatomic region. About two-thirds of cases present on the trunk, about one-fifth on the head and neck (the vast majority of these on the scalp), and about 15% on the leg. These lymphomas

are more common in men than women. Males outnumber females 4:1 in trunk lesions, whereas women disproportionately have head and leg lesions. Untreated, the lesions gradually increase in size and number, but extracutaneous involvement is uncommon. The prognosis is excellent, 5-year survival with treatment approaching 100%. Secondary cutaneous involvement of systemic follicular lymphoma has a poor prognosis.

Histologically, the neoplasm is composed of centroblasts (uncleaved nuclei with a peripheral nucleolus) and centrocytes (cleaved nuclei with a peripheral nucleolus). The diffuse form is more common than the follicular form. In the diffuse form, the neoplastic cells retain the normal BCL-6+ phenotype of a follicle center cell, but typically lose expression of CD10. The follicular growth pattern is composed of irregularly shaped asymmetrical follicles that crowd together like pieces of a jigsaw puzzle. The cells typically stain for both BCL-6 and CD10, and these stains demonstrate neoplastic cells that have “wandered” beyond the confines of the follicle center. Elongated “carrot-shaped” nuclei are often present within the follicular centers, and CD21 staining shows defects in the net of dendritic cells in the follicle center.

In early lesions, the neoplastic cells are of smaller size and there is a substantial portion of normal T cells surrounding and mixed with the neoplastic B cells. Over time, the neoplastic B cells become a more predominant portion of the infiltrate, the neoplastic cells are larger in size, and tumor-infiltrating T cells diminish. Immunophenotypically, the neoplastic cells stain with B-cell markers (CD20) and may be monotypic for immunoglobulin production, i.e. they stain for either κ or λ light chains, but not both. Immunoglobulin staining is commonly negative in tumorous lesions, but clonal rearrangement of the immunoglobulin gene can be demonstrated by polymerase chain reaction (PCR). The absence of expression of BCL-2, lack of adenopathy, and lack of involvement of the bone marrow help to exclude nodal follicular center lymphoma. Nodal follicular lymphoma usually expresses BCL-2 and there is a t(14:18) translocation in more than 80% of cases. BCL-2 expression is usually lacking in primary cutaneous follicular lymphoma.

Radiation therapy totaling 30–40 Gy and including all erythematous skin and a 2 cm margin of normal skin is very effective for lesions of the head and trunk. A combination of intralesional IFN- α , 5 MU every 4 weeks, and topical bexarotene gel, 1% twice, has also been used. Anthracycline-based chemotherapy or rituximab may be used for relapses, as well as for more aggressive lesions of the leg. In Europe, a few cases of PCFCL are associated with *Borrelia* infection and may arise in lesions of acrodermatitis chronica atrophicans.

Diffuse large B-cell lymphoma (primary cutaneous large B-cell lymphoma)

Clinically, lesions present as solitary or localized red or purple papules, nodules, or plaques. In general, solitary or localized lesions are typical of primary disease, and widespread lesions suggest secondary cutaneous involvement of primary nodal lymphoma. Lesions on the head and neck have an excellent prognosis. Lesions on the leg have a poorer prognosis, with a 5-year survival of about 50%, and are considered in some classifications as a separate entity (Fig. 32-16).

This group of lymphomas is composed of large lymphocytes. Tumors made up of sheets of centroblasts and immunoblasts (non-cleaved nuclei with peripheral or central nucleoli, respectively) should be stained for MUM1, a marker for leg-type lymphoma. If the tumor cells express MUM1, the prognosis is worse. Immunophenotypically, cells usually express CD20 and

Fig. 32-16 B-cell lymphoma of the leg.

monotypic immunoglobulin, and leg-type lymphoma expresses BCL-2. Secondary cutaneous involvement with nodal large B-cell lymphoma is also associated with a poor prognosis.

Richter transformation of chronic lymphocytic leukemia into a high-grade lymphoma occurs in 3–10% of patients with chronic lymphocytic leukemia. Its onset is often heralded by fever, night sweats, and weight loss. The lymphoma commonly arises in the lymph nodes or bone marrow, but can also present in the skin or internal organs.

Intravascular large B-cell lymphoma (malignant “angioendotheliomatosis,” angiotropic large-cell lymphoma)

Clinically, these patients present with variable cutaneous morphologies, often very subtle and nonspecific. Some cases resemble classic lymphoma with violaceous papules or nodules. Others more closely resemble intravascular thrombotic disorders, with livedo reticularis-like lesions or telangiectatic patches. Sclerotic plaques may also occur. Even normal skin can show the characteristic changes on biopsy. Patients often present with fever of unknown origin. CNS symptoms are prominent, with progressive dementia or multiple cerebrovascular ischemic events that may precede skin findings by many months.

Histologically, the features are characteristic and diagnostic. Dermal and subcutaneous vessels are dilated and filled with large neoplastic cells. Focal extravascular accumulations may be seen. The neoplastic cells are CD20+ and CD79a+, and monotypic for immunoglobulin. Clonal immunoglobulin gene rearrangements may be detected. Despite the large number of intravascular cells in the skin and other affected organs, the peripheral blood smears and bone marrow may be normal histologically. The prognosis is very poor. Multiagent chemotherapy is recommended. Rare cases of intravascular lymphoma may be of T-cell origin.

Plasmacytoma (multiple myeloma)

True cutaneous plasmacytomas are seen most commonly in the setting of myeloma. They are, however, rare, occurring in only 2% of myeloma cases. These cases are called secondary cutaneous plasmacytoma. They may also occur by direct extension from an underlying bone lesion (Fig. 32-17). They may appear at sites of trauma, such as biopsies or intravenous catheters (inflammatory oncotaxis). Most commonly, secondary cutaneous plasmacytomas occur in the setting of advanced myeloma and the prognosis is poor. Less commonly, the skin lesions may be the initial clinical finding, leading to the diagnosis of myeloma. Many cutaneous lesions formerly classified as primary cutaneous plasmacytomas are now classified as plasma cell-rich primary cutaneous marginal zone lymphoma.

Anetoderma may show plasmacytoma on biopsy. A rare manifestation of a solitary plasmacytoma of bone is an overlying erythematous skin patch that may be 10 cm or more in diameter. The chest is the most common location. Lymphadenopathy is present and some of the patients have or develop POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes). This syndrome has been called adenopathy and extensive skin patch overlying a plasmacytoma, or AESOP.

Histologically, there are nodular and diffuse collections of plasma cells with varying degrees of pleomorphism and atypia. The degree of atypia may predict prognosis. The cells are monotypic for immunoglobulin production and produce the same light chain as the myeloma. The immunoglobulin produced is most commonly IgG or IgA, and rarely IgD or IgE. CD79 is positive, but CD19 and CD20 are negative.

In addition to plasmacytomas, patients with myeloma may develop a vast array of cutaneous complications. These include normolipemic plane xanthomas, amyloidosis, vasculitis, and calcinosis cutis. An unusual but characteristic skin finding in myeloma is multiple follicular spicules of the nose, forehead, cheeks, and chin. They are yellowish and firm to palpation, and can be removed without bleeding. Numerous small ulcerations may occur on the trunk. Both the spicules and ulcers contain an eosinophilic material composed of the abnormal monoclonal protein produced by the malignant cells. The spicules are not made of keratin. Clinically similar cutaneous spicules composed of keratin can be seen in vitamin A deficiency, chronic renal failure, acquired immunodeficiency syndrome (AIDS), Crohn's disease, and other malignant diseases.

The appropriate treatment of plasmacytomas is determined by the presence or absence of associated systemic disease. Solitary or paucifocal primary cutaneous plasmacytomas have been treated successfully with local surgery and radiation therapy. Systemic chemotherapy may be required if these modalities fail. The treatment for secondary plasmacytomas and for patients with numerous primary cutaneous plasmacytomas is chemotherapy.

Cutaneous and systemic plasmacytosis

Cutaneous plasmacytosis and systemic plasmacytosis occur largely in Asians, slightly favoring males. They typically occur between the ages of 20 and 55. These conditions are characterized by polyclonal proliferations of plasma cells and hyperglobulinemia, and were originally considered variants of Castleman's disease. Cutaneous plasmacytosis affects only the skin but patients may have lymphadenopathy and systemic symptoms of fever and malaise. Systemic plasmacytosis has involvement in two or more organ systems, usually, in addition to skin, the lung, bone marrow, and liver. Dyspnea may occur due to interstitial pneumonia. Uncommonly, cases of systemic plasmacytosis may progress to lymphoma. The course is chronic and benign, and response to various cytostatic and immunosuppressive treatments has been poor. PUVA and topical tacrolimus have been reported to be effective for skin lesions. The skin lesions in cutaneous and systemic plasmacytosis are identical. They consist of multiple brown-red plaques, mostly of the central upper trunk, but also of the face. Lesions range from 1 to 3 cm in diameter. They are often considered simply postinflammatory hyperpigmentation until they are palpated. Histologically, they show a dense perivascular infiltrate of mature plasma cells, which stain for both κ and λ light chains (polyclonality). Elevated IL-6 has been reported in some patients.

Hodgkin disease

The vast majority of reports of cutaneous Hodgkin disease actually represent type A lymphomatoid papulosis (LyP). These two diseases have a considerable number of overlapping features. The type A cells of LyP have similar morphology and share immunophenotypic markers with Reed-Sternberg cells. LyP can be seen in patients with Hodgkin disease. Primary cutaneous Hodgkin disease without nodal

involvement is thus difficult to prove and is very, very rare, if it exists.

Most cases of Hodgkin disease of the skin usually originate in the lymph nodes, from which extension to the skin is either retrograde through the lymphatics or direct. Lesions present as papules or nodules, with or without ulceration. Lesions resembling scrofuloderma may occur. Miliary dissemination to the skin can occur in advanced disease.

Nonspecific cutaneous findings are common in patients with Hodgkin disease. Generalized, severe pruritus may precede other findings of Hodgkin disease by many months or may occur in patients with a known diagnosis. Secondary prurigo nodules and pigmentation may occur as a result of scratching. An evaluation for underlying lymphoma should be considered in any patient with severe itching, no primary skin lesions, and no other cause identified for the pruritus. Acquired ichthyosis, exfoliative dermatitis, and generalized and severe herpes zoster are other cutaneous findings in patients with Hodgkin disease.

Malignant histiocytosis (histiocytic medullary reticulosis)

Most cases considered to be malignant histiocytosis in the past are now considered to be other forms of lymphoma or lymphomas with large components of reactive histiocytes. Very rare cases of true malignancies of histiocytes may still occur and can have cutaneous lesions, most characteristically erythematous nodules. Often, the bone marrow examination in these patients is initially normal, but cases are rapidly progressive and fatal, and the bone marrow becomes involved.

Leukemia cutis

Clinical features

Cutaneous eruptions seen in patients with leukemia may be divided into specific (leukemia cutis) and nonspecific lesions (reactive and infectious processes). Overall, about 30% of biopsies from patients with leukemia will show leukemia cutis. All forms of leukemia can be associated with cutaneous findings, but skin disease is more common in certain forms of leukemia. Myeloid leukemia with monocytic differentiation involves the skin more commonly than other types of myeloid leukemia. CD68 and lysozyme immunostains can be helpful in distinguishing this form of leukemia. Dermatologic manifestations are commonly seen in patients with acute myelogenous leukemia (AML) and myelodysplastic syndrome (MDS). AML includes types M1-M5. In AML and MDS patients, only about 25% of skin biopsies will show leukemia cutis, the remainder showing complications of the leukemia. These include infections, graft versus host disease, drug reactions, or the reactive conditions associated with leukemia that are sometimes referred to as leukemids. By contrast, in patients with acute lymphocytic leukemia (ALL), chronic myelogenous leukemia (CML), and chronic lymphocytic leukemia (CLL), about 50% of biopsies will show leukemia cutis. Lesion presentation may be subtle, and may include macular erythema, hyperpigmentation, or morbilliform rash.

Specific eruptions

The most common morphology of leukemic infiltrations of the skin in all forms of leukemia is multiple papules or nodules

Fig. 32-18 Leukemia cutis.

Fig. 32-20 Gingival involvement in leukemia.

Fig. 32-19 Leukemia cutis.

(60% of cases) or infiltrated plaques (26%). These lesions are usually flesh-colored, erythematous, or violaceous (plum-colored) (Figs 32-18 and 32-19). They are rubbery on palpation and ulceration is uncommon. Extensive involvement of the face may lead to a leonine facies.

Less common manifestations of leukemia cutis are subcutaneous nodules resembling erythema nodosum or panniculitis, arciform lesions (in juvenile CML), ecchymoses, palpable purpura, erythroderma, ulcerations (which may resemble pyoderma gangrenosum or venous stasis ulceration), and urticaria-like, urticaria pigmentosa-like (in ALL), and guttate psoriasis-like lesions. Rare manifestations are a lesion resembling Sister Mary Joseph nodule and cutaneous sarcoïdal lesions. Myelogenous leukemia may be complicated by lesions resembling stasis dermatitis or chilblains. Gingival infiltration causing hypertrophy is common in and relatively unique to patients with acute myelomonocytic leukemia (Fig. 32-20).

Leukemia cutis most commonly occurs concomitant with or following the diagnosis of leukemia. The skin may also be a site of relapse of leukemia after chemotherapy, especially in patients who present with leukemia cutis. Uncommonly, leukemia cutis may be identified while the bone marrow and peripheral blood are normal. These patients are classified as "aleukemic leukemia cutis," as they have normal bone marrow evaluations and no circulating blasts. These cases are often misdiagnosed as cutaneous lymphomas and undertreated. They eventually relapse, with full-blown leukemia. The key to the diagnosis is a Leder stain, which will identify the atypical cells as myeloid. Systemic involvement occurs within 3 weeks

to 20 months (average 6 months). Leukemia cutis is a poor prognostic finding in patients with leukemia, with 90% of such patients having extramedullary involvement and 40% having meningeal infiltration.

The term congenital leukemia applies to cases appearing within the first 4–6 weeks of life. Leukemia cutis occurs in 25–30% of such cases, the vast majority being congenital myelogenous leukemia. The typical morphology is multiple, red or plum-colored nodules. In about 10% of cases of congenital leukemia cutis (or 3% of all cases of congenital leukemia), the skin involvement occurs while the bone marrow and peripheral blood are normal. Systemic involvement is virtually always identified in 5–16 weeks. Unlike in other forms of leukemia, in congenital leukemia, cutaneous infiltration does not worsen prognosis. Congenital leukaemia cutis has been complicated by disseminated linear calcinosis cutis. Early-onset aleukemic leukemia cutis can occasionally undergo spontaneous regression. One report involved a child with mastocytosis, who also developed a leukemia clone with a t(5; 17)(q35; q12), nucleophosmin (NPM)-retinoic acid receptor- α (RARA) fusion gene.

Granulocytic sarcoma (chloroma)

Granulocytic sarcomas are rare tumors of immature granulocytes. They occur in about 3% of patients with myelogenous leukemia. Granulocytic sarcoma is seen in four settings: in patients with known AML; in patients with CML or MDS as a sign of an impending blast crisis; in undiagnosed patients as the first sign of AML; or after BMT as the initial sign of relapse. Most lesions occur in the soft tissues, periosteum, or bone. Skin lesions represent 20–50% of reported cases. They may be solitary or multiple. They appear as red, mahogany, or violaceous firm nodules with a predilection for the face, scalp, or trunk.

The name chloroma comes from the green color of fresh lesions, which can be enhanced by rubbing with alcohol; this is caused by the presence of myeloperoxidase. This appearance is variable, so the preferred term is now granulocytic sarcoma.

The diagnosis is not difficult if the diagnosis of leukemia has been established. Such patients are treated with appropriate chemotherapy. However, if the skin lesion is the initial manifestation of leukemia, and the blood and bone marrow are normal, the lesion may be misdiagnosed as a large-cell lymphoma. The treatment of such patients is controversial, but most go on to develop AML within months, so chemotherapy is often given.

Hairy cell leukemia

Skin involvement is rare in hairy cell leukemia, and violaceous papules and nodules, which are the characteristic morphology of other forms of leukemia cutis, are extremely rare in hairy cell leukemia. Rather, a diffuse erythematous, nonpruritic eruption occurs, often in the setting of a systemic mycobacterial infection or a drug reaction. This may progress to erythroderma or a severe blistering eruption. Stopping the offending medication usually leads to resolution of the eruption. This is especially common in patients treated with 2-chlorodeoxyadenosine and allopurinol. The former treatment alone does not lead to these severe skin reactions, suggesting that the allopurinol is the cause. Patients with hairy cell leukemia also develop lesions of pustular vasculitis of the dorsal hands, a neutrophilic dermatitis closely related to bullous Sweet syndrome. This is sometimes termed a "vasculitis" in the oncology literature.

Nonspecific conditions associated with leukemia (leukemids)

Leukemia and its treatment are associated with a series of conditions that may also be seen in patients without leukemia, but which are seen frequently enough in leukemic patients to be recognized as a complication of that condition or its treatment.

When a dermatologist or dermatopathologist is consulted to evaluate a patient with leukemia and skin lesions, the differential diagnosis usually includes four groups of conditions: drug reactions, leukemia cutis, an infectious complication, and a reactive condition. Drug reactions include all forms of reactions, but are most commonly erythema multiforme, morbilliform reactions, or acral erythema. Infections may present in many ways but are usually purpuric papules, pustules, or plaques, if they are caused by bacteria or fungi. Ulceration is typical. Herpes simplex and herpes zoster should be considered in all erosive, ulcerative, or vesicular lesions. The reactive conditions include a group of neutrophilic dermatoses with considerable clinical overlap. These include Sweet syndrome, pyoderma gangrenosum, neutrophilic hidradenitis, and leukocytoclastic vasculitis. Transient acantholytic dermatosis and eosinophilic reactions resembling insect bites may occur, most commonly in patients with CLL. In CLL a pruritic and unremitting exfoliative erythroderma is a unique feature. A granulomatous rosacea-like leukemid and cutaneous reactive angiomatosis have also been described in patients with leukemia.

Evaluation of these patients must be complete, and extensive diagnostic tests and empiric treatment are often pursued until the diagnosis is established. In the acute setting, a clinical diagnosis is made based on morphology. Possible infectious complications are covered by appropriate antibiotics, especially if the patient is febrile or the diagnosis of a herpesvirus infection is made. A skin biopsy is often diagnostic. For herpes infections, a direct fluorescent antibody test should be done, as the results are virus-specific and rapid, so appropriate treatment can be given quickly. Once the diagnostic tests return, the therapy is tailored to the appropriate condition. Except for herpes infections, a skin biopsy is often required. If infection is considered, a portion of the biopsy should be sent for culture.

Cutaneous myelofibrosis

Myelofibrosis is a chronic myeloproliferative disorder characterized by a clonal proliferation of defective multipotential stem cells in the bone marrow. Overproduction and premature death of atypical megakaryocytes in the bone marrow produce excess amounts of platelet-derived growth factor, a potent stimulus for fibroblast proliferation and collagen production. Extramedullary hematopoiesis (EMH) is a hallmark of myelofibrosis. Myelofibrosis may coexist with signs of mastocytosis. Blast cells and committed stem cells escape the marrow in large numbers, enter the circulation, and form tumors of the same atypical clone in other organs, especially the spleen, liver, and lymph node. EMH in the skin of neonates is usually caused by intrauterine viral infections. In adults, cutaneous EMH has rarely been reported, characteristically associated with myelofibrosis. Skin lesions are dermal and subcutaneous nodules. Histologically, the cutaneous lesions are composed of dermal and subcutaneous infiltrates of mature and immature myeloid cells, erythroid precursors (in only half of cases), and megakaryocytic cells (which may predominate). There is marked production of collagen fibers in the cutaneous lesions by the mechanism described above. Myelofibrosis must be distinguished from CML, since both have elevated white blood cell counts with immature myeloid forms, defective platelet production, and marrow fibrosis. Both may terminate in blast crisis, and myelofibrosis may rarely convert to CML. CML is associated with the Philadelphia chromosome, whereas chromosomal abnormalities occur in 40% of myelofibrosis cases on various chromosomes.

Hypereosinophilic syndrome

Idiopathic hypereosinophilic syndrome (HES) is defined as eosinophilia with more than 1500 eosinophils/mm³ for more than 6 months, with some evidence of parenchymal organ involvement; there must also be no apparent underlying disease to explain the hypereosinophilia and usually no

evidence of vasculitis. Ninety percent of patients reported have been men, mostly between the ages of 20 and 50. Childhood cases are rare. Presenting symptoms include fever (12%), cough (24%), fatigue, malaise, muscle pains, and skin eruptions. Two pathogenic variants of HES have been defined: m-HES (myeloproliferative HES) and l-HES (lymphocytic HES). M-HES patients are overwhelmingly males, and anemia, thrombocytopenia, elevated serum B₁₂ levels, mucosal ulcerations, splenomegaly, and endomyocardial fibrosis are the clinical features. Isolated Loeffler's endocarditis has been reported as a presenting sign. Eosinophil clonality and interstitial deletion on 4q12 result in fusions of *FIP1qL1* and *PDGFRa* genes, forming an F/P fusion protein displaying constitutive activity, are pathogenically related to m-HES cases. Increased mast cells and elevated tryptase levels with myeloid precursors in peripheral blood and myelofibrosis may be found, suggesting that mast cells may be pathogenically related to this form of HES. Leukemia may develop in patients with m-HES. L-HES has been associated with circulating T-cell clones of CD4+ phenotype, which secrete Th2 cytokines, especially IL-5. Females and males are equally affected by l-HES and cutaneous manifestations are observed in virtually all patients. Skin manifestations include urticaria, angioedema, pruritus, eczema, and erythroderma. Splinter hemorrhages and necrotic skin lesions are seen in some HES patients as well. Endomyocardial fibrosis is uncommon, but pulmonary and digestive symptoms are common. Some cases of l-HES are clinically identical to Gleich syndrome or episodic angioedema and hypereosinophilia. Over time some patients with l-HES will develop lymphoma.

Treatment is determined by classifying cases appropriately as m-HES or l-HES. M-HES patients may be treated with corticosteroids, hydroxyurea, IFN- α , and chemotherapeutic agents. Imatinib mesylate (Gleevec, 100 mg/day or less) can be highly effective for m-HES patients with the F/P mutation, as imatinib inhibits the phosphorylation of the F/P protein and leads to apoptosis of cells producing this protein. This has rapidly become first-choice treatment for this subset of patients. Response may be dramatic, with eosinophil levels improving, and skin and gastrointestinal manifestations clearing in days. For l-HES patients, systemic glucocorticoids, and perhaps IFN- α with glucocorticoids, can be used and are usually effective. Monoclonal anti-IL-5 antibody, cyclosporine A, anti-IL-2R- α , infliximab, and CTLA-4-Ig may be treatment options. If lymphoma supervenes, intense chemotherapy and allogeneic stem cell transplantation can be considered.

Angioimmunoblastic lymphadenopathy with dysproteinemia (angioimmunoblastic T-cell lymphoma)

Angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) is an uncommon lymphoproliferative disorder. Patients are middle-aged or elderly and present with fever (72%), weight loss (58%), hepatomegaly (60%), polyclonal hyperglob-

ulinemia (65%), and generalized adenopathy (87%). Pruritus occurs in 44% and a rash in 46%. The skin eruption is usually morbilliform in character, resembling an exanthem or a drug reaction. Patechial, purpuric, nodular, ulcerative, and erythrodermic eruptions have also been reported, and may mimic infection. In about 30% of cases the eruption is associated with the ingestion of a medication. The eruptions usually resolve with oral steroids, misleading the clinician into believing that the eruption was benign. Reversible myelofibrosis has been described. Recent evidence suggests that the neoplastic cells are derived from germinal center T-helper cells, as they express genes unique to this population, including programmed death-1 (*PD-1*) and *CXCL13*.

Histopathologically, there is a patchy and perivascular dermal infiltrate of various types of lymphoid cells, plasma cells, histiocytes (enough to rarely give a "granulomatous" appearance), and eosinophils. The lymphoid cells are usually helper T cells (CD4+). Some portion of the lymphoid cells is atypical in most cases, suggesting the diagnosis. Blood vessels are increased and the endothelial cells are prominent, often cuboidal. Unfortunately, these changes may not be adequate to confirm the diagnosis. However, clonal T-cell gene rearrangement is found in three-quarters of these skin lesions and is the same as the clone in the lymph node. Immunophenotyping of the skin lesions does not give a consistent pattern. At times, the skin lesions will show leukocytoclastic vasculitis on biopsy. Lymph node biopsy is usually required to confirm the diagnosis and exclude progression to lymphoma.

AILD appears to develop in a stepwise fashion. Initially, there is an immune response to an unknown antigen. This immune reaction persists, leading to oligoclonal T-cell proliferation. Monoclonal evolution may occur, eventuating in lymphoma (angioimmunoblastic lymphoma [AILD-L]). These are usually T-cell lymphomas, but B-cell lymphomas can also occur. In the case of AILD-L, skin lesions may contain the neoplastic cells (secondary lymphoma cutis). In up to 50% of cases, multiple unrelated neoplastic cell clones have been identified. Clones identified in the skin may be different from clones found in lymph node. Trisomy 3 or 5, or an extra X chromosome may be found. AILD is an aggressive disease, with mortality ranging from 48% to 72% in various series (average survival time is 11–60 months). The cause of death is usually infection. Epstein-Barr virus and HHV 6 and 8 have been implicated in AILD.

Treatment of AILD has included systemic steroids, methotrexate plus prednisone, combination chemotherapy, fludarabine, 2-chlorodeoxyadenosine, IFN- α , and cyclosporine. Early treatment with systemic steroids during an oligoclonal or pre-lymphomatous stage may induce a long-lasting remission. Asymptomatic patients may not be treated initially but must be watched very closely. More aggressive chemotherapy achieves better remission. None the less, recurrence rates are high, and average survival is between 1 and 3 years.

Sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman disease)

Sinus histiocytosis with massive lymphadenopathy (SHML), or Rosai–Dorfman disease, usually appears in patients in the first or second decade of life as a febrile illness accompanied

Fig. 32-21 Rosai-Dorfman disease. (Courtesy of Ellen Kim, MD)

by massive cervical (and commonly other) lymphadenopathy, polyclonal hyperglobulinemia, leukocytosis, anemia, and an elevated sedimentation rate. Males and black persons are especially susceptible. Extranodal involvement occurs in 40% of cases, with skin being the most common site. Ten percent of patients with SHML have skin lesions and 3% of patients have disease detectable only in the skin. The terms cutaneous sinus histiocytosis or cutaneous Rosai-Dorfman disease have been applied to these cases. Skin lesions consist of isolated or disseminated yellow-brown papules, pustules, or nodules (Fig. 32-21), or macular erythema. Large annular lesions, resembling granuloma annulare, may occur. Most patients with cutaneous Rosai-Dorfman are older (40–60 years).

Histologically, there is a superficial and deep perivascular infiltrate of lymphocytes and plasma cells. Nodular and diffuse infiltration of the dermis by large, foamy histiocytes is present. A very important diagnostic feature is the finding of intact lymphocytes (and less commonly, plasma cells) in the cytoplasm of the histiocytic cells. This is called emperipolesis. Foamy histiocytes may be seen in dermal lymphatics. The cutaneous histology in some cases may be very nonspecific (except for the finding of emperipolesis), and only on evaluation of lymph node or other organ involvement does the diagnosis become clear. Immunohistochemistry and electron microscopy may be very useful, as the infiltrating cells are positive for CD4, factor XIIIa, and S-100, but do not contain Birbeck granules.

The cause of this condition is unknown, but numerous reports have identified HHV 6 in involved lymph nodes. The condition usually clears spontaneously, so no treatment is required. Numerous agents have been used therapeutically with variable success, but are only indicated if the condition puts the patient at risk for death or a significant complication (usually by compressing a vital organ). Treatments have included radiation, systemic corticosteroids, and thalidomide. Single and multiagent chemotherapy is met with mixed to poor response. To treat skin lesions, cryotherapy, topical steroids, acitretin, and intralesional steroids may be tried.

Polycythemia vera (erythremia)

Polycythemia vera (PCV) is characterized by an absolute increase of circulating red blood cells, with a hematocrit level of 55–80%. Leukocyte and platelet counts are also increased. The skin changes are characteristic. There is a tendency for the skin to be red, especially on the face, neck, and acral areas. The mucous membranes are engorged and bluish. The phrase “red as a rose in summer and indigo blue in winter” has been ascribed to Osler in describing PCV. Telangiectases, bleeding gums, and epistaxis are frequently encountered. Cyanosis, purpura, petechiae, hemosiderosis, rosacea, and koilonychia may also be present.

In 50% of patients with PCV, aquagenic pruritus occurs. In about two-thirds of patients, this is of limited severity and does not require treatment. The pruritus is typically triggered after a bath or shower, and the feeling induced may be itching, burning, or stinging. It usually lasts 30–60 min and is independent of the water temperature. Pruritus unassociated with water exposure may also occur. There is a concurrent elevation of blood and skin histamine. Pruritus is present in about 20% of patients at presentation and develops in the remaining 30% over the course of their disease. Patients with pruritus have lower mean corpuscular volumes and higher leukocyte counts. Some have suggested that iron deficiency plays a role in PCV-associated pruritus, so a ferritin level and a trial of iron therapy may be indicated. Platelet counts are no different between PCV patients who itch and those who do not.

The treatment of PCV-associated pruritus may be difficult. Initial therapy would include first- or second-generation H₁ antihistamines. Hydroxyzine was reported as the most effective antihistamine by a group of PCV patients. H₂ blockers can be added. Narrow-band UVB has been reported to be effective in 80% of patients. Topical therapy is of limited benefit, but paroxetine (Paxil), 20–60 mg/day, may be dramatically effective. Phlebotomy may be useful in patients with elevated hematocrits, and imatinib mesylate appears effective in many patients.

Diseases of the Skin Appendages

33

Diseases of the hair

Normal human hairs can be classified according to cyclical phases of growth. Anagen hairs are growing hairs, catagen hairs are those undergoing transition from the growing to the resting stage, and telogen hairs are resting hairs, which remain in the follicles for variable lengths of time before they fall out (teloptosis). The lag period between loss of the telogen hair and growth of a new anagen hair has been referred to as kenogen.

Anagen hairs grow for about 3 years (1000 days), with a range between 2 and 6 years. The follicular matrix cells grow, divide, and become keratinized to form growing hairs. As the matrix produces the hair shaft, it incorporates substances that may be useful in medical or forensic analysis. Catagen hairs are in a transitional phase, lasting 1 or 2 weeks, in which all growth activity ceases, with the eventual formation of the telogen "club" hair. Many apoptotic cells are present in the outer root sheath of the catagen hair as it involutes. Telogen club hairs are resting hairs, which continue in this state for 3–5 months (about 100 days) before they are released.

Among human hairs plucked from a normal scalp, 85–90% are anagen hairs and 10–15% are telogen hairs. Catagen hairs normally comprise less than 1% of scalp hairs. It has been estimated that the scalp normally contains about 100 000 hairs, and the average number of hairs shed daily is 100–150. The hair growth rate of terminal hairs is about 0.37 mm/day. Contrary to popular belief, neither shaving nor menstruation has any effect on hair growth rate. The average uncut scalp hair length is estimated to be 25–100 cm, although exceptional hairs may be as long as 170 cm (70 inches).

Human hair is also designated as lanugo, vellus, or terminal hair. Lanugo hair is the fine hair present on the body of the fetus. This is replaced by the vellus and terminal hairs. Vellus hairs are fine and usually light-colored, and have a narrow hair shaft thinner than the width of the inner root sheath. Terminal hairs are coarse, thick, and dark, except in blonds. Hair occurs on all skin surfaces except the palms, soles, labia minora, lips, nails, glans, and prepuce. Terminal hairs are commonly present on a man's face, chest, and abdomen, but vellus hairs usually predominate on these sites in women.

Causes of alopecia are generally divided into the broad categories of cicatricial and noncicatricial alopecia. The evaluation should take into account the patient's age and ethnicity. Examination of hair shafts can establish a diagnosis of trichodystrophy. Hair counts, hair pull, and hair pluck (trichogram) can establish the degree of hair shedding, the type of hair that is shed, and the anagen to telogen ratio. Biopsies can also determine anagen to telogen ratio, and provide information regarding the potential for regrowth, as well as providing a diagnosis. Biopsies are particularly valuable in the evaluation of cicatricial alopecia. Often, a correct diagnosis hinges on a synthesis of clinical, histologic, serologic, and immunofluorescent data.

Noncicatricial alopecia

Alopecia areata

Clinical features

Alopecia areata (in French, pelade) is characterized by rapid and complete loss of hair in one or more round or oval patches, usually on the scalp, bearded area, eyebrows, eyelashes, and less commonly, on other hairy areas of the body. Often the patches are from 1 to 5 cm in diameter. A few resting hairs may be found within the patches. Early in the course there may be sparing of gray hair, and white hairs are rarely affected. Sudden whitening of hair may represent widespread alopecia areata in a patient with salt and pepper hair. In about 10% of cases of alopecia areata, especially in long-standing cases with extensive involvement, the nails develop uniform pits that may form transverse or longitudinal lines. Trachyonychia, onychomadesis, and red or spotted lunulae occur, but less commonly. Dermoscopic examination typically demonstrates diffuse, round, or polycyclic perifollicular yellow dots.

Complete loss of scalp hair is referred to as alopecia totalis, and complete loss of all hair as alopecia universalis. In most cases, hair loss is confined to the scalp and is patchy in distribution. Loss may occur confluent along the temporal and occipital scalp (ophiasis) (Fig. 33-1) or on the entire scalp except for this area (saisapho). Rarely, alopecia areata may present in a diffuse pattern that may mimic pattern alopecia. Clues to the correct diagnosis include a history of periodic regrowth, nail pitting, and the presence of tapered fractures or exclamation point hairs (Fig. 33-2). Alopecia areata generally presents as an anagen effluvium, with an inflammatory insult to the hair matrix resulting in tapering of the hair shaft and in fracture of anagen hairs. As the hair miniaturizes or converts from anagen to telogen, the remaining lower portion of the hair rises above the level of the scalp, producing the exclamation point hair.

Alopecia areata is associated with a higher incidence than usual of atopic dermatitis, Down syndrome, lichen planus, and autoimmune diseases, such as systemic lupus erythematosus

Fig. 33-1 Ophiasis. (Courtesy of Shyam Verma, MD)

Fig. 33-2 Exclamation point hairs of alopecia areata.

(SLE), thyroiditis, diabetes mellitus, myasthenia gravis, and vitiligo. However, most cases of alopecia areata occur without associated disease, and routine screening for these disorders is of little value unless prompted by signs or symptoms.

Migratory poliosis of the scalp may represent a forme fruste of alopecia areata. Patients with this disorder present with migrating circular patches of white hair, but never lose hair. The histology resembles alopecia areata.

Etiologic factors

The preponderance of evidence supports an autoimmune etiology. Oligoclonal and autoreactive T lymphocytes are present in the peribulbar inflammatory infiltrate, and many patients respond to immune-modulating drugs. Affected alopecia areata scalp skin grafted on to nude mice with severe combined immunodeficiency demonstrates loss of infiltrating lymphocytes and hair growth. In this model, injecting T lymphocytes with scalp homogenate can reproduce the alopecia. Follicular melanocytes substitute for scalp homogenates to produce alopecia areata in this model, providing evidence that follicular melanocytes are the targets for activated T cells in this disease. This hypothesis is also supported by the observations that white hair is rarely affected and regrowing hair is often depigmented.

In early alopecia areata, the perifollicular and intrafollicular inflammatory infiltrate is composed of activated CD4+ and CD8+ T cells, together with macrophages and Langerhans cells. The early phase of hair loss appears to be mediated by

type 1 cytokines, including interleukin (IL)-2, interferon (IFN)- γ , and tumor necrosis factor (TNF)- α . The hair bulb normally represents an area of relative immune privilege during anagen, as evidenced by a very low level of expression of major histocompatibility complex (MHC) class Ia antigens. This immune privilege may prevent antigen recognition by autoreactive CD8+ T cells. Alopecia areata may be related to collapse of this immune privilege. IFN- γ -deficient mice are resistant to alopecia areata.

Onset of disease after Epstein-Barr virus infectious mononucleosis has been reported. Neuropeptides modify immune reactivity and may have a role in the disease. Heredity also plays a part. Overall, nearly 25% of patients have a positive family history; there are reports of twins with alopecia areata. Patients with "early onset, severe, familial clustering alopecia areata" have a unique and highly significant association with the HLA antigens DR4, DR11, and DQ7. The "later onset, milder severity, better prognostic" subsets of patients have a lower frequency of familial disease and do not share these HLA antigens. Familial alopecia areata associated with hereditary thrombocytopenia related to mutations in genes on chromosome 17 has been described. R620W (c.1858C>T, a variant of the protein tyrosine phosphatase nonreceptor 22 gene [*PTPN22*]) is associated with a variety of autoimmune disorders, including alopecia areata. It is associated with early onset of disease, widespread hair loss, and a positive family history.

Histology

In early disease there is a lymphoid infiltrate in the peribulbar area of anagen or early catagen follicles. Eosinophils may be present in the infiltrate, and lymphocyte-mediated damage to the bulb produces melanin pigment incontinence in the surrounding stroma. The hair structures enter an abnormal catagen phase, followed by telogen. During this phase, the presence of many catagen hairs and pigment casts within the follicular canal can cause histologic confusion with trichotillomania. In alopecia areata, the follicles eventually miniaturize, appearing as small dystrophic anagen hairs high in the dermis, often with a persistent lymphocytic peribulbar infiltrate. The presence of a peribulbar infiltrate helps to distinguish the miniaturized follicles of alopecia areata from those of androgenetic alopecia. Fibrous tract remnants beneath the miniaturized bulbs of alopecia areata may contain lymphoid cells, eosinophils, and melanin pigment. These findings are never present in trichotillomania or androgenetic alopecia. With time, the lymphocytes disappear, but focal eosinophils and pigment remain. Finally, only focal melanin pigment remains in the fibrous tract remnants. Hair fiber granulomas and scarring never occur. Every histologic feature of alopecia areata may be seen in syphilis. The presence of plasma cells is suggestive of syphilis, but plasma cells are also lacking in about one-third of syphilis biopsies. Plasma cells may be present in biopsies from any form of inflammatory alopecia if the biopsy is taken from the occipital scalp, as this site readily recruits plasma cells.

Differential diagnosis

The sharply circumscribed patch of alopecia with exclamation point hairs at the periphery and the absence of scarring are indicative of alopecia areata. Tinea capitis, androgenetic alopecia, early lupus erythematosus, syphilis, congenital triangular alopecia, alopecia neoplastica, and trichotillomania should be kept in mind when alopecia areata is considered. A biopsy will generally help to distinguish alopecia areata from these other entities, except syphilis, which may be indistinguishable. In endemic areas of southwest Asia, *Pheidole* ants shear hair shafts during the night, resulting in overnight loss of clumps

of hair. The resulting round patches of hair loss closely mimic alopecia areata.

Treatment

The natural course of the hair loss is highly variable. Some patches will regrow in a few weeks without any treatment. Various treatments can induce growth, but the inherent risks and cost must be weighed against the benefit of earlier regrowth. In his series of 63 consecutive responders to a follow-up questionnaire, Arnold found that, after reassurance only, hair had regrown in all but four patients after 1 year and in all but one after 2 years. The great majority had recovered in 3 months after their only office visit. Therefore, anecdotal reports of success must be interpreted carefully in the light of the high rate of spontaneous recovery.

Intralesional injections of corticosteroid suspensions are the treatment of choice for localized, cosmetically conspicuous patches, such as those occurring in the frontal hairline or involving an eyebrow. Injections of triamcinolone, 2–10 mg/mL, are typically given intradermally or in the superficial subcutaneous tissue. Large volumes and higher concentrations of triamcinolone present a greater risk of atrophy. Injection under significant pressure or with a small-bore syringe increases the likelihood of retinal artery embolization. High-strength topical steroids may be used as a safer first-line therapy, but are less reliable than injections. Several investigators have reported the use of pulsed oral corticosteroids in rapidly progressing or widespread disease. However, long-term treatment is frequently needed to maintain growth, and the attendant risks should be carefully weighed against the benefits. In a study of 66 patients aged 9–60 years, monthly methylprednisolone was administered at a dose of 500 mg/day during 3 days or 5 mg/kg twice a day over 3 days in children. More than 60% of patients with widespread patchy alopecia responded. Half of the patients with alopecia totalis had a good response, while a quarter of those with universal alopecia responded. Patients with ophiasic alopecia areata did not respond.

Induction of contact sensitivity to squaric acid dibutyl ester, dinitrochlorobenzene, and diphencyprone can be useful in refractory cases. In mice, contact immunotherapy is associated with a decrease in cutaneous activated T cells, a reduction in intrafollicular CD8+ lymphocytes, and reduced expression of CD44v3+ and CD44v10+ cells. These results suggest that blockade of leukocyte trafficking and extravasation is an important mechanism of action. Topical or oral methoxsalen and ultraviolet A (PUVA) therapy is an option for refractory or widespread lesions. Short-contact topical anthralin 1% cream (applied for 15–20 min and then shampooed off) can be of benefit. Topical minoxidil may be combined with other treatments or utilized as a single agent. Preliminary results suggest methotrexate and sulfasalazine may be beneficial. Biologics have produced mixed, and largely disappointing, results, and alopecia areata has developed during biologic therapy for other conditions. The 308 nm xenon chloride excimer laser (300–2300 mJ/cm²/session) has been reported to produce regrowth after 11 and 12 sessions over a 9–11-week period. Periocular pigmentation is associated with use of travoprost for eyelash disease. Therapeutic results are mixed.

Alopecia areata can cause tremendous psychological stress. Education about the disease process, cosmetically acceptable alternatives (especially information about wigs), and research into innovative therapies should all be made available to the patient. In addition to the information conveyed by the dermatologist, an excellent resource is the National Alopecia Areata Foundation (NAAF): E-mail: info@naaf.org, website: www.naaf.org.

Prognosis

The tendency is for spontaneous recovery in patients who are postpubertal at onset. At first, the regrowing hairs are downy and light in color; later, they are replaced by stronger and darker hair with full growth. Predictors of a poor prognosis are the presence of atopic dermatitis, childhood onset, widespread involvement, ophiasis, duration of longer than 5 years, and onychodystrophy. Acute diffuse and total alopecia is a newly defined subtype of alopecia areata that occurs in young adults and has a good prognosis.

Telogen effluvium

Telogen effluvium presents with excessive shedding of normal telogen club hairs. This excessive shedding of telogen hairs has several possible mechanisms. It most commonly occurs 3–5 months after the premature conversion of many anagen hairs to telogen hairs induced by surgery, parturition, fever, drugs, dieting, or traction. Local patches of early telogen conversion may be induced by papulosquamous diseases affecting the scalp. Alternatively, follicles may remain in prolonged anagen rather than normally cycling into telogen. This occurs during pregnancy. On delivery, many follicles are then released simultaneously into telogen, and shedding

occurs 3–5 months later. Prolongation of telogen also occurs during pregnancy, and results in an initial wave of hair loss soon after delivery or heralding early termination of a pregnancy. Shortening of the anagen phase occurs in pattern (androgenetic) alopecia, and results in telogen effluvium. Normally, anagen lasts about 1000 days and telogen about 100 days. This results in a 10:1 ratio of anagen to telogen hairs in the scalp. With progression of pattern alopecia, anagen shortens, and the ratio of anagen to telogen hairs falls. A greater proportion of hairs is in telogen at any one time, resulting in a chronic increase in telogen shed. Administration of topical minoxidil may produce a telogen effluvium by premature termination of telogen necessary to initiate anagen in responding follicles. This causes early telogen release and a brief telogen effluvium.

Whatever the cause of the telogen loss, the hair is lost “at the root.” Each hair will have a visible depigmented club-shaped bulb and will lack a sheath (Fig. 33-3). In most cases, loss is diffuse. Patients commonly have more than one mechanism for telogen hair loss. Patchy or diffuse telogen may be associated with papulosquamous diseases of the scalp. Perceptible thinning of the hair is more common in patients with pre-existing pattern alopecia. In patients with pattern alopecia, shortening of the hair cycle results in increased telogen shed. Superimposed papulosquamous disease, iron deficiency, or thyroid disease can result in even more telogen shed and accentuates the pattern loss.

Trichodynia is a common symptom in patients with telogen effluvium, as it is in pattern hair loss. Trichodynia often coexists with signs of depression, obsessive personality disorder, and anxiety.

Telogen shed may be estimated by the pull test: grasping 40 hairs firmly between thumb and forefinger, followed by a slow pull that causes minimal discomfort to the patient. A count of more than 4–6 club hairs is abnormal, but the result is influenced by recent shampooing (a count of 2–3 hairs being abnormal in a freshly shampooed scalp), combing, and the phase of telogen effluvium (whether it is resolving or entering a chronic phase). The clip test may also be useful; 25–30 hairs are cut just

above the scalp surface and mounted. Indeterminate and telogen hairs are short and of small diameter. Many hairs of this type may be present in telogen effluvium or pattern alopecia. Trichogram evaluation (50 hairs plucked with a Kelly clamp with rubber drains over the teeth) can also provide information on the anagen to telogen ratio.

Age, sex, race, and genetic factors influence the normal average daily hair loss in an individual. A full head of hair numbers about 100 000; of these, approximately 100–150 are lost daily. In telogen effluvium, estimates of loss vary from 150 to more than 400. Patients may be instructed to collect and count the hair daily; however, they should make sure they collect all small hairs and those that come out in washing and in the bed, as well as those present on the comb or brush. When the pull test is positive, hair shed counts are not needed. An alternative is to collect all hairs lost during a 1 min combing session. For this technique, developed by Dr Jeffrey Miller, the patient combs for 1 min prior to shampooing on 3 consecutive days. The patient is instructed to comb from the vertex to the anterior hairline. The normal range of lost hairs with this technique is 10–15. Loss of more than 50 is common in telogen effluvium. Serial 1 min hair counts can be performed to monitor progress.

Telogen effluvium is commonly related to protein or other nutrient deprivation (Fig. 33-4). Assessment of dietary habits and determination of iron saturation and ferritin are the simplest ways to determine nutritional status. Iron replacement is advisable if saturation or ferritin is low, but in one study iron replacement alone did not result in resolution of telogen effluvium. Iron may merely serve as a marker for overall nutritional status. Patients with evidence of deficiency should be given supplements to correct the identified deficiency and encouraged to eat a varied diet. Sources of blood loss, such as menstrual bleeding and gastrointestinal blood loss, should be investigated. Hypothyroidism, allergic contact dermatitis to hair dyes, and renal dialysis with secondary hypervitaminosis A may also be associated with telogen effluvium. Drug-induced telogen effluvium has been noted with the use of aminosalicic acid, amphetamines, bromocriptine, captopril, carbamazepine, cimetidine, coumarin, danazol, enalapril, etretinate, levodopa, lithium carbonate, metoprolol, metyrapone, pramipexole, propranolol, pyridostigmine, and trimethadione. Postnatal telogen effluvium of infants may occur between birth and the first 4 months of age. Usually, regrowth occurs by 6 months of age. Telogen counts by Kligman in six

Fig. 33-3 Anagen and telogen hair (anagen hair has a pigmented bulb and is surrounded by a gelatinous root sheath; telogen hair has a nonpigmented bulb and lacks a root sheath).

Fig. 33-4 Telogen effluvium secondary to crash dieting.

infants varied from 64% to 87%. He also found a tendency for the alopecia to occur in the male-pattern distribution. Idiopathic chronic telogen effluvium has been described by Whiting in a group of 355 patients (346 women and 9 men) with diffuse generalized thinning of scalp hair. Most were 30–60 years old, and their hair loss started abruptly, with increased shedding and thinning. There was a fluctuating course and diffuse thinning of the hair all over the scalp, accompanied by bitemporal recession. He found high telogen counts on horizontal sections of scalp biopsies and considers these patients to have a chronic form of telogen effluvium. This chronic form may respond to 5% minoxidil solution.

If a 4 mm punch biopsy is performed, 25–50 hairs are normally present for inspection in transverse (horizontal) sections. If more than 12–15% of terminal follicles are in telogen, this indicates a significant shift from anagen to telogen. Pattern (androgenetic alopecia) demonstrates miniaturization, variable hair shaft diameter, and an increased proportion of telogen hairs. Traction alopecia and trichotilosis (trichotillomania) result in an increased number of catagen and telogen hairs. Pigment casts, empty anagen follicles, trichomalacia, and catagen hairs help distinguish these entities from simple telogen effluvium.

No specific therapy is required for most patients with telogen effluvium. In the majority of cases the hair loss will stop spontaneously within a few months and the hair will regrow. Drug-induced telogen effluvium responds to discontinuation of the offending agent. The prognosis is good if a specific event can be pinpointed as a probable cause. Papulosquamous scalp disorders may precipitate telogen hair loss and should be addressed. Iron and thyroid status should be determined if the course is prolonged or if history or physical examination suggests an abnormality. Patients should be encouraged to eat a balanced diet. In a mouse model, sonic stress can produce catagen. This model may be useful in the study of agents for the treatment of telogen effluvium.

Anagen effluvium

Anagen effluvium usually results from hair shaft fracture. It is frequently seen following the administration of cancer chemotherapeutic agents, such as the antimetabolites, alkylating agents, and mitotic inhibitors. These agents result in temporary shutdown of the hair matrix with resultant tapering of the shaft (Pohl–Pinkus constrictions). Trichograms reveal tapered fractures. Only anagen hairs are affected. The 10% of scalp hairs in telogen have no matrix and are unaffected. The loss tends to be diffuse but not complete. It may resemble pattern alopecia. Severe loss is frequently seen with doxorubicin, the nitrosureas, and cyclophosphamide. When high doses are given, loss of anagen hairs becomes most apparent clinically in 1–2 months. The hair shafts are abruptly narrowed at the time of maximum drug effect, and when the very thin portion reaches the surface, the hair shafts all break at about the same time. With cessation of drug therapy, the follicle resumes its normal activity within a few weeks; the process is entirely reversible. It is apparent that mitotic inhibition merely stops the reproduction of matrix cells but does not perma-

Fig. 33-5 Loose anagen hair with “rumpled sock” cuticle.

nently destroy the hair. A pressure cuff applied around the scalp during chemotherapy and scalp hypothermia have been reported to prevent such anagen arrest, but as the scalp may be a site of metastasis, it may be better not to spare the scalp from the effects of chemotherapy. Topical minoxidil has been shown to shorten the period of baldness by an average of 50 days.

In addition to the cytotoxic chemotherapeutic agents, various agents, such as isoniazid INH, thallium, and boron may induce anagen effluvium. Anagen effluvium with tapered fractures also occurs in alopecia areata and syphilis. In these diseases, an inflammatory insult to the hair bulb results in Pohl–Pinkus constrictions and tapered fracture.

Anagen loss may also occur at the root. Loose anagen syndrome, described by Price in 1989, is a disorder in which anagen hairs may be pulled from the scalp with little effort. It occurs mostly in blond girls and usually improves with age. The syndrome appears to be related to a defect in the hair cuticle. Instead of anchoring the hair firmly, the cuticle simply folds back like a rumpled sock (Fig. 33-5), allowing the hair shaft to be extracted. Woolly hair can be associated with loose anagen hair syndrome. A keratin mutation, E337K in K6HF, was identified in three of nine families studied. Colobomas have also been associated with loose anagen hair.

Anagen hairs may be easily extracted from active areas of lupus erythematosus and lichen planopilaris. They commonly lack the root sheath that normally surrounds a plucked anagen hair (Fig. 33-6). Anagen effluvium has also been described in lesions of pemphigus.

Pattern alopecia (androgenetic alopecia)

Male-pattern baldness

Male-pattern alopecia or male-pattern androgenetic alopecia (common baldness) shows itself during the teens, twenties, or early thirties with gradual loss of hair, chiefly from the vertex and frontotemporal regions. The process may begin at any time after puberty, and the presence of “whisker” or kinky hair may be the first sign of impending male-pattern alopecia. The anterior hairline recedes on each side, in the

Fig. 33-6 Stain for citrulline demonstrates the inner root sheath (red) surrounded by an outer root in a plucked anagen hair from a normal scalp.

Geheimratswinkeln (“professor angles”), so that the forehead becomes high. Eventually, the entire top of the scalp may become devoid of hair. Several patterns of this type of hair loss occur, but the most frequent is the biparietal recession with loss of hair on the vertex. The rate of hair loss varies among individuals. Sudden hair loss may occur in the twenties and then proceed relentlessly, though very slowly, for a number of years. The follicles produce finer and lighter hairs with each hair cycle until terminal hairs are eventually replaced by vellus hairs. During evolution of the process, hair shafts vary significantly in diameter. The parietal and occipital areas are usually spared permanently from this process of progressive miniaturization.

Early-onset male-pattern alopecia is related to the androgen receptor gene. There is no doubt that inherited factors and the effect of androgens such as dihydrotestosterone on the hair follicle are important. Arguments for regarding the inheritance as polygenic include the high prevalence, gaussian curve of distribution in the population, increased risk with number of affected relatives, increased risk in relatives of severely affected women compared with mildly affected, and greater import of an affected mother than an affected father. The possibility that the early onset (before the age of 30) and later onset (after the age of 50) forms may be inherited separately by single genes is also hypothesized.

Male-pattern alopecia is dependent on adequate androgen stimulation and appears to be related to the androgen receptor gene. Eunuchs do not develop baldness if they are castrated before or during adolescence. If they are given androgen therapy, baldness may develop. The 5- α reduction of testosterone is increased in the scalp of balding individuals, yielding increased dihydrotestosterone. Androgen-inducible transforming growth factor (TGF)- β 1 derived from dermal papilla

cells appears to mediate hair growth suppression. In congenital 5- α -reductase deficiency, the type 2 isoenzyme is lacking and baldness does not occur. Pattern alopecia does occur in males with X-linked ichthyosis, indicating that steroid sulfatase is not critical for the production of alopecia.

Progressive shortening of the anagen phase of hair growth is noted as the hair shaft diameter decreases, so hairs are not only narrowing, but are becoming shorter. A higher proportion of telogen hairs in the affected area results in greater telogen shed. There may also be an increase in the duration of the lag phase between telogen and anagen (the kenogen lag phase).

Histologically, a decrease in anagen and increase in telogen follicles is present. Follicular miniaturization and variability in shaft diameter are noted. These features are particularly evident in transverse sections. Below the level of the miniaturized or telogen follicle, a vascular or fibromucinous fibrous tract remnant is present. These tracts appear numerous in cross-section. Many mast cells may be noted in the fibrous tract remnant, but inflammatory cells are absent. Sebaceous glands may be enlarged, and hair thinning may be associated with solar elastosis. Sparse lymphoid inflammation with spongiosis may be noted at the level of the follicular infundibulum. This may represent associated seborrheic folliculitis. A sparse lymphoid infiltrate may also be noted at the level of the hair bulge.

Miniaturized human hair follicles grafted on to immunodeficient mice can quickly regenerate and grow as well as or better than terminal follicles from the same individual. This suggests that even advanced pattern alopecia may be reversible. Unfortunately, available pharmacologic interventions produce little effect in advanced pattern alopecia.

Minoxidil, an oral hypotensive drug that causes hypertrichosis when given systemically, is available as topical solutions (Rogaine). Minoxidil promotes the survival of dermal papilla cells, prolongs anagen phase, and results in enlargement of shaft diameter. Clinically, apparent success is best in early cases (less than 10 years) of limited extent (bald area of less than 10 cm diameter on the vertex) in whom pretreatment hair density is above 20 hairs/cm². Minoxidil is available without a prescription as a 2% or a 5% solution. With the 2% solution, 26% of men studied showed moderate to dense regrowth, while 33% showed minimal regrowth after 4 months. Studies show a 45% increase in hair weight with the 5% solution compared to the 2% solution. In those who respond, regrowth can occur as early as 2 months after the first application. Those who respond must continue to use minoxidil indefinitely to maintain a response.

Finasteride, a type 2 5- α -reductase inhibitor, given as a 1 mg tablet daily, is effective in preventing further hair loss and in increasing the hair counts to the point of cosmetically appreciable results in men aged 18–41 with mild to moderate hair loss at the vertex, in the anterior midscalp, and in the frontal region. It has been shown to stop hair loss in up to 90% of men for at least 5 years. Approximately 65% of men demonstrate hair regrowth. As with minoxidil, continued use of the product is required to sustain benefits. Hair patterning on the temples is not improved. It has been shown to lower dihydrotestosterone in the scalp and the serum of treated patients. Hair growth will be evident only after 6 months or more on the drug. If no effect is seen after 12 months, further treatment is unlikely to be of benefit. In one study, regimens that included finasteride were more effective than minoxidil alone, and therapeutic efficacy was enhanced by combining the two drugs. Short-term side effects related to finasteride are infrequent; however, the need to take this medication indefinitely suggests that study of long-term side-effect profiles is critical. A prostate cancer prevention trial with a

different dosage form of the same drug showed a decrease in the incidence of cancer. However, those cancers that did occur in the treatment group had a higher average Gleason score. This could be because only lower-grade cancers were prevented. Dutasteride blocks both type 1 and type 2 5- α -reductase, and is effective in the treatment of male-pattern hair loss. Other treatments that show some promise in preliminary studies include fluridil (a topical antiandrogen that suppresses the human androgen receptor) and hormone-enriched topical cell culture medium. Hair transplantation using micrografts of hair follicles from the occipital area to the anterior scalp may satisfactorily recreate hairlines and give excellent cosmetic results.

Female-pattern alopecia (androgenetic alopecia in women)

Women generally have diffuse hair loss throughout the apical scalp with the part wider anteriorly. There is typically sparing of the frontal hairline, although a subset of women exhibits a “male” pattern of temporal recession. Although maintenance of the frontal hairline is the rule in women, a progressive decrease in hair density from the vertex to the front of the scalp does occur. The midline part is an important clinical clue, revealing a “Christmas tree pattern” of hair loss with the part tapering from the anterior to posterior scalp. The BASP classification has been suggested as a single hair loss classification scheme for use in men and women. It is based on basic (BA) types representing the shape of the anterior hairline, and specific (SP) types representing the density of hair on distinct areas (frontal and vertex). This is important because patients of either sex may demonstrate male or female patterns of alopecia. Phototrichograms and measurement of shaft diameter can be used to assess female-pattern alopecia. The same basic changes—reduced hair density and diameter, and diminished anagen and increased telogen hair—occur in women as in men. Sebaceous gland hyperplasia may be present, but is less common than in men. Transverse histologic sections demonstrate variability in the size of hair follicles (anisotrichosis).

The cause is now believed to be a genetic predisposition with an excessive response to androgens. Both women and men with pattern alopecia have higher levels of 5- α -reductase and androgen receptor in frontal hair follicles compared to the levels in occipital follicles. There is also evidence suggesting a hierarchy of androgen sensitivity within follicular units. Follicular miniaturization relates to unrepaired DNA damage and a reduced proliferation rate of matrix keratinocytes. Smoking may be an independent risk factor. Most women with pattern alopecia have normal menses and fertility. If other evidence of androgen excess is present, such as hirsutism, menstrual irregularities, or acne, or if the onset is sudden, evaluation as outlined for hirsutism (see below) should be performed. Men with spinal and bulbar muscular atrophy (Kennedy disease), an X-linked neurodegenerative disease caused by an expansion of a polymorphic tandem CAG repeat within the androgen receptor gene, have a decreased incidence of pattern alopecia.

Topical minoxidil is of benefit. Although some data suggest that 5% minoxidil may be of greater benefit than 2% minoxidil, the evidence is mixed. Given the higher cost of 5% minoxidil, the 2% formulation may be the best choice for many women. Oral antiandrogens, including spironolactone and cyproterone acetate, have been used to treat androgenetic alopecia in women. In one study, cyproterone acetate was more effective than minoxidil when there were other signs of hyperandrogenism, hyperseborrhea, and menstrual abnormalities, and when the body mass index was high. When these other factors were absent, minoxidil was the more effective treatment.

Treatment with finasteride is of no benefit for most women, although the subset with temporal recession may show some benefit. Finasteride treatment is contraindicated in women who may become pregnant. Hair transplantation, wigs, or interwoven hair may give satisfactory cosmetic results. In a pilot study, topical melatonin appeared to prolong anagen phase and may prove to be of some benefit. In some women, telogen effluvium may produce worsening of pre-existing pattern alopecia. Reversible causes of telogen effluvium, such as seborrheic dermatitis, nutrient deficiency, and thyroid disease, should be addressed.

Trichotillomania (trichotillois)

Trichotillomania is the compulsive practice of plucking hair from the scalp, brows or eyelashes. Typical areas are irregular patches of alopecia that contain hairs of varying length. The scalp has a rough texture, resulting from the short remnants of broken-off hairs. Trichotillomania is seen mostly in girls under the age of 10, but boys, or adults of either sex, may engage in the practice also. Some patients relate exquisite pain localized to a follicle that can only be relieved by plucking the hair.

When speaking with a patient with characteristic areas of alopecia, it has been suggested that it be asked not if but rather how removal of the hair is done. If this fails to uncover a history of hair pulling, shaving a 3 cm² area in the involved part of the scalp will result in hairs too short for plucking, and normal regrowth in the “skin window” within 3 weeks. Finally, a biopsy, especially if cut horizontally, may demonstrate empty anagen follicles, catagen hairs, pigment casts within the infundibulum, trichomalacia, and hemorrhage. Alopecia areata shares many of these histologic features, and care must be taken to search for the presence of peribulbar lymphocytes or inflammatory cells within the fibrous tract remnants.

Trichotillomania is usually a manifestation of an obsessive-compulsive disorder, but may also be associated with depression or anxiety. It may be associated with compulsive swallowing of the plucked hairs (trichophagia), and may

result in formation of a gastric bezoar. Behavior modification, psychotherapy, and appropriate psychopharmacologic medication (such as serotonin-reuptake inhibitors) may be helpful. Valproic acid, quetiapine and naltrexone have been reported as effective in some patients.

Other forms of noncicatricial alopecia

Alopecia syphilitica may have a typical moth-eaten appearance on the occipital scalp (Fig. 33-7), may show a generalized thinning of the hair, or may resemble alopecia areata. Other areas such as the eyebrows, eyelashes, and body hair may be involved. The alopecia may be the first sign of syphilis.

Follicular mucinosis (alopecia mucinosa) most commonly occurs on the scalp or beard area and manifests as a boggy red plaque or hypopigmented patch with hair loss. Comedone-like lesions may exude mucin when expressed. Biopsy demonstrates deposition of mucin in the outer root sheath and sebaceous glands. The mucin stains as hyaluronic acid, rather than epithelial sialomucin. Primary cases (unassociated with underlying disease) usually occur as localized lesions of the head or neck. Young people are primarily affected. The secondary type is associated with mycosis fungoides-type cutaneous T-cell lymphoma or a chronic inflammatory skin disease. Lesions associated with mycosis fungoides are generally widespread and chronic, and occur in older patients.

Vascular or neurologic alopecia, most often of the lower extremities, may be seen in diabetes mellitus or atherosclerosis. In meralgia paresthetica there may be alopecia of the anesthetic area of the outer thigh.

Endocrinologic alopecia may occur in various endocrinologic disorders. In hypothyroidism the hair becomes coarse, dry, brittle, and sparse. The proportion of telogen hairs has been shown to be 3–7 times higher than the normal 10%. In hyperthyroidism the hair becomes extremely fine and sparse. Oral contraceptives have been implicated in some instances of

Fig. 33-7 Syphilitic alopecia. (Courtesy of Brooke Army Medical Center Teaching File)

androgenetic alopecia. It develops in predisposed women who are usually taking androgenic progestogens. It is advisable to discontinue the androgen-dominant pill and substitute an estrogen-dominant oral contraceptive. Some women develop telogen effluvium 2–4 months after discontinuing anovulatory agents, which is analogous to postpartum alopecia.

Congenital alopecia occurs either as total or partial loss of hair, or a lack of initial growth, accompanied usually by other ectodermal defects of the nails, teeth, and bone. The hair is light and sparse, and grows slowly. Congenital triangular alopecia (Fig. 33-8) and aplasia cutis congenita are examples of congenital localized absence of hair, while hidrotic ectodermal dysplasia is an example of a diffuse abnormality of hair associated with dental and nail changes.

Lipedematous alopecia consists of thickening of the scalp that gives the impression of thick cotton batting. The hair may be normal or shortened and sparse. Biopsy shows an increase in thickness of the subcutaneous fat and variable lymphoid inflammation. This disease appears to affect black persons primarily.

González-Guerra E, et al: Lipedematous alopecia: an uncommon clinicopathologic variant of nonscarring but permanent alopecia. *Int J Dermatol* 2008 Jun; 47(6):605–609.

Cicatricial alopecia

Cicatricial alopecia appears as areas of hair loss with absence of follicular ostia (Fig. 33-9). Acute lesions may appear as erythematous plaques, perifollicular papules, keratotic follicular

Fig. 33-8 Triangular alopecia. (Courtesy of Brooke Army Medical Center Teaching File)

Fig. 33-9 Loss of follicular ostia in scarring alopecia.

spines, or pustules. Deep inflammatory lesions may be boggy or may resemble noncicatricial areata clinically. The inflammatory nature of the lesion may only be evident on biopsy.

Discoid lupus erythematosus, lichen planopilaris, sarcoidosis, and folliculitis decalvans are the most common inflammatory causes of cicatricial alopecia. Chronic bacterial and fungal infections may produce inflammatory alopecia that mimics primary scarring alopecia. For example, fungal folliculitis may mimic lupus erythematosus.

Biopsy can confirm the diagnosis and provide prognostic information regarding the potential for new growth. A 4 mm punch biopsy will provide the pathologist with an adequate specimen. Smaller specimens are of limited value. The punch should be placed parallel to the direction of hair growth to avoid transecting follicles, and the punch should be advanced to the deep subcutaneous fat. The biopsy site will typically bleed profusely, but a 4 mm-wide strip of gel foam advanced into the defect will generally provide rapid hemostasis. Sutures are rarely necessary, and as the scar from a sutured biopsy site generally stretches back to the original dimensions of the biopsy, suturing provides little benefit to the patient.

Where to biopsy, how many biopsies to obtain, and how to process the tissue depend on the suspected diagnosis and the preference of the pathologist. In all cases, a pathologist experienced in the interpretation of scalp biopsies is an advantage. The pathologist may prefer vertical or transverse (horizontal) sectioning of the specimen. Each has advantages. Every follicular unit in the specimen will be demonstrated in transverse sections. Vertical sections are superior for demonstrating changes in the surface epidermis, dermoepidermal junction, superficial dermis, and subcutaneous fat. In general, the features of androgenetic (pattern) alopecia, telogen effluvium, and trichotillomania are better demonstrated in transverse (horizontal) sections through the specimen. Alopecia areata and syphilitic alopecia are well demonstrated in transverse sections if serial step sections are obtained to demonstrate deeper planes of section or if the block is cut horizontally in a bread-loaf fashion prior to embedding. They are equally well demonstrated with serial vertical sections through the block. Lupus erythematosus and lichen planopilaris are more easily demonstrated in serial vertical sections.

The diagnostic yield can be enhanced by pairing vertical and transverse sections. If two biopsies are done, one specimen can be bisected vertically for direct immunofluorescence (DIF) and hematoxylin and eosin (H&E) processing. It is most easily split by laying it on its side and bisecting it with a 15 blade pushed cleanly through the specimen in a single downward motion. Sawing at the specimen will not produce a satisfactory result. One-half of the bisected specimen is placed in formalin, and the other half in immunofluorescent media. The second specimen can be bisected for transverse sections in the clinic or left for the laboratory to bisect after processing. If it is to be bisected in the clinic, it should be placed on its side. The 15 blade should be pushed downward through the specimen in a single motion at the level of the mid-dermis. All pieces for vertical and transverse sections may be placed in a single bottle to be embedded in a single cassette.

In many forms of cicatricial alopecia, a biopsy of an active inflammatory lesion will be most diagnostic. In lupus erythematosus, the biopsy must be from a lesion of several months' duration in order to demonstrate hyperkeratosis, follicular plugging, basement membrane thickening (Fig. 33-10), and dermal mucin. Only biopsies from established lesions of lupus will demonstrate reliable immunofluorescence.

When biopsies of the most active area of alopecia have failed to yield a definite diagnosis, a biopsy from a scarred area may provide additional information. Scars show loss of elastic tissue with the Verhoeff-van Gieson stain. The pattern of

Fig. 33-10 Basement membrane thickening in lupus erythematosus (periodic acid-Schiff [PAS] stain).

Fig. 33-11 Scarring alopecia (H&E stain).

elastic tissue loss is the “footprint” of the preceding inflammatory process (Figs 33-11 and 33-12). Lichen planopilaris and folliculitis decalvans both affect the infundibulum. Both result in wedge-shaped superficial dermal scars. Discoid lupus erythematosus results in scarring of both the follicular units and the intervening dermis. Morphea does not produce a scar, but rather hyalinization of collagen bundles with preservation of the elastic fibers. In idiopathic pseudopelade, the fibrous tract remnants are widened, but the elastic tissue sheath at the periphery of the fibrous tract is preserved.

Most patients with cicatricial alopecia experience gradual progression of the alopecia, and the prolonged course of the disease may lead to inappropriate therapeutic complacency. The progressive destruction of hairs will result in ever-expanding areas of permanent alopecia. Therefore, cicatricial alopecia must be treated aggressively and early to avoid

Fig. 33-12 Scarring alopecia (elastic stain). Normal elastic fibers (black) indicate the nonscarred portions of the dermis.

permanent disfigurement. Surgical revision of the hairless plaque is an option for stable end-stage alopecia, but unless the underlying disease is controlled, surgery may only lead to a flare of the underlying disease with progression of hair loss. Therapy may be forestalled by the inability to establish a definite diagnosis. To help guide therapy for patients who defy diagnosis, work groups of the North American Hair Research Society have proposed a classification scheme based on the type and pattern of inflammation. Some forms of destructive alopecia are lymphocyte-mediated, while some are suppurative processes. The type of infiltrate and the portion of the pilosebaceous unit affected can be used to guide therapy. This classification system may also allow patients to enroll in clinical trials, even in the absence of a definite diagnosis.

Lymphoid-mediated disorders

Lupus erythematosus

Chronic cutaneous lupus of the scalp (discoid lupus erythematosus [DLE]) is a common cause of cicatricial alopecia. In active disease, anagen hairs may be easily extracted from the involved area. Usually, erythema, atrophy, follicular plugging, and mottled hyperpigmentation and hypopigmentation are present. Patients with chronic cutaneous lupus of the scalp may or may not have accompanying SLE or skin lesions of DLE on other parts of the body. The external ear canal and concha should always be examined, as they are common sites for discoid lesions. Occasionally, alopecia occurs in a plaque of tumid lupus. Lupus panniculitis may occasionally result in alopecia in the absence of surface skin changes. SLE is often associated with discoid lesions of the scalp. Patients with SLE may also have short miniaturized "lupus hairs" on the anterior scalp.

Biopsy of early lesions of DLE is often nondiagnostic. Patchy lymphoid inflammation and perifollicular mucinous fibrosis may be the only histologic findings. Focal vacuolar interface dermatitis may or may not be noted. Active established lesions, present for several months, have a higher diagnostic yield. Active established lesions usually demonstrate hyperkeratosis, follicular plugging, vacuolar interface dermatitis, basement membrane zone thickening, pigment incontinence, and dermal mucin. Perivascular and periadnexal lymphoid infiltrates are patchy and involve the eccrine coil and fibrous tract remnants. Fibrous tract involvement creates dense vertical columns of lymphocytes. The underlying subcutaneous tissue may demonstrate nodular lymphoplasmacytic infiltrates and fibrin or hyaline rings around necrotic fat. Hypertrophic lesions of chronic cutaneous lupus erythematosus often demonstrate lichenoid dermatitis. DIF may be nonspecific, but active established lesions typically demonstrate a "full house"

Fig. 33-13 Frontal fibrosing alopecia. (Courtesy of Don Adler DO)

(continuous granular deposition of IgG, IgA, IgM, and C3) at the dermoepidermal junction. When present, this pattern is particularly helpful in distinguishing lichenoid hypertrophic lupus erythematosus from lichen planopilaris. Burnt-out lesions of DLE demonstrate loss of elastic fibers throughout the dermis, which differs from the focal peri-infundibular wedge-shaped scars of lichen planopilaris. In systemic lupus, there may be follicular atrophy associated with pronounced dermal mucinosis.

Chronic cutaneous lupus may respond to intralesional or potent topical corticosteroids, but systemic therapy is frequently required. Antimalarials, retinoids, dapsone, thalidomide, sulfasalazine, mycophenolate mofetil, and methotrexate have been used successfully. Topical tazarotene and topical calcineurin inhibitors are generally disappointing.

Lichen planopilaris

Lichen planopilaris presents with perifollicular erythema and progressive scarring. Small follicular papules may be noted, or the lesion may resemble the ivory white irregular patches of pseudopelade. In some patients, typical polygonal flat-topped papules are present on the wrists and ankles, and lacy white lesions are noted on the oral and genital mucosa. Widespread follicular papules may be present on the trunk or extremities. In most patients, however, only the scalp is involved. Frontal fibrosing alopecia appears to be a variant of lichen planopilaris. Most patients are older women with bandlike frontotemporal alopecia (Fig. 33-13). Graham Little-Piccardi-Lassueur syndrome includes cicatricial alopecia on the scalp, keratosis pilaris in the skin of the trunk and extremities, and noncicatricial hair loss in the pubis and axillae. It has been described in association with complete androgen insensitivity syndrome, a condition that also presents with noncicatricial alopecia in the axillary and pubic hair.

Diagnostic biopsies demonstrate lichenoid interface dermatitis of the follicular unit and sometimes the intervening epidermis. The entire fibrous tract may be filled with cytooid bodies (Fig. 33-14). The changes commonly occur focally and may be best visualized with serial vertical sections. Perifollicular mucinous fibrosis is common and focal perifollicular lymphoid infiltrates tend to involve the infundibulum (the infiltrates of lupus erythematosus tend to involve the isthmus). DIF may be negative or may reveal cytooid bodies and shaggy linear fibrin at the dermoepidermal junction.

Lichen planopilaris responds to oral and intralesional corticosteroids. Topical corticosteroids may be adequate in a few patients, but the activity of the disease waxes and wanes, and slow progression should not lead to therapeutic complacency. Oral retinoids can be effective. Alternative therapies

Fig. 33-14 Lichen planopilaris, note cytoid bodies completely fill the fibrous tract remnant.

include the other oral agents used to treat lupus; however, there are fewer data regarding their use in lichen planopilaris. As in lupus, topical tazarotene and topical macrolactams are generally disappointing. Biologics have been suggested as therapy, but onset of lichen planopilaris has been noted during etanercept therapy.

Hot comb alopecia and central centrifugal cicatricial alopecia

Hot comb alopecia was reported in the late 1960s as a scarring alopecia seen in black women who straightened their hair with hot combs for cosmetic purposes. It develops characteristically on the crown and spreads peripherally to form a large oval area of partial hair loss. The hot petrolatum used with the iron was thought to cause thermal damage to the hair follicle. However, Sperling et al reported a similar-appearing scarring alopecia in both men and women who did not report the use of hot combs. Some authors now regard hot comb alopecia, central centrifugal cicatricial alopecia (CCCA), and idiopathic pseudopelade to be one entity or overlapping entities that can be indistinguishable.

CCCA is seen most commonly in African American women, is slowly progressive, usually begins in the crown, and advances to the surrounding areas (Fig. 33-15). The term is often used as a broad category that includes cases once classified as hot comb alopecia and central elliptical pseudopelade in white women. Some patients will demonstrate crops of crusts at the periphery of the patches, a feature of folliculitis decalvans. Treatment of CCCA is difficult and often unsatisfactory. Discontinuation of chemical and heat processing, and reduction of traction are routinely recommended, but the effectiveness of these recommendations has yet to be substantiated. Cases with overlapping features of folliculitis decalvans may respond to long-term antibiotic therapy and topical corticosteroids. In such overlapping cases, the histology shows a lymphocytic infiltrate during the chronic stage, but periodic crops of pustules demonstrate a neutrophilic folliculitis.

Fig. 33-15 Central centrifugal cicatricial alopecia.

Neutrophil-mediated disorders

Folliculitis decalvans

Folliculitis decalvans presents with crops of pustules that result in cicatricial alopecia. Successive crops of pustules, crusts, or erosions lead to expansion of the alopecic patches. Staphylococci are sometimes cultured from the lesions, and some authors have suggested that folliculitis decalvans merely represents a chronic staphylococcal infection. It is more likely that follicular destruction is the result of an abnormal suppurative immune response. Staphylococci and other organisms probably play a role in inciting the response. The lesions often respond to long-term treatment with tetracycline. The improvement may reflect the antineutrophil effects of the drug or its antimicrobial effects. Many patients also respond to other forms of antistaphylococcal therapy, but the lesions generally recur after the antibiotic is discontinued. Chronic antibiotic treatment generally results in a continued response. Some sustained responses have been noted after combination therapy with rifampin and clindamycin. Rifampin alone has been used, but may promote the emergence of resistance. Selenium sulfide shampoo and topical corticosteroids may be useful as adjunctive therapy. Oral retinoids, oral and topical fusidic acid, and oral zinc sulphate have sometimes produced sustained responses.

A variant of folliculitis decalvans occurs in African American patients who present with pseudofolliculitis of the beard, acne keloidalis nuchae, and scarring alopecia in the vertex and parietal scalp. The scalp demonstrates ingrown hairs, crops of pustules or crusts, and permanent scarring alopecia. While pseudofolliculitis barbae is generally accepted to be the result of ingrown hairs, the pathogenesis of acne keloidalis nuchae remains in question. Histologically, ingrown hairs are common in advanced lesions. Early lesions may not demonstrate the hair. Some patients merely develop small papules on the nape of the neck, while others develop pustules, crusts, and progressive alopecia. This latter group overlaps with folliculitis decalvans.

Acne necrotica

Acne necrotica presents with discrete excoriated follicular papules in the scalp. Biopsy demonstrates an inflammatory crust and suppurative folliculitis. Usually there is no associated scarring alopecia, but occasional cases overlap with folliculitis decalvans.

Fig. 33-16 Erosive pustular dermatitis.

Fig. 33-18 Tufted doll's hairs, cicatricial alopecia.

Fig. 33-17 Dissecting cellulitis.

Erosive pustular dermatitis of the scalp

This often presents as expanding eroded patches with moist granulation tissue (Fig. 33-16). The lesions often follow trauma or a surgical procedure and tend to be chronic and progressive. They respond best to class I topical corticosteroids.

Dissecting cellulitis (perifolliculitis capitis abscessens et suffodiens of Hoffman)

This often coexists with acne conglobata and hidradenitis suppurativa. It may also occur with folliculitis decalvans. The lesions are deep, boggy, and suppurative (Fig. 33-17). They may respond to tetracyclines, retinoids, and intralesional corticosteroids.

Tufted folliculitis

Tufted folliculitis presents with doll's hair-like bundling of follicular units. It is seen in a wide range of scarring conditions, including chronic staphylococcal infection, chronic lupus erythematosus, lichen planopilaris, Graham Little syndrome, folliculitis decalvans (Fig. 33-18), acne keloidalis nuchae, immunobullous disorders, and dissecting cellulitis. Compound hairs (two or more hairs sharing a common

infundibulum) occur physiologically on the scalp and legs. They are common in the occipital scalp. Recurrent staphylococcal infection is more common in patients with many compound hairs and commonly leads to tufted folliculitis.

Other forms of permanent alopecia

Pseudopelade of Brocq

Also known as alopecia cicatrisata, this is a rare form of cicatricial alopecia in which destruction of the hair follicles produces multiple round, oval, or irregularly shaped, hairless, cicatricial patches of varying sizes. They are usually coin-sized and are white or slightly pink in color, with a smooth, shiny, marble-like or ivory, atrophic, "onion skin" surface. Interspersed in the patches may be a few spared follicles with hairs growing from them. A clinical inflammatory stage is completely absent. No pustules, crusts, or broken-off hairs are present. The onset is, as a rule, insidious, with one or two lesions appearing on the vertex. The condition affects females three times more commonly than males, and has a prolonged course. In advanced cases large irregular patches are formed by coalescence of some of the many small macules, a pattern referred to as "footprints in the snow." The alopecia is permanent and the disease is slowly progressive. Histologically, the majority of patients with clinical lesions of pseudopelade demonstrate true scarring (indicated by loss of elastic tissue) in a wedge-shaped pattern in the superficial dermis. The pattern is similar to that seen in lichen planopilaris and suggests that many cases classified as pseudopelade represent an end stage of lichen planopilaris. A subset of patients, however, demonstrates no perifollicular or interfollicular scarring at all. This subset has been called idiopathic pseudopelade. It shows significant clinical overlap with CCCA. In these patients, the dermis is contracted into a thin band of dense collagenous tissue. Elastic fibers are intact and quite thick as a result of elastic recoil related to dermal contraction. Fibrous tract remnants are wide and hyalinized with an intact elastic sheath. Lymphoid and neutrophilic inflammation is absent, but loss of the inner and outer root sheaths with subsequent hair fiber granuloma formation is noted. Sebaceous glands are decreased or absent, as they are in most forms of permanent alopecia. DIF is negative.

The end stage of many forms of cicatricial alopecia can resemble pseudopelade clinically, but, like lichen planopilaris, they demonstrate distinct patterns of elastic tissue loss in the dermis. Folliculitis decalvans is distinguished by periodic crops of pustules or crusts at the periphery of the alopecic patches. It produces superficial wedge-shaped scars similar to those of lichen planopilaris.

Fig. 33-19 Traction alopecia.

Topical and intralesional corticosteroids and long-term tetracycline in anti-inflammatory doses may be tried but are not often successful. The disease usually reaches an inactive end stage after many years.

Traction alopecia

Traction alopecia occurs from prolonged tension on the hair, either from wearing the hair tightly braided or in a ponytail, pulling the hair to straighten it, rolling curlers too tightly, or from the habit of twisting the hairs with the fingers. Traction alopecia most commonly involves the periphery of the scalp, especially the temples and above the ears (Fig. 33-19).

Sarcoidosis

Sarcoidosis of the scalp presents with diffuse or patchy hair loss. The involved scalp is often indurated and a raised peripheral border may be present. The lesions are often red-brown in color and may have an apple jelly appearance with diascopy. Biopsy reveals noncaseating granulomas. Treatment is as for other forms of sarcoidosis.

Pressure alopecia

Pressure alopecia occurs in adults after prolonged pressure on the scalp during general anesthesia, with the head fixed in one position. It may also occur in chronically ill persons after prolonged bed rest in one position (Fig. 33-20), which causes persistent pressure on one part of the scalp. It probably arises because of pressure-induced ischemia.

Tumor alopecia

Tumor alopecia refers to hair loss in the immediate vicinity of either benign or malignant tumors of the scalp. Syringomas, nerve sheath myxomas, and steatocystoma multiplex are benign tumors that may be limited to the scalp and cause alopecia. Alopecia neoplastica is the designation given to hair loss from metastatic tumors, most often from breast or renal carcinoma (Fig. 33-21).

Keratosis pilaris atrophicans

Keratosis pilaris atrophicans includes many forms of keratosis pilaris with cicatricial alopecia. Variants include keratosis pilaris atrophicans faciei, atrophoderma vermiculatum, keratosis follicularis spinulosa decalvans, and ichthyosis follicularis.

Fig. 33-20 Pressure alopecia with scalp demonstrating pressure-induced geometric pressure necrosis.

Fig. 33-21 Alopecia neoplastica.

Keratosis pilaris atrophicans faciei (ulerythema ophryogenes, keratosis pilaris rubra atrophicans faciei, folliculitis rubra, lichen pilare, or xerodermie pilaire symétrique de la face) begins in infancy as follicular papules with perifollicular erythema. Initially, the lesions are restricted to the lateral eyebrows. With time, they spread to involve the cheeks and forehead. There may be associated keratosis pilaris on the extremities and buttocks. The condition may also be associated with an atopic diathesis, ectodermal dysplasia, or Noonan syndrome.

Atrophoderma vermiculatum (acne vermoulanti, honeycomb atrophy, folliculitis ulerythema reticulata, ulerythema acneiforme, folliculitis ulerythematous reticulata, atrophoderma reticulata symmetrica faciei, atrophoderma reticulatum) presents with erythematous follicular papules on the cheeks in childhood. With time, the lesions develop into pit-like depressions (reticulate atrophy). Autosomal-dominant inheritance has been described. This condition generally spares the scalp and eyebrows.

Keratosis follicularis spinulosa decalvans is a rare X-linked disorder described by Siemens in 1926. The gene has been mapped to Xp21.2-p22.2. It begins in infancy with keratosis pilaris localized on the face, and then evolves to more diffuse

involvement. Progressive cicatricial alopecia occurs on the scalp, eyebrows, and sometimes eyelashes. The alopecia starts during childhood, and active disease may remit during the early teenage years. Corneal and conjunctival inflammation, corneal dystrophy, and blepharitis occur, and photophobia is usually a prominent finding.

Ichthyosis follicularis also demonstrates extensive spiny follicular hyperkeratosis, permanent alopecia, and photophobia. Palmar plantar keratosis, nail deformities, atopy, and recurrent cheilitis have been described.

Atrichia with papular lesions

Atrichia with papular lesions is a rare autosomal-recessive disorder with early onset of atrichia, followed by a papular eruption appearing within the first years of life. The condition has been linked to chromosome 8p21 and mutations have been detected in what is now referred to as the hairless gene. It is discussed in more detail in Chapter 27.

Hair color

Melanin in the hair follicles is produced in the cytoplasm of the melanocytes. Organelles involved include the endoplasmic reticulum, ribosomes, and Golgi apparatus. Melanocytes producing hair pigment are associated with the hair matrix, and melanogenesis occurs only during anagen. This cyclic melanin synthesis distinguishes follicular melanogenesis from the continuous melanogenesis of the epidermis. With age, cyclic melanocytic activity in the follicular unit declines. By 40 years of age most individuals show evidence of graying. Graying results primarily from a reduction in tyrosinase activity within hair bulb melanocytes. Defective migration of melanocytes from a diminishing reservoir in the outer root sheath may play a role. Physiologic graying may also be related to reactive oxygen species-mediated damage to nuclear and mitochondrial DNA in bulbar melanocytes. The melanocortin 1 receptor gene (*MCR1*) is closely related to red hair, freckling, and sun sensitivity.

The pigment in black and dark brown hair is composed of eumelanin, whereas in blond and red hair it is pheomelanin. In black hair the melanocytes contain the densest melanosomes. Brown hair differs only by its smaller melanosomes. Light brown hair consists of a mixture of the melanosomes of

dark hair and the incomplete melanosomes of blond hair. Many of the melanosomes in blond hair develop only on the matrix fibers and not in the spaces between the fibers.

Red hair shows incomplete melanin deposits on the matrix fibers to produce a blotchy-appearing melanosome. Pheomelanin is distinguished by its relatively high content of sulfur, which results from the addition of cysteine to dopaquinone along the biosynthetic pathway of melanin synthesis.

In gray hair (canities), melanogenic activity is decreased as a result of fewer melanocytes and melanosomes, as well as a gradual loss of tyrosinase activity. Graying of the scalp hair is genetically determined and may start at any age. Usually, it begins at the temples and progresses with time. The beard usually follows, with the body hair graying last. Premature whitening of scalp hair is usually caused by vitiligo, sometimes without recognized, or actually without, lesions of glabrous skin.

Early graying (before age 20 in white or before age 30 in black persons) is usually familial; however, it may occur in progeria, Rothmund-Thomson syndrome, Böök syndrome, and Werner syndrome.

In poliosis, gray or white hair occurs in circumscribed patches. This may occur in Waardenburg syndrome and piebaldism, Tietz syndrome, Alezzandrini syndrome, neurofibromatosis, and tuberous sclerosis. Poliosis is also found in association with regressing melanoma, vitiligo, and Vogt-Koyanagi syndrome, and may be seen in alopecia areata when the new hairs grow. Migratory poliosis without hair loss may represent a *forme fruste* of alopecia areata.

Green hair has been traced to copper in the water of a swimming pool. This occurs only in blond or light hair, and may be treated with topical EDTA, penicillamine-containing shampoos, or 1.5% aqueous 1-hydroxyethyl diphosphonic acid. Tars and chrysarobin stain light-colored hair brown.

Changes in hair color occur in various disorders. The hair is blond in phenylketonuria and homocystinuria. Light hair is also seen in oasthouse disease (familial methionine malabsorption), Menkes kinky hair syndrome, and albinism. In Griscelli and Chédiak-Higashi syndromes the hair has a silvery sheen. In kwashiorkor the hair assumes a red-blond color and may demonstrate periodic banding (flag sign, segmental heterochromia). Alternating light and dark bands may also occur in iron deficiency anemia and with courses of sunitinib. In vitamin B₁₂ deficiency and with IFN therapy, whitening may occur. The disorder has been called canities segmentata sideropenica. It responds completely to iron supplementation. Triparanol is associated with hypopigmented hair. Minoxidil (by changing vellus to terminal hairs) causes darkening of hair; another hypotensive agent, diazoxide, gives the hair a reddish tint. Chloroquine therapy may cause hair whitening, usually in redheads and blonds, but not in brunettes. Pigmentation of the eyelashes and irides has been described with latanoprost. Xanthotrichia (yellow hair) has been noted with selenium sulfide and dihydroxyacetone.

Many black patients with acquired immunodeficiency syndrome (AIDS) have experienced softening, straightening, lightening, and thinning of their hair. Patients with human immunodeficiency virus (HIV)-1 infection may also experience elongated eyelashes and telogen effluvium.

Hair structure defects

Examination of hairs for structural defects is greatly facilitated by a method devised by Shelley: putting a piece of double-stick tape on a microscope slide and aligning 5 cm segments of hair in parallel on it. Dermoscopy can be useful in assessing hair morphology. Microscopic mounts of hairs are best examined under a dissecting microscope or polarized light. Gold-coating and scanning electron microscopy can also be done on hairs so mounted. Hairs from multiple body sites may need to be sampled. This has been documented in Netherton syndrome where scalp hair can be normal while eyebrow hair demonstrates the characteristic hair shaft defect.

Hair casts (pseudonits)

Hair casts represent remnants of the inner root sheath. They often occur in great numbers and may mimic nits in the scalp. While nits are firmly cemented to the hair shaft, hair casts slide freely along the shaft. Taeb et al reviewed 36 published cases and distinguished two groups: girls between 2 and 8 years of age with diffuse involvement and no scalp disease, and children and adults with psoriasis, lichen planus, seborrheic dermatitis, or trichotillomania. Keipert made a similar distinction, separating a large group of cases with some keratinizing disorder of the scalp and dark, oddly shaped masses of keratin adherent to or surrounding the hairs, which he called parakeratotic hair casts; and lighter-colored tubular casts, 2–4 mm long, which he called peripilar hair casts. Taeb et al found 0.025% tretinoin lotion effective. False hair casts may occur as a result of hair spray or deodorant concretions. Immunoglobulin casts and cutaneous spicules have been noted in multiple myeloma.

Miller JJ, et al: Hair casts and cutaneous spicules in multiple myeloma. *Arch Dermatol* 2006 Dec; 142(12):1665–1666.

Pili torti

Also known as twisted hairs, pili torti is a malformation of hair characterized by twisting of the hair shaft on its own axis (Fig. 33-22). The hair shaft is segmentally thickened, and light and dark segments are seen. Scalp hair, eyebrows, and eyelashes may be affected. The hairs are brittle and easily broken.

In the classic type, unassociated with other disorders, onset is usually in early childhood; by puberty, it has usually improved. Clinically, it may be associated with patchy alopecia and short, broken hairs. It usually follows a dominant inheritance pattern, though recessive and sporadic cases have been reported. Acquired cases have been described in young women with anorexia nervosa. Pili torti may be seen with associated abnormalities. The Björnstad syndrome consists of congenital deafness of the cochlear type, with pili torti. Both autosomal-dominant and autosomal-recessive inheritance patterns have been described. *BCS1L* mutations cause the Björnstad syndrome. The gene encodes an ATPase necessary for the assembly of complex III in mitochondria. *BCS1L* mutations also cause lethal conditions, including the complex III deficiency and the GRACILE syndrome, with severe multisystem and neurologic manifestations.

Pili torti also may occur in citrullinemia (argininosuccinate synthetase deficiency), Menkes kinky hair syndrome, Bazex

Fig. 33-22 Pili torti.

follicular atrophoderma syndrome, ectodermal dysplasias, Crandall syndrome (pili torti, nerve deafness, hypogonadism), Netherton syndrome (along with bamboo hair), with isotretinoin and etretinate therapy, in anorexia nervosa, and in trichothiodystrophy.

Laron syndrome is an autosomal-recessive disease with primary insulin-like growth factor 1 deficiency and primary growth hormone insensitivity. Affected children have sparse hair and frontal recession. Pili torti et canaliculi, tapered hair, and trichorrhexis nodosa have been noted.

Hinson JT, et al: Missense mutations in the *BCS1L* gene as a cause of the Björnstad syndrome. *N Engl J Med* 2007 Feb 22; 356(8):809–819.

Menkes kinky hair syndrome

Pili torti, and often monilethrix and trichorrhexis nodosa, are all common in the hairs in this sex-linked recessively inherited disorder. It has also been called steely hair disease, because the hair resembles steel wool. The characteristic ivory color of the hair appears between 1 and 5 months of age. Drowsiness, lethargy, convulsive seizures, severe neurologic deterioration, and periodic hypothermia ensue with death at an early age. Hairs become wiry, sparse, fragile, and twisted about their long axes. Osteoporosis, and dental and ocular abnormalities are common. The skin is pale and the face pudgy, and the upper lip has an exaggerated “Cupid’s bow” configuration. The occipital horn syndrome, primarily a connective tissue disorder, is a milder variant of Menkes syndrome. Patients have a deficiency of serum copper and copper-dependent

enzymes, resulting from mutations in the *ATP7A* gene. The gene encodes a trans-Golgi membrane-bound copper transporting P-type ATPase. Loss of this protein activity blocks the export of dietary copper from the gastrointestinal tract and causes the copper deficiency. Low serum copper and ceruloplasmin are characteristic, but are not seen in all patients. They are particularly variable in the first weeks of life. Other tests helpful for screening include the ratio of catechols, such as dihydroxyphenylalanine to dihydroxyphenylglycol. High levels of the catechols DOPA, dihydroxyphenylacetic acid, and dopamine, and low levels of dihydroxyphenylglycol are characteristic. Studies of copper egress in cultured fibroblasts have also been used. Early detection allows for genetic counseling and the institution of copper histidine treatment, which is being studied and has shown promising results in some infants. Pamidronate treatment is associated with an increase in bone mineral density in children with Menkes disease. In zebra fish, antisense morpholino oligonucleotides directed against the splice-site junctions of two mutant calamity alleles were able to correct the molecular defect. This is a promising area for research.

Uncombable hair syndrome

First reported in 1973 by Dupré et al as *cheveux incoiffables* (undressable hairs) and by Stroud and Mehergan as spunglass hair, the microscopic abnormality of a triangular cross-sectional appearance with a longitudinal groove gives the disease its other name, *pili triangulati et canaliculi*.

Clinically, the defect is noted in the first few years of life as dry, blond, shiny hair that stands straight out from the scalp and cannot be combed (Fig. 33-23). On light microscopy it may appear quite normal when viewed lengthwise, but on horizontal sectioning and on scanning electron microscopy it shows the longitudinal grooves that make it abnormally rigid. These depressions are sometimes seen in unaffected persons, so that 50% of hairs need to be affected for the condition to be clinically detectable.

Autosomal-dominant, autosomal-recessive, and sporadic forms have been described. Uncombable hair has been associ-

Fig. 33-23 Uncombable hair syndrome.

ated with angel-shaped phalango-epiphyseal dysplasia. It has also been seen in combination with retinal dystrophy, juvenile cataract, and brachydactyly. It has also been reported in a patient who acquired the abnormality at age 39 after an episode of diffuse alopecia treated with spironolactone. Although there are usually no associated ectodermal defects, isolated cases have been reported in which uncombable hair is one component of several clustered findings. Until more experience is available in the literature, grouping of these cases into new syndromes is premature.

Some patients have responded clinically to biotin, 0.3 mg orally three times a day. Some cases improve spontaneously in late childhood.

Monilethrix

Monilethrix, also known as beaded hairs, is a rare hereditary disease. It is characterized by dryness, fragility, and sparseness of the scalp hair (Fig. 33-24), with fusiform or spindle-shaped swellings of the hair shaft separated by narrow atrophic segments. The hair tends to break at the delicate internodes. There is an occasional rupture at the node and longitudinal fissuring of the shaft, which also involves the nodes.

The disease is often associated with keratosis pilaris of the extensor surfaces, temples, and back of the neck. Hair on regions other than the scalp may be affected. Leukonychia may occur. Inheritance of monilethrix is an autosomal-dominant trait. It has been described in association with Menkes syndrome. Mutations in *desmoglein 4* are seen in monilethrix and in localized autosomal-recessive hypotrichosis, a disorder that shares clinical features with monilethrix but lacks the characteristic hair shaft changes. Several cases of monilethrix have been linked to the type II keratin gene cluster on chromosome 12q13. Causative heterozygous mutations of

Fig. 33-24 Monilethrix.

a highly conserved glutamic acid residue of the type II hair keratins hHb6 and hHb1 occur. Both hHb1 and hHb6 are largely coexpressed in cortical trichocytes of the hair shaft, confirming that monilethrix is a disease of the hair cortex. Improvement of the hair may occur during pregnancy, but after delivery the hair returns to its original state. Improvement may also occur with age and there may be seasonal improvement during the summer. Improvement with acitretin has been reported.

Trichorrhexis nodosa

The affected hair shafts fracture easily and may have small white nodes arranged at irregular intervals. These nodes are the sites of fraying of the hair cortex. The splitting into strands produces a microscopic appearance suggestive of a pair of brooms stuck together end to end by their bristles. The hairs soon break at these nodes (Fig. 33-25). The number of these nodes along one hair shaft varies from one to several, depending on its length. These fractured hairs are found mostly on the scalp, often in just a small area or areas, but other sites such as the pubic area, axillae, and chest may be involved.

Several categories or types of trichorrhexis nodosa have been described. Proximal trichorrhexis nodosa involves the proximal shafts of the hairs of black patients who traumatize their hair with styling or chemicals. The involved hairs break a few centimeters from the skin surface, resulting in patches of short hair. It appears to occur in genetically predisposed patients. Distal trichorrhexis nodosa affects primarily Asians and white patients; it occurs several inches from the scalp, and is associated with trichoptilosis, or longitudinal splitting, known as split ends. Acquired localized trichorrhexis nodosa is a common type in which the defect occurs in a localized area, a few centimeters across. A number of diseases accompany this type of trichorrhexis nodosa in which pruritus is a prominent symptom; scratching and rubbing may be the cause. Among such diseases are circumscribed neurodermatitis, contact dermatitis, and atopic dermatitis.

The occurrence of trichorrhexis nodosa in some patients with arginininosuccinic aciduria has suggested an etiologic connection. Trichorrhexis nodosa has been described in Menkes kinky hair syndrome, Netherton syndrome, hypothyroidism, ectodermal dysplasia, the syndrome of intractable infant diarrhea, and trichothiodystrophy. Trichoschisis, a clean transverse fracture across the hair shaft, is more commonly present in trichothiodystrophy. The curly hair that may result from isotretinoin therapy has been attributed to extensive trichorrhexis nodosa. Because trauma may induce this hair shaft

Fig. 33-25 Trichorrhexis nodosa.

abnormality, the specificity of this finding in the above conditions may simply be fortuitous.

Treatment is directed toward the avoidance of trauma to the hair.

Trichorrhexis invaginata

Also known as bamboo hair, trichorrhexis invaginata is caused by intussusception of the hair shaft at the zone where keratinization begins. The invagination is caused by softness of the cortex in the keratogenous zone. The softness may be caused by inadequate conversion of $-SH$ to $S-S$ proteins in the cortex. The patient with bamboo hair will have nodose ball-and-socket deformities, with the socket forming the proximal and the ball part forming the distal portion of the node along the hair shaft. This type of hair is associated with Netherton syndrome. Occasionally, only the proximal half of the abnormality is seen; this has been called golf tee hairs.

Trichorrhexis invaginata associated with congenital ichthyosiform erythroderma or ichthyosis linearis circumflexa constitutes Netherton syndrome. Atopic manifestations and high IgE levels are commonly present. The bamboo hairs may be present not only on the scalp but also on the eyebrows, eyelashes, and rarely in other hairy areas. Hair sparsity is noted all over the body. The bamboo hairs may become normal within a few years. Other reported findings include pili torti, trichorrhexis nodosa, moniliform hairs, urticaria, angioedema, growth retardation, recurrent infections, multiple epithelial neoplasms, and mental retardation. An autosomal-recessive mode of inheritance has been suggested, although reported cases involving women far outnumber men. Pathogenic mutations have been identified in serine protease inhibitor Kazal-type 5 (*SPINK5*) on chromosome 5q32, a gene encoding lymphoepithelial Kazal-type-related inhibitor (*LEKTI*), a serine protease inhibitor involved in skin barrier formation and immunity. PUVA has been reported to help the circumflex linear ichthyosis, while etretinate has been reported both to exacerbate and to improve skin findings.

Menne et al reported the bamboo hair defect in very thin, probably vellus, hairs in a 7-year-old boy with short, thin, brittle scalp hairs and no eyebrows. They termed this a cane-stick deformity.

Pili annulati (ringed hair, spangled hair)

Pili annulati is an unusual disease in which the hair seems banded by alternating segments of light and dark color when seen in reflected light. The light bands are caused by clusters of abnormal air-filled cavities, which scatter light, and reduplicated lamina densa in the region of the root bulb.

Hair growth is normal in patients with pili annulati, although it is rarely associated with trichorrhexis nodosa-like breaks of the hair shaft. There are no other associated abnormalities of skin or other organ systems. It is inherited by autosomal-dominant mode, begins in infancy, and requires no treatment, since the spangled appearance of the hair is not unattractive (Fig. 33-26). The condition has been reported to disappear following recovery from alopecia totalis.

Pili pseudoannulati

This anomaly of human hair mimics pili annulati. The two differ in that the light bands in pili annulati are caused by internal effects, whereas the bright segments in pili pseudoannulati are caused by reflection and refraction of light by flattened, twisted surfaces of hair. This latter type is a variant of normal hair.

Fig. 33-26 Spangled hair of pili annulati.

Kinking hair

Acquired progressive kinking of the hair, first described and named by Wise and Sulzberger in 1932, involves a structural abnormality of kinking and twisting of the hair shaft at irregular intervals. The main recognized variant of this disorder begins in men in their late teens or early twenties on the fronto-temporal or vertex regions, and then progresses to both the parietal and frontal areas. Usually straight, light brown hair becomes curly, frizzy, and lusterless.

When this occurs in the androgen-dependent areas of young men it is a precursor of male-pattern hair loss; usually these men have a strong family history of androgenetic alopecia. Treatment with topical minoxidil has not prevented development of hair thinning. "Whisker" hairs, the short dark hairs that grow anterior to the ears in young people who eventually develop androgenic alopecia, is felt to be a variant of acquired kinking of the hair.

Acquired hair kinking has been described in other clinical situations. Some reports detail prepubertal patients or women, as well as men, in whom kinking develops in non-androgen-dependent areas. In these reports alopecia has not developed, and the curly, frizzy hair may remain present or revert to its previous condition.

Widespread kinking of the hair may be induced by drugs, notably retinoids, and it may also occur in patients with AIDS.

Woolly hair

Woolly hair is present at birth and is usually most severe during childhood, when it is often impossible to brush the hair. In adult life there is a variable amelioration in the condition. There is a clear distinction between the appearance of the affected and nonaffected members of a family. Both autosomal-dominant and autosomal-recessive inheritance have been described. Woolly hair nevus has partial scalp involvement by woolly hair, which has a markedly reduced diameter. Naxos' disease is an autosomal-recessive syndrome with arrhythmic right ventricular cardiomyopathy, diffuse nonepidermolytic palmoplantar keratoderma, and woolly hair. Hair abnormalities are a reliable marker for subsequent heart disease. The disease is caused by a mutation in the gene encoding plakoglobin. Carvajal syndrome is a familial cardiovascular syndrome consisting of woolly hair, palmoplantar

keratoderma, and heart disease. It is caused by a recessive deletion mutation in desmoplakin.

Woolly hairs tend to unite into tight locks, whereas the hairs of black persons remain individual. The hair may not grow beyond a length of 12 cm, but may attain a normal appearance in adult life. In the familial group the eyebrows and hairs on the arms, legs, and pubic and axillary regions may be short and pale. There are no associated cutaneous or systemic diseases. A Dutch kindred has been described with premature loss of curly, brittle hair, premature loss of carious teeth, nail dystrophy, and acral keratoderma. It has been designated the curly hair-acral keratoderma-caries syndrome.

The microscopic findings of woolly hair include a decreased diameter, an ovoid shape on cross-section, a pili torti-like twisting about a longitudinal axis, trichorrhexis nodosa, and pili annulati.

Plica neuropathica (felted hair)

This is a curling, looping, intertwisting, and felting or matting of the hair in localized areas of the scalp. Predisposing factors include kinky hairs, changes in hair care, and a neurotic mental state. Plica polonica is an older name for this condition.

Pseudofolliculitis barbae

Pseudofolliculitis barbae are hairs that, after appearing at the surface, curve back and pierce the skin as ingrowing hairs. This results in inflammatory papules and pustules, which may scar (Fig. 33-27). In severe cases, large deforming keloids may result in the beard area. Pseudofolliculitis of the beard is seen in more than 50% of black men, who must sometimes give up shaving to alleviate the disorder. A single-nucleotide polymorphism, giving rise to a disruptive Ala12Thr substitution in the 1A α -helical segment of the companion layer-specific keratin K6hf appears to be partially responsible for the phenotype. White persons are uncommonly affected; however, it is more common in renal transplant recipients. Tenderness responds to mid-strength topical steroids. The use of clippers or chemical depilatories, glycolic acid lotion, and adjunctive antibiotic therapy may be helpful. Benzoyl peroxide 5%/clindamycin 1% gel has been shown to be effective in double-blind evaluation. Laser hair removal with the long-pulse Nd:YAG laser is

Fig. 33-27 Pseudofolliculitis barbae.

suitable for a wide range of skin types. The diode laser has also been used.

Pili multigemini

This rare malformation is characterized by the presence of bifurcated or multiple divided hair matrices and papillae, giving rise to the formation of multiple hair shafts within the individual follicles (Fig. 33-28). It sometimes follows lines of Blaschko. Mehregan et al reported a patient with cleidocranial dysostosis and extensive pili multigemini over the heavily bearded chin and cheek areas. There is no treatment.

Pili bifurcati

In this disorder, bifurcation is found in short segments along the shafts of several hairs. Each branch of the bifurcation is covered with its own cuticle. It has been seen in association with the trisomy 8 mosaic syndrome. Pili bifurcati differs from pili multigemini in which a single follicular matrix produces two different-sized hair shafts with separate cuticles that do not fuse again. Trichoptilosis is characterized by split distal ends that are never surrounded by a complete cuticle.

Lester L, et al: The prevalence of pili multigemini. *Br J Dermatol* 2007 Jun; 156(6):1362–1363.

Trichostasis spinulosa

Trichostasis spinulosa is a common disorder of the hair follicles that clinically gives the impression of blackheads (Fig. 33-29), but the follicles are filled with funnel-shaped, horny plugs within which are bundles of vellus hairs (Fig. 33-30). The hairs are round at their proximal ends and shredded distally. The disease occurs primarily on the nose and forehead, but

Fig. 33-28 A, Pili multigemini of beard. B, Multiple hair shafts in single follicle.

Fig. 33-29 Trichostasis spinulosa.

Fig. 33-30 Trichostasis spinulosa.

may also occur on the trunk and be accompanied by pruritus. Dermoscopy or microscopy can be used to establish the diagnosis. The condition may be more common in patients in renal failure.

Trichostasis spinulosa results from retention of telogen hairs, which are derived from a single hair matrix. It is primarily caused by a hyperkeratosis of the follicular infundibulum, which leads to a partial obstruction of the follicular orifice and thus does not permit shedding of small telogen hairs.

The plugs may be removed with hydroactive adhesive (Biore) pads. Keratolytics are also effective after using a wax depilatory. The pulsed diode laser has been used successfully, and application of 0.05% tretinoin solution, applied daily for 2 or 3 months, may also produce satisfactory results.

Pozo L, et al: Dermoscopy of trichostasis spinulosa. *Arch Dermatol* 2008 Aug; 144(8):1088.

Intermittent hair-follicle dystrophy

Birnbaum et al reported a disorder of the hair follicle leading to increased fragility of the shaft, with no identifiable biochemical disturbance. The prevalence of this disorder is unknown.

Bubble hair deformity

Bubble hairs appear as areas of hair with altered texture. Fragility has been reported. The hairs may be curved or straight and stiff. Small, bubble-like defects are found within the hair shafts on light and electron microscopy. The condition is produced by overheating of wet hair with a malfunctioning

hair dryer, analogous to the popping of popcorn. All damp hair will develop bubbles of gas when exposed to high heat.

Hypertrichosis

Hypertrichosis is an overgrowth of hair not localized to the androgen-dependent areas of the skin. Several forms exist. Many cases are induced by medications, including minoxidil, cyclosporine, and efalizumab. The excessive hair growth can be managed with bleaching, trimming, shaving, plucking, waxing, chemical depilatories, and electrosurgical epilation. Laser treatment with long-pulse Nd:YAG, diode, ruby, long- and short-pulse alexandrite lasers, and intense pulsed light sources can be effective. Skin type must be considered when choosing a laser system. The greatest experience in dark skin types has been with the long-pulse Nd:YAG laser.

Localized acquired hypertrichosis

Eyelash trichomegaly can occur with erlotinib, latanoprost, and intentionally with bimatoprost. Dermal tumors, such as melanocytic nevi, smooth muscle hamartomas, meningiomas, or Becker nevi, may have excessive terminal hair growth. Repeated irritation, trauma, occlusion under a cast, eczematous states, topical steroid use, linear melorheostotic scleroderma, lymphedema associated with filariasis, the Crow-Fukase (POEMS) syndrome, and pretibial myxedema may be other situations in which there is a localized increase in hair growth. Porphyrias generally show a localized hypertrichosis over the malar area, such as in porphyria cutanea tarda or variegate porphyria; however, in the Gunther variety of erythropoietic porphyria it may be generalized or more diffuse in nature.

Localized congenital hypertrichosis

Hypertrichosis cubiti (hairy elbows) consists of long vellus hair on the extensor surfaces of the distal third of the upper arm and the proximal third of the forearm bilaterally. It is a progressive, excessive growth of lanugo hairs that often begins in infancy; the hairs may reach a length of 10 cm. Later they become coarser, but regression has been observed during adolescence. There appear to be familial cases and a sporadic form. Short stature and some developmental abnormalities are present in some cases; however, there is no need for endocrine studies or other evaluation. The condition appears to be of cosmetic significance only.

Other causes of localized congenital hypertrichosis include congenital nevocytic nevi, anterior cervical hypertrichosis, and simple nevoid hypertrichosis. Localized hypertrichosis may be a sign of underlying spinal dysraphism when it occurs over the sacral midline.

Generalized congenital hypertrichosis (congenital hypertrichosis lanuginosa)

This rare type of excessive and generalized hairiness is a fully penetrant X-linked dominant trait. The entire body is covered with fine vellus hairs 2-10 cm long (Fig. 33-31). The scalp hair appears to be normal. Except for the palms and soles, all other areas are covered. Congenital hypertrichosis lanuginosa may be associated with dental anomalies and gingival fibromatosis. This type of hairiness has attracted considerable attention over the centuries. Hair removal by laser may be quite useful.

Other cases of congenital generalized hypertrichosis may be secondary to drug ingestion by the mother. The fetal hydantoin syndrome is characterized by hypertrichosis, depressed nasal bridge, large lips, a wide mouth, and a short, webbed

Fig. 33-31 Hypertrichosis lanuginosa. (Courtesy of Brooke Army Medical Center Teaching File)

Fig. 33-32 Hypertrichosis lanuginosa associated with an internal malignancy (malignant down).

neck. The fetal alcohol syndrome includes hypertrichosis, a small face, capillary hemangiomas, and physical and mental retardation. A case of generalized hypertrichosis and multiple congenital defects was reported by Kaler et al in a baby born to a mother who used minoxidil throughout pregnancy. Fetal valproate syndrome is characterized by generalized hypertrichosis sparing the palms and soles, coarse facies, gum hypertrophy, hypotonia, club feet and club hands, and abnormal dermatoglyphics.

Generalized or patterned acquired hypertrichosis

These cases include those caused by acquired hypertrichosis lanuginosa, those associated with various syndromes, and those secondary to drug intake. Acquired hypertrichosis lanuginosa (Fig. 33-32) is an ominous sign of internal malignancy. Syndromes associated with increased hair growth include lipotrophic diabetes, stiff skin syndrome, Down syndrome, Rubenstein-Taybi syndrome, Laband syndrome, Cornelia de Lange syndrome, Hurler syndrome, leprechaunism, Winchester syndrome, the Schynzel-Giedier syndrome, and hypertrichosis

Fig. 33-33 Hirsutism.

with acromegalic features. Drugs associated with hypertrichosis include minoxidil, cyclosporine, diphenylhydantoin, diazoxide, streptomycin, penicillamine, corticosteroids, danazol, psoralens, hexachlorobenzene, PUVA, topical bimatoprost, topical steroids, and topical androgens.

Hirsutism

Clinical features

Hirsutism is an excess of terminal hair growth in women in a pattern more typical of men. Androgen-dependent growth areas affected include the upper lip, cheeks (Fig. 33-33), chin, central chest, breasts, lower abdomen, and groin. This altered growth pattern of the hair may be associated with other signs of virilization, which include temporal balding, masculine habitus, deepening of the voice, clitoral hypertrophy, and amenorrhea. Acne is an additional sign of hyperandrogenism.

Pathogenesis

When virilization accompanies hirsutism, especially when progression is rapid, a neoplastic cause is likely. In the absence of virilization, a neoplastic cause is extremely unlikely. Most medically significant hirsutism is related to the polycystic ovarian syndrome (PCOS, hyperinsulinemic hyperandrogenism with anovulation). In a study of 873 patients with medically significant hirsutism, PCOS was present in 82%. Idiopathic hirsutism was present in 4.7%, and 6.75% of the patients had elevated androgen levels and hirsutism with normal ovulation.

Ethnic variation should be considered when evaluating hirsutism. Women of Southwest Asian, Eastern European and

southern European heritage commonly have facial, abdominal, and thigh hair; whereas Asian and Indian women generally have little terminal hair growth in these areas.

In women, androgen biosynthesis occurs in the adrenal and ovary. Testosterone and the androgen precursor androstenedione are secreted by the ovary. The adrenal contributions are preandrogens: dehydroepiandrosterone (DHEA), DHEA sulfate, and androstenedione. They require peripheral conversion in the skin and liver to testosterone.

Testosterone is converted to dihydrotestosterone, the androgen that promotes androgen-dependent hair growth, in the hair follicle by 5- α -reductase. Receptor molecules in the end organ are necessary for binding and hormone action at that level. Because testosterone is normally bound to carrier molecules in the plasma at a 99% level, and it is the unbound testosterone that is active, the levels of free testosterone correlate with clinical evidence of androgen excess.

Hirsutism may result from excessive secretion of androgens from either the ovary or the adrenal gland. The excessive secretion may be from functional excesses or, rarely, from neoplastic processes. Ovarian causes include PCOS (Stein-Leventhal syndrome), and a variety of ovarian tumors, both benign and malignant. PCOS is defined by anovulation (fewer than nine periods a year or periods longer than 40 days apart) with clinical evidence of hyperandrogenism. Ovarian cysts are not required for the diagnosis, and laboratory and imaging studies are not required to establish the diagnosis. The pathogenesis of PCOS may relate to insulin resistance with resultant elevated insulin levels leading to ovarian overproduction of androgens. Prevalence rates of PCOS for black and white women in the US are 8.0% and 4.8%, respectively.

Ovarian tumors include unilateral benign microadenomas, arrhenoblastomas. Leydig cell tumors, hilar cell tumors, granular/theca cell tumors, and luteomas are rare causes of hirsutism. In tumor-associated hirsutism, the onset is usually rapid, occurs with other signs of virilization, and begins between the ages of 20 and 40.

Adrenal causes include congenital adrenal hyperplasia (CAH) and adrenal tumors, such as adrenal adenomas and carcinomas. The adrenogenital syndrome or CAH is an autosomal-dominant disorder that may result from deficiencies of the following enzymes: 21-hydroxylase (most common form), 11 β -hydroxylase, or 3 β -hydroxy steroid dehydrogenase. Onset is generally in childhood, with ambiguous genitalia, precocious growth, and virilism. Nonclassic (adult-onset) CAH may present with hirsutism.

Pituitary causes include Cushing's disease, acromegaly, and prolactin-secreting adenomas. Prolactin-secreting microadenomas have a 20% incidence of hirsutism and acne. Prolactin elevations may be seen in patients with PCOS. Other conditions in which prolactin levels may be elevated and that may lead to hirsutism include hypothyroidism, phenothiazine intake, and hepatorenal failure.

Other causes of hirsutism include the exogenous intake of androgens. End-organ hypersensitivity may be a mechanism in patients with a normal evaluation. Drugs such as minoxidil, diazoxide, corticosteroids, and phenytoin, which have been reported to cause hirsutism, generally cause hypertrichosis—a generalized increase in hair that is not limited to the androgen-sensitive areas.

Evaluation

Most hirsutism is related to ethnic heritage or PCOS. 21-Hydroxylase-deficient nonclassic adrenal hyperplasia, the hyperandrogenic insulin-resistant acanthosis nigricans syndromes, and androgen-secreting tumors are relatively uncommon causes. A careful history and physical examination are

essential. The history should focus on onset and progression, virilization, menstrual and pregnancy history, and family/racial background. Physical examination may reveal signs of Cushing's disease, hypothyroidism, or acromegaly. Other signs to be evaluated are the distribution of muscle mass and body fat, clitoral dimensions, voice depth, and galactorrhea.

Laboratory evaluation is controversial. In the authors' opinion, testing is of value only when it affects management. If this is accepted, there is no mandatory hormonal testing for stable hirsutism in patients who have no signs of virilization. A diagnosis of PCOS does not require laboratory confirmation. Determination of serum lipids and testing for glucose intolerance may be the most important laboratory evaluations in patients with PCOS, as they have the greatest impact on management and long-term prognosis. When the history and physical examination suggest the possibility of a neoplasm, laboratory evaluation should include a total testosterone level. A dehydroepiandrosterone sulfate level is commonly performed if an adrenal cause is suspected. A 24 h urine cortisol test is the gold standard for the diagnosis of Cushing's disease. Measurement of thyroid-stimulating hormone (TSH), growth hormone, and somatomedin C levels are indicated if the history and physical examination suggest hypothyroidism or acromegaly.

Dexamethasone suppression tests are recommended by some authorities, but the results often do not affect management. A baseline 17-hydroxyprogesterone and adrenocorticotropic hormone (ACTH) stimulation test can screen for late-onset CAH, but steroid replacement has not been proved to result in better outcomes than empiric treatment with antiandrogens. Baseline 17-hydroxyprogesterone may be normal in some women with nonclassic 21-hydroxylase deficiency, and ACTH stimulation may result in overdiagnosis of the syndrome. An exaggerated 17-hydroxyprogesterone response to ACTH stimulation is common in PCOS at a pharmacologic dose (250 μ g) but not at a physiologic dose (1 μ g) of ACTH. An ovarian origin of hirsutism can be identified by a buserelin test in 30% of patients with hirsutism and by dexamethasone in 22% of patients, but data proving that buserelin challenge results in better outcomes are lacking. A prolactin level will screen for prolactin-secreting tumors, but will also lead to further expensive testing in many patients ultimately diagnosed with PCOS. A prolactin level should be obtained in any patient with galactorrhea, but is of limited value as a routine screening test for patients with hirsutism alone.

If signs of acromegaly, Cushing's disease, or virilization are present clinically, referral to an endocrinologist is recommended. The presence of major menstrual irregularities is also an indication for referral to an endocrinologist or gynecologist. Although 90% of women with hirsutism have an elevated testosterone level, elevations above 200 ng/dL and rapid onset or progressive virilization suggest serious underlying disease. A major elevation in the DHEA sulfate level (greater than 7000 ng/mL) suggests an adrenal neoplasm, and imaging of the adrenal gland is recommended. Many patients with late-onset CAH will have normal screening DHEA sulfate. Patients with prolactin levels above 20 ng/mL should likewise be referred for further evaluation with an MRI or CT scan. Polymorphisms in the gene coding for sex hormone-binding globulin have been identified in some families with hirsutism, but such testing does not affect management.

Treatment

Various forms of mechanical, chemical, and laser epilation can be performed, as for hypertrichosis. Spironolactone with various oral contraceptives, cyproterone acetate plus ethinyl estradiol, gonadotropin-releasing hormone agonists such as

leuprolide and nafarelin, flutamide, finasteride, and topical eflornithine have been used successfully alone and in various combinations to treat hirsutism. The optimal combination and dosage remain to be determined. Finasteride at doses of 2.5–5 mg/day has been shown to decrease hair number and diameter in women with hirsutism. The combination of spironolactone, 100 mg/day, plus finasteride, 5 mg/day, has been shown to be superior to spironolactone, 100 mg/day, alone. An analysis of the current literature suggested that spironolactone alone, 100 mg/day, is superior to finasteride alone, 5 mg/day, and low-dose cyproterone acetate alone, 12.5 mg/day for the first 10 days of a cycle, in the treatment of hirsutism. As spironolactone is commonly used at a dose of 100 mg twice a day, further studies are needed comparing this higher dose with other modes of therapy. In a prospective, randomized study of Diane 35 (cyproterone acetate [CPA], 2 mg, and ethinyl estradiol, 35 µg), Diane 35 plus spironolactone, and spironolactone alone, all treatments were well tolerated. Combination therapy resulted in superior measured endocrine responses, but the authors concluded that spironolactone alone was the most cost-effective treatment. The choice of an oral contraceptive (OC) is also controversial. Third-generation OCs result in a significant increase in sex hormone-binding globulin and decrease in free testosterone, but both second- and third-generation OCs are clinically effective in treating hirsutism. When flutamide is used, initial treatment with 250 mg/day is followed by a long maintenance treatment period using 125 mg/day.

Insulin sensitizers are being studied in the treatment of hirsutism, particularly PCOS. The best data to date are for metformin. Metformin therapy has been shown to control menstrual cycles and improve fertility in women with PCOS. It causes a decline in testosterone and insulin levels. Oligomenorrheic women with an increased luteinizing hormone (LH) to follicle-stimulating hormone (FSH) ratio and lower testosterone levels respond best. Spironolactone, 50 mg/day, was superior to metformin, 1000 mg/day, in the treatment of hirsutism and menstrual cycle frequency in a study of 82 adolescent and young women with PCOS. Doses of 200 mg/day are commonly used to treat hirsutism. At this dose, menstrual irregularities induced by the drug are common, and it may be best used in combination with an OC pill. Yasmin, which contains the progestogen drospirenone, has been shown to provide good cycle control for women with PCOS, with an improvement in acne but not in other symptoms of the syndrome. Good correlation has been noted between an increase in ovulation frequency with clomiphene citrate and the chance of pregnancy in women with PCOS. Other options include acarbose, gonadotrophins, and laparoscopic ovarian drilling. Infertility is best managed by a specialist in this field. Empiric treatment with an antiandrogen may be as good as steroid replacement for the management of hirsutism in patients with nonclassic CAH.

Trichomycosis axillaris

Discrete nodules, 1–2 mm in size and attached firmly to the hair shafts of the axillary or pubic areas, characterize trichomycosis. The color of the nodules may be yellow (Fig. 33-34), red, or black. Hyperhidrosis of the affected regions is usually present. A yellowish discoloration of the axillae is sometimes noted. Large numbers of *Corynebacterium* are present in the concretions. The disorder may coexist with erythrasma and pitted keratolysis. Treatment with topical antibiotic preparations, such as topical clindamycin or erythromycin, or naftifine, which has antibacterial properties, combined with any modality that will decrease the hyperhidrosis, is effective, but shaving is faster.

Rho NK, et al: A corynebacterial triad: prevalence of erythrasma and trichomycosis axillaris in soldiers with pitted keratolysis. *J Am Acad Dermatol* 2008 Feb; 58(2 Suppl):S57–S58.

Associated hair follicle diseases

Pityriasis amiantacea (tinea amiantacea)

Thick, asbestos-like (amiantaceous), shiny scales on the scalp characterize pityriasis amiantacea. The silvery-white or dull

Fig. 33-34 Trichomycosis axillaris. (Courtesy of Anthony Slagel, MD)

gray crusting may be localized or, less often, generalized over the entire scalp. The proximal parts of the hairs are matted together by the laminated crusts. There are no structural changes in the hair, but in some patches where the crusting is thick, there may be some purulent exudate under the crust and temporary alopecia such as occurs after some cases of furunculosis of the scalp.

The cause is most often severe or untreated seborrheic dermatitis or psoriasis. In a prospective study of 85 patients, psoriasis was documented in 35% and processes suggesting seborrheic dermatitis or atopic dermatitis occurred in another 35%. Tinea capitis was the eventual diagnosis in 13%. Staphylococcus was found in 96.5%, compared with 15% of controls. The patient should shampoo daily or every other day with selenium sulfide suspension, or a tar- or steroid-containing shampoo, for a couple of weeks. Prior application of peanut oil or a keratolytic a few hours before shampooing facilitates removal of the scales and crusts. With such debridement, followed by topical steroid solution in Caucasians or steroid ointment in African Americans, the secondary bacterial infection usually resolves without the need for oral antistaphylococcal therapy.

Folliculitis nares perforans

Perforating folliculitis of the nose is characterized by small pustules near the tip of the inside of the nose. The lesion becomes crusted, and when the crust is removed it is found that the bulbous end of the affected vibrissa is embedded in the inspissated material. The affected hairs are typical of those occurring inside the nostril. *Staphylococcus aureus* may at times be cultured from the pustules. The hair should be removed and antibiotic ointment such as mupirocin applied.

White SW, et al: Pseudofolliculitis vibrissae. *Arch Dermatol* 1981; 117:368.

Acquired perforating dermatosis

Perforating folliculitis, Kyrle's disease, and acquired perforating collagenosis are designations that have been supplanted by the more inclusive term acquired perforating dermatosis. The condition is not uncommon and is most often associated with renal failure or diabetes or both. Between 4% and 10% of dialysis patients develop umbilicated dome-shaped papules on the legs, or less often on the trunk, neck, arms, or scalp, with variable itchiness (Fig. 33-35). Early lesions may be pustular; late lesions resemble prurigo nodularis both clinically and histologically. There is a central hyperkeratotic cone that projects into the dermis, so that when it is removed, a pitlike depression remains. Usually the papules are discrete, but they may coalesce to form circinate plaques. Coalescing verrucous plaques are frequently seen, especially on the lower extremities. Koebner phenomenon may also be observed, in which case plaques or elevated verrucous streaks are formed. The latter are seen primarily in the antecubital and popliteal spaces. Atrophic scars are seen on involution of these lesions.

Histologically, the epidermis becomes edematous, the granular layer disappears, and parakeratosis develops. Eventually, the epidermis becomes atrophic, with disruption of the sites over the papillae. Through these sites necrobiotic connective tissue, degenerating inflammatory cells, and collagen bundles are extruded into a cup-shaped epidermal depression.

Fig. 33-35 Acquired perforating disease in uremia. (Courtesy of Curt Samlaska, MD)

The condition is felt to be a response to trauma, usually scratching or rubbing in response to the pruritus of the associated renal failure or dry skin. Other predisposing conditions reported include HIV infection, sclerosing cholangitis or other liver diseases, hypothyroidism, hyperparathyroidism, Hodgkin disease, in areas of healed herpes zoster, and as a reaction to laser hair removal or TNF- α inhibitors.

Ultraviolet treatment of either PUVA or UVB type helps the pruritus of renal disease and improves the perforating disorder. Hydration of the skin with a soaking tub bath in plain water, followed immediately (without drying) by triamcinolone ointment, is also useful. Topical retinoic acid (0.1% cream), allopurinol, doxycycline, isotretinoin, and etretinate have been effective in flattening lesions. HIV-infected patients may respond well to thalidomide. The disease may remit promptly after renal transplantation.

Reactive perforating collagenosis

Reactive perforating collagenosis is an inherited condition characterized by pinhead-sized, skin-colored papules that grow to a diameter of 4–6 mm and develop a central area of umbilication in which keratinous material is lodged (Fig. 33-36). The discrete papules may be numerous and involve sites of frequent trauma such as the backs of the hands, forearms, elbows, and knees. The lesion reaches a maximum size of about 6 mm in 4 weeks and then regresses spontaneously in 6–8 weeks.

It is believed that this is caused by a peculiar reaction of the skin to superficial trauma. Koebnerization is often observed. Young children are most frequently affected. Most reports

Fig. 33-36 Reactive perforating collagenosis.

support an autosomal-recessive mode of inheritance; however, a family in which it appeared to be inherited by autosomal dominance has been reported.

No specific treatment is indicated, since the lesions involute spontaneously. Tretinoin 0.1% cream may be effective.

Ramesh V, et al: Familial reactive perforating collagenosis. *J Eur Acad Dermatol Venereol* 2007; 21:766.

Traumatic anserine folliculosis

Traumatic anserine folliculosis is a curious gooseflesh-like follicular hyperkeratosis that may result from persistent pressure and lateral friction of one skin surface on another. Such friction is often caused by habitual pressure on the elbows, chin, jaw, or neck, often while watching television. Two-thirds of patients who develop this are atopic.

Padilha-Gonçalves A: Traumatic anserine folliculosis. *J Dermatol* 1979; 6:365.

Erythromelanosis follicularis faciei et colli

Erythromelanosis follicularis faciei et colli is an erythematous pigmentary disease involving the follicles. A reddish-brown, sharply demarcated, symmetrical discoloration involves the preauricular and maxillary regions. At times the pigmentation may be blotchy. In addition, follicular papules and erythema are present. Under diascopic pressure the reddish-brown area, containing telangiectases, becomes pale and the light brown pigmentation becomes more apparent. Pityriasiform scaling and slight itching may occur. Keratosis pilaris on the arms and shoulders is frequently found. It preferentially affects Asian and Indian patients.

Histologically, a slight hyperkeratosis occurs, with epidermal hyperpigmentation and dilation of the upper dermal vessels. The hair follicles may be enlarged in the infundibular area and the sebaceous glands may be hypertrophic. A lymphocytic infiltration surrounds the adnexa.

Emertcan AT, et al: Erythromelanosis follicularis faciei et colli associated with keratosis pilaris in two brothers. *Pediatr Dermatol* 2006; 23:31.

Sardana K, et al: An observational analysis of erythromelanosis follicularis faciei et colli. *Clin Exp Dermatol* 2008; 33:333.

Disseminate and recurrent infundibulofolliculitis

Hitch and Lund described a disseminate follicular eruption on the torso of a black man that involved all the pilosebaceous structures. The lesions were irregularly shaped papules pierced by a hair. They likened the eruption to cutis anserina viewed through a magnifying glass. The eruption is mildly pruritic at times, and is chronic, with recurrent exacerbations. The papules are uniform, and 1 or 2 mm in diameter; they involve all the follicles in the affected areas, which are usually the upper trunk and neck, though the entire trunk and proximal extremities may be involved. Rarely, pustules may occur.

Histologically, the infundibular portion of the follicles is chiefly affected, and the lesions are inflammatory rather than hyperkeratotic. Edema, lymphocytic and neutrophilic infiltration, and slight fibroblastic infiltration surround the affected follicles.

Treatment with topical steroids, isotretinoin, or PUVA may be effective.

Aroni K, et al: Disseminate and recurrent infundibulofolliculitis: response to isotretinoin. *J Drugs Dermatol* 2004; 3:434.

Hinds GA, et al: A case of disseminate and recurrent infundibulofolliculitis responsive to treatment with topical steroids. *Dermatol Online J* 2008; 14:11.

Lichen spinulosus

Lichen spinulosus (keratosis spinulosa) is chiefly a disease of children and is characterized by minute filiform horny spines, which protrude from follicular openings independent of any papules. The spines are discrete and grouped. The lesions appear in crops and are symmetrically distributed over the trunk, limbs, and buttocks (acne corne). There is a predilection for the neck, buttocks, abdominal wall, popliteal spaces, and the extensor surfaces of the arms. Little or no itching is present. Occasional cases of a generalized form in adults with HIV infection or alcoholism have been reported.

Histologic evaluation shows simple inflammatory changes and follicular hyperkeratosis. The lesions may respond to keratolytics and emollients, such as salicylic acid, lactic acid, or urea gels or ointments. Tretinoin or tacalcitol creams are other alternatives. The lesions tend to involute at puberty.

Foreman SB, et al: Lichen spinulosus. *Arch Dermatol* 2007; 143:122.

Kim SH, et al: Successful treatment of lichen spinulosus with topical tacalcitol cream. *Pediatr Dermatol* 2010; (epub).

Disorders of the sweat glands

Hyperhidrosis

Hyperhidrosis, or excessive sweating, may be localized to one or several areas or it may be more generalized. True generalized hyperhidrosis is rare, and even hyperhidrosis caused by systemic diseases is usually accentuated in certain regions.

Palmoplantar hyperhidrosis (emotional hyperhidrosis)

This type of hyperhidrosis is usually localized to the palms, soles, and/or axillae, and may be worse during warm temperatures. Patients with palm and sole hyperhidrosis may also have axillary hyperhidrosis, but only 25% of patients with axillary hyperhidrosis have palmoplantar hyperhidrosis. The hands may be cold and show a dusky hue. The soggy keratin of the hyperhidrotic soles is frequently affected by pitted keratolysis and has a foul odor. Sweating may be intermittent; in these cases anxiety, stress, or fear may trigger it. When sweating is constant, usually emotion is not as important.

This type of sweating can be autosomal-dominantly inherited. Its onset is in childhood for the palmar type and adolescence for axillary disease. It tends to improve with age. Sweating typically ceases during sleep.

Gustatory hyperhidrosis

Certain individuals regularly experience excessive sweating of the forehead, scalp, upper lip, perioral region, or sternum a few moments after eating spicy foods, tomato sauce, chocolate, coffee, tea, or hot soups. Gustatory sweating may be idiopathic or caused by hyperactivity of the sympathetic nerves (Pancoast tumor or postoperatively), sensory neuropathy (diabetes mellitus or subsequent to zoster), parotitis or parotid abscess, and surgery or injury of the parotid gland (auriculotemporal syndrome of von Frey). Frey syndrome occurs in one-third or more of patients following parotid surgery. Fortunately, only 10% of affected patients require treatment.

Other localized forms of hyperhidrosis

Localized sweating can occur over lesions of blue rubber bleb nevus, glomus tumors, and hemangiomas (sudoriferous hemangioma), and in POEMS syndrome, Gopalan syndrome, complex regional pain syndrome, as a result of spinal cord tumors (especially when unilateral palmar hyperhidrosis is the complaint), and pachydermoperiostosis.

Generalized hyperhidrosis

Febrile diseases, vigorous exercise, or a hot, humid environment, such as a tropical milieu, may induce generalized hyperhidrosis. Hyperthyroidism, acromegaly, diabetes mellitus, pheochromocytoma, hypoglycemia, salicylism, substance abuse, lymphoma, carcinoid syndrome, pregnancy, and menopause may also produce generalized hyperhidrosis. Additional causes of hyperhidrosis include concussion, Parkinson's disease, other disturbances of the sympathetic nervous system, and metastatic tumors producing a complete transection of the spinal cord. Drugs such as anticholinesterases, antidepressants of the selective serotonin-reuptake inhibitor or tricyclic types, antiglaucoma agents, bladder stimulants, opioids, and sialogogs may cause hyperhidrosis.

Treatment

The therapy of generalized hyperhidrosis is aimed at treating the underlying systemic disease. Virtually all cases of hyperhidrosis seen by dermatologists are of the palmoplantar or axillary types, and the treatments discussed below relate primarily to these conditions.

Topical medication Topical aluminum chloride or aluminum chlorhydroxide are the most commonly used agents for hyperhidrosis. For the axillae, application of a 10–35% solution nightly to a very dry axilla (blown dry with a hair dryer) is usually very effective. To limit irritation, lower concentrations should be tried first. Also, it should be washed off in 6–8 h. Occlusion is usually not required. In palmar hyperhidrosis the application of aluminum chloride nightly in up to a 50% concentration, alone or occluded with plastic gloves, has pro-

duced good results for some patients. If topical treatment is effective when performed nightly, the frequency may be reduced to as little as once or twice a week with continued benefit.

Iontophoresis Iontophoresis with plain tap water is an alternative for patients for whom topical treatments fail. It is frequently effective, using either a Drionic device or a Fischer unit. Treatments generally require 20–30 min sessions each day or twice a day. Once response has occurred, treatments may be used intermittently (as little as once every 2 weeks) for maintenance. Use of glycopyrrolate 0.01% and aluminum chloride 2% in the iontophoresis medium may hasten the response. A new dry-type iontophoresis has been described but is not readily available.

Botulinum toxin Injection of botulinum A toxin into 4 cm² areas on the palms, soles, or axillae dramatically reduces sweating at the treated areas to at least 25% and often to less than 10% of baseline rates. Dosages vary according to the type of botulinum toxin A and the site of treatment. Grunfeld et al offer a complete review of injection techniques and tips. Complications are rare but include some grip weakness when higher doses are used in the palms. This problem, the expense, and the painful injections limit its use in the palms and soles especially. The hypohidrosis continues for an average of 7 months, with some patients continuing to have substantial benefit at 16 months after one injection. Repeated injections generally do not lose efficacy and result in similar response and complication rates. This form of treatment should be offered to all patients who fail topical treatments before surgical modalities are considered. Frey syndrome remits for 1–1.5 years in nearly every patient treated. This treatment may be considered for other rare forms of localized hyperhidrosis. Myobloc (botulinum toxin B) is also effective, but with more limited duration of response.

Internal medication The use of anticholinergic agents such as propantheline bromide, oxybutynin (available in an extended-release formulation which may result in lower efficacy), and glycopyrrolate may be helpful. The dosage of each is regulated by the patient's tolerance and response. Often, sweating is suppressed just as anticholinergic side effects reach intolerable levels, and this approach has to be abandoned. Side effects of acetylcholine-blocking agents may also cause or aggravate such conditions as glaucoma and convulsions. The effects on sweating generally last 4–6 h, and many patients prefer to use the medication to ensure dryness for special occasions only, rather than as continuous treatment. Other agents reported to reduce localized hyperhidrosis include diltiazem and clonidine.

Surgical treatment Axillary hyperhidrosis may be effectively controlled by excision of the most actively sweating portion of the axillary skin, followed by undercutting and subcutaneous resection of the sweat glands for 1–2 cm on each side of the elliptical excision. This procedure is virtually always effective. Alternatively, liposuction or surgical ultrasonic aspiration removal may be used. The most important preoperative consideration is the accurate mapping of the most active sweating areas of the axillae. The responsible eccrine glands are not necessarily located in the same areas as the axillary hair and are often in a reasonably limited area. Mapping may be performed with cobalt chloride or starch iodide.

Upper thoracic sympathectomy has been found to be effective in excessive palmar sweating when all other measures have failed. Sympathetic denervation of the upper extremities is performed via endoscopy by reversibly clipping or performing resection of the fourth thoracic sympathetic ganglion. Acute surgical complications occur in less than 2% but include chronic pain, infection, pneumothorax, hemothorax, bleeding, pneumonia, and even death. Sweating of the hands is stopped

completely. Only 60% of patients are satisfied, however, since compensatory and gustatory hyperhidrosis occurs in more than two-thirds of patients. This may be severe and as debilitating as the original problem. Topical glycopyrrolate may sometimes help alleviate compensatory hyperhidrosis, but it does not decrease with time. Horner syndrome may rarely result. Endoscopic thoracic sympathetic block at T4 is being evaluated as another alternative.

Anhidrosis (hypohidrosis)

Anhidrosis is the absence of sweating. Hypohidrosis, or reduced sweating, is part of the spectrum of these disorders. Dysfunction in any step in the normal physiologic process of sweating can lead to decreased or absent sweating. It may be localized or generalized. Generalized anhidrosis occurs in anhidrotic ectodermal dysplasia, miliaria profunda (tropical asthenia), Sjögren syndrome, Fabry syndrome, hereditary sensory neuropathy (type IV) with anhidrosis, and in some patients with diabetic neuropathy, thyroid dysfunction, and multiple myeloma. A large number of drugs may cause hypohidrosis. These include anticholinergics, antidepressants of the tricyclic type, antiepileptics, antihistamines, anti-hypertensives, antipsychotics, antiemetics, antivertigo drugs, bladder antispasmodics, gastric antisecretory drugs, muscle

relaxants, neuromuscular paralytics, and opioids. Anhidrosis may follow infections, be part of a neurodegenerative disorder, occur as a symptom related to toxin exposure, be a paraneoplastic phenomenon, or be secondary to autoimmune inflammation. Atopic dermatitis is frequently associated with reduced sweating and pruritus when sweating is triggered. Patients with psoriasis may have similar symptoms, but less frequently.

Anhidrosis with pruritus is a rare syndrome of young adults. Severe itching occurs whenever they are stimulated to sweat. No sweat is delivered to the skin surface, but when the body temperature is raised by about 0.5°C, fine papules appear at each eccrine orifice. The associated pruritus is so severe that patients feel completely incapacitated and distracted. Cooling immediately resolves the symptoms. This may represent one form of tropical asthenia or a mild form of the autonomic neuropathies described below. The natural history is unknown, but spontaneous resolution may occur after several years. These patients are frequently misdiagnosed as having cholinergic urticaria.

Segmental anhidrosis may be associated with tonic pupils (Holmes-Adie syndrome); this is called Ross syndrome. Patients have heat intolerance and segmental areas of anhidrosis on the trunk, arms, or legs. Loss of deep tendon reflexes in the arms, trunk, and legs is consistently seen. Compensatory segmental hyperhidrosis of functionally intact areas may occur. A selective degeneration of the cholinergic sudomotor neurons is the hypothesized abnormality.

Autonomic neuropathies associated with antibodies to nicotinic acetylcholine receptors may cause a variety of symptoms related to dysfunction of systems controlled by autonomic nerves. There is a spectrum of abnormalities ranging from severe autonomic failure characterized by orthostatic hypotension, gastrointestinal dysmotility, anhidrosis, bladder dysfunction, and sicca syndrome to isolated anhidrosis and heat intolerance. In this condition a biopsy may reveal an inflammatory infiltrate surrounding the eccrine glands, and some patients respond to pulse steroids or immunosuppressants. It may also spontaneously resolve.

Anhidrosis localized to skin lesions occurs regularly over plaques of tuberculoid leprosy. This is also true of segmental vitiligo (but not generalized type), in the hypopigmented streaks of incontinentia pigmenti, in lesions of syringolymphoid hyperplasia with alopecia and anhidrosis, and on the face and neck of patients with the rare Bazex syndrome consisting of follicular atrophoderma, basal cell carcinomas, and hypotrichosis, an X-linked dominant disorder.

Bromhidrosis

Also known as fetid sweat, osmidrosis and malodorous sweating, bromhidrosis is chiefly encountered in the axillae. Bacterial

decomposition of apocrine sweat, producing fatty acids with distinctive offensive odors, is considered to be the cause. Often, patients who complain of offensive axillary sweat actually have no offensive odor; the complaint represents a delusion, paranoia, phobia, or a lesion of the central nervous system. Intranasal foreign body and chronic mycotic infection in the sinuses are additional causes. True bromhidrosis is usually not recognized by the patient.

Fish odor syndrome should be considered in patients presenting with complaints of offensive odor. It is caused by excretion of trimethylamine (which smells like rotten fish) in the eccrine sweat, urine, saliva, and other secretions. This chemical is produced from carnitine and choline in the diet and is normally metabolized in the liver. An autosomal-dominant defect in the ability to metabolize trimethylamine because of a defect in flavin-containing mono-oxygenase 3 is the cause of this syndrome. Dietary reduction of foods high in carnitine and choline is beneficial.

Antibacterial soaps and many commercial deodorants are quite effective in controlling axillary malodor. Frequent bathing, changing of underclothes, shaving of the axillae, and topical application of aluminum chloride (Drysol) are all helpful measures. Surgical removal of the glands either by excision or tumescent liposuction is possible, as in axillary hyperhidrosis, but this is rarely indicated. Botulinum toxin A injections in the axilla have controlled body odor in this site as well in the pubic area.

Plantar bromhidrosis is produced by bacterial action on eccrine sweat-macerated stratum corneum. Hyperhidrosis is the chief associated factor, and pitted keratolysis is often present. Careful washing with an antibacterial soap and the use of dusting powders on the feet are helpful in eliminating bromhidrosis. Use of topical antibiotics, such as clindamycin, may be beneficial. Previously described measures to control plantar hyperhidrosis should be instituted. Botulinum toxin A is likely to be effective.

Chromhidrosis

Chromhidrosis, or colored sweat, is an exceedingly rare functional disorder of the apocrine sweat glands, frequently localized to the face or axilla. It has been less often noted on the abdomen, chest, breasts, thighs, groin, genitalia, and lower eyelids. The colored sweat may be yellow (most common), blue, green, or black. The colored secretion appears in response to adrenergic stimuli, which cause myoepithelial contractions. Colored apocrine sweat fluoresces and is caused by lipofuscin. Treatment with botulinum toxin A or topical capsaicin has been reported to be effective.

Eccrine chromhidrosis is caused by the coloring of the clear eccrine sweat by dyes, pigments, or metals on the skin surface. Examples are the blue-green sweat seen in copper workers and the "red sweat" seen in flight attendants from the red dye in the labels in life-vests. Brownish staining of the axillae and undershirt may occur in ochronosis. Bile secretion in eccrine sweat occurs in patients with liver failure and marked hyperbilirubinemia. Small, round, brown or deep-green macules occur on the palms and soles.

Fox-Fordyce disease

Fox-Fordyce disease is rare, occurring mostly in women during adolescence or soon afterward. It may occasionally be familial in nature. It is characterized by conical, flesh-colored or grayish, intensely pruritic, discrete follicular papules in areas where apocrine glands occur. The axillae and areolae are the primary sites of involvement, but the umbilicus, pubes, labia majora, and perineum may be affected. Apocrine sweating does not occur in affected areas, and hair density may be decreased. In some cases there is no itching. Ninety percent of cases occur in women between the ages of 13 and 35, but the disease may present postmenopausally or in males. Pregnancy invariably leads to improvement.

Histologically, Fox-Fordyce disease is characterized by obstruction of the follicular ostia by orthokeratotic cells. An inflammatory infiltrate of lymphocytes surrounds the upper third of the hair follicles and upper dermal vessels. There is an associated spongiosis of the infundibulum at the site of entrance of the apocrine duct into the hair follicle. In one case, detached apoecrine cells obstructed the duct. Foam cells have been noted to be a histologic marker, as many of the above findings are either nonspecific or difficult to demonstrate. Localized axillary xanthomatosis has been postulated to be either a variant of Fox-Fordyce disease or a type of verruciform xanthoma.

No form of therapy is universally effective for Fox-Fordyce disease. Oral contraceptive pills, topical tretinoin or adapalene, topical pimecrolimus or weak corticosteroid creams, intralesional steroids, topical clindamycin solution, benzoyl peroxide, isotretinoin, and UV phototherapy have all been effective in small numbers of patients. Excision or liposuction-assisted curettage may be successful in axillary sites.

Granulosis rubra nasi

Granulosis rubra nasi is a rare familial disease of children, occurring on the nose, cheeks, and chin. It is characterized by diffuse redness, persistent hyperhidrosis, and small dark red papules that disappear on diascopic pressure. The tip of the nose is red or violet. There may be a few small pustules. Hyperhidrosis precedes the erythema (Fig. 33-37). The tip of the nose is cold and is not infiltrated. The disease disappears spontaneously at puberty without leaving any traces. The cause is unknown. Histologically, blood vessels are dilated and there is an inflammatory infiltrate about the sweat ducts.

Fig. 33-37 Early granulosus rubra nasi.

Treatment is with local preparations for relief of the inflammation, and reassurance that with puberty there is usually involution of the process.

Akhdari N: Granulosus rubra nasi. *Int J Dermatol* 2007; 46:396.

Hidradenitis

Hidradenitis is a term used to describe diseases in which the histologic abnormality is primarily an inflammatory infiltrate around the eccrine glands. This group includes neutrophilic eccrine hidradenitis and idiopathic plantar hidradenitis (recurrent palmoplantar hidradenitis).

Neutrophilic eccrine hidradenitis

Ninety percent of patients with neutrophilic eccrine hidradenitis (NEH) have a malignancy. It has been described primarily in patients with acute myelogenous leukemia (AML); however, other leukemias, lymphomas, and uncommonly solid tumors may be present. It usually begins about 10 days after the start of chemotherapy. While the majority of patients have been treated with cytarabine, it has not been uniformly linked to any chemotherapeutic agent and may occur in patients who have not been treated. Patients with AML in remission have been reported to develop NEH with associated sclerodermoid changes that herald a relapse of the leukemia. Granulocyte colony-stimulating factor (G-CSF), imatinib mesylate, zidovudine, acetaminophen, and various antibiotics have also been implicated as triggers for this neutrophilic dermatosis.

The lesions are typically erythematous and edematous papules and plaques of the extremities, trunk, face (peri-orbital), and palms (in decreasing frequency). Pigmentation, purpura, or pustules may be present within the papules and plaques. Fever and neutropenia are often present. Histologically, there is a dense neutrophilic infiltrate around and infiltrating eccrine glands. Necrosis of sweat glands may be present, with or without the inflammatory infiltrate. Syringosquamous metaplasia may occur. This finding can also occur in fibrosing alopecia, in burn scars, adjacent to various nonmelanoma skin cancers and ischemic and surgical ulcers, in alopecia mucinosa, and in ports of radiation therapy.

The lesions may recur with repeated courses of chemotherapy, but many do not. Resolution over 1–4 weeks (average, 10 days) usually occurs. Nonsteroidal anti-inflammatory drugs or oral corticosteroids may hasten the healing. Prophylactic administration of dapsone prevented recurrence in one patient.

Infectious neutrophilic hidradenitis may present as a recurrent, pruritic, papular eruption. *Serratia*, *Enterobacter cloacae*,

Nocardia, and *Staphylococcus aureus* have been implicated, and appropriate antibiotics for bacterial agents are curative. The diagnosis is confirmed by histologic evaluation and culture of affected tissue (surface cultures may not be adequate). Additionally, many HIV-infected patients have developed neutrophilic eccrine hidradenitis.

Recurrent palmoplantar hidradenitis

Recurrent palmoplantar hidradenitis is primarily a disorder of healthy children and young adults. Lesions are primarily painful, subcutaneous nodules on the plantar surface, resembling erythema nodosum. Rarely, palmar lesions also occur. In some children *Pseudomonas* infection may be the cause (pseudomonal hot foot, see Chapter 14). Children may present refusing to walk because of plantar pain. The condition is typically recurrent, and may be triggered by exposure to wet shoes or cold, damp weather. The use of oral and topical steroidal preparations may be beneficial.

Nail-associated dermatoses

Numerous dermatoses are associated with characteristic, sometimes specific, nail changes. Many are considered elsewhere.

Lichen planus of nails

The reported incidence of nail involvement in lichen planus varies from less than 1% to 10%. Lichen planus of the nails may occur without skin changes, but 25% with nail disease will have lichen planus at other locations. Although it may occur at any age, most commonly it begins during the fifth or sixth decade of life. The nail plate may be markedly thinned, and at times distinct papules of lichen planus may involve the nailbed. Twenty-nail dystrophy (trachyonychia) may be the

Fig. 33-38 Pterygium caused by lichen planus. (Courtesy of Lawrence Lieblich, MD)

sole manifestation of lichen planus. Other nail changes are irregular longitudinal grooving and ridging of the nail plate, thinning of the nail plate, pterygium formation (Fig. 33-38), shedding of the nail plate with atrophy of the nailbed, subungual keratosis, or even onychopapilloma, erythronychia (red streaks), subungual hyperpigmentation, and nail degloving. This latter sign is a newly described entity where there is partial or total shedding of the nail or the entire nail apparatus. The surrounding skin may also slough. This may be caused by trauma, ischemia and gangrene, or severe dermatologic disease such as toxic epidermal necrolysis or lichen planus.

The histologic changes of lichen planus may be evident in any individual nail constituent or a combination of them. The one most frequently involved is the matrix.

Treatment is mostly unsatisfactory. Intralesional injection of corticosteroids may be of help in some patients. Digital nerve blocks should be considered before infiltration of the matrix or nailbed. Topical corticosteroids under polyethylene occlusive dressings are usually inadequate. Clobetasol combined with tazarotene may be successful. Oral prednisone (0.5–1 mg/kg for 3 weeks) or oral retinoids in combination with topical steroids applied to the involved sites has been successful in some patients. Tosti et al reported that typical lichen planus of the nails in children responded to 0.5–1 mg/kg/month of intramuscular triamcinolone acetate given for 3–6 months, until the proximal half of the nail was normalized. Disease recurred in only two patients during the follow-up period. While twenty-nail dystrophy was not treated, patients spontaneously improved; those with idiopathic atrophy of the nails were unchanged. (See Chapter 12 for additional therapeutic considerations.)

Psoriatic nails

Nail involvement in psoriasis is common, with reported incidences varying from 10% to 78%. Older patients, those with active exacerbations of disease, and those with psoriatic arthritis are more likely to express nail abnormalities. In the nail plate there may be pits (Fig. 33-39), or much less often, furrows or transverse depressions (Beau's lines), crumbling nail plate, or leukonychia, with a rough or smooth surface. Splinter hemorrhages are found in the nailbed, with reddish discoloration of a part or all of the nailbed, and horny masses. In the hyponychia, subungual hyperkeratosis, oil spots, and a yellowish-green discoloration may occur in the area of onycholysis. Onychomycosis may be closely simulated. The severity of nail disease may correlate with the severity of skin and joint disease. Pustular psoriasis may produce onycholysis, with lakes of pus in the nailbed or in the perionychial areas. Rarely, anonychia may result. Other papulosquamous diseases may affect the nails like psoriasis, with the exception of nail pitting. Reiter's disease, pityriasis rubra pilaris, Sézary syndrome, and acrokeratosis paraneoplastica produce as a rule hypertrophic nails with subungual hyperkeratosis.

Psoriatic nail disease may be a solitary finding or be part of a widespread skin and nail involvement. The treatment options selected depend on the degree of cutaneous and nail involvement. (See Chapter 10 for additional information and therapeutic options.) Successful systemic treatment of psoriasis will usually also improve or clear the nail changes. Methotrexate, PUVA, cyclosporine, the biologics, or acitretin may be effective. All local therapies have limitations. Intralesional injection of triamcinolone acetate suspension, 3–5 mg/mL, with a 30-gauge needle is frequently helpful. Digital nerve block facilitates adequate injection. Topical 5-fluorouracil (5-FU) applied to the proximal nailfold has been reported to be effective. It is best to avoid the free edge of the nail when applying 5-FU, as it may cause distal onycholysis. Topical cyclosporine and topical tazarotene 0.1% gel may also be helpful. Topical calcipotriol improves about 50% of patients with localized pustular psoriasis of the nails and may be used as a maintenance treatment after successful intervention with systemic retinoids.

Darier's disease

Longitudinal, subungual, red or white streaks, associated with distal wedge-shaped subungual keratoses, are the nail signs diagnostic for Darier-White disease. Keratotic papules on the dorsal portion of the nailfold may clinically resemble acrokeratosis verruciformis, but histologically have features of Darier's disease. Other nail findings include splinter hemorrhages and leukonychia. All of these findings are less pronounced on the toenails.

De Berker DA, et al: Localized longitudinal erythronychia. *Arch Dermatol* 2004; 140:1253.

Clubbing

Clubbing is divided into two types: idiopathic and acquired, or secondary. The changes occur not only in the nails but also in the terminal phalanges. The nails bulge and are curved in a convex arc in both transverse and longitudinal directions. The eponychium is thickened. The angle formed by the dorsal surface of the distal phalanx and the nail plate (Lovibond's angle) is approximately 160°; however, with clubbing this angle is obliterated and becomes 180° or greater (Fig. 33-40). There is no diamond-shaped window when the dorsal surfaces of the corresponding finger of each hand are opposed (Schamroth's sign). The soft tissues of the terminal phalanx are bulbous and of are mobile when pressure is applied over the matrix. Thickening of the nailbed is present and can be assessed reliably by a plain radiograph of the index finger.

Idiopathic clubbing is either of the isolated dominantly inherited type or of the pachydermoperiostosis type with its associated findings. In the hereditary isolated type, a homozygous missense mutation in exon 6 of the human *HPGD* gene encoding NAD(+)-dependent 15-hydroxyprostaglandin dehydrogenase (15-PGDH) has been identified. Secondary (acquired) clubbing is usually a consequence of pulmonary, cardiac, thyroid, hepatic, or gastrointestinal disease. Around 36% of HIV patients has been documented to express clubbed nails. Typically, there is periostitis, with periosteal new bone formation in the phalanges, metacarpals, and distal ulna and radius. This is called hypertrophic osteoarthropathy and is responsible for the painful clubbing. It typically occurs in men with bronchogenic carcinoma. Unilateral or asymmetrical clubbing may also occur in Takayasu arteritis and sarcoidosis.

Tariq M, et al: Mutation in the *HPGD* gene encoding NAD+ dependent 15-hydroxyprostaglandin dehydrogenase underlies isolated congenital nail clubbing. *J Med Genet* 2009; 46:14.

Shell nail syndrome

Cornelius et al described a shell nail in association with bronchiectasis. The nail resembles a clubbed nail, but the nailbed is atrophic instead of being a bulbous proliferation of the soft tissue.

Cornelius CE: Shell nail syndrome. *Arch Dermatol* 1969; 100:118.

Koilonychia (spoon nails)

Spoon nails are thin and concave, with the edges everted so that if a drop of water were placed on the nail, it would not run off (Fig. 33-41). Koilonychia may result from faulty iron metabolism and is one of the signs of Plummer-Vinson syndrome, as well as of hemochromatosis. Spoon nails have been observed in coronary disease, syphilis, polycythemia, and acanthosis nigricans. Familial forms are also known to occur. Other associations include psoriasis, lichen planus, Raynaud disease, scleroderma, acromegaly, hypothyroidism and hyperthyroidism, monilethrix, palmar hyperkeratoses, and steatocystoma multiplex. A significant number of cases are idiopathic. Manual trauma in combination with cold exposure may result in seasonal disease. Sherpas are Tibetan people living in the Nepalese Himalayas, who often serve as porters on mountain-climbing expeditions. Chronic cold exposure, in combination with hypoxemia, may contribute to the high frequency with which koilonychia is observed among them.

Kumar G, et al: Koilonychia, or spoon-shaped nails, is generally associated with iron-deficiency anemia. *Ann Emerg Med* 2007; 49:243.

Congenital onychodysplasia of the index fingers

Congenital onychodysplasia of the index fingers is defined by the presence of the condition at birth, index finger involvement (unilateral or bilateral), variable distortion of the nail or lunula, and polyonychia, micronychia, anonychia, hemionychogryphosis, or malalignment. It may also involve adjacent fingers, such as the middle fingers and thumbs. An underlying bone dysplasia may be present beneath the involved nail. Cases have occurred in an autosomal-dominant pattern; other proposed causes include in utero ischemia or exposure to teratogens.

Prais D, et al: Prevalence and new phenotypic and radiologic findings in congenital onychodysplasia of the index finger. *Pediatr Dermatol* 1999; 16:201.

Trachyonychia

The nails may become opalescent, thin, dull, fragile, and finely ridged longitudinally (and as a result, distally notched). When this involves all 20 nails, it is referred to as twenty-nail dystrophy. This latter presentation may be seen at any age from 1½ years to adulthood, although it is most commonly diagnosed in children. It can be idiopathic or caused by alopecia areata, psoriasis, lichen planus, atopy, ichthyosis vulgaris, or other inflammatory dermatoses. Familial forms exist. In some cases spongiosis may be found on nail biopsy. Trachyonychia has also been reported associated with autoimmune processes such as selective IgA deficiency, vitiligo, sarcoidosis, and graft versus host disease. Unilateral involvement may occur in complex regional pain syndrome. Thus it is caused by a heterogeneous group of inflammatory conditions. Tazarotene alone or in association with topical steroids may improve the condition. Childhood cases may resolve spontaneously; in one study 50% cleared within 6 years.

Soda R, et al: Treatment of trachyonychia with tazarotene. *Clin Exp Dermatol* 2005; 30:301.

Onychauxis

In onychauxis the nails are thickened but without deformity (simple hypertrophy). Simple thickening of the nails may be the result of trauma, acromegaly, Darier's disease, psoriasis, or pityriasis rubra pilaris. Some cases are hereditary.

Treatment involves periodic partial or total debridement of the thickened nail plate by mechanical or chemical (40% urea paste) means. Matricectomy and nail ablation are options, as they are in onychogryphosis, congenital nail dystrophies, and chronic painful nails such as recalcitrant ingrown toenails or splits within the medial or lateral third of the nail.

Baran R, et al: Matricectomy and nail ablation. *Hand Clin* 2002; 18:696.

Singh G, et al: Nail changes and disorders among the elderly. *Indian J Dermatol Venereol Leprol* 2005; 71:386.

Onychogryphosis

Hypertrophy may produce nails resembling claws or a ram's horn. Onychogryphosis may be caused by trauma or peripheral vascular disorders but is most often caused by neglect (failure to cut the nails for very long periods). It is most commonly seen in the elderly.

Some recommend avulsion of the nail plate with surgical destruction of the matrix with phenol or the CO₂ laser, if the blood supply is good.

Baran R, et al: Matricectomy and nail ablation. *Hand Clin* 2002; 18:696.

Mohrenschlager M, et al: Onychogryphosis in elderly persons. *Cutis* 2001; 68:233.

Onychophosis

A common finding in the elderly, onychophosis is a localized or diffuse hyperkeratotic tissue that develops on the lateral or proximal nailfolds, within the space between the nailfolds and the nail plate. It may involve the subungual area, as a direct result of repeated minor trauma, and most frequently affects the first and fifth toes. The use of comfortable shoes should be encouraged. The areas involved should be debrided and treated with keratolytics. Emollients are also helpful.

Singh G, et al: Nail changes and disorders among the elderly. *Indian J Dermatol Venereol Leprol* 2005; 71:386.

Anonychia

Absence of nails, a rare anomaly, may be the result of a congenital ectodermal defect, ichthyosis, severe infection, severe allergic contact dermatitis, self-inflicted trauma, Raynaud phenomenon, lichen planus, epidermolysis bullosa, or severe exfoliative diseases. Permanent anonychia has been reported as a sequel of Stevens-Johnson syndrome. It may also be found in association with congenital developmental abnormalities, such as microcephaly, and wide-spaced teeth (autosomal-recessive inheritance), the autosomal-dominant Cooks syndrome (bilateral nail hypoplasia of digits 1-3, the absence of nails of digits 4 and 5 of the hands, total absence of all toenails, and absence or hypoplasia of the distal phalanges of the hands and feet), DOOR syndrome (deafness, oncho-osteodystrophy, mental retardation), and the glossopalatine syndrome (abnormal mouth, tongue being attached to the temporomandibular joint).

It may also present as an autosomal-recessive disorder with anonychia as the solitary finding. It has been found to be caused by a mutation in the *R-spondin 4* gene. R-spondins are secreted proteins that activate the Wnt/ β -catenin signaling pathway. *R-spondin 4* is exclusively expressed in the mesenchyme underlying the digit tip epithelium in embryonic mice.

Al Hawsawi K, et al: Anonychia congenita totalis. *Int J Dermatol* 2002; 41:397.

Bruchle NO, et al: RSPO4 is the major gene in autosomal-recessive anonychia and mutations cluster in the furin-like cysteine-rich domains of the Wnt signaling ligand R-spondin4. *J Invest Dermatol* 2008; 128:791.

Ishii Y, et al: Mutations in R-spondin 4 underlie inherited anonychia. *J Invest Dermatol* 2008; 128:867.

Pall A, et al: Twenty-nail anonychia due to lichen planus. *J Dermatol* 2004; 31:146.

Onychoatrophy

Faulty underdevelopment of the nail may be congenital or acquired. The nail is thinned and small. Vascular disturbances, epidermolysis bullosa, lichen planus, Darier's disease, multicentric reticulohistiocytosis, and Hansen's disease may cause onychoatrophy. It is also seen in congenital syndromes such as Apert, Goltz, Turner, Ellis-van Creveld, nail-patella, dyskeratosis congenita, cartilage-hair hypoplasia, progeria, hypohidrotic ectodermal dysplasia, incontinentia pigmenti, popliteal web, trisomy 13 and trisomy 18, and as a side effect of etretinate therapy.

Al Hawsawi K, et al: Anonychia congenita totalis. *Int J Dermatol* 2002; 41:397.

Onychomadesis

Onychomadesis is a periodic idiopathic shedding of the nail beginning at its proximal end. The temporary arrest of the

Fig. 33-42 Beau's lines.

function of the nail matrix may cause onychomadesis. Neurologic disorders, peritoneal dialysis, cutaneous T-cell lymphoma, Kawasaki's disease, pemphigus vulgaris, drug allergy, and keratosis punctata palmaris et plantaris have been reported causes. It may appear as a periodic finding in runners. Immobilization from casting for fractures may cause onychomadesis and pyogenic granuloma formation. Medications such as antineoplastic agents, azithromycin, and retinoids may cause onychomadesis also.

Bodman MA: Nail dystrophies. *Clin Podiatr Med Surg* 2004; 21:663.

Mehra A, et al: Idiopathic familial onychomadesis. *J Am Acad Dermatol* 2000; 43:349.

Tosti A, et al: Onychomadesis and pyogenic granuloma following cast immobilization. *Arch Dermatol* 2001; 137:231.

Beau's lines

Beau's lines are transverse furrows that begin in the matrix and progress distally as the nail grows (Fig. 33-42). They are ascribed to the temporary arrest of function of the nail matrix. Although usually found to be bilateral, unilateral Beau's lines may occur. Various systemic and local traumatic factors may cause this. They may result from almost any systemic illness or major injury, such as a broken hip. Some specific associations are childbirth, measles, paronychia, acute febrile illnesses, high altitude exposure, and drug reaction. When the process is intermittent, the nail plate may resemble corduroy. Shelley "shoreline" nails appear to be a very severe expression of essentially the same transient growth arrest. They have been reported in all 20 nails of a newborn.

Guhl G, et al: Beau's lines and multiple periungual pyogenic granulomas after long stay in an intensive care unit. *Pediatr Dermatol* 2008; 25:278.

Mortimer NJ, et al: Beau's lines. *N Engl J Med* 2004; 351:1778.

Piraccini BM, et al: Drug-induced nail diseases. *Dermatol Clin* 2006; 24:387.

Half and half nails

Half and half nails show the proximal portion of the nail white and the distal half red, pink, or brown, with a sharp line of

Fig. 33-43 Half and half nails.

demarcation between the two halves (Fig. 33-43). Seventy-six percent of hemodialysis patients and 56% of renal transplant patients have at least one type of nail abnormality. Half and half nails are the most frequent, affecting 20% of hemodialysis patients. Absence of lunula, splinter hemorrhage, and half and half nails were significantly more common in hemodialysis patients, while leukonychia was significantly more common in transplant patients.

Salem A, et al: Nail changes in chronic renal failure patients under haemodialysis. *J Eur Acad Dermatol Venereol* 2008; 22:1326.

Saray Y, et al: Nail disorders in hemodialysis patients and renal transplant recipients: a case control study. *J Am Acad Dermatol* 2004; 50:197.

Muehrcke's lines

Muehrcke described narrow white transverse bands occurring in pairs as a sign of chronic hypoalbuminemia. The lines may resolve when serum albumin is raised to or near normal (Fig. 33-44). Unlike Mees' lines, the disturbance appears to be in the nailbed, not in the nail plate. Similar lines have been reported in patients with normal albumin levels who are receiving chemotherapy. In a case of unilateral Muehrcke's lines associated with trauma, it was suggested that edema effects this change by inducing microscopic separation of the normally tightly adherent nail from its bed.

Alam M, et al: Muehrcke's lines in a heart transplant recipient. *J Am Acad Dermatol* 2001; 44:316.

Chen W, et al: Nail changes associated with chemotherapy in children. *J Eur Acad Dermatol Venereol* 2007; 21:186.

Morrison-Bryant M, et al: Muehrcke's lines. *N Engl J Med* 2007; 30:917.

Mees' lines

Mees described single or multiple white transverse bands in 1919 as a sign of inorganic arsenic poisoning. They have also been reported in thallium poisoning, septicemia, dissecting aortic aneurysm, parasitic infections, chemotherapy, and both acute and chronic renal failure.

Chauhan S, et al: Mees' lines. *Lancet* 2008; 372:1410.

Hall AH: Chronic arsenic poisoning. *Toxicol Lett* 2002; 128:69.

Lu CI, et al: Short-term thallium intoxication. *Arch Dermatol* 2007; 143:93.

Uede K, et al: Skin manifestations in acute arsenic poisoning from the Wakayama curry-poisoning incident. *Br J Dermatol* 2003; 149:757.

Fig. 33-44 Muehrke's lines.

Fig. 33-45 Terry nails.

Zhao G, et al: Clinical manifestations of acute thallium poisoning. *Eur Neurol* 2008; 60:292.

Terry nails

In Terry nails the distal 1–2 mm of the nail shows a normal pink color (Fig. 33-45), while the entire nail plate or proximal end has a white appearance as a result of telangiectases in the nailbed. These changes have been noted in 25% of hospitalized patients, most commonly those with cirrhosis, chronic congestive heart failure, and adult-onset diabetes, and in very elderly patients.

Blyumin M, et al: Terry nails. *Cutis* 2005; 76:172.

Fig. 33-46 Onychoschizia.

Onychorrhexis (brittle nails)

Brittleness with breakage of the nails may result from frequent soap and water exposure, nail polish remover, hypothyroidism, anorexia or bulimia, or after oral retinoid therapy. It affects up to 20% of the population, women twice as often as men. *Fragilitas unguium* (nail fragility) is part of this process. In a series of 35 patients treated with biotin, 63% showed clinical improvement. The nail plate thickness in patients treated with biotin increases by 25%. Daily application of white petrolatum after soaking in water is also helpful.

Uyttendaele H, et al: Brittle nails: pathogenesis and treatment. *J Drugs Dermatol* 2003; 2:48.

Van de Kerkhof PC: Brittle nail syndrome. *J Am Acad Dermatol* 2005; 53:644.

Onychoschizia

Splitting of the distal nail plate into layers at the free edge (Fig. 33-46) is a very common problem among women and represents a dyshesion of the layers of keratin, possibly as a result of dehydration. Longitudinal splits may also occur. Patients with biotinidase deficiency may manifest onychoschizia, along with total or partial alopecia and an eczematous or desquamating periorificial eruption. Hypotonia, seizures, and developmental delay in children and depression in adults are the most common systemic abnormalities. Lack of treatment may result in loss of hearing and vision.

Nail polish should be discontinued; nail buffing can be substituted. Frequent application of emollients may be helpful. Biotin has also been shown to be effective in doses up to 2.5 mg/day, or 2–4 times that much in deficient patients.

Redondo-Mateo J, et al: Facial erythema and onychoschizia. *Arch Dermatol* 2005; 141:1457.

Stippled nails

Small, pinpoint depressions in an otherwise normal nail characterize this type of nail change. This may be an early change seen in psoriasis. Stippled nails are also seen with some cases of alopecia areata, in early lichen planus, psoriatic or rheumatoid arthritis, chronic eczematous dermatitis, perforating granuloma annulare, and in some individuals with no apparent disease. The deeper, broader pits are more specific for psoriasis. The pitting in alopecia areata tends to be shallower and more regular, suggesting a “Scotch plaid” (tartan) pattern.

Tosti A, et al: Prevalence of nail abnormalities in children with alopecia areata. *Pediatr Dermatol* 1994; 11:12.

Fig. 33-47 Racquet nails.

Racquet nails (nail en raquette)

In racquet nails, the end of the thumb is widened and flattened, the nail plate is flattened as well, and the distal phalanx is abnormally short (Fig. 33-47). Racquet nails occur on one or both thumbs and are apparently inherited as an autosomal-dominant trait.

Baran R, et al: Baran and Dawber's Diseases of the Nails and Their Management. Oxford: Blackwell Scientific, 2008.

Chevron nail (herringbone nail)

This entity appears to be a rare transient fingernail ridge pattern of children. The ridges arise from the proximal nailfold and converge in a V-shaped pattern toward a midpoint distally.

Parry EJ: Chevron nail/herringbone nail. *J Am Acad Dermatol* 1999; 40:497.

Zaiac MN, et al: Chevron nail. *J Am Acad Dermatol* 1998; 38:773.

Hapalonychia

Softened nails result from a defect in the matrix that makes the nails thin and soft so that they can be easily bent. This type of nail change is attributed to malnutrition and debility. It may be associated with myxedema, rheumatoid arthritis, anorexia, bulimia, Hansen's disease, Raynaud phenomenon, oral retinoid therapy, or radiodermatitis.

Baran R, et al: Baran and Dawber's Diseases of the Nails and Their Management. Oxford: Blackwell Scientific, 2008.

Platonychia

The nail is abnormally flat and broad. It may be seen as part of an autosomal-dominant condition in which multiple nail abnormalities are present in many members of a large family.

Hamm H, et al: Isolated congenital nail dysplasia: a new autosomal dominant condition. *Arch Dermatol* 2000; 136:1239.

Nail-patella syndrome (hereditary osteo-onychodysplasia, Fong syndrome)

Nail-patella syndrome comprises numerous anomalies and is characterized by the absence or hypoplasia of the patella and congenital nail dystrophy. Triangular lunulae are characteristic (Fig. 33-48). Other bone features are thickened scapulae, hyperextensible joints, radial head abnormalities, and posterior iliac horns. The skin changes may also include webbing of the elbows. Eye changes such as cataracts, glaucoma, and heterochromia of the iris may also be present.

Fig. 33-48 Nail-patella syndrome. (Courtesy of Marshall Guill, MD)

Hyperpigmentation of the pupillary margin of the iris ("Lester iris") is a characteristic finding in about half the cases. Patients with nail-patella syndrome may exhibit glomerulonephritis with urinary findings of albuminuria, hematuria, and casts of all kinds, especially hyaline casts. They may be predisposed to developing hemolytic-uremic syndrome, edema, and hypertension. Sixty percent of patients have renal abnormalities, and 20% suffer from renal failure. It is an autosomal-dominant trait localized to the distal long arm of chromosome 9. Limb and kidney defects seen in LIM-homeodomain protein *Lmx1b* mutant mice are similar to those present in patients with nail-patella syndrome. Mutations of the human *LMX1B* gene result in this syndrome.

Onychophagia

Nail biting is a common compulsive behavior that may markedly shorten the nail bed, sometimes damages the matrix, and at times leads to pterygium formation. It is a difficult habit to cure. If there is strong motivation, habit reversal training with awareness training, competing response training, and social support may help. Psychopharmacologic intervention with medications, such as serotonin-reuptake inhibitors, and hypnosis are other options.

Twohig MP, et al: Evaluating the efficacy of habit reversal: comparison with a placebo control. *J Clin Psychiatry* 2003; 64:40.

Onychotillomania

Onychotillomania is a compulsive neurosis in which the patient picks constantly at the nails or tries to tear them off. Like onychophagia, this obsessive-compulsive disorder may be treated by biofeedback, cognitive-behavioral methods, hypnosis, or psychopharmacologic agents.

Inglese M, et al: Onychotillomania. *Cutis* 2004; 73:171.

Onycholysis

Onycholysis is a spontaneous separation of the nail plate, usually beginning at the free margin and progressing proximally. Rarely, the lateral borders may be involved, with spread confined to these. Less often, separation may begin proximal to the free edge, in an oval area 2–6 mm broad, with a yellowish-brown hue (“oil spot”). This is a lesion of psoriasis; ordinary distal onycholysis is also commonly due to psoriasis. The nail itself is smooth and firm with no inflammatory reaction. Underneath the nail a discoloration may occur from the accumulation of bacteria, most commonly *Pseudomonas*, or yeast, most commonly *Candida*. Color changes, such as green (a result of pyocyanin from *Pseudomonas*), black, or blue may be seen. One or more nails may be affected.

Onycholysis is noted most commonly in women, probably secondary to traumatically induced separation. It is common in patients with hand dermatitis. Keratinization of the distal nailbed, chronic exposure to irritants, untreated dermatitis, and secondary infection with *Candida albicans* are potential reasons for the failure of the nail to reattach itself.

Systemic causes are many: hyper- and hypothyroidism, pregnancy, porphyria, pellagra, and syphilis. Onycholysis has also been associated with atopic dermatitis, eczema, lichen planus, congenital abnormalities of the nails, trauma induced by clawing, pinching, stabbing (manicuring), and foreign-body implantation. It may be caused by mycotic, pyogenic, or viral (herpes) infections. Women should be checked for vaginal candidiasis, because that anatomic location may be the source of the infection opportunistically invading and aggravating onycholysis. Chemical causes may include the use of solvents, nail polish base coat, nail hardeners containing formalin derivatives, artificial fingernails, and allergic or irritant contact dermatitis from their use. Rarely, photo-onycholysis may occur during or soon after therapy with tetracycline derivatives, psoralens, fluoroquinolones, or chloramphenicol, and subsequent exposure to sunlight. Chemotherapeutic agents and systemic retinoids may induce onycholysis. On rare occasions it may be a sign of subungual exostoses, squamous cell carcinoma, or metastasis. Autosomal-dominant hereditary forms are also known.

Trauma and chemical irritants should be completely avoided and the nailbed should be kept completely dry. The affected portion of the nail should be kept clipped away. Drying by exposing the nailbed in this way will rid the area of *Pseudomonas* and assist greatly in eliminating *Candida*. The combination of drying and topical steroids to minimize inflammation will often allow for reattachment of the nail and improvement or cure. Usually, this process takes 3–6 months or more to occur.

Median nail dystrophy (dystrophia unguis mediana canaliformis, solenonychia)

Median nail dystrophy consists of longitudinal splitting or canal formation in the midline of the nail. The split, which often resembles a fir tree, occurs at the cuticle and proceeds outward as the nail grows (Fig. 33-49). Trauma has been sus-

Fig. 33-49 Median nail dystrophy.

pected of being the chief cause. Repeated typing with the nail tip on personal digital assistants or Blackberry™-type devices has been reported to cause a median nail dystrophy. Some cases will resolve with avoidance of trauma; however, many will persist for years despite scrupulous care. The deformity may result from a papilloma or glomus tumor in the nail matrix, producing a structure like a tube (solenos) distal to it. Familial cases and an onset with isotretinoin therapy are other associations.

Sweeney SA, et al: Familial median canaliform nail dystrophy. *Cutis* 2005; 75:161.

Pterygium unguis

Pterygium unguis forms as a result of scarring between the proximal nailfold and matrix. The classic causative example is lichen planus. It has been reported to occur as a result of sarcoidosis, porokeratosis of Mibelli, peripheral circulatory disturbances, and Hansen's disease. Onychomatricoma may uncommonly simulate pterygium, but histologic examination will confirm the nature of this benign tumor.

Kim DS, et al: Pterygium unguis formation in porokeratosis of Mibelli. *Br J Dermatol* 2007; 156:1384.

Richert BJ, et al: Pterygium of the nail. *Cutis* 2000; 66:343.

Pterygium inversum unguis

Pterygium inversum unguis is characterized by adherence of the distal portion of the nailbed to the ventral surface of the nail plate (Fig. 33-50). The condition may be present at birth or acquired, and may cause pain with manipulation of small objects, typing, and close manicuring of the nail. It is a condition resulting from the extension of the zone of the nailbed that normally contributes to the formation of the nail plate. This eventually leads to a more ventral and distal extension of the hyponychium. The most common forms of pterygium inversum unguis are the acquired secondary forms caused by systemic connective tissue diseases, particularly progressive systemic sclerosis and SLE.

Hangnail

Hangnail is an overextension of the eponychium (cuticle), which becomes split and peels away from the proximal or lateral nailfold. These lesions are painful and annoying, so that persistent cuticle biting frequently develops. Trimming these away with scissors is the best solution. The use of emollient creams to keep the cuticle soft is also recommended.

Lee HJ, et al: Minor cutaneous features of atopic dermatitis in South Korea. *Int J Dermatol* 2000; 39:337.

Pincer nails

Pincer nails, trumpet nails, or omega (from the shape of the Greek letter) nails are alternative terms for a common toenail disorder in which the lateral edges of the nail slowly approach one another, compressing the nailbed and underlying dermis (Fig. 33-51). It may less often occur in the fingernails and, surprisingly, is usually asymptomatic. Uncommonly, pain, recurrent or chronic infections, or even underlying osteomyelitis may complicate this condition. It may be an autosomal-dominantly inherited condition, acquired after trauma, or associated with Kawasaki's disease, renal disease, lupus erythematosus or use of β -blockers.

Some treatment success has been obtained with the use of commercial plastic braces after flattening of the nail. Urea ointment under occlusion, various surgical approaches, or chemical matricectomy with phenol and surgical nailbed repair have also been reported to be effective.

Onychocryptosis (unguis incarnatus, ingrown nail)

Ingrown toenail is one of the most frequent nail complaints. It occurs chiefly on the great toes, where there is an excessive lateral nail growth into the nailfold, leading to this painful, inflammatory condition. The lateral margin of the nail acts as a foreign body and may cause exuberant granulation tissue. *Unguis incarnatus* may be caused by wearing improperly fitting shoes and by improper trimming of the nail at the lateral edges so that the anterior portion cuts into the flesh as it grows distally. Drugs such as isotretinoin, lamivudine, and indinavir may induce periungual granulation tissue mimicking onychocryptosis.

In mild cases, soaking the foot in warm soapy water and insertion of a cotton pad, dental floss, or a flexible plastic tube beneath the distal corner of the offending nail may make surgery unnecessary. When surgical intervention is necessary, simple removal of the lateral portion of the nail plate can produce significant relief. Another simple operation involves removal of the overhanging lateral nailfold so that the nail does not cut into it. When healed, the nail edge resembles that of the thumb, and an excellent functional result occurs. The nail is not altered, since it is not touched.

Partial or complete nail avulsion with ablation of the nail matrix will prevent recurrence. Ablation can be accomplished surgically, with phenol, 10% sodium hydroxide, or with a CO₂ laser. When phenol is used, the proximal nailfold should be incised and reflected to avoid burning the nailfold. As an alternative, it can be left in place and injected with a corticosteroid to reduce the subsequent inflammation. Liquid nitrogen spray to the area of tissue and nail involved for a freeze time of 20–30 s has been successful in some patients, but may be painful and is reserved for patients in whom other surgical approaches are not appropriate.

Retronychia

Retronychia is an unusual event associated with ingrowing of the nail plate into the proximal nail fold. It then induces a chronic paronychia. The cause in the few cases reported has been trauma, usually of the great toe. An incomplete shedding of the nail plate results in the new growing nail pushing the old partially detached nail plate up and backwards into the proximal nail fold. Avulsion is curative.

Leukonychia or white nails

Four forms of white nail are recognized: leukonychia punctata, leukonychia striata, leukonychia partialis, and leukonychia totalis. The punctate (Fig. 33-52) variety is common in completely normal persons with otherwise normal nails. Leukonychia striata, transverse white parallel line, may be hereditary, of traumatic origin, or associated with systemic diseases such as HIV or Kawasaki's, or with drugs such as those used in chemotherapy. Partial leukonychia may occur with tuberculosis, nephritis, complex regional pain syndrome, Hodgkin disease, chilblains, metastatic carcinoma, or Hansen's disease, or be idiopathic.

Leukonychia totalis may be hereditary and is of a simple autosomal-dominant type. It may also be associated with typhoid fever, Hansen's disease, cirrhosis, ulcerative colitis, nail biting, use of emetine, complex regional pain syndrome, cytostatic agents, and trichinosis. Leukonychia may result from abnormal keratinization, with persistence of keratohyalin granules in the nail plate.

A syndrome comprising leukonychia totalis, multiple sebaceous cysts, and renal calculi in several generations has been reported. Other reports have linked total leukonychia with deafness or with koilonychia; however, it is most often inherited as an isolated finding.

Fig. 33-52 Leukonychia punctata.

Longitudinal erythronychia

Longitudinal red bands in the nail plate that commence in the matrix and extend to the point of separation of the nail plate and nailbed may occur on multiple nails with inflammatory conditions such as lichen planus or Darier's disease, or as an isolated finding. When only a localized single or bifid streak is present, this may signal a benign or malignant tumor of the matrix. The fingernails of middle-aged persons are most commonly affected, with the thumbnail being most frequently involved. There may be a distal keratosis seen, as with Darier, human papilloma virus (HPV) infection, or a squamous cell carcinoma. Excision of this distal keratosis, however, usually does not result in cure or diagnostic findings; biopsy of the affected matrix is necessary. Since this may lead to a scar with a permanent split of the nail plate, observation may be indicated. As in longitudinal melanonychia, if the band broadens over time, then an excisional biopsy is indicated, as this may be secondary to an amelanotic melanoma.

de Berker DAR, et al: Localized longitudinal erythronychia. *Arch Dermatol* 2004; 140:1253.

Jellinek NJ: Longitudinal erythronychia. *J Am Acad Dermatol* 2010; (epub).

Melanonychia

Black or brown pigmentation of the normal nail plate is termed melanonychia. It may be present as a normal finding on many digits in black patients, as a result of trauma, systemic disease, or medication, or as a postinflammatory event from such localized events as lichen planus or fixed drug reaction. Pigmentation of the nails may occur with acanthosis nigricans, Addison's disease, Peutz-Jeghers syndrome, and vitamin B₁₂ deficiency, after adrenalectomy for Cushing syndrome, as a part of Laugier-Hunziker syndrome (pigmentation of the nails associated with buccal and lip hyperpigmentation), with PUVA or ionizing radiation treatment, and as a drug-induced melanocyte activation with such medications as chemotherapy, antimicrobials, minocycline, antivirals (zidovudine [Fig. 33-53] or lamivudine), or metals (gold, arsenic, thallium, or mercury). Drugs may induce both transverse and longitudinal bands, with multidrug chemotherapy causing the majority of the former. Friction may cause longitudinal pigmented bands in the toenails, and subungual hemorrhage or black nail caused

Fig. 33-53 Zidovudine-induced hyperpigmentation of the nail.

Fig. 33-54 Longitudinal melanonychia.

by *Proteus mirabilis* or *Trichophyton rubrum* may enter into the differential diagnosis of a dark nail.

Longitudinal black or brown banding of the nails has been reported to occur in 77–96% of black persons and 11% of Asians. It is a rare finding in white children; however, it is not uncommon in white adults. In a series by Duhard, the prevalence of melanonychia was 12.6 in 100 in a white hospitalized population, and 1.4 in 100 in 4400 white clinic-based patients. The risk increased with age, the peak occurring between the ages of 56 and 65.

When only one nail is affected by melanonychia striata (a single longitudinal band of brown or black color [Fig. 33-54]), a tumor of the nail matrix is the most important consideration. The location in the matrix can be inferred from the location of the pigment in the nail plate when viewed end-on. Dorsal nail-plate pigmentation results from a proximal matrix lesion. Ventral nail-plate pigmentation is the result of a lesion in the distal matrix.

Tosti et al studied 100 white adult patients with a single band of longitudinal melanonychia of unknown cause. Biopsies revealed melanocytic hyperplasia in 65, nevi in 22, melanocytic activation in 8, and melanoma in 5. Whereas they were unable to ascertain any clear clinical criteria that would exclude melanoma, they recommended a biopsy of any adult with the appearance of a longitudinal band of pigment in only one nail without a clear relation to a definite cause. Other reasons to biopsy include a band that has a triangular shape (one that is wider at the proximal part compared with the distal part), a blurred lateral border of the band, a lack of homogeneity of the pigmentations (bands or lines of different color), or pigmentation of the periungual skin (Hutchinson's sign). The latter is not pathognomonic, however, as Bowen's disease may produce this appearance, and pigmentation of the nail matrix and proximal nailbed may reflect through the nailfold (pseudo-Hutchinson's sign). Finally, dermoscopic features that suggest melanoma are a brown coloration of the background and the presence of irregular coloration, spacing, or thickness of longitudinal lines or disruption of their parallelism. Retracting the proximal nailfold to expose the origin of the streak at the

matrix allows selection of the best biopsy site. The recommended biopsy is one that includes the whole lesion; this may be accomplished by the tangential matrix excision, which may leave minimal scarring in some cases, or more certainly this is accomplished by longitudinal excision.

Recommendations for prepubertal children, however, are different. Longitudinal melanonychia that appears in children is usually benign in nature, and it is recommended that since an ungual melanocytic band can appear at an age when other nevi appear, the majority can be followed. If the lesion is alarming in its appearance, especially if it is widening or darkening, sampling the whole lesion via tangential matrix or longitudinal excision is, however, necessary.

Green nails

When onycholysis is present, a green discoloration may occur in the onycholytic area as a result of an infection with *Pseudomonas aeruginosa* (see Chapter 14). The color change may also occur as transverse green stripes. The stripes are ascribed to intermittent episodes of infection. Green nails may also result from copper in tap water.

Hengge UR, et al: Green nails. *N Engl J Med* 2009; 360:1125.

Staining of the nail plate

Nicotine, dyes (including hair dyes and nail polish), potassium permanganate, mercury compounds, hydroquinone, elemental iron, mepacrine, photographic developer, anthralin, chrysa-robin, glutaraldehyde, or resorcin may cause nail-plate staining. This is only a partial list; a complete listing is given in the article by Jeanmougin et al. A helpful diagnostic maneuver to distinguish nail-plate staining from exogenous sources and nail-plate pigmentation from melanin or endogenous chemicals is to scrape the surface of the nail plate several times firmly with a glass slide or scalpel blade. Exogenous stains frequently scrape off completely if the agent has not penetrated the entire nail plate. If the stain follows the curvature of the lunulae, it is probably endogenous; if it follows the curvature of the proximal and lateral nailfolds, it is exogenous.

Coulson IH: "Fade out" photochromonychia. *Clin Exp Dermatol* 1993; 18:87.

Jeanmougin M, et al: Nail dyschromia. *Int J Dermatol* 1983; 22:279.

Red lunulae

Dusky erythema confined to the lunulae has been reported in association with alopecia areata. Twenty percent of patients with SLE have been reported to have this abnormality. It may

also be seen in patients on oral prednisone for severe rheumatoid arthritis or dermatomyositis, in cardiac failure, cirrhosis, lymphogranuloma venereum, psoriasis, vitiligo, chronic urticaria, lichen sclerosus et atrophicus, CO₂ poisoning, chronic obstructive pulmonary disease, twenty-nail dystrophy, and reticulosarcoma. The cause may be vascular congestion.

Cohen PR: Red lunulae: case report and literature review. *J Am Acad Dermatol* 1992; 26:292.

Tunc SE, et al: Nail changes in connective tissue diseases. *J Eur Acad Dermatol Venereol* 2007; 21:497.

Spotted lunulae

This distinctive change occurs with alopecia areata.

Cohen PR: The lunula. *J Am Acad Dermatol* 1996; 34:943.

Purpura of the nail beds

Purpura beneath the nails usually results from trauma. Causes of toe involvement include physical pressure on the toes, such as that seen in surfing caused by a windsurfer trying to maintain his/her balance, or exogenous pressure exerted from poorly fitting shoes. It may simulate a melanoma if the patient does not communicate the acuteness at onset.

Adams BB: Dermatologic disorders of athletes. *Sports Med* 2002; 32:309.

Blue nails

A blue discoloration of the lunulae is seen in argyria and cases of hepatolenticular degeneration (Wilson's disease). The blue color in the latter is probably related to the changes in copper metabolism by the patient. It has also been reported in hemoglobin M disease and hereditary acrolabial telangiectases. Lunular blue color, as well as blue discoloration of the whole nailbed, occurs with some therapeutic agents, especially 5-FU, minocycline, imipramine, mepacrine and other antimalarials, hydroxyurea, phenolphthalein, and azidothymidine. Blue discoloration may also result from subungual hematoma, blue nevi, and melanotic whitlow. Blue nails are a normal variant finding in Black people.

Yellow nail syndrome

The yellow nail syndrome is characterized by marked thickening and yellow to yellowish-green discoloration of the nails often associated with systemic disease, most commonly lymphedema and compromised respiration. The nails are typically overcurved both transversely and longitudinally, grow very slowly (less than 0.2 mm/week), are often subject to onycholysis, and lose both lunulae and cuticles (Fig. 33-55). Lymphedema, pleural effusions, chronic pulmonary infections, and chronic sinusitis most commonly precede the nail changes. Other less frequently associated conditions include autoimmune disorders, immunodeficiency states, the use of gold or d-penicillamine, and malignancies. In the latter cases, treatment of the underlying lymphoma or solid tissue tumor has resulted in improvement of the nail findings. Individual

Fig. 33-55 Yellow nail syndrome.

clinical responses have been seen with oral zinc or 800 IU/day of d- α -tocopherol alone or in combination with itraconazole. While approximately 30–50% of patients experience spontaneous improvement in the condition of their nails, fluconazole taken in combination with vitamin E cured or improved all 13 patients treated by Baran et al.

Neoplasms of the nailbed

Various benign and malignant neoplasms may occur in or overlying the nail matrix and in the nailbed. Signs heralding such neoplasms are paronychia, ingrown nail, onycholysis, pyogenic granuloma, nail-plate dystrophy, longitudinal erythronychia, bleeding, and discolorations. Symptoms of pain, itching, and throbbing may also occur with various neoplasms.

Benign tumors of the nails include verruca, pyogenic granuloma, fibromas, nevus cell nevi, myxoid cysts, angiofibromas (Koenen tumors), onychopapillomas, and epidermoid cysts. Pyogenic granuloma-like lesions may occur during treatment with isotretinoin, lamivudine, indinavir, or the epidermal growth factor receptor inhibitor family of drugs. Glomangioma is readily recognized by exquisite tenderness in the nailbed. Enchondroma of the distal phalanx often presents as a paronychia. Subungual exostoses may also present as an inflammatory process, but more commonly resemble a verruca at the start. Most of these are on the great toe, and radiographic evaluation will aid in the diagnosis of these last two entities. Onychopapillomas are benign tumors of the nail bed which usually present as longitudinal erythronychia. Tender swelling of the distal finger with nail distortion and radiographic evidence of solitary lytic changes can be caused by intraosseous epidermoid cysts.

Onychomatricoma is a benign tumor of the nail matrix. It presents as a yellow thickened plate growing out from under the proximal nailfold and then extending distally in a longitudinal band (Fig. 33-56). There is an increased transverse curvature of the nail and splinter hemorrhages often are seen in the proximal nail. Uncommonly, it can appear as a cutaneous horn emanating from the proximal nailfold, with dorsal

Fig. 33-56 Onychomatricoma.

Fig. 33-57 Bowen's disease.

pterygium formation. Biopsy at the matrix origin will permit diagnosis.

Bowen's disease and squamous cell carcinoma of the nailbed are uncommon. Radiographs may reveal lytic changes in the distal phalanx. Metastases are rare. Mohs surgery is the treatment of choice. When they occur on more than one digit, they are proven to be secondary to HPV infection. Bowen's disease may be pigmental (Fig. 33-57). When keratoacanthoma occurs, there is often lysis of underlying bone, which fills in after excision of the tumor. Basal cell carcinoma may occur, but is uncommon in this location.

Subungual melanoma (Fig. 33-58) is frequently diagnosed late in the course of growth, since it simulates onychomycosis or subungual hematoma, with which it is confused. Amelanotic melanoma may occur and may be mistaken for granuloma pyogenicum. Although melanoma is rare among Japanese, periungual and subungual melanoma is more frequently found in Japanese than in other ethnic populations. Discussion of melanoma in this location may be found in Chapter 30 and in the melanonychia section of this chapter.

Onycholemmal carcinoma is a slowly growing malignant tumor of the nail bed epithelium. It is composed of small cysts filled with eosinophilic amorphous keratin. The cyst wall is lined with atypical keratinocytes. No granular layer is seen. Also solid nests and strands of atypical keratinocytes fill the dermis and may invade the bone. Mohs excision or even disarticulation of the digit may be necessary.

Fig. 33-58 Subungual melanoma.

Evaluation of these masses may be carried out by plain x-ray, looking for bone lysis or other changes. MRI by both T1-weighted spin-echo images and turbo spin-echo T2-weighted images may offer excellent diagnostic information about these tumors as well.

Disorders of the Mucous Membranes

34

Lesions on the mucous membranes may be more difficult to diagnose than lesions on the skin, and not merely because they are less easily and less often seen. There is less contrast of color and greater likelihood of alterations in the original appearance because of secondary factors, such as maceration from moisture, abrasion from food and teeth, and infection. Vesicles and bullae rapidly rupture to form grayish erosions, and the epithelium covering papules becomes a soggy lactescent membrane, easily rubbed off to form an erosion. Grouping and distribution are less distinctive in the mouth than on the skin, and not infrequently it is necessary to establish the diagnosis by observing the character of any associated cutaneous lesions or by noting subsequent developments.

Cheilitis

Cheilitis exfoliativa

The term cheilitis exfoliativa has been used to designate a primarily desquamative, mildly inflammatory condition of the lips, of unknown cause, and also a clinically similar reaction secondary to other disease states. The former is a persistently recurring lesion that produces scaling and sometimes crusting; it most often affects the upper lip. The recurrent exfoliation leaves a temporarily erythematous and tender surface.

In the latter form, the lips are chronically inflamed and covered with crusts that from time to time tend to desquamate, leaving a glazed surface on which new crusts form. Fissures may be present, and there may be burning, tenderness, and some pain. The lower lip is more often involved, with the inflammation limited to the vermilion part. The cheilitis may be secondary to seborrheic dermatitis, atopic dermatitis, psoriasis, retinoid therapy, pyorrhea, long-term actinic exposure, or the habit of lip-licking (Fig. 34-1). Uncommonly, the initial or only manifestation of atopic dermatitis may be a chronic cheilitis. Irritating or allergenic substances in lipsticks, dentifrices, and mouthwashes may be causative factors. Dyes in lipsticks may photosensitize. Candidiasis may be present. Cheilitis may be part of the Plummer-Vinson syndrome or Sjögren syndrome. Cheilitis is not uncommon in patients with acquired immune deficiency syndrome (AIDS), and it is a known common complication of protease inhibitor therapy. These and other uncommon causes of cheilitis are discussed in more detail within the specific entities.

The only uniformly effective treatment is the elimination of causes when they can be found. Topical tacrolimus ointment, pimecrolimus cream, or low-strength corticosteroid ointments and creams are usually helpful. If the underlying etiology is determined, specific therapy may be instituted. When there are fissures, petrolatum or zinc oxide ointment may be useful.

Allergic contact cheilitis

The vermilion border of the lips is much more likely to develop allergic contact sensitivity reactions than is the oral mucosa. Allergic cheilitis is characterized by dryness, fissuring, edema, crusting, and angular cheilitis. Over 90% of patients are women and over half of the reactions are due to lipsticks. While patch testing with standard allergens will reveal a relevant positive in approximately 25–30% of patients, about 1 in 5 will only react to their own product. It may result from use of topical medications, dentifrices and other dental preparations, anti-chap agents, lipsticks, and sunscreen-containing lip balms; from contact with cosmetics, nail polish, rubber, and metals; or from eating foods such as mangoes. Fragrance and nickel are the most commonly identified individual sensitizers.

Treatment includes discontinuation of exposure to the offending agent and administration of topical tacrolimus, pimecrolimus, or corticosteroid preparations.

Actinic cheilitis

Actinic cheilitis is an inflammatory reaction of the lips to chronic excessive sunlight exposure over many years. The lower lip, which is usually the only one involved, becomes

Fig. 34-1 Cheilitis secondary to lip-licking.

Fig. 34-2 Actinic cheilitis.

scaly, fissured, atrophic, and at times eroded and swollen; leukoplakia and even squamous cell carcinoma may develop (Fig. 34-2). Painful erosions may occur; actual ulceration is very rare unless carcinoma has developed. Hereditary polymorphous light eruption can resemble chronic actinic cheilitis, but it has no malignant potential.

Avoiding sun exposure and the use of sunscreen containing lip pomades suffice to minimize further damage. A biopsy should be performed on any suspicious, thickened areas that persist; preferably, a shave technique should be used to avoid scarring.

Cryosurgical treatment may be effective, particularly for localized lesions. In cases with diffuse involvement, application of topical 5-fluorouracil (5-FU), imiquimod, or photodynamic therapy may be curative. Treatment with a CO₂ or Er:YAG laser, dermabrasion, or electrodesiccation may be required for severe disease and provides excellent results. Long-term follow-up is necessary; one study of 43 patients showed that 15% of CO₂-treated lesions developed squamous cell carcinoma over an average follow-up time of 29 months. Should treatment fail, vermilionectomy of the lower lip may be necessary. Excision of the exposed vermilion mucous membrane with advancement of the labial mucosa to the skin edge of the outer lip is effective, but this is performed less frequently since the advent of laser therapy. Refer to Chapter 29 for more information on actinic cheilitis.

Cheilitis glandularis

Cheilitis glandularis is characterized by swelling and eversion of the lower lip, patulous openings of the ducts of the mucous glands, cysts, and general enlargement of the lips (Fig. 34-3). Mucus exudes freely to form a gluey film that dries over the lips and causes them to stick together during the night. When the lip is palpated between the thumb and index finger, the enlarged mucous glands feel like pebbles beneath the surface. The lower lip is the site of predilection.

In general, two types are recognized: cheilitis glandularis simplex and cheilitis glandularis apostematosa. (Apostematosa means "with abscess formation.") The latter type probably stems from the simplex form by the development of infection. Cheilitis glandularis is a chronic inflammatory reaction that is due to an exuberant response to chronic irritation, or to atopic, factitious, or actinic damage.

On biopsy, there is a moderate histiocytic, lymphocytic, and plasmacytic infiltration in and around the glands. Some believe it to be a disorder of ductal ectasia. Cheilitis glandularis has been reported to eventuate in squamous cell carcinoma, but these cases may be attributed to chronic sun exposure, which frequently precedes cheilitis glandularis.

Treatment depends on the nature of the antecedent irritation; in most cases, treatment as described for actinic cheilitis is appropriate. Surgical debulking may be necessary. Intralesional triamcinolone may be beneficial in some cases, as may the combination of minocycline and tacrolimus ointment.

Angular cheilitis

Angular cheilitis is synonymous with perleche. Fissures radiate downward and outward from the labial commissures. It is an intertriginous dermatitis caused by excessive wetness or dryness. It is often complicated by secondary infection with *Candida albicans* or *Staphylococcus aureus*.

The disease usually occurs in elderly people who wear dentures, but it may develop simply from an overhanging of the upper lip and cheek, and recession and atrophy of the alveolar ridges in old age. Measuring the facial dimensions with a ruler and tongue blade will help with objective assessment of the importance of decreased vertical facial dimension in the development of perleche. If the distance from the base of the nose to the lower edge of the mandible is greater than or equal to 6 mm less than the distance from the center of the pupil to the parting line of the lips, the vertical dimension is decreased. In these circumstances, drooling is usually a factor. In children, angular cheilitis occurs commonly in thumb suckers, gum chewers, and lollipop eaters. Other inciting factors include riboflavin deficiency, anorexia nervosa, Down syndrome, intraoral candidiasis, especially in patients with diabetes, AIDS, chronic mucocutaneous candidiasis, Sjögren syndrome, orthodontic treatment, drug-induced xerostomia, and atopic dermatitis.

Opening the "bite" by improving denture fit, capping teeth, replacing lost teeth, or increasing denture height, combined with topical use of nystatin and iodochlorhydroxyquin in hydrocortisone ointment, is usually effective when the condition is associated with anatomically predisposing factors. Stubborn cases typically respond to a slightly stronger corticosteroid, such as desonide, in combination with a topical anticandidal agent. Injection of collagen or insertion of Softform implants to obliterate the angular creases may be beneficial. Therapy for underlying diseases should be maximized. If *S. aureus* is present, mupirocin ointment may be needed. Excision of the region, followed by a rotating flap graft, is another therapeutic option, but surgery should be reserved for resistant cases.

Plasma cell cheilitis

This is also referred to as plasma cell orificial mucositis or, when the gingival is the site of involvement, plasma cell gingivitis. It is characterized by a sharply outlined, infiltrated, dark red plaque with a lacquer-like glazing of the surface of the involved area.

This lesion has the same microscopic features as Zoon balanitis plasmacellularis. There is plasma cell infiltration in a bandlike pattern. Plasma cell cheilitis is not a response that is specific for any stimulus but rather represents a reaction pattern to any one of a variety of stimuli. Successful therapies include application of topical tacrolimus ointment or clobetasol propionate ointment twice a day.

Plasmoacanthoma

Plasma cell cheilitis and plasmoacanthoma have been reported in the same patient and are believed to represent a spectrum

Fig. 34-4 Fixed drug eruption.

of the same disease. Plasmoacanthoma is a verrucous tumor with a plasma cell infiltrate involving the oral mucosa, particularly along the angles. Other locations may occur, such as the perianal, periumbilical, or inguinal areas and toe webs. *C. albicans* has been found within the tissue, suggesting that it may be implicated as a cause of this disease. Excision, destruction, anticandidal preparations, and intralesional steroids are all options for treatment.

Drug-induced ulcer of the lip

Painful or tender, well-defined ulcerations without induration on the lower lip may heal after withdrawal of oral medications. The causative drugs may be phenylbutazone, chlorpromazine, phenobarbital, methyldopa, or thiazide diuretics.

Solar exposure appears to be a predisposing causative influence; in some cases this reaction may represent a fixed drug photoeruption. On rare occasions, fixed drug eruptions may also involve the lip; usually the culprit is naproxen, one of the oxicams, or trimethoprim-sulfamethoxazole (Fig. 34-4).

Pemberton MN, et al: Fixed drug eruption to oxybutynin. *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 2008; 106:e19.

Other forms of cheilitis

Several diseases discussed elsewhere may affect the lips, including lichen planus, lupus erythematosus, atopic dermatitis, and psoriasis. A high percentage of patients with Down syndrome have cheilitis of one or both lips. Lip-biting may be a factor.

Oral and cutaneous Crohn's disease

Crohn's disease is a chronic granulomatous disease of any part or parts of the bowel, to which the names terminal ileitis, regional enteritis, and granulomatous colitis have also been given. Patients with Crohn's disease may develop inflammatory hyperplasia of the oral mucosa, with metallic dysgeusia and gingival bleeding. Reported typical changes include diffuse oral swelling, focal mucosal hypertrophy and fissuring (cobble-stoning), persistent ulceration, polypoid

lesions, indurated fissuring of the lower lip, angular cheilitis, granulomatous cheilitis, or pyostomatitis vegetans. Oral involvement occurs in 10–20% of cases of Crohn's disease, and 90% have granulomas on biopsy. Males with early-onset disease are most often affected. Concomitant involvement of the anal and esophageal mucosa is common.

Many cases of Crohn's disease with other cutaneous manifestations have been reported, notably pyoderma gangrenosum (more closely associated with ulcerative colitis) and erythema nodosum, polyarteritis nodosa, pellagra, pernicious anemia, an acrodermatitis-like eruption, urticaria, and necrotizing vasculitis. Direct extension to perianal skin may occur.

Metastatic Crohn's disease denotes noncaseating granulomatous skin lesions in patients with Crohn's disease. In the absence of bowel involvement, the diagnosis cannot be made. Genital swelling or condyloma-like lesions, leg ulceration, pyogenic granuloma-like lesions of the retroauricular skin, or erythematous nodules, plaques, or ulcers in other locations are the morphologic appearances seen.

Treatment of the gastrointestinal manifestations with sulfasalazine, metronidazole, systemic corticosteroids, infliximab, or immunosuppressive medications such as cyclosporine, azathioprine, mycophenolate mofetil, and methotrexate can improve the cutaneous findings. Several delivery systems use only the active ingredient of sulfasalazine, mesalamine. These include Asacol, Pentasa, Rowasa, and olsalazine, and they may be useful in treating the skin involvement of Crohn's disease. A mouthwash containing triamcinolone acetonide, tetracycline, and lidocaine may provide symptomatic and objective improvement. Cutaneous ulcerated granulomas and erythematous plaques caused by Crohn's disease may respond to high-potency topical corticosteroids or tacrolimus ointment. Curettage and zinc by mouth have resulted in healing in several reported patients. Dietary manipulation is another measure that can be helpful in select individuals. The course is often prolonged over several years.

Pyostomatitis vegetans

Pyostomatitis vegetans, an inflammatory stomatitis, is most often seen in association with ulcerative colitis but may also occur in other inflammatory bowel diseases, such as Crohn's disease. Edema and erythema with deep folding of the buccal mucosa characterize it, together with pustules, small vegetating projections, erosions, ulcers, and fibrinopurulent exudates (Fig. 34-5). Eroded pustules fuse into shallow ulcers, resulting in characteristic "snail-track" ulcers. It has also been associated with sclerosing cholangitis. Several cases have been reported without any underlying systemic disorder.

Fig. 34-5 Pyostomatitis vegetans. (Courtesy of Charles Casima, MD)

Histologically, there are dense aggregates of neutrophils and eosinophils. At times, crusted erythematous papulopustules that coalesce into asymmetrical annular plaques may occur with or after the oral lesions. These associated skin lesions favor the axilla, groin, and scalp, and are termed pyodermitis vegetans. Topical corticosteroids or tacrolimus ointment may be effective; systemic steroids or infliximab, however, are usually necessary.

Cheilitis granulomatosa

Cheilitis granulomatosa is characterized by a sudden onset and progressive course, terminating in chronic enlargement of the lips. Usually, the upper lip becomes swollen first; several months may elapse before the lower lip becomes swollen. Usually only enlargement is present, without ulceration, fissuring, or scaling. The swelling remains permanently. It may be a part of the Melkersson-Rosenthal syndrome when associated with facial paralysis and plicated tongue.

The cause is unknown. Histologically, it is characterized by an inflammatory reaction of lymphocytes, histiocytes, and plasma cells, and by tuberculoid granulomas consisting of epithelioid and Langerhans giant cells. In the differential diagnosis, solid edema, angioedema, cheilitis glandularis, sarcoidosis, oral Crohn's disease, infectious granulomas, contact allergy and Ascher syndrome must be considered. This may be the presenting sign in a patient who will develop Crohn's disease or sarcoidosis at a later time.

Treatment with intralesional injections of corticosteroids is sometimes successful. In the firmly established case, surgical repair of the involved lip through a mucosal approach and, in some cases, concomitant intralesional steroid treatment give best results. Other anecdotally effective medications include tetracyclines, roxithromycin, hydroxychloroquine, clofazimine, and sulfasalazine.

Melkersson–Rosenthal syndrome

Melkersson in 1928 and Rosenthal in 1930 described a triad consisting of recurring facial paralysis or paresis, soft nonpitting edema of the lips, and scrotal tongue. Attacks usually start during adolescence, with permanent or transitory paralysis of one or both facial nerves, repeated migraines, and recurring edema of the upper lip, cheeks, and occasionally the lower lip and circumoral tissues. Swelling of the skin and mucous membranes of the face and mouth is the dominant finding and most important diagnostic feature (Fig. 34-6). In order of frequency, the swelling occurs first on the upper lip, then the lower lip, and then other regions. Chronic eyelid swelling may occur.

Extrafacial swellings appear on the dorsal aspect of the hands and feet, and in the lumbar region. The pharynx and respiratory tract may be involved, with thickening of the mucous membrane. The relapsing condition produces an overgrowth of connective tissue, edema, and atrophy of the muscle fibers, with permanent deformities of the lips, cheeks, and tongue.

The cause is unknown. The association at times with megacolon, otosclerosis, and craniopharyngioma supports the theory of a neurotrophic origin. It may be familial.

Histopathologic evaluation shows a tuberculoid type of granuloma with lymphedema and a banal perivascular infiltrate. In the differential diagnosis, a number of diseases characterized by edema of the lips must be considered. Ascher syndrome consists of swelling of the lips with edema of the eyelids (blepharochalasis) and is inherited. Melkersson–Rosenthal syndrome must also be differentiated from the acute swellings produced by angioedema, trauma, and infections of all sorts. Lymphangioma, hemangioma, neurofibroma, and sarcoidosis are some of the diseases to be considered on a clinical basis.

Melkersson–Rosenthal syndrome is frequently seen in an incomplete form, and other granulomatous diseases may present as swellings of the lips or oral–facial tissues. It is worthwhile considering these as a group called orofacial granulomatosis so that various underlying disease states or etiologic factors will not be missed when evaluating such patients. Oral Crohn’s disease, patients who will develop typical

Fig. 34-6 Melkersson–Rosenthal syndrome. (Courtesy of Curt Samlaska, MD)

Crohn’s or sarcoidosis in the future, cheilitis granulomatosa, sarcoidosis, granulomatous infiltrates associated with tooth infections, and patients with food or contact allergic reactions should all be considered.

There is no satisfactory treatment, although intralesional injections of corticosteroids may be beneficial. Decompression of the facial nerve may be indicated in those patients with recurrent attacks of facial palsy. Surgery alone or combined with intralesional steroid injections may be more successful than either alone. Odontogenic infection has been reported to initiate this condition and antibiotic therapy for this may lead to remission. Clofazimine, thalidomide, and prednisone combined with minocycline or tetracycline have been reported to improve individual patients.

Fordyce’s disease (Fordyce spots)

Fordyce spots are ectopically located sebaceous glands, clinically characterized by minute orange or yellowish pinhead-sized macules or papules in the mucosa of the lips, cheeks, and, less often, the gums. Similar lesions may occur on the areola, glans penis, and labia minora. Prominent lip involvement may result in a lipstick-like mark left on the rim of a glass mug after consuming a hot beverage (Meffert’s sign). Involvement of the labial mucosa with pseudoxanthoma elasticum may simulate Fordyce spots.

Because the anomaly is asymptomatic and inconsequential, treatment should be undertaken only if there is a significant cosmetic problem. The CO₂ laser, electrodesiccation and curettage, bichloroacetic acid, photodynamic therapy, and isotretinoin are therapeutic options.

Stomatitis nicotina

Also known as smoker’s keratosis and smoker’s patches, stomatitis nicotina is characterized by distinct umbilicated papules on the palate. The ostia of the mucous ducts appear as red pinpoints surrounded by milky white, slightly umbilicated asymptomatic papules. The intervening mucosa becomes white and thick and has a tendency to desquamate in places, leaving raw, beefy-red areas. Ulceration and the formation of aphthous ulcers may occur.

This condition is attributed to heavy smoking in middle-aged men, although it has also been reported in nonsmokers who habitually drink hot beverages. Heat may be the causative event. Indeed, the most severe cases are associated with the type of tobacco use that produces intense heat—pipe and reverse smoking.

Treatment consists of abstaining from the use of tobacco or ingestion of hot liquids.

Taybos G: Oral changes associated with tobacco use. *Am J Med Sci* 2003; 326:179.

Torus palatinus

Torus palatinus is a bony protuberance in the midline of the hard palate, marking the point of junction of the two halves of the palate. It is asymptomatic. Exostoses also commonly occur in the floor of the mouth, involving the inner surface of the mandible.

Piera-Navarro N, et al: Clinical evaluation of hard tissue proliferations of the mouth. *Med Oral* 2002; 7:97.

Tran KT, et al: Torus palatinus. *N Engl J Med* 2007; 356:1759.

Fissured tongue

Also known as furrowed tongue, scrotal tongue, or lingua plicata, fissured tongue is a congenital and sometimes familial condition in which the tongue is generally larger than normal and there are plicate superficial or deep grooves, usually arranged so that there is a longitudinal furrow along the median raphe, reminiscent of scrotal rugae (Fig. 34-7).

Fissured tongue is seen in Melkersson-Rosenthal syndrome and in many patients with Down syndrome. Individual case reports have been seen in association with pachyonychia congenita, pemphigus vegetans, and Cowden syndrome. Geographic tongue occurs together with fissured tongue in 50% of patients, and both are more commonly present in psoriasis patients than nonpsoriatics.

The condition gives rise to no difficulty, and treatment is not necessary, except that the deep furrows should be kept clean by use of mouthwashes. Herpetic geometric glossitis may mimic fissured tongue, but is painful, affects predominately immunocompromised individuals, and is centered on the back of the dorsal tongue.

Fig. 34-7 Fissured tongue.

Geographic tongue

Geographic tongue is also known as lingua geographica, transitory benign plaques of the tongue, glossitis areata exfoliativa, and benign migratory glossitis. In some patients it is a manifestation of atopy, and in others, of psoriasis. However, in most it is an isolated finding.

The dorsal surface of the tongue is the site usually affected. Geographic tongue begins with a small depression on the lateral border or the tip of the tongue, smoother and redder than the rest of the surface. This spreads peripherally, with the formation of sharply circumscribed ringed or gyrate red patches, each with a narrow yellowish-white border, making the tongue resemble a map. The appearance changes from day to day; patches may disappear in one place and manifest themselves in others. The disease is characterized by periods of exacerbation and quiescence. The lesion may remain unchanged in the same site for long periods. The condition is frequently unrecognized because it produces no symptoms except for the occasional complaint of glossodynia.

There are two clinical variants of geographic tongue. In one type, discrete, annular "bald" patches of glistening, erythematous mucosa with absent or atrophic filiform papillae are noted. Another type shows prominent circinate or annular white raised lines that vary in width up to 2 mm. The clinical appearance and histopathologic findings of the tongue lesions in pustular psoriasis, reactive arthritis (Reiter syndrome), and geographic tongue are identical; when the tongue lesions occur with psoriasis or reactive arthritis, the name annulus migrans has been suggested for this entity (Fig. 34-8). It has been reported as being acquired in patients with AIDS or as a result of lithium therapy.

Histologically, the main features are marked transepidermal neutrophil migration with the formation of spongiform pustules in the epidermis and an upper dermal mononuclear infiltrate.

Although treatment is not usually necessary, a 0.1% solution of tretinoin solution (Retin-A) applied topically has produced clearing within 4–6 days.

Fig. 34-8 Annulus migrans.

Fig. 34-9 Black hairy tongue.

Black hairy tongue

Black or brown hairy tongue occurs on the dorsum of the tongue anterior to the circumvallate papillae, where black, yellowish, or brown patches form, consisting of hairlike intertwining filaments several millimeters long (Fig. 34-9). The “hairs” result from a benign hyperplasia of the filiform papillae of the anterior two-thirds of the tongue, resulting in retention of long conical filaments of orthokeratotic and parakeratotic cells. It occurs far more frequently in men than in women.

Black hairy tongue may be associated with several conditions that may be predisposing factors in its causation: smoking, use of oral antibiotics, psychotropic drugs, and presence of *Candida* on the surface of the tongue.

This lesion may be differentiated both clinically and histologically from oral hairy leukoplakia, which is seen in human immunodeficiency syndrome (HIV)-infected patients. Hairy leukoplakia is usually seen on the lateral surface of the tongue at first in corrugated patches, then with time as solid white plaques that are adherent. Microscopic examination reveals acanthosis, parakeratosis, irregular projections of keratin, and vacuolated keratinocytes with Epstein-Barr virus present within them.

A toothbrush may be used to scrub off the projections, either alone, with 1–2% hydrogen peroxide, or after application of Retin-A gel, 40% aqueous solution of urea, or papain (meat tenderizer). Such predisposing local factors as smoking, antibiotics, and oxidizing agents should be eliminated, if possible, and scrupulous oral hygiene should be maintained.

Smooth tongue

Also known as bald tongue or atrophic glossitis, the smooth glossy tongue is often painful and results from atrophy of the filiform and eventually the fungiform papillae (Fig. 34-10). When present with vitamin B₁₂ deficiency, it has been termed Moeller or Hunter glossitis. It begins with the tip and lateral surfaces of the tongue becoming intensely red, well-defined irregular patches in which the filiform papillae are absent or thinned and the fungiform papillae are swollen. The disease is chronic and the patches are painful and sensitive so that eating may be difficult and taste impaired. With time, the entire tongue becomes smooth and a leukoplakia may result. Treatment of pernicious anemia with vitamin B₁₂ therapy will

Fig. 34-10 Smooth tongue in Plummer-Vinson syndrome.

result in improvements in the appearance and sensitivity of the tongue.

Atrophic glossitis is also a distinctive sign of pellagra; it results from a deficiency of niacin or its precursor, tryptophan. The sides and tip of the tongue are erythematous and edematous, with imprints of the teeth. Eventually, the entire tongue assumes a beefy-red appearance. Small ulcers appear, and all the mucous membranes of the mouth may be involved. Later, the papillae become atrophied to produce a smooth, glazed tongue, as seen in pernicious anemia. Burning or pain in the ulcers may be present. Increased salivary flow early in the disease may lead to drooling and angular cheilitis. In malabsorption syndrome, riboflavin deficiency, anorexia nervosa, alcoholism, and sprue, similar changes may be noted. Vitamin B complex is curative.

Patients with iron-deficiency anemia, alone or when combined with esophageal webs (Plummer-Vinson syndrome), folic acid deficiency, syphilis, amyloidosis, celiac disease, Sjögren syndrome, and Riley-Day syndrome, may all manifest smooth tongue. Candidiasis may result in tongue pain and a partial or total atrophic appearance, along with a red or magenta color, on the dorsum of the tongue. In such cases, anticandidal therapy results in rapid improvement.

Eruptive lingual papillitis

Lacour and Perrin first described this acute, self-limiting inflammatory stomatitis in 1997. It affects children of both sexes equally, with a mean age of onset of 3½ years. It has a seasonal distribution, with the majority of cases occurring in the spring. Fever (40%), difficulties in feeding (100%), and intense salivation (60%) are common symptoms. The tongue

Fig. 34-11 Eruptive lingual papillitis.

examination reveals inflammatory hypertrophy of the fungiform papillae on the tip and dorsolateral sites (Fig. 34-11). Additional signs include submandibular or cervical adenopathy (40%) and angular cheilitis (10%). Associated skin eruptions have not been described. Spontaneous involution occurs in a mean of 7 days with a range of 2–15 days. Recurrence is noted in 13%. It is felt to be the result of a viral infection, and the 50% transmission among family members further supports this theory.

Median rhomboid glossitis

Median rhomboid glossitis is characterized by a shiny oval or diamond-shaped elevation, invariably situated on the dorsum in the midline immediately in front of the circumvallate papillae (Fig. 34-12). The surface is abnormally red and smooth. In some instances, a few pale yellow papules surmount the elevation. On palpation the lesion feels slightly firm, but it usually causes no symptoms. It persists indefinitely, with little or no increase in size. There is no relationship to cancer. One report noted its presence a patient with pachyonychia congenita.

It may result from abnormal fusion of the posterior portion of the tongue, but it is nearly always chronically infected with *Candida*. If there is palatal inflammation above the inflamed part of the tongue, AIDS should be suspected and an HIV test obtained. Histologically, the changes are those of a simple, chronic inflammation with fibrosis, and usually with fungal hyphae in the parakeratin layer. Treatment with oral antifungals, such as itraconazole, may lead to improvement.

Fig. 34-12 Median rhomboid glossitis.

Eosinophilic ulcer of the oral mucosa

Eosinophilic ulcer occurs most commonly on the tongue, but may occur anywhere in the oral mucosa. It is characterized by an ulcer with indurated and elevated borders that is usually covered by a pseudomembrane. It develops rapidly, most commonly on the posterior aspect of the tongue, and spontaneously resolves in a few weeks. A traumatic cause has been postulated for this benign, self-limited disorder. The histopathologic findings show a predominantly eosinophilic infiltrate in company with some histiocytes and neutrophils.

In some multifocal, recurrent cases, CD30+ cells have been reported. These patients may have the oral counterpart of primary cutaneous CD30+ lymphoproliferative disease, or may simply be a simulator of this disorder. HIV-infected patients may develop ulcerations of the oral mucosa, resulting from a variety of infectious agents, such as herpes simplex virus (HSV), candidiasis, and histoplasmosis. However, 5 of the 16 patients they reported had no evidence of infection and simply showed eosinophilic infiltrates below the ulcer.

Caviar tongue

William Bean gave the picturesque name caviar tongue to the purplish venous ectasias so commonly found on the undersurface of the tongue after the age of 50. They are attributed to elastic tissue deterioration with aging and may be associated with Fordyce angiokeratomas of the scrotum. Phleboliths or thrombophlebitis may occasionally complicate this condition.

Kocsard E, et al: The histopathology of caviar tongue. *Dermatologica* 1970; 140:318.

Cutaneous sinus of dental origin (dental sinus)

In dental (or odontogenous) sinus, chronic periapical infection about a tooth produces a burrowing, practically asymptomatic,

Fig. 34-13 Odontogenic sinus.

occasionally palpable, cordlike sinus tract that eventually appears beneath the surface of the gum, palate, or periorificial skin. It forms a fistulous opening with an inflamed red nodule at the orifice. It may appear anywhere from the inner ocular canthus to the neck but is most often seen on the chin or along the jawline (Fig. 34-13). Bilateral involvement has been reported. Dental radiography is diagnostic. Pyogenic granuloma, actinomycosis, squamous cell carcinoma, osteomyelitis of the mandible, congenital fistulas, the deep mycoses, bisphosphonate-related osteonecrosis of the jaw, and foreign body reactions must be considered in the differential diagnosis.

Treatment requires the removal of the offending tooth or root canal therapy of the periapical abscess.

Neoplasms

Many tumors may involve the oral cavity. Most are discussed elsewhere in this book, and several are uncommon entities that affect specialized oral structures, such as the many subtypes of benign and malignant proliferations that occur in the major and minor salivary glands. These will not be covered further here, and only a few selected neoplasms will be presented.

Leukoplakia

Clinical features

Leukoplakia presents as a whitish thickening of the epithelium of the mucous membranes, occurring as lactescent superficial patches of various shapes and sizes that may coalesce to form diffuse sheets. The surface is generally glistening and opalescent, often reticulated, and may even be somewhat pigmented. The white pellicle is adherent to the underlying mucosa and attempts to remove it forcibly cause bleeding. At times it is a thick, rough, elevated plaque. The lips, gums, cheeks, and edges of the tongue are the most common sites, but the lesion

Fig. 34-14 Oral hairy leukoplakia of HIV.

may arise on the anus and genitalia. Leukoplakia is found chiefly in men over the age of 40.

Biopsy of these white lesions may reveal orthokeratosis or parakeratosis with minimal inflammation, or there may be evidence of varying degrees of dysplasia. There is a benign form that is usually a response to chronic irritation and that has very little chance of conversion into the precancerous dysplastic form. Premalignant leukoplakia, with atypical cells histologically, is present in only about 10–20% of leukoplakia. Unfortunately, it is not possible to predict clinically which lesions will be worrisome histologically, except that if ulceration, red areas, or erosions are scattered throughout, the lesion is most likely precancerous. Therefore, biopsy is indicated.

When the lesion occurs on the lip, leukoplakia is closely related to chronic actinic cheilitis, which consists of a circumscribed or diffuse keratosis, almost invariably on the lower lip. It is preceded by an abnormal dryness of the lip and may be caused by smoking (especially pipe smoking) or chronic sun exposure. This type of leukoplakia is distinguished from squamous cell carcinoma of the lip by the absence of infiltration, from lichen planus and psoriasis of the lips and mouth by the absence of lesions elsewhere, and from lupus erythematosus by the absence of telangiectases. Biopsy is necessary, however, to differentiate these conditions fully.

Intraoral leukoplakia appears to progress to squamous cell carcinoma in not more than 1% per year. In time, an extensive, thick, white pellicle may cover the tongue or oral mucosa. In old lesions the epithelium may be desquamated and there may be fissures or ulcerations. Such changes are associated with more or less hyperemia and tenderness, and with a tendency to bleed after slight trauma. If transformation to carcinoma occurs, it generally follows a 1 to 20-year lag time, with the exception that immunosuppressed transplant patients may have a rapid course of transformation.

Oral hairy leukoplakia is a term used to describe white, corrugated plaques that occur primarily on the sides of the tongue of patients with AIDS (Fig. 34-14). This is a virally induced lesion, discussed in Chapter 19, which has a characteristic histology.

Leukoplakia of the vulva usually occurs in obese women after menopause as grayish white, thickened, pruritic patches that may become fissured and edematous from constant rubbing and scratching. Secondary infection with edema, tenderness, and pain may occur. It is differentiated from lichen planus by the absence of discrete, rectangular, or annular flat papules of violaceous hue in the mucosa outside the thickened patches, about the anus, on the buccal mucosa, or on the skin. Leukoplakia of the vulva is most frequently confused with lichen sclerosus et atrophicus and other vulval atrophies. On

the penis, though leukoplakia may occur, a similar precancerous process called erythroplasia (of Queyrat) is usually seen instead.

Etiology

Numerous factors are involved in the cause of leukoplakia. It may develop as a result of tobacco smoking, use of smokeless tobacco, areca, qat, or betel nut chewing, reverse smoking, alcohol, poorly fitting dentures, sharp and chipped teeth, or improper oral hygiene. Extensive involvement of the lips and oral cavity with leukoplakia may exist for years without any indication of carcinoma. On the other hand, small, inflamed patches may be the site of a rapidly growing tumor, which, with relatively insignificant local infiltration, may involve the cervical lymphatics. Carcinoma in leukoplakia usually begins as a localized induration, often about a fissure, or as a warty excrescence or a small ulcer. There is a 6–10% transformation rate of intraoral leukoplakia into squamous cell carcinoma. Predictors of a higher risk of squamous cell carcinoma development include older age, female sex, nonsmokers, large size, presence on the lateral or ventral tongue, floor of the mouth, or retromolar/soft palate complex, erythroleukoplakia, and a nonhomogeneous morphology.

The degree of epithelial atypia may be considered in staging the risk of developing malignancy. Aneuploid leukoplakia has a high rate of transformation into aggressive squamous cell carcinoma, and the cancers derived from it are more likely to be lethal.

Treatment

It must be remembered that cancer develops frequently on histologically dysplastic leukoplakia, so that its complete removal should be the goal in each case—first by conservative measures, then by surgery or destruction, if necessary. The use of tobacco should be stopped, and proper dental care obtained. Fulguration, simple excision, cryotherapy, and CO₂ laser ablation are effective methods of treatment. Medical therapies that have been the subject of randomized clinical trials may lead to temporary resolution of the lesions, but relapses and adverse effects are common and there is no evidence that they prevent the transformation to malignancy.

Leukoplakia with tylosis and esophageal carcinoma

Leukoplakia associated with tylosis and esophageal carcinoma is extremely rare but may occur.

Epidermization of the lip

Relatively smooth leukokeratosis of the lower vermilion, blending evenly into the skin surface distally and having a steep, sharp, irregular proximal margin, may easily be mistaken clinically for precancerous leukoplakia. Histologically, it shows only hyperkeratosis, without parakeratosis or cellular atypia. A shallow shave excision suffices to cure it and to rule out precancerous leukoplakia; no fulguration is required.

Erythroplakia

The term erythroplakia is applied to leukoplakia that has lost (or has not developed) the thick keratin layer that makes leukoplakia white; it is the usual pattern in mucocutaneous junctions. A focal red patch with no apparent cause should be suspected of being precancerous when found on the floor of the mouth, soft palate, or buccal mucosa, or under the tongue (Fig. 34-15). Histologically, there is cellular atypia, pleomorphism, hyperchromatism, and increased mitotic figures.

Fig. 34-15 Erythroplakia.

Carcinoma in situ or invasive carcinoma is found in 90% of lesions.

Oral florid papillomatosis

Oral florid papillomatosis is a confluent papillomatosis covering the mucous membranes of the oral cavity. The distinctive picture is that of a white mass resembling a cauliflower, covering the tongue and extending on to the other portions of the mucous membranes, including the oropharynx, larynx, and trachea. Usually there is no lymphadenopathy.

The course of the disease is progressive. Many lesions eventually in squamous cell carcinoma, whereas others continue for many years, the patient dying of some intercurrent disease. Oral florid papillomatosis should be regarded as a verrucous carcinoma, which has been defined as a distinctive, slowly growing, fungating tumor representing a well-differentiated squamous cell carcinoma in which metastases occur very late or not at all. The histologic features are those of papillomatosis, acanthosis, and varying degrees of dysplasia of the epithelium, without disruption of the basement membrane. It is reasonable to expect the eventual development of epidermoid carcinoma in most patients. Esophageal involvement and keratotic papules of the extremities may occur. In the differential diagnosis, leukoplakia, proliferative verrucous leukoplakia, candidiasis, acanthosis nigricans, and condyloma acuminatum should be considered. The recommended treatment is surgical excision; however, it is often followed by recurrence and spread. Recombinant interferon- α 2a in combination with a CO₂ laser has also been used.

Proliferative verrucous leukoplakia

Proliferative verrucous leukoplakia is a slowly progressive condition that begins as multifocal sites of hyperplasia of the oral mucous membranes and proceeds to thicken and enlarge until squamous cell carcinoma results (Fig. 34-16). Women outnumber men 4:1. Initially flat, usually white patches are present, but the lesions relentlessly become warty, exophytic masses. The patches may involve the lips and chin. Seventy percent develop squamous cell carcinoma (most frequently of the palate and gingiva), with 40% of the total dying of proliferative verrucous leukoplakia-associated carcinoma. It has been irregularly associated with human papillomavirus (HPV)-16 infection, and risk factors for squamous cell carcinoma of the oral cavity are usually not present. Treatment is difficult because of the multifocal nature of the lesions. Aggressive early surgical therapy is best. Many patients develop recurrence after only a short interval. Laser treatment

Fig. 34-16 Proliferative verrucous leukoplakia, three sites of SCC: lip and twice in the palate.

Fig. 34-17 Oral squamous cell carcinoma.

or photodynamic therapy should be considered primary options.

Squamous cell carcinoma

Squamous cell carcinoma is the most common oral malignancy, comprising 2–3% of all new cancers. With nearly 30 000 yearly cases in the US, it is the tenth most common malignancy. It occurs primarily in older men. The most frequent sites are the lower lip, tongue, soft palate, and floor of the mouth (Fig. 34-17). Squamous cell carcinoma of the lip develops from actinic damage, with 95% of the cases involving the lower lip. Intraoral lesions frequently develop from leukoplakia or erythroplakia, at sites of frequent irritation, or from long-standing mucosal inflammatory disease such as ulcerative lichen planus. About 20% of oral squamous cell cancers have an associated focus of leukoplakia; these tend to be diagnosed at a less advanced stage than those where no associated leukoplakia exists. Verrucous carcinomas occur in the oral mucosa as they do on the skin. Tobacco-smoking, the use of smokeless tobacco, areca, qat, or betel nut-chewing, and reverse smoking are risk factors for the development of intraoral squamous cell carcinoma. Alcohol has not been shown to be an independent risk factor. They may also complicate xeroderma pigmentosa (the tip of the tongue), dyskeratosis congenita, dystrophic epidermolysis bullosa, erosive lichen planus, and oral submucous fibrosis. Unfortunately, the survival rate has remained at 50% for many years because

Fig. 34-18 Acquired dyskeratotic leukoplakia.

disease is often discovered late, after it has metastasized to the cervical lymph nodes. Exfoliative cytology is a practical and accurate aid to oral cancer screening.

Acquired dyskeratotic leukoplakia

James and Lupton reported a patient with acquired dyskeratotic leukoplakia, which manifested as distinctive white plaques on the palate, gingivae, and lips (Fig. 34-18). There were similar lesions of the genitalia of the patient. Histologically,

there was a unique finding of clusters of dyskeratotic cells in the prickle-cell layer in all affected sites.

Aggressive laser treatment was followed by recurrence. Use of tretinoin afforded some improvement, but the condition continues unabated after 20 years.

James WD, et al: Acquired dyskeratotic leukoplakia. *Arch Dermatol* 1988; 124:117.

White sponge nevus

The mouth, vagina, or rectum may be the site of this spongy, white overgrowth of the mucous membrane, with acanthosis, vacuolated prickle cells, and acidophilic condensations in the cytoplasm of keratinocytes, which have been shown by electron microscopy to be aggregated tonofilaments. The buccal mucosa is the most common site of involvement. There are no extramucosal lesions. Progression of the disorder generally stops at puberty. The disease is inherited as an autosomal-dominant disorder. A mutation in the mucosal keratin pair *K4* and *K13* has been identified as the inherited defect. HPV-16 DNA has been identified in some patients, the significance of which remains to be determined. Antibiotics, particularly tetracycline, may give significant improvement. A 0.25% aqueous preparation of tetracycline as a mouth rinse, 5 mL swished in the mouth for 1 min twice daily, has been successful.

Melanocytic oral lesions

A wide variety of melanocytic lesions appear on the mucous membranes. Nevi of the oral mucosa in general are very uncommon. Among the melanocytic nevi of the cellular type, the intramucosal type is the most frequent, with the compound nevus next and the junction nevus occurring only rarely. Ephelis, lentigo, blue nevus, and labial melanotic macules are other types of focal hyperpigmentation. Ephelides darken on sun exposure and are usually limited to the lower lip. The blue nevus has dendritic cells in the submucosa. Lentiginos show acanthosis of rete ridges on biopsy. Oral melanotic macules are solitary, sharply demarcated, flat, pigmented lesions that occur chiefly in young women, do not change on sun exposure, and show only acanthosis and basal-layer melanin on biopsy.

Oral melanoacanthoma is a simultaneous proliferation of keratinocytes and melanocytes. It is most commonly observed in young black patients (average age, 23) on the buccal mucosa. It seems to be a reactive process, usually following trauma and resolving spontaneously in 40% of patients.

Melanoma occurs uncommonly, mostly in older patients. It is recognized by being larger than the usual benign pigmented lesion and more irregular in shape, with a tendency to ulcerate and bleed. A peripheral areola of erythema and satellite pigmented spots may be present. There is a striking predilection for palatal (or, less often, gingival) involvement. The overall prognosis is poor (less than 5% survival at 5 years) because the lesions are usually deeply invasive by the time they are discovered. Whereas oral nevi are uncommon, biopsy of solitary pigmented oral lesions is indicated when the clinical diagnosis is uncertain. Biopsy of a pigmented tumor will occasionally reveal a squamous cell carcinoma.

Melanosis

Pigmentation of the oral cavity tends to occur most frequently in black persons. In other races, the darker the skin, the more mucosal pigmentation may be expected. Oral melanosis may occur with Albright syndrome, Peutz-Jeghers syndrome, Carney complex, Laugier-Hunziker disease, and Addison's disease, or rarely, as an idiopathic process with no associated disease.

James et al reported a patient with inflammatory acquired oral hyperpigmentation that first occurred at age 30 with numerous distinct pigmented macules, similar to those seen in Peutz-Jeghers syndrome. However, the condition progressed rapidly to a diffuse oral hyperpigmentation (Fig. 34-19). This appeared to be caused by an undefined inflammation, and slow partial resolution occurred after several years of observation.

In the differential diagnosis of oral hyperpigmentation, these other entities should be included. The amalgam tattoo is a focal, brownish-blue macule incurred from fragments of dental silver or amalgam being implanted into the gums (Fig. 34-20).

Fig. 34-19 Oral melanosis.

Fig. 34-20 Amalgam tattoo.

Heavy-metal poisoning may also induce such lesions. Bismuth, lead, and cis-platinum may produce a pigmented line along the gums near their margin. A multitude of medications will cause pigmentation. Amodiaquine, chloroquine, oral contraceptives, phenothiazines, phenolphthalein, quinacrine, quinine, thallium, tobacco, and zidovudine are among the most common of these.

Osseous choristoma of the tongue

Osseous choristoma of the tongue presents as a nodule on the dorsum of the tongue containing mature lamellar bone without osteoblastic or osteoclastic activity. This does not recur after simple excision.

Naik VR, et al: Choristoma of the base of the tongue. *Indian J Pathol Microbiol* 2009; 52:86.

Peripheral ameloblastoma

This is a neoplasm of the gingivae, which appears most often on the lower jaw. The mean age at onset is the early fifties and men outnumber women. It presents as a growing pink to red sessile or pedunculated mass. Excision is followed by recurrence in 19% of the cases, but the lesion is benign. Basal cell carcinoma can be simulated histologically.

Curran AE, et al: Peripheral desmoplastic ameloblastoma. *J Oral Maxillofac Surg* 2008; 66:820.

Vanoven BJ, et al: Peripheral ameloblastoma of the maxilla. *Am J Otolaryngol* 2008; 29:357.

Trumpeter's wart

Trumpeter's wart is a firm, fibrous, hyperkeratotic, pseudoepitheliomatous nodule on the upper lip of a trumpet player. A similar callus may grow on the lower lip of trombone players.

Gambichler T, et al: Skin conditions in instrumental musicians. *Contact Dermatitis* 2008; 58:217.

Epulis

The term epulis means any benign lesion situated on the gingiva. The majority of these are reactive processes that display varying degrees of fibrosis, inflammation, and vascular proliferation on biopsy. Giant cell epulis (peripheral giant cell granuloma) is a solitary, bluish-red, 10–20 mm tumor occurring on the gingiva between or about deciduous bicuspids and incisors. Lesions may be induced by dental implants. Similar lesions may occur in the autosomal-dominantly inherited syndrome, cherubism. Histologically, they resemble giant cell tumor of the tendon sheath.

Salum FG: Pyogenic granuloma, peripheral giant cell granuloma and peripheral ossifying fibroma. *Minerva Stomatol* 2008; 57:227.

Scarano A, et al: Peripheral giant cell granuloma associated with a dental implant. *Minerva Stomatol* 2008; 57:529.

Pyogenic granuloma

Pyogenic granuloma is an exuberant overgrowth of granulation tissue, frequently occurring in the oral cavity, most often

involving the gingiva. It may also occur on the buccal mucosa, lips, tongue, or palate. It is a red to reddish-purple, soft, nodular mass that bleeds easily and grows rapidly, but is usually not painful. When it develops during pregnancy, it is called pregnancy tumor or granuloma gravidarum. Surgical excision, pulsed dye or Nd:YAG lasers, and cryosurgery offer effective methods of treatment.

Gordon-Nunez MA, et al: Oral pyogenic granuloma. *J Oral Maxillofac Surg* 2010; 68:2185.

Jafarzadeh H: Oral pyogenic granuloma. *J Oral Sci* 2006; 48:167.

Granuloma fissuratum

Granuloma fissuratum is a circumscribed, firm, whitish, fissured, fibrous granuloma occurring in the labioalveolar fold. The lesion is discoid, smooth, and slightly raised, about 1 cm in diameter. The growth is folded like a bent coin, so that the fissure in the bend is continuous on both sides with the labioalveolar sulcus. Symptoms are slight. It is an inflammatory fibrous hyperplasia that usually results from chronic irritation caused by poorly fitting dentures. In the dental literature it is called epulis fissuratum, particularly when there is a deep cleft traversing the lesion. Treatment is by surgical extirpation, CO₂ laser ablation, or electrodesiccation after biopsy.

Bhattacharyya I: Epulis fissuratum. *Today's FDA* 2008; 20:15.

Angina bullosa haemorrhagica

The sudden appearance of one or more blood blisters of the oral mucosa characterizes this entity. There is no associated skin or systemic disease. The blisters may be recurrent, occur most often in the soft palate, and usually present in middle-aged or elderly patients. No treatment is necessary.

Sera D, et al: Angina bullosa haemorrhagica. *Eur J Dermatol* 2010; 20:509.

Yip HK: Angina bullosa haemorrhagica. *Gen Dent* 2004; 52:162.

Mucoccele

The term mucoccele refers to a lesion that occurs as a result of trauma or obstruction of the minor salivary ducts. The most common type is the mucous extravasation phenomenon, which is usually seen inside the lower lip because it is caused by trauma from biting (Fig. 34-21). The inside of the upper lip and buccal mucosa are uncommonly involved. It presents as a soft, rounded, translucent projection; it commonly has a bluish tint. The lesion varies from 2 to 10 mm in diameter. It is painless, fluctuant, and tense. Incision of it, or sometimes merely compression, releases sticky, straw-colored fluid (or bluish fluid if hemorrhage has occurred into it). Usually, the

Fig. 34-21 Mucoccele.

lesions are solitary; however, multiple superficial mucoceles have been reported to occur with graft versus host disease and lichenoid inflammation. In these cases topical steroids may help prevent recurrences.

The cause is rupture of the mucous duct, with extravasation of sialomucin into the submucosa to produce cystic spaces with inflammation. Granulation tissue formation is followed by fibrosis. Excisional biopsy will document the diagnosis and eliminate the problem. Cryotherapy and laser ablation have also been reported to be successful.

There are true mucous retention cysts where there is true obstruction of the duct leading to an epithelial-lined cavity. They are seen more in the posterior portions of the oral mucosa. A ranula (from *Rana*, the frog genus) is a mucocele of the floor of the mouth.

Two other cysts that may be present in the mouth are the parotid duct cyst, which occurs in musicians who use wind instruments (the cyst develops opposite the upper second molar on the buccal mucosa), and the dermoid cyst, which may occur on the floor of the mouth, especially in the sublingual area.

Acute necrotizing ulcerative gingivostomatitis (trench mouth, Vincent's disease)

Acute necrotizing ulcerative gingivitis (ANUG) is characterized by a rapid onset of characteristic punched-out ulcerations appearing on the interdental papillae and marginal gingivae. A dirty white pseudomembrane may cover the ulcerations. The lesions may spread rapidly and involve the buccal mucosa, lips, and tongue, as well as the tonsils, pharynx, and entire respiratory tract. The slightest pressure causes pain and bleeding. There is a characteristic foul, fetid odor that is always present. ANUG may lead to loss of attachment of the gingiva and alveolar bone (necrotizing ulcerative periodontitis).

Trench mouth begins in a nidus of necrotic tissue, which provides an anaerobic environment for the infection by fusospirochetal organisms (*Bacteroides fusiformis*) in association with *Borrelia vincentii* and other organisms. Poor dental hygiene, smoking, poor nutrition, ingestion of methylenedioxymethamphetamine (ecstasy), and immunosuppression are predisposing factors. It may be seen as a component of the oral infections and inflammatory lesions that occur in immunocompromised HIV-infected patients.

Acute herpetic gingivostomatitis, primary HSV infection, may be confused with ANUG. Young children are susceptible to this severe febrile stomatitis with lymphadenitis. It is not primarily gingival in location and does not cause necrosis of the interdental papillae. Noma is a form of fusospirochetal gangrenous stomatitis occurring in children with low resistance and poor nutrition. The onset is often triggered by measles. At the onset there is ulceration of the buccal mucosa; this rapidly assumes a gangrenous character and extends to involve the skin and bones, with resultant necrosis. It may end in the patient's death.

Treatment consists of thorough dental hygienic measures under the supervision of a dentist. Penicillin with debridement is the treatment of choice. Use of a 3% hydrogen peroxide mouthwash is also helpful.

Acatlasemia

Acatlasemia (Takahara's disease) is a rare disease in which the enzyme catalase is deficient in the liver, muscles, bone marrow, erythrocytes, and skin. There are several forms. The absence of catalase leads to progressive gangrene of the mouth, with recurrent ulcerations resulting from increased susceptibility to infection by anaerobic organisms.

Nearly 60% of affected individuals develop alveolar ulcerations, beginning in childhood. The mild type of the disease is characterized by rapidly recurring ulcers. In the moderate type, alveolar gangrene develops, with atrophy and recession of the alveolar bone, so that the teeth fall out spontaneously. In the severe type, widespread destruction of the jaw occurs. After puberty, all lesions heal, even in individuals who have the severe type.

There is no gross difference in appearance between the blood of an acatalasemic patient and that of a normal individual, but when hydrogen peroxide is added to a sample of blood, acatalasemic blood immediately turns blackish-brown and the peroxide does not foam. Normal blood remains bright and causes the peroxide to foam exuberantly because of the presence of erythrocyte catalase.

Acatlasia is a rare peroxisomal disorder and is inherited as an autosomal-recessive trait. Treatment consists of extraction of the diseased teeth and the use of antibiotics to control the harmful effects of the offending bacteria.

Perner H, et al: Acatlasemia—Takahara's disease. *Hautarzt* 1999; 50:590.

Cyclic neutropenia

Cyclic, or periodic, neutropenia is characterized by a decrease of circulating neutrophils and dermatologic manifestations. At regular intervals (21 days), neutropenia and mouth ulcerations develop, usually accompanied by fever, malaise, and arthralgia. Ulcerations of the lips, tongue, palate, gums, and buccal mucosa may be extensive. The ulcers are irregularly outlined and are covered by a grayish-white necrotic slough. The anterior teeth may show a grayish-brown discoloration. Premature alveolar bone loss and periodontitis occur. In addition, opportunistic cutaneous infections, such as abscesses, furuncles, noma, pyomyositis, and cellulitis, may develop during the neutropenic stage. Urticaria and erythema multiforme have been reported.

There is a cyclic depression of neutrophils occurring at intervals of 12–30 days (average, 21 days) and lasting 5–8 days. The neutrophils in the peripheral blood regularly fall to low levels or completely disappear. Some cases have been associated with agammaglobulinemia. The cause of cyclic neutropenia is a germline mutation of the gene encoding neutrophil elastase (*ELANE*). This is thought to produce apoptosis of bone marrow progenitor cells. Both the autosomal-dominant disease and sporadic cases have this abnormality. Severe congenital neutropenia is caused by a mutation in the same gene but at a

different site. The latter condition predisposes to the development of myelodysplasia and acute myelogenous leukemia, while cyclic neutropenia does not.

In the differential diagnosis are other periodic fever syndromes, including periodic fever, aphthous stomatitis, pharyngitis and adenopathy (PFAPA) syndrome, Mediterranean fever, Hibernian fever and hyperimmunoglobulin D syndrome, tumor necrosis factor receptor-associated periodic syndrome (TRAPS), and pyogenic sterile arthritis, pyoderma gangrenosum and acne (PAPA) syndrome. All share a predisposition to the development of aphthous-like oral ulcerations. PFAPA syndrome is defined clinically and is characterized by 4 days of high fevers (over 40°C) that recur at regular intervals every 2–8 weeks, separated by wellbeing between episodes. Associated with fevers are aphthous stomatitis (70%), pharyngitis (72%), and cervical adenitis (88%). The disease is not familial, begins before 5 years of age, and responds to small doses of prednisone for 1–2 days. Tonsillectomy has been reported to cure it.

Use of recombinant human granulocyte colony-stimulating factor (G-CSF) has been successful in the treatment of cyclic neutropenia patients. If the potential side effects limit use of this therapy, cyclosporine has been reported to be effective also. Administering antibiotics during infections seems to expedite recovery. Careful attention to oral hygiene, including plaque control, helps improve mouth lesions and reduces the risk of infections. Death may occur from pneumonia, sepsis, gangrenous pyoderma, or granulocytopenia.

Recurrent intraoral herpes simplex infection

Recurrent intraoral infection with HSV is characterized by numerous small, discrete vesicles occurring in one or a few clusters. The site of involvement is a key feature in suspecting the diagnosis. The keratinized or masticatory mucosa (the palate, gingiva, and tongue) is affected. The grouped vesicles rupture rapidly to form punctate erosions with a red base. Smears from the base prepared with Wright stain will show giant multinucleated epithelial cells. Immunofluorescent tests and viral cultures are also confirmatory.

The differential diagnosis of this uncommon manifestation of HSV includes oral herpes zoster, herpangina, and oral aphthosis. The latter two involve nonattached mucosa, whereas recurrent HSV involves mucosa fixed to bone. Differentiation from zoster is made on clinical grounds or by culture and immunofluorescent testing.

Chronic progressive ulcerative and nodular intraoral herpes are seen occasionally in HIV-infected patients, or those with leukemia or neutropenia (Fig. 34-22). Mucosal toxicity to chemotherapy may be mimicked. Solitary painful erosions of the tongue or attached mucosa should be tested for HSV in such patients. Additionally, herpetic geometric glossitis, linear longitudinal, cross-hatched, or branching fissures of the dorsal tongue, usually along the central area, may occur. This may be quite painful and limit oral intake. While it usually affects only immunocompromised patients, at least one immunocompetent patient has been affected.

Recurrent aphthous stomatitis (canker sores, aphthosis)

Clinical features

Aphthous stomatitis is a painful, recurrent disease of the oral mucous membrane. It begins as small, red, discrete, or grouped papules, which in a few hours become necrotizing ulcerations. They are small, round, shallow, white ulcers (aphthae), generally surrounded by a ring of hyperemia (Fig. 34-23). As a rule, they are tender; they may become so painful that they interfere with speech and mastication. They are mostly about 5 mm in diameter but may vary in size from 3 to 10 mm. When larger, they are called major aphthae. A third subcategory, herpetiform aphthae, consists of small 1–3 mm lesions grouped into a coalescing larger plaque, which may take 1–4 weeks to resolve. Usually, 1–5 lesions occur per attack; however, they may occur in any number. They are located in decreasing frequency on the buccal and labial mucosa, edges of the tongue, buccal and lingual sulci, and soft palate. There is a marked predilection for the nonkeratinized mucosa (any not bound to underlying periosteum). This and the fact that they

are rarely confluent, even when they occur as small crops of 1 or 2 mm lesions (herpetiform aphthae), help to distinguish them from the uncommon recurrent intraoral HSV infection. Aphthae may also occur on the vagina, vulva, penis, anus, and even the conjunctiva. When they involve the oral and genital mucosa and are nearly always present in numbers greater than or equal to three, the term complex aphthosis is applied.

The lesions tend to involute in 1–2 weeks, but recurrences are common. These recurrences may be induced by trauma, such as self-biting, toothbrush injury, and dental procedures, spicy foods, citrus, fresh pineapple, walnuts, allergy, emotional stress, or hormonal changes in women, such as in menstruation, pregnancy, menarche, and menopause. A familial predisposition has also been described as familial epidemic aphthosis.

Recurrent aphthous stomatitis is the most common lesion of the oral mucosa, affecting from 10% to 20% of the population. It starts commonly in the second or third decade and patients may experience recurrent bouts of lesions several times yearly for many decades. When present in neonates or young children, autoinflammatory syndromes should be considered. In PFAPA syndrome, the high fevers and associated findings occur with striking periodicity every 4 weeks, last 4–6 days, and resolve only to recur the following month. The children are otherwise well. One or two doses of prednisone (2 mg/kg) abort the attack and tonsillectomy may cure it. Aphthous oral ulcerations may also be seen in familial Mediterranean fever, TRAPS, hyperimmunoglobulinemia D and periodic fever, PAPA syndrome, and the newly defined deficiency of the interleukin-1-receptor antagonist (DIRA) syndrome.

Ulcerations such as these may also be the presenting sign in Behçet syndrome, HIV infection, malabsorption syndromes, gluten-sensitive enteropathy, pernicious anemia, cyclic neutropenia, neutropenia, ulcerative colitis, and Crohn's disease. History, physical examination, complete blood count, and long-term follow-up documenting the recurrent course in the absence of other symptoms will secure the diagnosis. Some patients have aphthosis associated with low folate, B₁₂ or iron levels, so testing should include evaluation of these.

Etiologic factors

Although individual patients often suspect that one of the factors mentioned above is responsible for precipitating their recurrence, infectious or immunologic causation is favored by investigators. The true cause is unknown.

Histologically, the lesion consists of a lymphocytic inflammatory infiltration with occasional plasma cells and eosinophils, which suggests delayed hypersensitivity.

Diagnosis

Aphthous stomatitis must be differentiated from mucous patches of early syphilis, candidiasis, Vincent angina, the avitaminoses (particularly pellagra and scurvy), erythema multiforme, pemphigus, cicatricial pemphigoid, lichen planus, primary HSV infection of the mouth, recurrent labial herpes, and recurrent intraoral HSV infection.

Treatment

No permanent cure is available. Several topical agents will lessen the pain. A mixture of equal parts of elixir of Benadryl and Maalox, held in the mouth for 5 min before meals, is soothing. Kaolin may also be added to the mixture. Lidocaine (Xylocaine Viscous) 2% solution, keeping 1 teaspoonful in the

mouth for several minutes, is helpful in allaying pain. Another useful topical anesthetic is dyclonine hydrochloride (Dyclone) 0.5% applied to the lesions. A large number of reasonably effective over-the-counter remedies are also available. Triggers, such as spicy foods, citrus, walnuts, pineapple, and other irritating substances should be avoided.

One may use other measures to shorten the course and induce healing of lesions. A mixture of equal parts of fluocinonide ointment and Orabase, applied to the ulcers three or four times a day, is effective in aiding the healing of existing ulcers; however, it does not prevent new ulcers. Some patients object to the thick, sticky texture of Orabase and prefer fluocinonide gel. Clobetasol ointment can also be very effective. Intralesional steroids and short 3- or 4-day courses of oral steroids may help, particularly for indolent or large lesions. Nonsteroidal alternatives include 5 mL of an oral suspension containing 250 mg of tetracycline; this is held in the mouth for 2 min and then swallowed. This is done four times daily for 1 week. Amlexanox 5% oral paste (Aphthasol) is a useful topical therapy both to induce healing and to relieve pain. Sucralfate suspension, alone or compounded with a topical steroid, may be useful, as has been described in peptic ulcer disease and the ulcerations of Behçet's disease.

To try to prevent new lesions, known triggers for the individual patient should be avoided as much as possible. Colchicine at 0.6 mg per day for 1 week, then increasing to 1.2 or even 1.8 mg per day, is recommended. If this is ineffective or gastrointestinal or other side effects limit dosage, dapsone may be added to colchicine or substituted for it. It is given in steadily increasing doses of 25 mg for 3 days, then 50 mg for 3 days, then 75 mg for 3 days, then 100 mg for 7 days. If the blood count is normal, no side effects are present, and the disease is not controlled, further increases to 125 or even 150 mg may be given. Thalidomide is another effective alternative, but caution regarding teratogenicity and neurotoxicity is necessary if this is to be considered. One method is thalidomide, 300 mg/day to start, 200 mg/day after 10 days, and 100 mg/day after 2 months. Relapses are treated with 100 mg/day for 12 days.

Several investigators have reported finding low folate, iron, or B₁₂ levels in about 20% of aphthosis patients investigated, but others do not see this with such high frequency. Still, it is worth investigating, as correction of the abnormality clears or improves the condition in most cases where an abnormality exists. Two studies document improvement with cyanocobalamin, even of those without abnormalities.

Fig. 34-24 Major aphthae.

Major aphthous ulcer (periadenitis mucosa necrotica recurrens)

In Sutton's disease, a major aphthous ulcer begins as a small shotlike nodule on the inner lip, buccal mucosa, or tongue, which breaks down into a painful, sharply circumscribed ulcer with a deeply punched-out and depressed crater. It may at times begin in the faucial pillars or oropharynx (Fig. 34-24). It may persist for 2–12 weeks before healing with a soft, pliable scar. There are seldom more than 1–3 lesions present at one time. However, remissions tend to be short, and new lesions may appear before old ones have quite healed. The term major aphthous ulcers has supplanted the unwieldy Latin name for this disease.

The cause is unknown, but evidence favors an immunologic or infectious etiology. These painful lesions are frequently present in HIV-infected patients who may experience similar lesions in the esophagus, rectum, anus, and genitals.

Treatment is difficult, and the general measures discussed under recurrent aphthae should be employed. Intralesional or systemic steroids in short courses, which may be effective, are often given. If recurrences are such that systemic steroids are prescribed for more than two or three short courses per year, alternative oral medications such as colchicine, dapsone, or thalidomide may be tried.

Behçet syndrome (oculo-oral-genital syndrome)

Clinical features

Behçet syndrome consists of recurrent oral aphthous ulcerations that recur at least three times in one 12-month period in the presence of any two of the following: recurrent genital ulceration, retinal vasculitis or anterior or posterior uveitis, cutaneous lesions (erythema nodosum; pseudofolliculitis or papulopustular lesions; or acneiform nodules in postadolescent patients who are not receiving corticosteroid treatment), or a positive pathergy test.

Oral lesions occur on the lips, tongue, buccal mucosa, soft and hard palate, tonsils, and even in the pharynx and nasal cavity. The lesions are single or multiple, 2–10 mm or larger in diameter, and sharply circumscribed, with a dirty grayish

Fig. 34-25 Behçet disease.

base and a surrounding bright red halo. Other patients show deep ulcerations that leave scars resembling those caused by Sutton major aphthous ulcers. The lesions are so painful that eating may be difficult. A foul mouth odor is in most cases markedly noticeable.

Genital lesions occur in men on the scrotum (Fig. 34-25) and penis or in the urethra, and in women, on the vulva, cervix, or vagina; they may be found in both sexes on the genitocrural fold, anus, or perineum, or in the rectum. These ulcerations are similar to those seen in the mouth. In addition, macules, papules, and folliculitis may develop on the scrotum. Lesions in women may lead to deep destruction of the vulva. Swellings of the regional nodes and fever may accompany oral and genital attacks.

The ocular lesions start with intense periorbital pain and photophobia. Retinal vasculitis is the most classic eye sign and the chief cause of blindness. Conjunctivitis may be an early accompaniment of uveitis, and hypopyon a late one. Iridocyclitis is frequently seen. Both eyes are eventually involved. Untreated disease leads to blindness from optic atrophy, glaucoma, or cataracts.

Neurologic manifestations are mostly in the central nervous system and resemble most closely those of multiple sclerosis. Remissions and exacerbations are the rule. Thrombophlebitis occurs with some frequency. Thrombosis of the superior vena cava may also occur. Arthralgia is most often present in the form of polyarthritis.

Unfortunately, the international criteria include nonspecific common cutaneous lesions (pseudofolliculitis, papulopustular or acneiform lesions). Demonstration of either leukocytoclastic vasculitis or a neutrophilic vascular reaction on histologic examination of a lesion would make the cutaneous criteria more specific.

There is a relatively high prevalence of Behçet's disease in the Far East and Mediterranean countries, whereas in the US and Western Europe it is much less common. In large series of patients from areas of high prevalence, men with an age of onset in the thirties predominate. They tend to have a worse prognosis than women. Mangelsdorf et al reported on 25 patients seen in a university dermatology referral practice in the US; 22 of their patients were young women with a high frequency of mucocutaneous lesions and a low prevalence of ocular involvement. This may reflect referral bias or could indicate that the disease is less severe in the US.

On histologic examination, the early lesions show a leukocytoclastic vasculitis. There is perivascular infiltration, which is chiefly lymphocytic in older lesions, with endothelial proliferation that obliterates the lumen. The cause of Behçet's disease

has been postulated to have an infectious, immunologic, and/or genetic basis but the evidence is still inconclusive for any of these.

Diagnosis

Usually the disease starts with one oral ulceration, followed by others. It may take years before additional lesions develop. Therefore, the diagnosis requires two classic signs in addition to oral ulcerations. In women anal and genital lesions predominate, often with subsequent involvement of the eyes.

Behçet's disease must be differentiated from herpetic or aphthous stomatitis, pemphigus, oral cancer, and Stevens–Johnson syndrome (erythema multiforme). A skin puncture or pathergy test may be used to investigate patients further; however, it is not reliable in that it may be negative in otherwise well-documented cases. It is done by injecting 0.1 mL of normal saline solution into the skin or by simply pricking the skin with a sterile needle. A pustule appears at the site within 24 h. If results are negative, the test should be repeated at 2–5 points before results are accepted. Pathergy has been observed in patients with Behçet's disease, pyoderma gangrenosum, Sweet syndrome, and bowel-associated dermatosis–arthritis syndrome.

Treatment

Usually, the ulcerations heal spontaneously. Mild mouthwashes and toothpastes and restricted use of the toothbrush should be prescribed when there are oral lesions. With regard to treating the symptoms and healing of the aphthae, local treatments as described for aphthae may be used. Sucralfate suspension has been studied in Behçet oral and genital ulcers, and was found to decrease pain and healing time. On the whole, the therapeutic problem of aphthosis is not the healing of the individual lesions but the prevention of new attacks. For that purpose, several options exist, none of which is optimal. Colchicine, 0.6 mg twice a day, may be started for 2 weeks. In the absence of response and gastrointestinal side effects, the dose may be increased to three times a day. Although this may not totally alleviate the mucocutaneous lesions, it may decrease their recurrence rate by 50% or more. Dapsone may be substi-

tuted or added to this for improvement of response. The usual therapeutic final dose is 100 mg/day. Thalidomide has been found to be effective in many patients. One dosing method is thalidomide, 200 mg twice a day for 5 days, and 100 mg twice a day for 15–60 days. It has no effect on iridocyclitis. Of course, long-term treatment will commonly be complicated by neurotoxicity and the teratogenicity of this medication is well known.

Methotrexate, in a weekly oral dose of 7.5 to 20 mg, should be reserved for severe refractory cases, as should more aggressive systemic treatments such as systemic corticosteroids, azathioprine, chlorambucil, cyclosporine, interferon- α , tumor necrosis factor antagonists, and cyclophosphamide.

The long-term outlook is for intermittent recurrent flares that may be life-long. Blindness, neurologic impairment, and vascular thromboses are potential serious complications.

Cutaneous Vascular Diseases

35

Raynaud phenomenon and Raynaud's disease

Raynaud phenomenon occurs in the presence of an associated disease, usually collagen vascular disease, and often systemic sclerosis/scleroderma. This is also called secondary Raynaud's phenomenon. Raynaud's disease (or primary Raynaud's disease) occurs in the absence of such disease. In a series of 165 patients with Raynaud, 51 had primary disease (Raynaud's disease). A defined connective tissue disease was present in about one-third of the remaining patients, but 54 had undefined connective tissue disease (35 with positive antinuclear antibody [ANA] titer). In another study of 142 patients with idiopathic Raynaud phenomenon followed for more than 10 years, 14% progressed to a definite connective tissue disease. The initial presence of ANAs, thickening of fingers, older age at onset, and female sex were predictors of connective tissue disease. In a larger study of 586 patients with Raynaud, followed by sequential nailfold capillary microscopy and autoantibody determinations, these two investigations were able, in 80% of cases, to identify the 12.6% of patients who went on to develop systemic sclerosis. The absence of nailfold capillaroscopic findings is also predictive of primary Raynaud's disease (no associated systemic disease). Laser Doppler perfusion imaging may enhance the evaluation of vascular damage from Raynaud's. Technetium digital blood flow scintigraphy may aid in the early diagnosis of Raynaud's of either the primary or the secondary type.

Many of the studies on pathogenesis and therapy in Raynaud are conducted on patients with systemic sclerosis/scleroderma, so it may not be possible to translate these findings to patients with Raynaud's disease. However, it appears that cold exposure is a major trigger of vasospasm in all Raynaud's patients. There appears to be an exaggerated sympathetic response to cold. This may be due to both excessive vasoconstrictor tone and a weak systemic vasodilatation process, centrally mediated at least in part. The abnormal sympathetic response may also explain why some patients say that "stress" triggers Raynaud attacks. High homocysteine levels have been detected in patients with both primary and secondary Raynaud's disease. Patients with systemic sclerosis and Raynaud's phenomenon have elevated levels of endothelin (ET-1), and this correlated with both nailfold capillaroscopic findings and more advanced disease.

Raynaud phenomenon

Raynaud phenomenon is produced by an intermittent constriction of the small digital arteries and arterioles. The digits have sequential pallor, cyanosis, and rubor. The involved parts are affected in paroxysms by the attacks of ischemia, which cause them to become pale, cold to the touch, and numb. The phenomenon is more frequently observed in cold weather. When exposed to cold, the digits become white

(ischemic), then blue (cyanotic), and finally red (hyperemic). In time, the parts may fail to regain their normal circulation between attacks and become persistently cyanotic and painful. If this phenomenon persists over a long period, punctate superficial necrosis of the fingertips develops (Fig. 35-1); later, even gangrene may occur.

Raynaud phenomenon occurs most frequently in young to middle-aged women. It occurs with scleroderma, dermatomyositis, lupus erythematosus, mixed connective tissue disease (MCTD), Sjögren syndrome, rheumatoid arthritis, and paroxysmal hemoglobinuria. Scleroderma was the underlying diagnosis in more than half of patients in one series. Occlusive arterial diseases, such as embolism, thromboangiitis obliterans, arteriosclerosis obliterans, and large-vessel vasculitis (Takayasu's disease), may be present. In addition, various diseases of the nervous system, including cervical rib, scalenus anticus syndrome, and complex regional pain syndrome (reflex sympathetic dystrophy), may produce the disorder. Physical trauma, such as hand-transmitted vibration as occurs with pneumatic hammer operation, can induce a syndrome identical to Raynaud's and has been termed "vibration white finger" or "hand-arm vibration syndrome". Pianists and typists may also develop this phenomenon. Raynaud's is a well-recognized complication following cold injury, especially frostbite. Pharmacological agents, such as bleomycin, ergot, β -blockers (including eyedrops), cyclosporine, interferon (IFN)- α and β , vinyl polychloride exposure, and cocaine, may also be the cause. The clumping of red blood cells is believed to be responsible for the induction of Raynaud phenomenon, with high titers of circulating cold agglutinins. It may occur in cryoglobulinemia and polycythemia vera. Patients with cancer may develop Raynaud's as a paraneoplastic phenomenon. Endocrine disorders, such as acromegaly, pheochromocytoma, carcinoid, and hypothyroidism, may present with or be associated with Raynaud's. Raynaud's of the nipple is a variant of Raynaud's that is difficult to diagnose. It presents with severe pain during lactation, and must be distinguished from nipple candidiasis and eczema. Patients report the onset of symptoms during pregnancy, and when asked, will say that the symptoms are triggered by cold and accompanied by biphasic or triphasic color changes of the nipple. Nifedipine can be highly effective in this condition and is safe for use during lactation, since little is found in the breast milk.

Simple tests and physical examination will generally distinguish between Raynaud's disease and Raynaud phenomenon. Sclerodactyly, digital pitted scars, puffy fingers with telangiectases, positive ANA, subcutaneous calcifications, basilar lung fibrosis, and changes on nailfold capillary microscopy (avascular "skip" areas with irregularly dilated capillary loops) are signs of connective tissue disease. An anticentromere antibody is an indicator of CREST (Calcinosis, Raynaud's syndrome, Esophageal dysmotility, Sclerodactyly, Telangiectasia) syndrome. Measuring rewarming after cold exposure can distinguish hand-arm vibration syndrome

Fig. 35-1 Raynaud phenomenon with fingertip necrosis.

(HAVS) from Raynaud's. HAVS patients will all rewarm their hand temperature by $>2.2^{\circ}\text{C}$ in the first 30 seconds, and will rewarm their hand temperature by 5°C in the same time period as normal persons (less than 5 min 30 sec); in Raynaud's patients, rewarming averages 7 min and is always longer than 5 min 30 sec.

Raynaud's disease (primary Raynaud's disease)

Raynaud's disease is a primary disorder of cold sensitivity primarily seen in young women. The intermittent attacks of pallor, cyanosis, hyperemia, and numbness of the fingers are identical to those in Raynaud phenomenon. The disease is usually bilateral, and gangrene occurs in less than 1% of cases.

The diagnosis requires the absence of the diseases enumerated under Raynaud phenomenon. Although some suggest that Raynaud's disease should be present for 2 years before being classified as a primary process, it may take as long as 11 years for some systemic disorders to manifest. Overall, fewer than half of patients presenting with Raynaud symptoms will prove to have a connective tissue disease. The prognosis is good for primary Raynaud's disease.

Treatment

Treatments have often been studied only in patients with Raynaud's phenomenon and digital ulceration, so not all treatments can be assumed to be effective in primary Raynaud's disease or Raynaud's secondary to other causes. If an underlying cause is found, treatment of that associated condition will often lead to improvement of the Raynaud's. In both primary and secondary Raynaud's, exposure to cold should be avoided. This includes avoidance of exposure to cold not only of the extremities but also of other parts of the body, since vaso-spasm may be induced by reduction of core body temperature. Warm gloves should be worn whenever possible. Residence in a warm climate is helpful. Trauma to the fingertips should be avoided. Smoking is absolutely contraindicated. An attack of Raynaud's may be broken at times by swinging the affected arm in a wide circle from the shoulder—the "windmill" maneuver. The use of standard nitroglycerin paste has had minimal efficacy and can produce systemic side effects. A new form of topical nitroglycerin, known as MQX-503, has been reported to improve Raynaud's while having the same side effects as placebo. Alternative treatments, including ginkgo and other herbal medications, have limited efficacy when compared to the standard treatments below, and cannot be recommended for patients with significantly symptomatic disease.

Calcium channel-blockers are the first-line therapy used in Raynaud's due to their efficacy and low side-effect profile. Prolonged-release amlodopine or nifedipine is usually recommended. Two-thirds of treated patients will respond favorably. The phosphodiesterase inhibitor sildenafil has been effective in both reducing the frequency of Raynaud's episodes and in healing digital ulcers. It has become the second-line agent of choice. Tadalafil has not been compared to sildenafil, but has not been effective in secondary Raynaud's in scleroderma, and substitution of tadalafil for sildenafil for cost savings may not be appropriate in the treatment of Raynaud's. An angiotensin II-receptor type I antagonist (losartan) or selective serotonin-reuptake inhibitors (fluoxetine or venlafaxine) may be useful in refractory cases. Quinapril is not effective, suggesting that not all angiotensin-converting enzyme (ACE) inhibitors are effective in Raynaud's. Intravenous biweekly N-acetylcysteine has been effective in reducing the number of attacks and was relatively side effect-free. The use of statins (specifically atorvastatin) in patients with Raynaud's due to systemic sclerosis/scleroderma was associated with a reduction in Raynaud's-associated symptoms. This may be through the vasoprotective actions of statins, since statin administration was associated with reduction of circulating markers of vascular injury, which are commonly elevated in scleroderma patients. Bosentan, an endothelin receptor (ETA and ETB) antagonist, significantly reduces the frequency of Raynaud's attacks and reduces new digital ulcers. Iloprost, a prostaglandin analog, has substantial efficacy in scleroderma-associated Raynaud's and digital ulceration, when given intravenously but not orally. Oral cisaprost has minimal or no efficacy. Treprostinil and epoprostenol have preliminary data supporting their benefit.

In cases that are refractory to the medical treatments outlined above, surgical modalities can be considered. If single digits are involved, botulinum toxin injections in the palm around each involved neurovascular bundle may lead to dramatic and, at times, immediate pain reduction. Ulcerations of the affected digits heal following the injections. The duration of response is often months to years, and can be repeated with similar efficacy. Local digital sympathectomy can be effective, and avoids amputation of chronically ulcerated digits. Cervical sympathectomy and endoscopic thoracic sympathectomy may give initial relief, but Raynaud's symptoms often recur after 1 year to 18 months. However, despite the return of the Raynaud's symptoms, digital ulceration is markedly reduced. Compensatory hyperhidrosis is a common complication of thoracic sympathectomy.

Erythromelalgia

Also called erythromelalgia and acromelalgia, erythromelalgia is a not uncommon condition. The population-based incidence is 1.3 per 100 000 per year: 2.0 per 100 000 in women and 0.6 per 100 000 in men per year. Erythromelalgia is an easily recognized clinical syndrome characterized by paroxysmal vasodilation affecting the feet, with burning, localized pain, redness, and high skin temperature. Infrequently, the hands (Fig. 35-2), face, and ears may be involved. The burning paroxysms may last from a few minutes to several days, and are usually triggered by an increase in environmental temperature or exercise. The average patient has 1–2 attacks per week, but in some patients, the attacks are much more frequent. Often, relief can only be obtained by immersing the burning feet in ice water. Over 20% of patients will have evidence of cold injury, and more than 1% will suffer gangrene or undergo amputation. Quality of life is severely impacted by this condition.

Erythromelalgia can be considered primary, secondary, and familial. For treatment purposes, secondary cases of erythromelalgia should be carefully divided into those associated with myeloproliferative diseases, often with elevated platelets, and others. Myeloproliferative diseases complicated by erythromelalgia include polycythemia vera, thrombotic thrombocytopenic purpura, and various forms of thrombocytopenia. Administration of romiplostim, a thrombopoiesis-stimulating protein, has resulted in erythromelalgia. Low-dose aspirin is effective therapy for erythromelalgia associated with platelet abnormalities. If this fails, other methods to reduce the platelet count should be considered.

Fig. 35-2 Erythromelalgia of the hands (normal hands lateral to the patient's).

Acquired erythromelalgia has been reported secondary to topical exposure to isopropyl alcohol and after mushroom poisoning with *Clitocybe acromelalga* and *Clitocybe amoenolens*. Medications that have induced erythromelalgia include calcium channel-blockers (both nifedipine and verapamil), ergot derivatives such as bromocriptine and pergolide, and cyclosporine. There may be a long period of treatment (years) with these agents before the appearance of the erythromelalgia. Stopping the offending medication usually leads to improvement of symptoms within weeks.

In the vast majority of cases seen by dermatologists, erythromelalgia is probably a neurological disorder. It can be seen in various neurological conditions or diseases associated with neurological sequelae, such as peripheral neuropathy, myelitis, multiple sclerosis, autoimmune small-fiber axonopathy, or diabetes mellitus. Two patients with autoimmune disease and idiopathic thrombocytopenic purpura developed erythromelalgia and responded to intravenous immunoglobulin (IVIG) therapy. Erythromelalgia is sometimes associated with Raynaud phenomenon, both disorders of abnormal neurovascular function. In many cases, no associated neurological disease may be detected by routine neurological examination, but careful neurological testing will reveal evidence of a small-fiber neuropathy in the majority of such cases.

Inherited, familial, or hereditary erythromelalgia usually has its onset in childhood or adolescence (early or late onset). Familial cases have an autosomal-dominant inheritance pattern. Familial erythromelalgia is now known to be an "inherited neuronal ion channelopathy." The mutation is in the gene *SCN9A*, which encodes a peripheral sodium channel $Na_v1.7$. This is a mainly peripheral sodium channel with robust expression in dorsal root ganglion neurons and sympathetic ganglion neurons, especially those with nociceptive function. This sodium channel acts as a "threshold" channel and sets the gain in nociceptors. Many mutations in the affected gene have been mapped. Gene mutations causing erythromelalgia occur in areas that affect the structure of the actual channel by substituting amino acids in this critical location. The mutations causing erythromelalgia are gain-of-function mutations. The amount of gain of function correlates with the age of onset of the disease, more significant mutations having earlier onset. The nature of the mutation also affects the binding of medications to the channel, so various mutations may have different responses to same medication, depending on whether that mutation allows the drug to bind to the channel. Other gain-of-function mutations in the *SCN9A* gene cause "paroxysmal extreme pain disorder" (formerly called familial rectal pain syndrome). This disorder has prominent autonomic manifestations that include skin flushing (sometimes with only half of the face turning red [harlequin color change]), syncope with bradycardia, and severe burning pain—most commonly rectal, ocular, or mandibular. One mutation in $Na_v1.7$ produced a clinical syndrome with features of both erythromelalgia and paroxysmal extreme pain disorder. Autosomal-recessive nonsense mutations that cause loss of function of the $Na_v1.7$ channel result in the inability to sense pain. These patients are otherwise neurologically normal.

When severe, erythromelalgia is a life-altering disease, and aggressive management is warranted. Patients may benefit from referral to special clinics for pain management or pain rehabilitation. At times, simple measures such as immersion in cool water may stop pain crises. Biofeedback can be of benefit. In general, no more than 50% of patients with erythromelalgia of the neuropathic type will respond to any one medication, so the treatment must be tailored to each patient, and often combinations of agents are used. Topical amitriptyline 1% and ketamine 0.5% in a gel are safe topical options, and are especially reasonable for affected thin-skinned areas, such

as the face or ears, where penetration would be optimal. Oral amitriptyline, sertraline, nortriptyline, and venlafaxine have shown benefit in some multiple patients. Oral magnesium in extremely high doses (>1 g per day in liquid form) was beneficial in one patient. Mexiletine, carbamazepine, and the combination of carbamazepine and gabapentin are also reported to be effective in individual patients. Neurosurgical intervention has been used in the most severely affected, carefully selected cases that have failed medical management.

Red ear syndrome

Red ear syndrome describes a rarely reported disorder characterized by relapsing attacks of redness and burning affecting both ears, but usually only one ear at a time. The attacks are more common in the winter and are precipitated by touching, movements, and exposure to warmth. Associated conditions include neural disorders of the trigeminal and glossopharyngeal nerves, migraines, and lupus erythematosus. It is unclear if red ear syndrome is a disease sui generis or is actually erythromelalgia of the ears. Treatment with oral and topical tricyclics has been beneficial. Red ear syndrome must be distinguished from the springtime variant of polymorphous light eruption seen in young males with cold exposure, relapsing polycondritis (the lobe is also involved in red ear syndrome), cellulitis, and borrelial lymphocytoma.

Livedo reticularis, livedo racemosa

Livedo reticularis is the term used to describe a netlike, mottled or reticulated, pink or reddish-blue discoloration of the skin, mostly on the extremities, especially the legs. It is more prominent with exposure to cold, and may vanish with warming. It is commonly seen on the lower extremities in young children and women. The pathogenic basis is reduced blood flow through and lowered oxygen tension in the venous plexus of the skin. *Cutis marmorata* is another name for livedoid physiologic mottling of skin exposed to cold. For clinical purposes, it is best to separate livedo reticularis (a benign condition in most cases) from fixed livedo reticularis, better known as livedo racemosa. Livedo racemosa forms irregular networks, and broken circular segments that are fixed and do not vary appreciably with temperature changes (Fig. 35-3). The lesions are usually asymptomatic. If necrosis or purpura occurs over the livedoid areas, the terms necrotizing livedo and “retiform

Fig. 35-3 Livedo racemosa.

purpura” respectively may be used. Livedo racemosa and livedo with purpura or necrosis are almost always associated with significant systemic disease that requires treatment. Unfortunately, the literature does not always accurately separate these entities, and patients may present with variable livedo (resembling livedo reticularis) and later develop more fixed lesions. In addition, some patients who have more variable livedo may have serious underlying disease that may require evaluation and treatment. These patients may not be easily identifiable initially on physical examination features alone. In this section, the term livedo will be used to describe this cutaneous finding and its association with other conditions. When livedo reticularis is seen, the clinician should consider the following categories of diseases as possibly causal: physiologic, hypercoagulable states (including myelodysplasias, cancer, and antiphospholipid and Sneddon syndromes), vasculitis (especially medium- and large-vessel), emboli, medications, and neurologic disorders.

Drugs may cause livedo. Amantadine (Symmetrel) may be not uncommonly associated with livedo reticularis. Quinidine and quinine may be associated with a photosensitivity that is livedoid in appearance, but on biopsy an interface dermatitis will be present. Minocycline can cause livedo, and this is a marker for the development of an antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis in these patients. The medication must be stopped immediately. Other medications associated with livedo include gemcitabine, heparin (perhaps associated with heparin-induced antiplatelet antibodies), IFN- β , and bismuth.

Neurological disorders can create livedo reticularis by altering innervation and consequently blood flow in the skin. Brain injury, multiple sclerosis, diabetes mellitus, poliomyelitis, and Parkinson’s disease are some examples.

Many of the syndromes with fixed livedo (livedo racemosa) have important systemic implications. These conditions can be either primary thrombotic processes or vascular inflammatory processes. If the vessels of the skin are affected, are the vessels in other organs, specifically the central nervous system (CNS) and kidneys, at risk? Sneddon syndrome usually occurs in young to middle-aged women. They present with livedo, and then develop cerebrovascular infarcts. The prognosis is poor.

Frequently, patients have antiphospholipid antibodies (up to 85%) and may have enough features to be diagnosed with systemic lupus erythematosus (SLE). They would be accurately diagnosed as having antiphospholipid antibody syndrome. Other connective tissue diseases, such as dermatomyositis, rheumatoid arthritis, and systemic sclerosis, may have antiphospholipid/anticardiolipin antibodies and hence feature livedo. For this reason, patients with SLE and livedo are apt to have more severe disease manifestations, such as renal disease, vasculitis, and anticardiolipin antibodies, even in the absence of full-blown Sneddon syndrome. Headache may be the presenting symptom in these patients, and the misdiagnosis of migraine may initially be entertained. Not all patients with Sneddon syndrome can be diagnosed as having antiphospholipid antibody syndrome, however, and their optimal evaluation and management is unclear. Other significant disorders with livedo as a skin manifestation include thrombotic processes (hypercoagulable states, type I cryoglobulinemia), microangiopathic hemolytic anemias (thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, and disseminated intravascular coagulopathy), medium- and large-vessel vasculitides, and septicemia. Moyamoya disease is a rare, chronic cerebrovascular occlusive condition characterized by progressive stenosis of the arteries in the circle of Willis. Patients present with ischemic strokes or cerebral hemorrhages. Both idiopathic moyamoya disease and disease connected with factor V Leiden mutation have been associated with livedo reticularis. Divry-van Bogaert syndrome, with livedo racemosa, seizures, and significant CNS disease, may be related to moyamoya or Sneddon syndrome.

Oxalosis may lead to livedo reticularis from deposition of oxalate crystals in and around blood vessel walls. The characteristic crystals are seen on biopsy. Calciphylaxis, with calcium deposits in vessels and tissue, may cause livedo by a still unclear mechanism. Other possible causes of livedo include cryofibrinogenemia, Graves' disease (associated with anticardiolipin antibodies), atrial myxoma, tuberculosis (perhaps as a complication of vascular inflammation—vascular-based tuberculid), and syphilis.

Cholesterol emboli

Cholesterol emboli resulting from severe atherosclerotic disease, usually of the abdominal aorta, may cause unilateral

Fig. 35-4 Livedo reticularis secondary to cholesterol emboli.

or bilateral livedo of the lower extremities. The livedo may not be present with the patient supine, and may only be present when the legs are dependent. Patients frequently have concomitant cyanosis (blue toes), purpura, nodules, ulceration, or gangrene (Fig. 35-4). Pain often accompanies the skin lesions. Acute renal failure occurs in up to 75% and about one-third of patients will have characteristic skin lesions. An eosinophilia on complete blood count is present in 80% of cases. Older men with severe atherosclerotic disease are at greatest risk. They are often on anticoagulant therapy, and many have recently undergone vascular surgery or instrumentation. Slightly more than 1% of left heart catheterizations are complicated by cholesterol emboli. The differential diagnosis includes vasculitis, septic staphylococcal emboli resulting from endocarditis or an infected aneurysm, and periarteritis nodosa. Mortality is around 75% at 1 year. Deep biopsy with serial sections may demonstrate the characteristic cholesterol clefts within thrombi. Frozen section evaluation with polarized microscopy is particularly sensitive. Livedo reticularis of recent onset in an elderly person warrants consideration of this diagnosis.

Evaluation of the patient with possible cutaneous vascular disorders

In the evaluation of patients who present with livedo, purpura, or ulceration, a broad differential diagnosis must be considered. Among the diseases considered should be primary pathology of the cutaneous vasculature. In general, these vascular disorders of the skin are divided into two main groups: vasculitis and vasculopathy. Vasculitis includes disorders in which the primary damage in the blood vessels occurs due to inflammatory cells infiltrating and damaging the vessel walls. As a consequence of inflammation within vessels, the clotting cascade is triggered and thrombosis may be seen adjacent to and in the late stages of healing vasculitic lesions. In vasculopathy, the primary process is thrombosis. This is usually due to a hypercoagulable state. Once thrombosis occurs, inflammatory cells enter the vessel and vessel wall in an attempt to re-establish local circulation. Thus late in the process of a primary thrombotic process, vascular inflammation is seen and can be misinterpreted as a "vasculitis." Emboli can be considered thrombotic events and late lesions from embolic lesions may also be inflammatory and misleading histologically. All these processes—vasculitis, vasculopathy,

and emboli—alter cutaneous blood flow and can be accompanied by livedo. If vessels lose competence they may leak, creating purpura, and if vasculitis, vasculopathy, or emboli are severe enough or affect a large enough vessel, the viability of the overlying skin is compromised, and necrosis and ulceration may occur. Complicating this situation is the fact that patients may have both a vasculitis and a hypercoagulable state, resulting in biopsies that, at times, are pathogenically discordant. A patient with an inherited or acquired disorder of coagulation and a drug-induced cutaneous vasculitis would be a not uncommon example. The above discussion makes it clear that this area of differential diagnosis is a difficult one for even the most skilled dermatologist. Careful sampling of early lesions, with large and deep biopsies if necessary, may be required to find the “primary” vascular pathology. Since vasculitis may be a focal process, step sections may be required to find the diagnostic features. In addition, the diagnosis proposed must be interpreted in the context of other elements of the patient’s medical condition, such as medications, infections, underlying diseases, and involvement of other organ systems besides the skin.

Livedoid vasculopathy

Synonyms for livedoid vasculopathy include livedoid vasculitis, atrophie blanche, segmental hyalinizing vasculitis, livedo reticularis with summer/winter ulceration, and PURPLE (painful purpuric ulcers with reticular pattern of the lower extremities). The vasculopathy is characterized clinically by early focal, painful purpuric lesions of the lower extremities that frequently ulcerate and heal slowly (Fig. 35-5). The ulcers heal, with small, stellate and reticulated, white scars, referred to as atrophie blanche (Fig. 35-6). The ulcers may be ringed by telangiectasis and hemosiderin-induced hyperpigmentation. Livedo racemosa may be present on the affected extremity or be more widespread. About two-thirds to three-quarters of the patients are female; the mean age of onset is 45 years. The condition is bilateral in 80% of patients and ulceration occurs in 70%.

Histologically, livedoid vasculopathy is characterized by hyaline thrombi within small and at times medium vessels in the dermis. Perivascular hemorrhage may be present. Leukocytoclastic vasculitis is *not* found, and the biopsies can be described as showing “intravascular thrombosis without inflammation.” Focal lymphocytic intravascular and perivascular inflammation may be seen, but this is considered second-

ary to the thrombotic process, rather than a primary and pathogenic component of the disease. By direct immunofluorescence, fibrin, C3, and IgM are often found in the vessel walls, but these are again considered secondary to the thrombosis. In biopsies of older lesions, recanalizing vessels may demonstrate endothelial proliferation. Biopsy of the atrophie blanche-like lesions may show lobular vascular proliferation, as observed in chronic stasis dermatitis. In about 15% of patients, an initial biopsy does not reveal diagnostic histology and a second biopsy is required. After two biopsies, diagnostic pathology is found in 98% of patients.

The pathogenic etiology is considered to be a hypercoagulable state that results in spontaneous thrombosis of superficial skin vessels. The thrombosis results in low tissue oxygen tension, with local hypoxia and skin damage. However, the hypercoagulable state can be identified with current testing technology in only about 40% of patients. In livedoid vasculopathy, testing should include anticardiolipin antibody, lupus anticoagulant, factor V Leiden gene mutation (usually heterozygous), protein C, S, or antithrombin III heterozygous deficiency, prothrombin *G20210A* gene mutation, cryoproteins, and homocysteine level. The finding of methylenetetrahydrofolate reductase (MTHFR) deficiency with or without hyperhomocysteinemia has been reported in livedoid vasculopathy, but the pathogenic significance of this is unclear. Plasminogen activator inhibitor-1 (*PAI-1*) mutation with increased *PAI-1* plasma levels has been found in some patients with livedoid vasculopathy. *PAI-1* is an important inhibitor of fibrinolysis, and elevated levels are associated with an increased risk of thrombosis.

Not surprisingly, underlying connective tissue disease, carcinomas, myeloma, lymphoma, venous insufficiency, deep venous thrombosis, and cerebrovascular accident have been seen in association with livedoid vasculopathy. These are all conditions associated with a prothrombotic state in some patients. Mononeuropathy multiplex has been reported in association with livedoid vasculopathy.

There is a broad differential diagnosis for livedoid vasculopathy, since many conditions can cause livedo reticularis with ulceration of the lower extremity. The conditions that must be excluded include small-vessel vasculitis (especially

Fig. 35-5 Livedoid vasculopathy.

Fig. 35-6 Atrophie blanche.

that associated with hepatitis C virus and essential mixed cryoglobulinemia or a connective tissue disease), microscopic polyarteritis, polyarteritis nodosa (PAN) (both cutaneous and systemic), peripheral vascular disease, erythema induratum mimicking PAN, and hydroxyurea-associated leg ulceration.

The treatment of livedoid vasculopathy is directed at treating the hypercoagulable state. About one-third of patients are smokers, and this should be stopped. Patients with venous insufficiency should be managed with elevation, compression, and bandaging as appropriate. These patients may improve with this local therapy alone. If venous insufficiency ulcerations with an atrophie blanche appearance are slow to heal, consideration for treatment with the livedoid vasculopathy therapeutic ladder should be considered. Agents demonstrated to be effective in livedoid vasculopathy (in order of their recommended use) include: low-dose aspirin, oral pentoxifylline, oral dipyridamole, folic acid and a B complex multivitamin (in patients with MTHFR mutation and elevated homocysteine), danazol or stanazol (to increase endogenous antithrombotic proteins), heparin (low molecular weight or regular), and warfarin. Warfarin may be slightly superior to heparin. No treatment is universally beneficial in all patients, and treatment may need to be tailored to individual response and disease activity. In patients with connective tissue diseases (and antiphospholipid antibodies) hydroxychloroquine may be beneficial. In refractory cases, tissue plasminogen activator infusion, IVIG, and rituximab can be considered. Hyperbaric oxygen may accelerate ulcer healing. Other treatments that have been reported as effective include PUVA, niacin, iloprost, and ketanserin. Systemic immunosuppressives usually are of no benefit in cases with true livedoid vasculopathy. If there is a dramatic response to steroids, another diagnosis should be sought.

Calciphylaxis

Calciphylaxis is an increasingly reported syndrome that is potentially fatal. It occurs most commonly in the setting of chronic renal failure, often with type 2 diabetes, and obesity. Women outnumber men 3:1 to 4:1. About 1–4% of patients on hemodialysis and 4% of patients on peritoneal dialysis develop calciphylaxis. About half of calciphylaxis patients are diabetic and more than half have a body mass index (BMI) of >30. Every gain in the BMI of 1 point over 30 increases the risk for calciphylaxis by 10%. Calciphylaxis occurs on the background of extensive calcification of the media of medium-sized and small arterioles. Parathyroid hormone (PTH) levels are often abnormal (either high or low), and calciphylaxis may also be seen in the setting of primary hyperparathyroidism, as well as secondary hyperparathyroidism of renal failure. Tumors may also produce PTH-related proteins and be associated with calciphylaxis. In about 20% of calciphylaxis patients, the Ca X PO₄ product will be greater than 70, a sensitive but not specific marker for calciphylaxis. The arteriolar calcification is a chronic process due to many metabolic factors and signaling molecules that cause vascular smooth-muscle cells to transform to an osteogenic phenotype. Thus the vascular calcification in calciphylaxis and most cases of calcific uremic arteriopathy is due to local deposition of calcium in the blood vessels by the vascular smooth muscles cells. It is *not* metastatic or dystrophic calcification. Liver disease and systemic corticosteroid therapy increase the risk for development of calciphylaxis by 2–3-fold.

Calciphylaxis begins as fixed livedo reticularis (livedo racemosa). Areas within the livedo become increasingly violaceous and eventually purpuric, bullous, and necrotic. Subcutaneous nodules may herald the onset of the livedo and be associated with it. Affected tissue in calciphylaxis has reduced tissue oxygenation. Lesions affect the legs below the knees in 90% of cases. More proximal lesions, and lesions of the fatty areas of the thighs, buttocks, and abdomen occur in about two-thirds of cases. Severe pain is a cardinal feature of calciphylaxis, often requiring narcotic analgesia for control. Ischemic myopathy may occur in severe cases, and muscle pain may precede the appearance of the skin lesions. Necrotic skin lesions are very resistant to healing and infection of open wounds with septicemia is a common cause of death. The 1-year survival of all calciphylaxis patients is about 40%, and only 10% in patients with both proximal and distal disease.

An optimum biopsy to confirm the diagnosis of calciphylaxis should be adjacent to the necrotic area where there is erythema or early purpura. Ideally, it should be deep and large enough to identify diagnostic features. This may require an incisional rather than a simple punch biopsy. Since vascular calcification is common in all patients with chronic renal failure, this alone cannot confirm the diagnosis. In addition,

there should be evidence of tissue damage (necrosis), extravascular calcification, and thrombosis in the arterioles of the dermis and subcutaneous tissue.

The pathogenesis of calciphylaxis is still being elucidated. In most cases, it occurs on the background of extensive calcification of arterioles of the skin. The calcification triggers intimal proliferation and narrows the arterioles. Gradually or rather suddenly, the patient will develop areas of livedo and necrosis. This heralds the onset of vascular thrombosis. The mechanism that triggers this thrombotic phase of calciphylaxis and the appearance of the skin lesions is unclear. Some of these may be prothrombotic states, such as female gender, warfarin administration, trauma, the presence of cancer, edema, and anatomic location. The skin overlying fatty areas, such as the medial thighs, abdomen, and breasts of women, is particularly susceptible to thrombotic diseases such as diffuse dermal angiomatosis and warfarin and heparin necrosis. This may be caused by low blood flow or the reduced circulation due to tethering and kinking of vessels due to gravity. In some patients, low protein C levels are identified. Human immunodeficiency virus (HIV) infection and cryofibrinogenemia have also been associated. A useful model to consider pathogenically is that calciphylaxis is analogous to atherosclerotic myocardial disease. There is a gradual and progressive abnormality of the vasculature, with narrowing of the vessel lumen (by plaque in the case of atherosclerosis and by intimal calcification in the case of calciphylaxis). The acute symptomatology is triggered by thrombosis of the narrowed vessel, leading to occlusion of the vessel and downstream anoxia and necrosis. As in atherosclerotic disease, treatment for calciphylaxis should be directed at early prevention of intimal calcification. Unlike atherosclerosis, however, it is unclear how to prevent intimal calcification in the setting of renal disease.

Penile calciphylaxis is a particularly painful variant. The glans penis develops a deep necrotic ischemic ulceration. The risk factors are diabetes and renal failure. Penectomy is often required for pain management. One case resembled temporal arteritis.

Much of the treatment for calciphylaxis is directed at altering abnormal calcium metabolism. Low calcium dialysis, oral phosphate binders, cinacalcet, bisphosphonates, and intravenous sodium thiosulfate have all been used with some success. Once the ulcerations are present, gentle debridement is associated with healing and increased survival. Painful ulcers may also respond to hyperbaric oxygen therapy. Parathyroidectomy is best reserved for cases refractory to the above regimens and a marked elevation of PTH.

Marshall–White syndrome and Bier spots

The marbled mottling produced in the forearm and hand by occluding the brachial artery with a tight sphygmomanometer cuff is characterized initially, and chiefly, by pale macules 1–2 cm in diameter. These were described by Bier in 1898 and are known as Bier spots. Wilkin re-examined this phenomenon with laser Doppler velocimetry and concluded that the red spots on the hand are caused by relative vasodilation, with vasoconstriction in the pale areas.

Wilkin JK, et al: Bier's spots reconsidered: a tale of two spots, with speculation on a humerus vein. *J Am Acad Dermatol* 1986; 14:411.

Purpura

Purpura is the term used to describe extravasation of blood into the skin or a mucous membrane. It presents as distinctive brownish-red or purplish macules a few millimeters to many centimeters in diameter. Several terms are used to describe various clinical manifestations of purpura.

Petechiae are superficial, pinhead-sized (<3 mm), round, hemorrhagic macules, bright red at first, then brownish or rust-colored. They are most commonly seen in the dependent areas, are evanescent, occur in crops, regress over a period of days, and most often imply a disorder of platelets rather than a coagulation factor disorder. These disorders typically give rise to ecchymoses or hematomas rather than petechiae. Petechiae may also be a sign of vasculitis.

Ecchymoses are better known as bruises or “black and blue marks.” These extravasations signify a deeper and more extensive interstitial hemorrhage, which forms a flat, irregularly shaped, bluish-purple patch. Such patches gradually turn yellowish and finally fade away. They are characteristic of scurvy.

Vibices (singular, vibex) are linear purpuric lesions.

Hematoma designates a pool-like collection of extravasated blood in a dead space in tissue that, if of sufficient size, produces a swelling that fluctuates on palpation. Hematomas are usually walled off by tissue planes.

Pathogenesis

Purpura may result from hyper- and hypocoagulable states, vascular dysfunction, and extravascular causes, including idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation (DIC), drug-induced thrombocytopenia, bone marrow failure, congenital or inherited platelet function defects, acquired platelet function defects (aspirin, renal or hepatic disease, or gammopathy), and thrombocytosis secondary to myeloproliferable

diseases. Most of these disorders produce findings of nonpalpable purpura. Ecchymosis predominates in procoagulant defects, such as hemophilia, anticoagulants, vitamin K deficiency, and hepatic disease resulting in poor procoagulant synthesis. There is often a component of trauma. Increased frequency of ecchymotic skin can be the result of poor dermal support of blood vessels, most often localized to the area of trauma, and may result from actinic (senile) purpura, topical or systemic corticosteroid therapy, scurvy, systemic amyloidosis, Ehlers–Danlos syndrome, or pseudoxanthoma elasticum.

Primarily prothrombotic disorders form characteristic “retiform” purpura or purpura associated with livedo reticularis. These include disorders in which fibrin, cryoglobulin, or other material occludes vessels. Representative causes include monoclonal cryoglobulinemia, cryofibrinogenemia, DIC, purpura fulminans, protein C/S deficiency, warfarin-induced necrosis, heparin necrosis, cholesterol emboli, oxalate crystal occlusion, and antiphospholipid syndrome.

Evaluation

A history and physical examination are often all that is necessary. A family history of bleeding or thrombotic disorders, duration of symptoms, use of drugs and medications that might affect platelet function and coagulation, as well as a review of medical conditions that may result in altered coagulation, should be documented. Physical examination should stress the size, type, and distribution of purpura; a search for telangiectases; a joint examination; and an evaluation of skin elasticity, unusual scars, and unusual body habitus. Correlation of purpura morphology with pathogenesis allows for a more focused approach.

A complete blood cell count and differential can be used to assess for microangiopathic anemia, screen for myeloproliferative disorders, and assess the number and morphology of platelets. A bleeding time is the preferred method of assessing platelet function. The partial thromboplastin time (PTT) and the prothrombin time (PT) are tests to evaluate abnormal coagulation states.

Thrombocytopenic purpura

Thrombocytopenic purpura may be classified into two large categories: states resulting from accelerated platelet destruction and states resulting from deficient platelet production. Accelerated platelet destruction may be immunologic or non-immunologic. The former may be due to antibodies (auto-immune or drug-induced thrombocytopenia), isoantibodies (congenital or post-transfusion), immune complex disease, or other immunologic processes, such as erythroblastosis fetalis, neonatal lupus, scleroderma, other connective tissue diseases, or acquired immunodeficiency syndrome (AIDS). The group of thrombocytopenias with accelerated platelet destruction includes thrombotic thrombocytopenic purpura and DIC. Deficient platelet production may be related to diseases such as aplastic anemia and leukemia.

Immune thrombocytopenic purpura (immune thrombocytopenia)

Immune thrombocytopenic purpura (ITP) was also known as idiopathic thrombocytopenic purpura or Werlhof’s disease. It is an autoimmune disease characterized by an isolated thrombocytopenia (platelet count <100 000). The causative antibodies are directed at molecules on the platelet surface, leading to their premature sequestration and destruction, primarily in the spleen. ITP is called primary in the absence of another cause, or secondary if there is a causal association, e.g.

Fig. 35-7 Oral hemorrhagic bullae as the presenting complaint in immune thrombocytopenic purpura.

“secondary ITP (SLE-associated).” Bleeding symptoms are minimal or absent in a large proportion of cases. Cutaneous manifestations can include an acute or gradual onset of petechiae or ecchymoses in the skin and mucous membranes, especially in the mouth. Epistaxis, conjunctival hemorrhages, hemorrhagic bullae in the mouth (Fig. 35-7), and gingival bleeding may occur. Melena, hematemesis, and menorrhagia are also present, and the latter may be the first sign of this disease in young women. Chronic leg ulcers occasionally develop.

Bleeding can occur when the platelet count drops below 50 000/mm³. Post-traumatic hemorrhage, spontaneous hemorrhage, and petechiae may appear. The risk of serious hemorrhage is greatly increased at levels below 10 000/mm³. The gravest complication is intracranial hemorrhage. ITP may be fatal, but most mortality in adults occurs secondary to treatment complications. Bleeding time is usually prolonged and coagulation time is normal, whereas the clot retraction is abnormal and capillary fragility is increased. Increased numbers of megakaryocytes are found in the bone marrow.

The age of onset determines the clinical manifestations and course. In children the onset is often acute and follows a viral illness in 50–60% of patients. Parvovirus B19 is frequently complicated by thrombocytopenia, which may be ITP or simply a consequence of reduced bone marrow production of platelets. The average lag between purpura and the preceding infection is usually 2 weeks (range 1–4). Most of these cases resolve spontaneously. Since children are at much less risk of developing serious hemorrhagic complications, a more conservative management approach may be taken. A few patients will develop chronic thrombocytopenia, and deaths, usually from cerebral hemorrhage, have been reported. In a series of 332 children with ITP, 58 (17%) had episodes of major hemorrhage. One death resulted from sepsis. In another series of 427 cases, 323 (72%) had mild to benign disease. Roughly 85% of children who undergo splenectomy experience remission. More than half of the remaining patients spontaneously remit within 15 years.

The chronic form occurs most often in adults, is persistent, and has a female to male ratio of between 2:1 and 4:1. Secondary ITP is more common in adults. HIV, hepatitis C, and autoimmune disease are the most common associated diseases. Treatment of the associated disease may lead to improvement of the thrombocytopenia. Breast cancer has been associated with ITP, with a parallel course in one-third of cases. Other malignancies have also been associated with ITP. *Helicobacter pylori* infection as a cause of ITP is controversial, but testing for *H. pylori* antibodies and treatment for infection have limited toxicity so could be considered.

IITP in the elderly is more difficult to manage. Patients more frequently have major bleeding complications, more complications from immunosuppressive agents, especially corticosteroids, and more complications from splenectomy. Corticosteroids have a particularly low response rate in elderly IITP patients. Danazol has demonstrated reasonable safety and efficacy in the elderly.

The differential diagnosis of IITP includes drug-induced thrombocytopenia, myelodysplasia, thrombotic thrombocytopenic purpura, and congenital/hereditary thrombocytopenia. The goal of treatment for IITP is to raise the platelet count above 20 000 to 30 000 and to stop all bleeding symptoms. Platelet transfusions are indicated if there is significant bleeding or if the platelet count is dangerously low. If the platelet count is above 20 000–30 000, the patient may be closely monitored. The treatment of IITP has changed with the availability of new treatment approaches. Initial treatment is a short course of corticosteroids, either for 1–2 weeks or as monthly pulses. IVIG or anti-D may be given with this treatment. If the patient relapses or has persistent symptoms, systemic corticosteroids are given with any of the following: rituximab, anti-D, IVIG, or a thrombopoietin agonist. Splenectomy can be considered a second-line treatment, although age >60 years makes this treatment less desirable. Danazol can be added as a second-line agent, especially in the elderly. When second-line treatments have failed in patients with chronic and persistent or worsening disease, immunosuppression with mycophenolate mofetil, azathioprine, cyclosporine, vincristine, lymphoma-type chemotherapeutic regimens, and even autologous transplantation could be considered.

Drug-induced thrombocytopenia

Thrombocytopenic purpura resulting from drug-induced antiplatelet antibodies may be caused by drugs such as heparin, sulfonamides (antibiotics and hydrochlorothiazide), digoxin, quinine, quinidine, chlorothiazides, penicillin, cephalosporins, minocycline, acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), statins, fluconazole, protease inhibitors, H₂ blockers, antiplatelet agents, rifampin, and lidocaine.

Heparin-induced thrombocytopenia (HIT) is associated with life-threatening arterial and venous thrombosis and, to a lesser extent, hemorrhagic complications. The platelet count

usually begins to fall 4–14 days after starting heparin, more commonly in a patient with prior exposure to the medication. Platelet counts drop to about 50% of their pre-HIT level, usually with a nadir of about 50 000, and rarely 10 000. HIT is mediated by an antibody to the platelet factor 4 (PF4)–heparin complex. The antibody cross-links FcγRII receptors on the platelet surface, resulting in platelet activation, aggregation, and simultaneous activation of blood-coagulation pathways. Tests for HIT antibodies include immunoassays (such as enzyme-linked immunoassay [ELISA]) and functional tests.

Treatment for drug-induced thrombocytopenia consists of removal of the offending agent. Corticosteroids are helpful in moderately high dosage (60 mg/day prednisone) and are usually only necessary as a brief course. When a clinical diagnosis of HIT is made, heparin should be stopped immediately and treatment with an alternative anticoagulant should be started, if required. In patients with thrombosis, warfarin therapy can begin when the platelet count has normalized.

Thrombotic microangiopathy

The diagnosis of a thrombotic microangiopathy is made in the presence of a microangiopathic hemolytic anemia and thrombocytopenia in the absence of another plausible explanation. Thrombotic thrombocytopenic purpura and hemolytic uremic syndrome are the two major diseases in this group. Certain drugs, such as cyclosporine, quinine, ticlopidine, clopidogrel, mitomycin C, docetaxel, trastuzumab, and bleomycin, have been associated with a thrombotic microangiopathy.

Thrombotic thrombocytopenic purpura

Also known as Moschowitz syndrome, thrombotic thrombocytopenic purpura (TTP) was in the past diagnosed with the pentad of thrombocytopenia, hemolytic anemia, renal abnormalities, fever, and disturbances of the CNS. Many cases, however, do not have renal disease, and CNS findings are not required for the diagnosis. The diagnosis of TTP requires only a Coombs-negative hemolytic anemia and thrombocytopenia with platelet aggregation in the microvasculature. Most patients will develop neurological findings. Fever is present in 75%. Multiple ecchymoses and retiform purpura may be found on the skin. The presence of schistocytes on a blood smear is the morphologic hallmark of the disease, and a schistocyte count of greater than 1% in the absence of other known causes of thrombotic microangiopathy strongly suggests a diagnosis

of TTP. Tests may show a decreased hematocrit and decreased platelets, an elevated lactate dehydrogenase, and elevated indirect bilirubin. A delay in diagnosis may lead to a mortality rate as high as 90%.

Biopsies demonstrate hemorrhage and fibrin occlusion of vessels. Inflammation is absent. Studies of plasma samples from patients with active TTP have often shown the presence of unusually large von Willebrand factor (VWF) multimers. The underlying cause of TTP is a congenital or acquired deficiency of the VWF cleaving protease, ADAMTS13. VWF is secreted by the endothelial cell in long multimers, which should be cleaved into monomers by ADAMTS13 and released into the circulation. Instead, multimers circulate and extend from the surface of the endothelial cells in the microvasculature. Platelets adhere to these multimers and the surface of the endothelial cell, leading to microvascular thrombosis.

TTP is divided into two forms, idiopathic and congenital (Upshaw-Schulman syndrome). Congenital TTP is less common (<10% of cases), and usually presents in infancy or childhood with jaundice and thrombocytopenia. Some patients with a congenital deficiency of ADAMTS13 do not present until adulthood or may even remain asymptomatic. The course is frequently relapsing TTP at regular intervals. Idiopathic TTP is a rare disease (about 10 per million per year). Females represent 70% of cases and black people have a nine-fold risk of developing idiopathic TTP. Idiopathic TTP is due to an autoantibody directed against ADAMTS13 that can be detected in up to 85% of cases. Neurological symptoms are the most frequent presentation, and range from confusion to seizures or coma.

Until exchange plasmapheresis was instituted as the treatment of choice, 80% of these patients died; now, 80% survive. Plasma exchange therapy is the primary treatment. It clears the VWF multimers, reduces the autoantibody, and replenishes the inhibited ADAMTS13. Plasma exchange is usually continued daily until clinical symptoms improve and the platelet count is above 150 000. In conjunction with plasma exchange, glucocorticoids may be given, although their success is variable. Cyclosporine and rituximab have been used in refractory cases, with promising results. Splenectomy may be used in refractory cases. Congenital TTP is usually much easier to treat, with only small amounts of normal plasma infusion required to provide the missing ADAMTS13 and stop the clotting.

Hemolytic uremic syndrome

Hemolytic uremic syndrome (HUS) has many similarities to TTP but is now considered a distinct entity, both clinically and pathogenetically. HUS is most commonly a disease of childhood. Patients have a microangiopathic hemolytic anemia, often following a diarrheal illness caused by Shiga toxin (Stx)-producing *Escherichia coli*. The annual incidence is 6.1 cases per 100 000. It is the most common cause of acute renal injury requiring transplantation in children aged 1–5. *Streptococcus pneumoniae* infection can also be followed by HUS. Cases of HUS not following such infections are called “atypical HUS.”

Fever is usually absent in HUS cases. Renal insufficiency occurs in all patients and is the hallmark of HUS. Neurological disease can occur but affects less than half of cases.

The pathogenic mechanism of typical HUS is endothelial damage due to the bacterial toxin and subsequent complement activation on the endothelial surface. The affected vessels are thickened, endothelial cells are detached, and the vascular lumen is narrowed and occluded by platelet thrombi. The renal vessels are at particular risk, since the subendothelial membrane is exposed and this membrane is particularly at risk for complement-mediated damage. In atypical and familial

HUS, similar complement activation via the alternative pathway (through C3b) occurs on endothelial surfaces, leading to endothelial damage and intravascular thrombosis.

In atypical and familial HUS, mutations in the alternative complement cascade have been identified. Complement factor H (CFH) mutations are most common and many patients are heterozygotes. The abnormal CFH complexes with the normal CFH, inactivating it. CFH is the major downregulator of the alternative complement cascade as it degrades C3b. Loss of CFH activity allows for unopposed C3b activity and complement activation. Other mutations are in complement factor I (CFI), which cleaves C3b and C4b. Mutations in membrane cofactor protein (MCP), a cofactor for CFI, in C3 itself, in complement factor B (a component of C3b), and in thrombomodulin can also cause atypical HUS. The type of mutation determines the clinical course of atypical HUS, with CFH, CFI, CFB, and thrombomodulin mutations having rates of death or end-stage renal disease of more than 50%. Recurrence of HUS occurs in more than three-quarters of patients with CFH and CFI mutations. Some patients are compound heterozygotes with mutations in two different genes noted above. About 6% of patients have an autoantibody to CFH and have “auto-immune HUS.”

Although HUS is a disorder caused by a genetic deficiency in most cases, onset may not occur until middle age. About 67% of atypical HUS occurs during childhood, with almost all patients with anti-CFH antibodies diagnosed before age 16. Oral contraceptives may trigger HUS in 8% of patients with CFH and 20% of patients with CFI mutations.

HUS is treated with plasma exchange as soon as the diagnosis is made. Corticosteroids, azathioprine, mycophenolate mofetil, and rituximab may be used in atypical HUS. The role of cadaver kidney transplantation in atypical HUS is unclear due to the high rate of recurrence and loss of the graft. The likelihood for a successful outcome following transplantation is dependent on mutation type.

Nonthrombocytopenic purpura (dysproteinemic purpura)

Cryoglobulinemia and cryofibrinogenemia

The term cryoglobulinemia refers to the presence in the serum of proteins that precipitate at temperatures below 37°C and redissolve on rewarming. These tend to be chronic conditions, unless the underlying disease process is treated. Abnormal serum proteins behaving as cryoglobulins and cryofibrinogens may be IgG, IgM, or both. Type I cryoglobulinemia occurs most frequently in multiple myeloma and macroglobulinemia, and is of a monoclonal IgM, IgG, or Bence Jones cryoglobulin form. Type II cryoglobulins are monoclonal and have rheumatoid factor-like activity. They are autoantibodies to the constant region of IgG. They occur in many connective tissue diseases and may also be due to the B-cell proliferation seen in hepatitis C virus (HCV) infection. Mixed cryoglobulinemia (type III), in which the cryoglobulins are of various classes, are associated with HCV infection in more than 90% of cases.

Purpura is most apt to occur on exposed surfaces after cold exposure. It may be of sudden onset and may clear rapidly once the patient is kept warm. Marked brown hyperpigmentation of the dorsal feet, at times in a livedoid pattern, may suggest this diagnosis. Cryoglobulinemia can be the cause of chronic leg ulcers (Fig. 35-8). An unusual clinical presentation of type I cryoglobulinemia in association with multiple myeloma is follicular hyperkeratosis of the central face, especially the nose.

In monoclonal disease, the biopsy reveals amorphous, jelly-like, eosinophilic material in the vessel lumen. In types II and III cryoglobulinaemia, a skin biopsy reveals classic leukocytoclastic vasculitis, and less commonly features of polyarteritis nodosa.

Treatment of type I cryoglobulinemia is to address the associated myeloproliferative disorder. Thalidomide was beneficial in one patient with a type I cryoglobulin, retiform purpura and clonal plasma cell expansion. For cryoglobulinemia associated with HCV or connective tissue disease, options include plasmapheresis, IVIG, systemic steroids, immunosuppressors, and colchicine. Simple plasma exchange can be helpful, but cryofiltration apheresis is the best method to remove cryoproteins in the treatment of cryoprecipitate-induced diseases.

Fig. 35-8 Cryoglobulinemia.

Reduction of the HCV viral load is the long-term solution in HCV-associated cases and can result in disappearance of the cryoglobulins. IFN treatment produced an exacerbation of vasculitis in one reported patient. Mixed cryoglobulinemia with renal, neurologic, and cardiac disease refractory to other treatments can respond to rituximab.

In contrast to cryoglobulinemia, cryofibrinogenemia is rarely symptomatic. The precipitating cryofibrinogen is a cold insoluble complex of fibrin, fibrinogen, and fibrin split products with albumin, cold insoluble globulin, factor VIII, and plasma proteins. Associated collagen-vascular disorders, infections, and malignancies are significantly more frequent in patients with combined cryofibrinogen and cryoglobulin than in those with isolated cryofibrinogenemia. Cryofibrinogen has been associated with calciphylaxis in the setting of renal disease, and livedoid vasculopathy when accompanied by other prothrombotic risks. Familial primary cryofibrinogenemia manifests as painful purpura with slow-healing ulcerations and edema of both feet during the winter months.

Waldenström hyperglobulinemic purpura (purpura hyperglobulinemica)

Waldenström hyperglobulinemic purpura presents with episodic showers of petechiae occurring mainly on the lower extremities. The dorsum of the feet is intensely involved, and the petechiae diminish on the ascending parts of the feet (Fig. 35-9). A diffuse “peppery” distribution is commonly noted, resembling Schamberg’s disease. The petechiae may be induced or aggravated by prolonged standing or walking, or by wearing constrictive garters or stockings.

Serum protein electrophoresis demonstrates a broad-based peak (polyclonal hypergammaglobulinemia). The bulk of the protein increase is IgG, though occasionally increased amounts of IgA are also found. IgM is usually normal or decreased. Rheumatoid factor in varying amounts is present in almost all

Fig. 35-9 Waldenström hyperglobulinemic purpura.

patients. Antithyroglobulins, increased erythrocyte sedimentation rate (ESR), leukopenia, antinuclear factors, and proteinuria may be found. Almost 80% of patients with hypergammaglobulinemic purpura of Waldenström have antibodies to Ro/SSA.

Hyperglobulinemic purpura occurs most commonly in women and is frequently seen with Sjögren syndrome and rheumatoid arthritis. Adverse fetal outcomes in these women may be associated with the associated autoantibodies (SSA/SSB). Hyperglobulinemic purpura may also be a primary chronic benign illness. When it is associated with hepatitis C, it has a predilection for men, and has manifestations that usually last longer than those associated with Sjögren syndrome.

In about one-third of patients, leukocytoclastic vasculitis is present. Patients with leukocytoclastic vasculitis have a higher prevalence of articular involvement, peripheral neuropathy, Raynaud phenomenon, renal involvement, ANA, rheumatoid factor, and anti-Ro/SSA antibodies. The course of the disease is essentially benign, but chronic. Rare deaths are related to associated cryoglobulin disease. Hyperglobulinemic purpura may be a manifestation or harbinger of connective tissue or hematopoietic diseases, and rarely, progression to myeloma has been reported.

Patients often improve with support stockings. Steroids should be reserved for severe disease. Indomethacin and hydroxychloroquine may be of value in the treatment of milder disease, especially in patients who have connective tissue disease or are SSA/B (Ro/La)-positive. Aspirin and colchicine have been used with some success.

Waldenström macroglobulinemia

Waldenström macroglobulinemia (WM) is a lymphoplasma-cytic lymphoma of B lymphocytes, with proliferation of monoclonal lymphocytes in bone marrow, lymph nodes, and spleen. Lymphadenopathy, hepatosplenomegaly, and anemia are characteristic. Elevated levels of IgM in the circulation define this unique and rare lymphoproliferative disease, and the IgM is responsible for some of the skin manifestations of this disorder. Elderly men are predominately affected, and there is a strong familial predisposition. The cutaneous manifestations of WM can be divided into two categories: nonspecific and specific. Nonspecific manifestations are related to the hyperviscosity syndrome created by the circulating IgM, and include purpura of the skin and mucous membranes. The purpura may be surmounted by giant tense bullae. Bleeding of the gums and epistaxis can occur. The IgM may behave as a cryoglobulin, resulting in purpura, livedo, cutaneous ulcerations, and vasculitis. Urticaria (some patients satisfying the diagnostic criteria for Schnitzler’s syndrome), disseminated xanthoma, and amyloid deposition can be seen. Specific skin lesions are of two types: specific skin deposits of aggregates of the IgM (IgM storage lesions), and cutaneous infiltrates with neoplastic lymphoid cells. The specific skin lesions usually occur once the diagnosis of WM is already known, but uncommonly the skin

lesions are the first clue to the diagnosis. The specific IgM deposits present clinically as subepidermal blisters (clinically and histologically resembling bullous amyloidosis) or translucent 1–3 mm papules. They are found most commonly on the lower extremity, even on the sole. Slight hyperkeratosis may be seen over the papules. Histologically, the papules are composed of dermal nodular homogenous and fissured pink deposits with a tendency to involve newly formed vessels. They are periodic acid-Schiff (PAS)-positive, but negative for Congo red. Direct immunofluorescence will identify the dermal globules as being composed of IgM and is a useful diagnostic approach. When WM results in specific cutaneous lymphoid aggregates, the presentation is very nonspecific. Small red–brown to violaceous macules, papules, nodules, or plaques may be present, usually on the face. Rosacea is often initially entertained as a diagnosis. Widespread skin involvement with a “deck-chair” sign (sparing the abdominal skin folds) has been reported.

The natural history of WM is that of an indolent myelodysplasia. Treatment is directed at reducing the volume of neoplastic cells and should be managed by an oncologist. Most indolent and asymptomatic patients are followed or treated only when clinical disease occurs. Given the risk of secondary neoplasms, fludarabine is avoided, unless other options are not possible. Combinations of cyclophosphamide, systemic steroids, and rituximab or bortezomib, systemic steroids and rituximab are initial therapeutic options. Plasmapheresis can be effective in controlling acute symptoms of hyperviscosity syndrome. Rituximab is not used as a monotherapy in WM patients with hyperviscosity, as they may experience a flare of their disease. Soluble CD27 can be used as a marker to determine response to therapy.

Purpura secondary to clotting disorders

Hereditary disorders of blood coagulation usually result from a deficiency or qualitative abnormality of a single coagulation factor, as in hemophilia or von Willebrand's disease. Acquired disorders commonly result from multiple coagulation factor deficiencies, as in liver disease, biliary tract obstruction, malabsorption, or drug ingestion. Acquired clotting disorders may also involve platelet abnormalities, as in DIC. Hemorrhagic manifestations are common and may be severe, especially in hereditary forms. Ecchymoses and subcutaneous hematomas are common, especially on the legs. Severe hemorrhage may follow trauma, and hemarthrosis is frequent. Other hemorrhagic manifestations include respiratory obstruction resulting from hemorrhage into the tongue, throat, or neck; epistaxis; gastrointestinal and genitourinary tract bleeding; and, rarely, CNS hemorrhage.

Sham RL, et al: Evaluation of mild bleeding disorders and easy bruising. *Blood Rev* 1994; 8:98.

Drug- and food-induced purpura

Drug-induced purpura may be related to platelet destruction, vessel fragility, interference with platelet function, or vasculitis. Drug-induced thrombocytopenic purpura was discussed earlier in this chapter. Examples of purpurogenic drugs are: aspirin and other NSAIDs, allopurinol, thiazides, gold, sulfonamides, cephalosporins, hydralazine, phenytoin, quinidine, ticlopidine, and penicillin. Combinations of diphenhydramine and pyridylidone can induce purpuric mottling and areas of necrosis. Cocaine-induced thrombosis with infarctive skin lesions is associated with skin popping.

Topical EMLA cream can induce purpura within 30 min of application, a result of a toxic effect on the capillary endothelium. Agave ingestion can induce purpura and vasculitic-like lesions due to a direct toxic effect on the endothelium. Purpura has been associated with the use of acetaminophen in patients afflicted with infectious mononucleosis. Small-vessel vasculitis, including urticarial vasculitis, has been caused by the ingestion of tartrazine dye. Pseudoephedrine can induce a pigmented purpura-like reaction. Patch testing reproduced the eruption. Purpuric contact dermatitis is rare and usually caused by rubber chemical or textile dyes.

Purpura fulminans

Also known as purpura gangrenosa, this is a severe, rapidly fatal reaction. There are three forms of the disease:

1. that associated with infection and DIC
2. hereditary deficiency of protein C or S
3. that which follows a febrile illness that leads to an acquired protein S deficiency.

The most common form is that which is associated with an infectious illness, usually bacterial septicemia, but sometimes a viral infection (varicella). Asplenic patients, who are at risk for pneumococcal or meningococcal sepsis, are also predisposed to purpura fulminans. Neonates with homozygous protein C or protein S deficiencies may suffer purpura fulminans (Fig. 35-10). Some patients develop transient deficiencies of proteins C and S in response to infection. A number of cases of purpura fulminans associated with infections and factor V Leiden mutation, with normal protein C and protein S levels, have been reported. Meningococemia, streptococcal sepsis, *Capnocytophaga* sepsis (from dog bite), staphylococcal septicemia, and urosepsis are the most common causes. Rickettsial disease and malaria may present as purpura fulminans. Active HHV-6 replication with acquired protein S deficiency and purpura fulminans has been described. Purpura fulminans presents as the sudden appearance of large ecchymotic areas, especially prominent over the extremities, progressing to acral hemorrhagic skin necrosis. (Fig. 35-11). The term "symmetrical peripheral gangrene" is used to describe cases when acral gangrene is present. Fever, shock, and DIC usually accompany the skin lesions, which on biopsy show noninflammatory

Fig. 35-10 Neonatal purpura fulminans secondary to homozygous protein C deficiency.

Fig. 35-11 Purpura fulminans.

necrosis, with platelet-fibrin thrombi occluding the blood vessels.

Other disease, such as the fibrinolysis syndrome, may have purpura fulminans as part of the symptom complex. An acquired form has been reported secondary to alcohol and acetaminophen ingestion, as well as from diclofenac or propylthiouracil. When purpura fulminans occurs in the setting of SLE, the catastrophic antiphospholipid antibody syndrome (CAPS) must be considered (Fig. 35-12). Purpura fulminans has been reported as a presenting feature of the Churg-Strauss syndrome and other ANCA-positive vasculitides.

Management is usually supportive, with treatment of the underlying disease process (antibiotics for the septicemia) and replacement therapy using fresh frozen plasma. Protein C and antithrombin replacement is useful in treating patients shown to have deficiencies. Plasmapheresis has been used in nonbacterial cases. Heparin anticoagulation can be used. Despite these measures, amputations (often multiple extremities) and deaths continue to occur in patients with severe disease. The use of pressors to maintain blood pressure during the septic episode may contribute to reduced peripheral circulation and peripheral tissue damage. Fasciotomy during the initial management of these patients may reduce the depth of soft-tissue involvement and the extent of amputations.

Disseminated intravascular coagulation

Up to two-thirds of patients with disseminated intravascular coagulation (DIC) have skin lesions, which may be the initial manifestation of the syndrome. Minute, widespread petechiae, ecchymoses, ischemic necrosis of the skin, and hemorrhagic bullae are the usual findings. Purpura fulminans may supervene and progress to symmetrical peripheral gangrene. DIC may be initiated by a variety of disorders, including septicemic hypotension, hypoxemia, acidosis, malignancies, chemotherapy, obstetric crises, antiphospholipid antibody syndrome, SLE, arthropod envenomation, and leukemia. Long-term treatment with granulocyte colony-stimulating factor (G-CSF) has also been reported to precipitate DIC. Children with kaposiform hemangioendotheliomas are at risk for consumptive coagulopathy (Kasabach-Merritt syndrome).

DIC is the result of widespread intravascular coagulation in which certain coagulation factors are consumed faster than they can be replaced. Laboratory findings include decreased platelets, decreased fibrinogen (only in severe cases; normal in 57% of cases), elevated PT/PTT (50–60% of cases), and increased fibrin degradation products and D-dimers. Control of the underlying disease is the paramount consideration, and often antibiotics or surgical drainage of loculated infection may lead to spontaneous resolution of DIC. Bleeding is treated with platelet transfusion in the presence of thrombocytopenia and fresh frozen plasma to correct coagulation factor abnormalities. Heparin is considered when thrombosis in the form of venous, arterial, or widespread microvascular thrombosis (purpura fulminans) is present. Protein C concentrate may benefit patients with severe sepsis and DIC.

Congenital fibrinogen disorders

Deficiencies of fibrinogen are classified as reductions in quantity (afibrinogenemia or hypofibrinogenemia) or in quality (dysfibrinogenemia). Afibrinogenemia occurs at a rate of about 1 per million in the population. It may present at birth with umbilical cord bleeding. Epistaxis, menorrhagia, hemarthrosis (but much less than in hemophilia and with far fewer musculoskeletal sequelae), trauma, and surgery-related bleeding can occur. The severity of the bleeding tendency is highly variable from patient to patient, some suffering no bleeding problems at all. Pregnancy complications include recurrent miscarriage and peripartum hemorrhage. Ironically, due to the loss of the antithrombotic effect of fibrinogen, thrombotic events are increased in afibrinogenemia. Arterial and venous thrombosis can occur. Patients with hypofibrinogenemia are more numerous, and in general are less symptomatic and only occasionally require treatment. Hypofibrinogenemia can be associated with pregnancy losses and rarely liver disease due to accumulation of abnormal fibrinogen in the endoplasmic reticulum of hepatocytes. Dysfibrinogenemia is asymptomatic in 55% of cases, 25% exhibit bleeding tendencies, and 20% have a tendency to thrombosis. This represents only 0.8% of patients with deep venous thrombosis, so screening for this condition is not cost-effective, unless there is a family history. Mutations in the fibrinogen gene cluster cause all three of these fibrinogen disorders.

Blueberry muffin baby

Originally coined to describe the characteristic appearance of the purpuric lesions observed in newborns with congenital rubella, the term blueberry muffin baby is associated with many disorders that produce extramedullary erythropoiesis. The eruption consists of generalized dark blue to magenta, nonblanchable, indurated, round to oval, hemispheric papules ranging from 1 to 7 mm. Lesions favor the head, neck, and trunk.

Etiologic factors include congenital infections (toxoplasmosis, rubella, cytomegalovirus, and parvovirus B19), hemolytic disease of the newborn (Rh incompatibility, blood group incompatibility), hereditary spherocytosis, twin transfusion syndrome, neuroblastoma, rhabdomyosarcoma, Langerhans cell histiocytosis, and congenital leukemia. Patients with multiple vascular disorders, such as hemangiopericytoma, hemangioma, blue rubber bleb nevus, and glomangioma, may be mistaken for “blueberry muffin” baby. Evaluation should include a peripheral blood cell count, hemoglobin level, TORCH serologies, viral cultures, and a Coombs test. A skin biopsy may also be helpful in determining the cause.

Miscellaneous purpuric manifestations

Deep venous thrombosis

Deep venous thrombosis (DVT) is a common medical condition that can result in immediate (pulmonary embolism) or long-term consequences (venous insufficiency, postphlebotic syndrome). Risk factors include female gender, obesity, immobilization, low atmospheric pressure, winter season, and the presence of cancer. In 35% of cancer-associated cases, the thrombosis is the first sign of the cancer. The use of erythropoiesis-stimulating agents doubles the risk of venous thromboembolism (VTE) for cancer patients. Hereditary mutations that result in a hypercoagulable state also increase the risk for VTE. The left leg is more often affected than the right. The mean age is 52 years. Significant superficial vein thrombosis is considered a risk factor for DVT. The risk of pulmonary embolism from DVT is the major concern. Treatment includes preventive strategies (exercise, weight control, and prophylaxis for high-risk settings—postoperative, post-stroke, and immobilized cancer patient).

Superficial thrombophlebitis

Painful induration with erythema, often in a linear or branching configuration forming cords, is the classic presentation of

Fig. 35-13 Superficial migratory thrombophlebitis.

superficial venous thrombosis (Fig. 35-13). Patients may also exhibit indurated subcutaneous nodules and overlying purpura or brown discoloration indicative of postinflammatory hyperpigmentation.

Primary hypercoagulable states that may be associated with superficial thrombophlebitis include deficiencies of anti-thrombin III, heparin cofactor II, protein C, protein S, and factor XII; disorders of tissue plasminogen activator; abnormal plasminogen; dysfibrinogenemia; and lupus anticoagulant. Secondary hypercoagulable states include varicosities, malignancy (Trousseau syndrome), pregnancy, oral contraceptive use, infusion of prothrombin complex concentrates, Behçet's disease, thromboangiitis obliterans, acute thrombophlebitis of superficial veins of the breast (Mondor's disease), septic thrombophlebitis, psittacosis, secondary syphilis, intravenous catheters, intravenous drugs (sugar solutions, protein hydrolysates, calcium, potassium, hypertonic concentrates, diazepam, nitrogen mustard, acridinylanside, dacarbazine, and carmustine), and street drugs (cocaine, bulking agents such as paregoric, quinine, dextrose, sucrose, and lactose).

In the evaluation of superficial thrombophlebitis, one should consider the possibility of underlying deep venous disease. Superficial femoral vein involvement should alert the physician to underlying deep venous disease requiring anticoagulation. Lesser saphenous vein thrombophlebitis is also frequently associated with underlying DVT. Elliptic biopsies across the palpable cord may be required to exclude other considerations such as sarcoidal granulomas, cutaneous polyarteritis nodosa, Kaposi sarcoma, and vasculotropic metastasis.

Treatment is directed at the underlying cause. Leg elevation and local heat will help to promote the dissolution of clots, which may take up to 8–12 weeks to resolve. Heparin therapy may reduce the incidence of thromboembolic complications in high-risk individuals.

Mondor's disease

Mondor's disease occurs three times more frequently in women than in men, and most patients are between 30 and 60

Fig. 35-14 Mondor's disease.

years of age. The sudden appearance of a cordlike thrombosed vein along the anterior-lateral chest wall is characteristic (Fig. 35-14). It is at first red and tender and subsequently changes into a painless, tough, fibrous band. There are no systemic symptoms. Both sides of the chest have the same rate of involvement. Mondor's disease may be associated with strenuous exercise, pregnancy, intravenous drug abuse, jellyfish stings, breast cancer, and breast surgery. The condition represents a localized thrombophlebitis of the veins of the thoracoepigastric area. The veins involved are the lateral thoracic, thoracoepigastric, and superior epigastric. In the end stage, a thick-walled vein remains that has a hard, ropelike appearance and, on occasion, may result in a furrowing of the breast. Exceptionally, a vein coursing up the inside of the upper arm and across or into the axilla may be thrombosed, leading to the "axillary web syndrome." Similar string-like phlebitis findings have been described in the penis, antecubital fossa, groin, and abdomen.

Treatment is symptomatic, with hot, moist dressings and analgesics or NSAIDs. The disease process runs its course in 3 weeks to 6 months.

Postcardiotomy syndrome

Between 2 and 3 weeks after pericardiotomy, fever, pleuritis, pericarditis, or arthritis may appear, together with petechiae on the skin and palate. This syndrome may be confused with infectious mononucleosis and bacterial endocarditis.

Orthostatic purpura (stasis purpura)

Prolonged standing or even sitting with the legs lowered (as in a bus, airplane, or train) may produce edema and a purpuric eruption on the lower extremities. Elevation of the

Fig. 35-15 Child abuse, purpura of the face from the sole of a shoe.

legs and the use of elastic stockings are helpful preventive strategies.

Obstructive or traumatic purpura

Purpura may be evoked by mechanical obstruction to the circulation, with resulting stress on the small vessels. This may be encountered in cardiac decompensation, or after convulsions, vomiting episodes, the Valsalva maneuver, pertussis, or sexual climax. Nonpalpable purpura has been reported in association with the use of a mucus-clearing device, which requires the patient to exhale forcefully through a flutter valve (flutter valve purpura). Local obstruction of the blood flow with purpura may result from compression of the veins by tumors or a gravid uterus or by occlusions from thrombosis.

Purpuric lesions in children bring into question the possibility of the battered child (Fig. 35-15). Bruises and ecchymoses on the genital area, buttocks, or hands are suggestive of an abused child. Linear lesions on accessible areas raise the question of factitial disease. Ecchymoses of bizarre shapes may also correspond to trauma inflicted during religious rituals or cultural practices. Coin-rubbing and cupping performed as remedies for common diseases are examples. "Passion purpura" on the palate may result from fellatio, or on the neck or upper arms (a "hickey") from biting and sucking. Facial, cheek, and periorbital purpura can be postictal and may be mistaken for spousal abuse. Bathtub suction-induced purpura occurs on the lower back location in a U-shaped distribution. It may be mistaken for abuse.

Paroxysmal nocturnal hemoglobinuria (PNH)

This acquired intravascular hemolytic anemia usually occurs in young adults, median age 40 years. It is an acquired clonal disorder resulting from a somatic mutation in a multipotent hematopoietic stem cell that produces all the bone marrow-derived cell lines (neutrophils, lymphocytes, platelets, and erythrocytes). The clinical manifestations are intravascular hemolysis, smooth muscle dystonia due to depletion of tissue nitric oxide (abdominal pain, esophageal spasm, fatigue, erectile dysfunction), and life-threatening venous thrombosis. Some cases occur after recovery from aplastic anemia. Widespread cutaneous thrombosis, with initial erythematous cutaneous plaques progressing to hemorrhagic bullae, can occur. Vascular thrombi are found on biopsy. The cause of PNH is a mutation in an X-linked gene, phosphatidylinositol glycan class A (*PIGA*). The product of this gene is the first step in the biosynthesis of all GPI anchors on the surface of hematopoietic cells. Erythrocytes in PNH lack two GPI-anchored proteins, CD55 and CD59, which prevent complement activation on the erythrocyte surface. CD55 accelerates the rate of breakdown of membrane-bound C3 convertase, and CD59 reduces the number of membrane attack complexes that are formed. The diagnosis of PNH can be made by detecting the loss of CD55 and CD59 through monoclonal antibody tests. The FLAER (fluorescent aerolysin) flow cytometry test is now commonly used to diagnose PNH. Hematopoietic stem-cell transplantation may be curative, after either ablative or non-ablative conditioning regimens. Eculizumab, a humanized monoclonal antibody against C5, inhibits terminal complement activation. It stabilizes hemoglobin levels and reduces transfusion requirements in PNH patients.

Paroxysmal hand hematoma (Achenbach syndrome)

Spontaneous focal hemorrhage into the palm or the volar surface of a finger may result in transitory localized pain, followed by rapid swelling and localized bluish discoloration. The lesion resolves spontaneously within a few days. Spontaneous hemorrhage from an arteriole appears to be responsible. The acute nature, purpuric findings, and rapid resolution are distinguishing features of Achenbach syndrome.

Robertson A, et al: Paroxysmal finger haematomas (Achenbach's syndrome) with angiographic abnormalities. *J Hand Surg [Br]* 2002; 27:391.

Easy bruising syndromes

Young women who bruise easily despite normal coagulation profiles and normal platelet counts may have antiplatelet antibodies. Otherwise, specific platelet function defects should be suspected. Bernard–Soulier syndrome is a rare inherited disorder characterized by giant platelets, thrombocytopenia, and a prolonged bleeding time. It is caused by genetic defects of the glycoprotein Ib–IX complex that constitutes the VWF

receptor. Sebastian syndrome consists of giant platelets, leukocyte inclusions, and thrombocytopenia. Fechtner syndrome is a rare type of familial thrombocytopenia associated with large platelets, leukocyte inclusions, and features of Alport syndrome. The May–Hegglin anomaly consists of easy bruising with giant platelets and Dohle-like cytoplasmic inclusions in granulocytes. The inclusions appear as electron-dense long rods and needles oriented along the long axis of the spindle. All four of these syndromes are due to abnormalities in the *MYH-9* gene. Glanzmann thrombasthenia, with dysfunctioning alphaIIb beta3 receptor, is a platelet storage pool defect causing similar clinical findings.

Painful bruising syndrome (autoerythrocyte sensitization, Gardner–Diamond syndrome, psychogenic purpura)

Painful bruising syndrome is a distinctive localized purpuric reaction occurring primarily in young to middle-aged women who usually manifest personality disorders. There may be depression, anxiety, hysterical or masochistic character traits, or inability to deal with hostile feelings. A recurrent type of eruption, it is characterized by extremely painful and tender, ill-defined ecchymoses about the extremities (Fig. 35-16) and sometimes on the face or trunk. The lesions evolve in a few hours and resolve within 5–8 days. New lesions may appear in crops. Emotional upsets are generally associated with the appearance of these painful purpuric lesions. Some patients will report a premonition as to when they will develop new

Fig. 35-16 Gardner–Diamond syndrome.

lesions a few hours ahead of time by the tingling and burning sensation at the site of a future lesion. Extracutaneous somatic symptoms are common, such as headache, paresthesias, transient paresis, syncope, diplopia, abdominal distress, diarrhea, nausea and vomiting, and arthralgia.

Gardner and Diamond reported that intracutaneous injections of erythrocyte stroma evoked typical lesions. Since then, many have reported similar reactions to autologous whole blood, packed or washed red cells, or fractions of erythrocyte stroma. These are hard to assess, because similar reactions have been reported to substances as diverse as hemoglobin, phosphatidyl serine, histamine, histidine, trypsin, purified protein derivative (PPD), autologous serum, and platelets. Blinded, controlled testing, trying to avoid factitial trauma, has given mixed responses. Abnormalities in tissue plasminogen activator-dependent fibrinolysis, thrombocytosis, and anticardiolipin antibodies have also been implicated. Most now believe this syndrome is psychosomatic and artifactual. The most effective treatment is to address the underlying psychological dysfunction. Improvement of the underlying psychopathology usually leads to disappearance of the cutaneous manifestations.

Pigmentary purpuric eruptions (progressive pigmentary dermatosis, progressive pigmented purpura, purpura pigmentosa chronica)

The pigmented purpuric eruptions (PPE) are a group of common dermatoses of unknown pathogenesis.

The most common variant of progressive pigmentary dermatosis is Schamberg's disease. The typical lesions are thumbprint-sized and composed of aggregates of pinhead-sized petechiae resembling grains of cayenne pepper on a background of golden-brown hemosiderin staining. The lesions commonly begin on the lower legs, with slow proximal extension (Fig. 35-17). These lesions seldom itch. The favored sites are around the lower shins and ankles, but lesions may be more widespread and occasionally affect the upper extremities or trunk.

Majocchi's disease is also known as purpura annularis telangiectodes. The early lesions are 1–3 cm annular patches composed of dark red telangiectases with petechiae and hemosiderin staining. Central involution and peripheral extension produce ringed, semicircular, target-like, or concentric rings, such as are seen on the cross-cut section of a tree trunk. The eruption begins symmetrically on the lower extremities, spreads up the legs, and may extend on to the trunk and arms. Involution of individual patches is slow and, because new lesions continue to form, may continue indefinitely. The lesions are asymptomatic.

Gougerot-Blum syndrome (pigmented purpuric lichenoid dermatitis) is characterized by minute, rust-colored to violaceous, lichenoid papules that tend to fuse into plaques of various hues between red, violaceous, and brown (purpura with lichenoid dermatitis). Favorite locations are the legs, thighs, and lower trunk. The chief difference between this and Schamberg's disease is the deeper color and the presence of

Fig. 35-17 Schamberg's disease.

induration, both of which relate to the presence of a lichenoid band of lymphoid inflammation. Similar lesions have also occurred during IFN therapy for hepatitis C.

Ducas and Kapetanakis pigmented purpura is scaly and eczematous. The eczematous patches also demonstrate petechiae and hemosiderin staining. Pruritus is common, and the lesions are often more extensive than the other pigmented purpuras. It is distinguished histologically by the presence of spongiosis. Purpuric pityriasis rosea may resemble Ducas and Kapetanakis purpura.

Lichen aureus is characterized by the sudden appearance of one or several golden or rust-colored, closely packed macules or lichenoid papules. The macules may be grouped into a patch and may occur on any part of the body, but the vast majority of lesions occur on the feet or lower leg. The patches are usually solitary and asymptomatic, but may occasionally be painful. Adults predominate, but children may also be affected.

Rare variants of the pigmented purpuric dermatoses are the linear or zosteriform type and the transitory type. These tend to be more transient than the other variants. A single case of evolution to linear morphea has been reported.

Histologically, all forms of pigmented purpura demonstrate superficial perivascular lymphocytic (and at times granulomatous) infiltrate associated with extravasation of red cells and, in later lesions, hemosiderin deposition. The degree of hemosiderin deposition may be variable and insufficient to confirm the diagnosis histologically. The infiltrating cells are primarily CD4+ lymphocytes. There may be a lichenoid band of lymphoid inflammatory cells (Gougerot-Blum type) or spongiosis (Ducas and Kapetanakis type). An iron stain (Perl, Prussian blue, ferricyanide) is sometimes used to demonstrate the hemosiderin deposition.

Cutaneous T-cell lymphoma may begin with clinical lesions that resemble pigmented purpura. In addition, lesions of pigmented purpuric dermatosis may demonstrate clonality. Patients with more widespread lesions above the knee are much more likely to have clonal infiltrates and eventually meet histological criteria for the diagnosis of cutaneous T-cell lymphoma.

In most cases of pigmented purpuric dermatosis, the etiology is unknown. Patients with stasis dermatitis and venous insufficiency may develop lesions that bear a superficial clinical resemblance to Schamberg's disease. Their lesions are more diffuse and do not form well-circumscribed macules. Oral medications can induce eruptions that closely resemble Ducas-Kapetanakis purpura. These include acetaminophen, aspirin, glipizide, IFN- α , and medroxyprogesterone injections. Stopping the offending medication will lead to resolution of the eruption. Pigmented purpuric contact dermatitis may simulate a PPE. Inciting allergens include nickel sulfate, fragrance mix, and Disperse Blue dyes. Patch testing on the back may be negative, but a positive response may be seen when the offending allergen is applied to a lesion. As with pigmenting drug eruptions, pigmented purpuric contact dermatitis should be suspected when the lesions are more widespread (sites other than the legs) and especially if they have an eczematous character.

Anecdotal reports of benefit from topical steroids make a therapeutic trial for 4–6 weeks reasonable. Oral rutoside, 50 mg twice a day, and ascorbic acid, 500 mg twice a day, have cleared a few patients. PUVA and narrow-band ultraviolet (UV) B have demonstrated efficacy and should be considered when the above modalities fail. Immunosuppressive therapy with cyclosporine and methotrexate has also been effective, but is usually not warranted in such a pauci-symptomatic disorder. If immunosuppression is considered, CTCL (cutaneous T-cell lymphoma) must be excluded, and patch testing and drug withdrawal should have been undertaken.

Purpuric agave dermatitis

Agave americana is a large, thick, long-leaved, subtropical plant with a striking blue-gray color. It is commonly used in ornamental beddings in the southwestern US. The plant grows up to 2 metres in diameter and may overgrow the surrounding landscape. As these plants are very deep-rooted and difficult to remove, some individuals have attempted removal with the help of a chain saw. A striking purpuric dermatosis occurs in a pattern corresponding to the splatter of the plant's sap.

Histologically, there is vascular damage at the level of the capillary and postcapillary venule, with a sparse infiltrate of neutrophils and karyorrhectic debris, suggesting low-grade leukocytoclastic vasculitis. Papulovesicular lesions have also been described. The plant's sap contains calcium oxalate crystals, as well as various acrid oils and saponins. The causative component is unknown.

VASCULITIS

Vasculitis is a clinicopathologic process characterized by inflammation and necrosis of blood vessels. Since the clinical morphology correlates with the size of the affected blood vessel(s), these disorders are classified by the blood vessel(s) affected. Diseases may involve vessels of overlapping size. In general, small-vessel disease (affecting postcapillary venules) causes urticarial lesions and palpable purpura; small-artery disease manifests as subcutaneous nodules; medium-sized arteries with necrosis of major organs, livedo, purpura, and mononeuritis multiplex; and large-vessel disease with symptoms of claudication and necrosis.

Classification

Numerous classification schemes have been proposed, all of which have limitations. It is important to remember that infectious and thrombotic conditions, which "classically" show thrombosis of vessels histologically, may also at times show true leukocytoclastic vasculitis. Hence, infectious, embolic, and thrombotic causes of vessel damage must always be considered before unequivocally diagnosing a case as an "inflammatory" vasculitis. Leukocytoclastic vasculitis is also commonly seen adjacent to suppurative folliculitis and at the base of chronic ulcers. The discovery of the association of some forms of small- and medium-vessel vasculitides with positive ANCA has made their diagnosis and classification much easier (Box 35-1).

Small-vessel vasculitis

Cutaneous small-vessel vasculitis (cutaneous leukocytoclastic vasculitis)

The vast majority of cases of cutaneous leukocytoclastic vasculitis (LCV) follow an acute infection or exposure to a new medication. Palpable purpura is the hallmark of this disease, with lesions ranging from pinpoint to several centimeters in diameter (Fig. 35-18). Annular, vesicular, bullous, or pustular lesions may develop. Small ulcerations may develop, but when ulceration is prominent, one must suspect either a vasculitis of larger vessels (small to medium arterioles) or the presence of both a vasculitis and a hypercoagulable state. Lesions of LCV predominate on the ankles and lower legs, affecting mainly dependent areas or areas under local pressure. Edema, especially of the ankles, is usually noted. In the hospitalized or bedridden patient, the buttocks and posterior

Box 35-1 Classification of vasculitis

I. Cutaneous small-vessel (postcapillary venule)

- A. Idiopathic cutaneous small-vessel vasculitis
- B. Henoch–Schönlein purpura
- C. Acute hemorrhagic edema of infancy
- D. Urticarial vasculitis
- E. Cryoglobulinemic vasculitis
- F. Erythema elevatum diutinum
- G. Granuloma faciale
- H. Other diseases with leukocytoclastic vasculitis: drug-induced vasculitis, malignancy (lymphoreticular more common than solid tumor), connective tissue diseases, hyperglobulinemic purpura, inflammatory bowel disease, bowel-associated dermatitis–arthritis syndrome (bowel bypass), HIV infection, and neutrophilic dermatoses (Behçet; Sweet; erythema nodosum leprosum; septic vasculitis; autoinflammatory conditions—familial Mediterranean fever, and serum sickness)

II. Medium-vessel

- A. Polyarteritis nodosa
 - 1. Benign cutaneous forms
 - 2. Systemic form

III. Mixed size (medium and small) vessel disease

- A. Connective tissue disease associated (usually rheumatoid vasculitis)
- B. Septic vasculitis
- C. ANCA-associated
 - 1. Microscopic polyangiitis
 - 2. Wegener granulomatosis
 - 3. Allergic granulomatosis (Churg–Strauss)
 - 4. Occasional drug-induced (most are postcapillary venule only)

IV. Large-vessel vasculitis

- A. Giant-cell arteritis
- B. Takayasu arteritis

thighs are dependent areas and may be the initial or primary site of involvement. Mild pruritus, fever, and malaise may occur. Arthralgias or, less commonly, frank arthritis may be seen. Other systemic involvement is rare and should raise the consideration of another diagnosis. Although, in general, systemic involvement is not found or is minimal, serious systemic disease can accompany cutaneous LCV and should be looked for in every patient.

The lesions usually resolve within 3–4 weeks, with residual postinflammatory hyperpigmentation. Ten percent of cases of cutaneous LCV may have recurrences. A persistent underlying cause must be sought in cases that are chronic.

Histology

There is angiocentric segmental inflammation of the postcapillary venule, with expansion of the vessel wall, fibrin deposition, and infiltration by neutrophils that show fragmentation of their nuclei (karyorrhexis or leukocytoclasia). Endothelial cell swelling is common, but endothelial necrosis suggests more serious illness (including septic vasculitis, ANCA-associated vasculitis). Vascular thrombosis may be present. The presence of tissue eosinophilia favors a medication as the cause. Immunofluorescence and ultrastructural studies have shown the presence of immunoglobulins, complement components, and fibrin deposits within postcapillary venule walls if the biopsy is taken within the first 24 h. Later, fibrin is prominent, but immunoglobulin deposits may have been destroyed. An important exception is Henoch–Schönlein purpura, which

Fig. 35-18 Leukocytoclastic vasculitis, palpable purpura.

usually demonstrates prominent IgA deposits, even in more advanced lesions.

Pathogenesis

Cutaneous small-vessel vasculitis is felt to be caused by circulating immune complexes. These complexes lodge in vessel walls and activate complement. Various inflammatory mediators are produced, contributing to endothelial injury. Cocaine use may cause or exacerbate small-vessel vasculitis.

Etiology

Most cases of cutaneous LCV are post-infectious or drug-induced. Drugs in virtually every class have been reported as causing LCV, and the time from when the medication was started to the onset of the eruption may be hours to years, making any ingested agent a possible cause. A host of infectious agents, such as β -hemolytic *Streptococcus* group A, *Mycoplasma*, and rarely *Mycobacterium tuberculosis* may cause palpable purpura. Patients with lymphoproliferative neoplasms, as well as solid tumors (lung, colon, genitourinary, and breast cancer) may experience cutaneous small-vessel vasculitis at some time during the course of their disease. A recurrence of the LCV may mark the return of a treated malignancy. Cutaneous LCV may be the initial manifestation of a medium or mixed-vessel vasculitis.

Clinical evaluation

The clinical evaluation is critical in separating those cases of benign cutaneous vasculitis (usually following an infection or induced by a medication) from those cases associated with more serious underlying disease or which have significant systemic involvement. It may not be possible on initial physical examination to separate the more benign-behaving cases from those associated with more serious disease. The history

should focus on possible infectious disorders, prior associated diseases, drugs ingested, and a thorough review of systems. Screening laboratory tests may help to elucidate the underlying cause or extent of organ involvement. When the history suggests a recent drug and the patient is clinically well, nothing more than a urinalysis may be required. A complete blood count, urinalysis, strep throat culture or ASO titer, hepatitis B and C serologies, and ANA and rheumatoid factor are a reasonable initial screen for patients with no obvious cause for their vasculitis. Serum protein electrophoresis, serum complements, ANCAs, and cryoglobulins may be required in some cases. A skin biopsy should be performed to confirm the diagnosis of LCV. Direct immunofluorescence should be performed to identify Henoch-Schönlein purpura.

Treatment

The initial treatment of most cases of leukocytoclastic vasculitis in patients who are clinically well and have a normal urinalysis should be nonaggressive, since the majority of cases are acute and self-limited, affect only the skin, and do not threaten progressive deterioration of internal organs. Rest and elevation of the legs is likely to be helpful. Analgesics and avoidance of trauma and cold are prudent general measures. An identified antigen or drug should, of course, be eliminated and any identified infectious, connective tissue, or neoplastic disease treated.

A variety of systemic treatments may be required for severe, intractable, or recurrent disease, especially if significant organ involvement is present. For disease limited to the skin, NSAIDs can be considered for the arthralgias. Colchicine, 0.6 mg 2–3 times a day, or dapsone, 50–200 mg/day, as trials of 2–3 weeks each, may be useful for chronic vasculitis. Low doses of colchicine and dapsone may be combined, if either medication alone is unsuccessful or effective doses of either drug cannot be reached. Although one controlled trial suggested that colchicine was ineffective in LCV, even in that trial a portion of the patients did respond and flared when the drug was stopped. Oral antihistamines, by blocking the vasodilation induced by histamine, may reduce immune complex trapping and improve LCV. Systemic corticosteroids, in doses ranging from 60 to 80 mg/day, are recommended for patients with serious systemic manifestations or necrotic lesions. Usually, a brief course leads to resolution, and chronic treatment is rarely required. In refractory patients immunosuppressive agents, such as mycophenolate mofetil, 2–3 g/day; methotrexate, 5–25 mg/week; or azathioprine, 50–200 mg/day (2–3.5 mg/kg/day), may be considered. Azathioprine dosing is based on thiopurine methyltransferase levels. In more difficult cases, cyclophosphamide, monthly intravenous pulses of steroids or cyclophosphamide, or cyclosporine, 3–5 mg/kg/day, may be effective. The tumor necrosis factor (TNF)-blockers, especially infliximab and to a lesser degree etanercept, may be effective in cutaneous small-vessel vasculitis. These agents may also cause vasculitis. Rituximab has been effective in refractory cases.

Cutaneous vasculitis and connective tissue disease

Patients with various connective tissue diseases (SLE, Sjögren's syndrome, rheumatoid arthritis [RA], and dermatomyositis) may develop cutaneous vasculitic lesions. Vasculitis in the setting of connective tissue disease may be associated with significant internal organ involvement, especially of the peripheral and central nervous system and the kidneys (glomerulonephritis). Ischemic digital infarcts are seen in addition to palpable purpura. Ulceration of vasculitic lesions is not uncommon and may be particularly difficult to manage in the patient with RA. The prevalence of vasculitis in patients with RA has decreased with improved treatment of RA. Treatment is the same as for cutaneous LCV, along with management of the underlying connective tissue disease.

Subtypes of small-vessel vasculitis

Henoch-Schönlein purpura

Henoch-Schönlein purpura (HSP) is characterized by purpura, arthralgias, and abdominal and renal disease. Typically, mottled purpura appears on the extensor aspects of the extremities, which become hemorrhagic within a day and start to fade in about 5 days (Fig. 35-19). New crops may appear over a period of a few weeks. Urticarial lesions, vesicles, necrotic purpura, and hemangioma-like lesions may also be present at some stages. It occurs primarily in male children, with a peak age between 4 and 8 years; however, adults may also be affected. A viral infection or streptococcal pharyngitis is the usual triggering event. *H. pylori* infection has been implicated in some childhood and adult cases.

In about 40% of cases, the cutaneous manifestations are preceded by mild fever, headache, joint symptoms, and

Fig. 35-19 Henoch-Schönlein purpura.

abdominal pain for up to 2 weeks. Arthralgia progressing to arthritis produces periarticular swelling around the knees and ankles. There may be pulmonary hemorrhage, which can be fatal. Abdominal pain and gastrointestinal bleeding may occur at any time during the disease; severe abdominal pain may even suggest—or portend—an acute surgical abdomen. Paralytic ileus may occur. Vomiting, rebound tenderness, and distention are other manifestations. Gastrointestinal radiographs may show “spiking” or a marbled “cobble-stone” appearance. Renal involvement manifests as microscopic or even gross hematuria, and may occur in 25% or more of patients. The long-term prognosis in children with gross hematuria is very good; however, progressive glomerular disease and renal failure may develop in a small percentage, so that careful follow-up is necessary for those with hematuria.

IgA, C3, and fibrin depositions have been demonstrated in biopsies of both involved and uninvolved skin by immunofluorescence techniques. Since IgA immune complexes persist longer in vasculitis, they are easier to identify than the IgG/M-containing immune complexes in other forms of LCV. In patients with abdominal pain suggestive of HSP but with no skin lesions, one can inject histamine (as used as a control by the allergists) into the skin and biopsy the area 4 h later. This “histamine trap test” may identify IgA in vessels and confirm the diagnosis of HSP.

In adults, HSP is not rare. Adult patients have IgA glomerulonephritis or other renal abnormalities in more than 50% of cases. Purpura above the waist in adults was more common in patients with glomerulonephritis. In adult patients with HSP and upper gastrointestinal symptoms (gastritis), a search for *H. pylori* infection should be undertaken. If an association with *H. pylori* can be confirmed, treatment of the gastrointestinal infection may lead to resolution of the HSP. HSP in adults can be associated with an underlying malignancy. Males represent 90% or more of malignancy-associated HSP cases. Solid tumors are seen in more than half of cases (especially non-small-cell lung cancer, prostate cancer, and renal cancer). Forty percent of cases have a hematological malignancy. About half of the cases present within 1 month of the diagnosis of the malignancy.

Treatment is supportive. The usual duration of illness is 6–16 weeks. Between 5% and 10% of patients will have persistent or recurrent disease. Dapsone, 50 to 200 mg/day, or colchicine, 0.6 mg/day to 1.2 mg twice a day, can be used initially if treatment is required and skin lesions are the primary concern. For abdominal pain, an H₂ blocker and/or corticosteroids (prednisone at 1 mg/kg/day) can be effective. Corticosteroids are more effective for abdominal pain than is analgesia. The value of systemic corticosteroids in the treatment of renal disease is controversial, but they may be used preventively or to treat active nephritis. IVIG can be used in refractory skin disease and persistent abdominal pain, and to arrest rapidly progressive glomerulonephritis. NSAIDs are best avoided, as they may cause renal or gastrointestinal complications.

Acute hemorrhagic edema of infancy

Also known as Finkelstein’s disease, Seidlmayer syndrome, medallion-like purpura, infantile postinfectious iris-like purpura and edema, and purpura en cocarde avec oedème, acute hemorrhagic edema (AHE) of infancy affects children under the age of 2 with a recent history of an upper respiratory illness (75%), a course of antibiotics, or both. The children are often nontoxic in appearance. There is abrupt onset of large cockade, annular, or targetoid purpuric lesions involving the face, ears, and extremities (Fig. 35-20). Scrotal purpura may also occur. Early in the course there may first be acral edema, with subsequent proximal spread. The edema is nontender and may be asymmetrical. A low-grade fever is common, and involvement of internal organ systems (joint pains, gastrointestinal symptoms, and renal involvement) is rare. Routine laboratory tests are unremarkable. Spontaneous recovery without sequelae occurs within 12–20 days. The differential diagnosis includes HSP, meningococemia, erythema multiforme, urticaria, and Kawasaki’s disease. There are some similarities between HSP and AHE (postinfectious, seasonal, favors males), but it is different in that it favors younger children (<2 years), resolves more quickly, lacks IgA on direct immunofluorescence in most cases, and is rarely associated with systemic symptoms. In one family, a child under 4 developed AHE while the sibling aged 16 developed HSP following the same pharyngitis. From a clinical point of view, the most urgent need is to exclude the possibility of septicemia, especially meningococemia.

Urticarial vasculitis

A significant percentage of patients (reported as high as 5–10%, but probably less) with fixed urticarial lesions will have vasculitis histologically. This is termed “urticarial” vasculitis (Fig. 35-21). This urticarial morphology is maintained throughout the course of the illness. Microscopic hemorrhage into the urticarial plaques may occur, resulting in a bruise-like appearance as the lesions fade. Determination of the serum complement levels (CH50, C3, C4, and anti-C1q precipitins) is critical in the evaluation of urticarial vasculitis. Patients with normal complement levels usually have a leukocytoclastic vasculitis, which is idiopathic, limited to the skin, self-resolving, and best considered a subset of cutaneous small-vessel vasculitis. Hypocomplementemic urticarial vasculitis is a distinctive syndrome seen virtually always in women. Clinical features include arthritis (50%), arthralgias, angioedema, eye symptoms, asthma and obstructive pulmonary disease (20%), and gastrointestinal symptoms (20%). Glomerulonephritis may be present. A rare subset of patients with hypocomplementemic urticarial vasculitis has Jaccoud’s arthropathy and serious valvular heart disease.

Underlying diseases associated with all forms of urticarial vasculitis include gammopathies (IgG and IgM gammopathy), SLE, Sjögren syndrome, serum sickness, and viral infections, especially hepatitis C. Patients with hypocomplementemic urticarial vasculitis can have anti-C1q antibodies directed against the collagen-like region of that molecule, a feature used to define this disease. Patients with SLE may also have these autoantibodies. Many patients with hypocomplementemic urticarial vasculitis will have positive ANAs, and up to one-quarter will have positive anti-dsDNA antibodies. The vast majority (96%) will have a positive “lupus band test.” Over time, more than 50% will meet the criteria for the diagnosis of SLE. For this reason, some consider hypocomplementemic urticarial vasculitis a form of SLE. Patients with HCV infection may develop hypocomplementemic or normocomplementemic urticarial vasculitis without a detectable cryoglobulin.

Three clinical features distinguish the skin lesions of urticarial vasculitis from true urticaria:

1. The lesions are often painful, rather than pruritic.
2. The lesions last longer than 24 h and are fixed, rather than migrating.

Fig. 35-21 Urticarial vasculitis.

3. On resolving, there is postinflammatory purpura or hyperpigmentation.

More difficult is the distinction of urticarial vasculitis from neutrophilic urticaria, as patients with the latter condition can have painful, more persistent lesions. Histologic evaluation is critical.

Histologically, patients with hypocomplementemic urticarial vasculitis will show both leukocytoclastic vasculitis and diffuse interstitial neutrophils. Eosinophils are more likely to be seen in patients with neutrophilic urticaria or normocomplementemic urticarial vasculitis. Sweet syndrome shows a more intense dermal infiltrate with marked upper dermal edema. Sweet syndrome and vasculitis share the presence of karyorrhexis. While virtually all biopsies of idiopathic urticaria demonstrate neutrophils, karyorrhexis is usually distinctly absent. In neutrophilic urticaria, neutrophils will be found in the dermis and in the vessel walls (moving from the vascular compartment into the skin). Finding neutrophils in the vessel walls alone without fibrinoid necrosis of vessel walls and leukocytoclasia is insufficient to make the diagnosis of urticarial vasculitis. Most patients with urticarial lesions with neutrophilic infiltrates and normal complements have neutrophilic urticaria rather than urticarial vasculitis.

Other neutrophilic disorders that are in the differential diagnosis of urticarial vasculitis include mixed cryoglobulinemia, Schnitzler syndrome, the autoinflammatory syndromes (CIAS-1/NALP-3 mutations), and neutrophilic dermatosis associated with connective tissue disease. Mixed cryoglobulinemia will be seen most frequently in the context of HCV infection and may present with urticarial, purpuric, or even necrotic/ulcerative lesions. Vasculitis should be seen on biopsy. The other three conditions all can have cutaneous lesions that are urticarial and clinically very similar. They tend to have less dermal edema than is typical of either urticaria or Sweet syndrome. Histologically, they lack vasculitis but show tissue neutrophilia with leukocytoclasia. Schnitzler is diagnosed by the finding of an IgM monoclonal gammopathy. The autoinflammatory syndromes are diagnosed by their characteristic features and genetic testing. In some patients with adult-onset Still disease or SLE, transient macules and papules coalescing into plaques may be seen. This condition has been termed “neutrophilic urticarial dermatitis”, but its pathogenesis remains unknown. In the setting of such neutrophilic urticarial lesions, ferritin measurement and a workup for SLE are appropriate.

The treatment of hypocomplementemic urticarial vasculitis is directed at the symptomatology and severity of the disease. Indomethacin has been particularly effective. Antihistamines, dapsone, and colchicine may be tried. The addition of pentoxifylline to dapsone may be effective. Antimalarials can be beneficial, as would be expected in this autoimmune connective tissue disease. Immunosuppressive therapy with prednisone and the steroid-sparing agent mycophenolate mofetil (2 g/day) can be considered in refractory and severe cases.

Cryoglobulinemic vasculitis

About 15% of patients with a circulating cryoprecipitable protein are symptomatic and have cryoglobulinemic vasculitis. They typically have mixed cryoglobulinemia. Mixed cryoglobulinemia follows a benign course in half of cases, but in about one-third liver or renal failure occurs. Fifteen percent of cases develop malignancy, usually B-cell lymphoma, and less frequently hepatocellular or thyroid cancer. By far the most common cause of cryoglobulinemic vasculitis is HCV infection, but autoimmune diseases and lymphoproliferative disorders can also be associated with cryoglobulinemic vasculitis. Cryoglobulinemic vasculitis usually presents with macular or palpable purpura, typically confined to the lower extremities. Lesions may be limited or severe. Two-thirds of patients show confluent areas of hemosiderosis of the feet and lower legs, characteristic of prior episodes of purpura. While only 30% of patients report an exacerbation with cold exposure, up to 50% will have Raynaud phenomenon and cold-induced acrocyanosis of the ears. Other morphologies include ecchymoses, livedo reticularis, urticaria, and ulcerations. Widespread systemic vasculitis occurs in about 10% of patients. Neuropathy and other neurologic complications occur in 40% of patients. Arthralgias, xerostomia, and xerophthalmia are frequent complaints. Laboratory evaluation will reveal a cryoglobulin, hypocomplementemia (90%), and a positive rheumatoid factor (70%). ANCA are rarely positive. A skin biopsy will show LCV.

The treatment of cryoglobulinemic vasculitis is the treatment of the underlying disease if possible. In the case of HCV infection, this usually is IFN- α plus ribavirin. Cryoglobulinemic vasculitis associated with HCV may also be flared by IFN treatment. Colchicine, dapsone, IVIG, infliximab, and rituximab (an anti-CD20 monoclonal antibody) can be attempted. In severe cases plasmapheresis may be beneficial.

Macular lymphocytic arteritis (lymphocytic thrombophilic arteritis)

This is a rarely reported condition that affects predominantly non-Caucasian females. It presents with multiple ill-defined brown macules on the lower legs resembling postinflammatory hyperpigmentation. Histologically, a vessel in the subcutaneous fat is infiltrated with lymphocytes but there is no destruction of the vessels. Neutrophils are absent.

Golfer's and exercise-related "vasculitis"

This syndrome, which occurs mostly in hot weather, affects primarily older men (age >50). Golfing or exercise with prolonged walking is the trigger. The syndrome is characterized by asymptomatic or pruritic, burning, or stinging, purpuric, macular or slightly raised papules and plaques, predominately just above the sock line near the ankles. Mild ankle swelling may be present. The lesions resolve in under 3 days in most patients. Histologically, true LCV is not seen, but erythrocytes and neutrophils are present in the affected tissue. About half of the patients are on antithrombotic agents. This syndrome probably represents a form of purpura due to anticoagulation and prolonged erect posture rather than a true vasculitis.

Saleh Z, Mutasim DF: Macular lymphocytic arteritis: a unique benign cutaneous arteritis, mediated by lymphocytes and appearing as macules. *J Cutan Pathol* 2009; 36:1269.

Erythema elevatum diutinum

A rare condition, erythema elevatum diutinum (EED) is considered to be a chronic fibrosing leukocytoclastic vasculitis. Classically, multiple orange to yellow papules and plaques develop over the joints (Fig. 35-22), particularly the elbows, knees, hands, and feet. Lesions may also involve the buttocks and areas over the Achilles tendon. Petechiae and purpura can be associated with early lesions. More rarely, large plaques

Fig. 35-22 Erythema elevatum diutinum.

with nodules at the periphery may affect the trunk and extremities. Scattered nodules on the trunk with no acral lesions constitute another rare variant. With time, the papules take on a doughy to firm consistency and develop a red or purple color. In HIV infection, skin-colored or red nodules affect the soles, producing lesions resembling keloids, Kaposi sarcoma, or bacillary angiomatosis. Pruritus, arthralgias, and pain have been reported; however, most patients are asymptomatic. Some patients with EED will develop pyoderma gangrenosum-like ulcerations, which in one case presented as a phagedenic penile ulceration. Systemic complications are rare, but an unusual and potentially rapidly destructive keratitis can lead to blindness. EED has been associated with HIV infection, SLE, Sjögren syndrome, lymphoma, breast cancer, lymphoepithelioma-like carcinoma, dermatitis herpetiformis, and celiac disease. IgA monoclonal gammopathy may be detected. Chronic and recurrent streptococcal infections cause exacerbations of the disease in some patients. These may all represent conditions with persistent circulating immune complexes that might trigger a chronic vasculitis. Pathogenically, ANCA (60% IgA and 33% IgG) are found in EED. ANCA-positive vasculitides, such as Wegener granulomatosis, have rarely been reported to have EED-like lesions.

Histologically, early lesions are a leukocytoclastic vasculitis, but with prominent interstitial neutrophils. Well-formed lesions are composed of nodular and diffuse mixed infiltrates of neutrophils and nuclear dust, eosinophils, histiocytes, and plasma cells that often extend into the subcutaneous fat. The prominence of eosinophils; the chronicity of the process, which results in an onion skin-like perivascular fibrosis; and the admixture of plasma cells and many lymphocytes are the hallmarks of EED. Erythrocyte extravasation may lead to extracellular cholesterol crystals in long-standing cases.

Dapsone is the treatment of choice. Patients with celiac disease may respond to a gluten-free diet. Tetracycline and nicotinamide, sulfapyridine, colchicine, antimalarials, and intralesional or systemic steroids have all been reported as effective in a limited number of cases. Intermittent plasma exchange has been used successfully in patients with IgA paraproteinemia. The interstitial keratitis also responds to dapsone. Unfortunately, the late nodular lesions may not resolve with dapsone treatment.

Granuloma faciale

Characterized by brownish-red, infiltrated papules, plaques (Fig. 35-23), and nodules, granuloma faciale involves the facial areas, particularly the nose. Healthy, middle-aged (mean 53 years) white men (male to female ratio, 5:1) are most typically affected. Childhood cases have been reported. Extrafacial disease occurs in up to 20% of cases, usually affecting the upper trunk and extremities.

The pathology of granuloma faciale is similar to that of EED, with focal leukocytoclastic vasculitis, diffuse dermal neutrophilia with leukocytoclasia, tissue eosinophilia, and perivascular fibrosis.

A variety of treatment options are available. Intralesional corticosteroids are the recommended first approach. Cryotherapy in combination with intralesional corticosteroids has been shown to be very effective. Topical corticosteroids may also be useful. Although controlled clinical trials are lacking, dapsone, colchicine, or antimalarials could be considered if the patient remains unresponsive. Laser treatment with pulsed dye and argon lasers has been effective in multiple cases, making it a reasonable consideration as first-line treatment.

Polyarteritis nodosa

Polyarteritis nodosa (PAN) is characterized by necrotizing vasculitis affecting primarily the small to medium-sized arteries. There are two major forms, the benign cutaneous and the systemic, although even long-standing benign cutaneous PAN can evolve into systemic disease. There are ten diagnostic criteria for systemic PAN:

1. livedo racemosa
2. polymorphonuclear arteritis
3. leg pain/myopathy/weakness
4. mono-/polyneuropathy
5. positive hepatitis B virus (HBV) serology
6. weight loss >4 kg
7. testicular pain/tenderness
8. diastolic blood pressure >90 mmHg
9. elevated BUN/creatinine
10. arteriographic abnormality.

Separating systemic PAN from microscopic polyangiitis (MPA) can be difficult, and the skin manifestations clinically and histologically are of no benefit in this regard.

PAN is 2–4 times more common in men than in women and the mean age of presentation is 45–50 years. A cutaneous vasculitis identical to PAN has been seen in intravenous drug abusers (see below) and in association with SLE, inflammatory bowel disease, hairy cell leukemia, familial Mediterranean fever, and Cogan syndrome (nonsyphilitic interstitial keratitis and vestibulo-auditory symptoms). Infectious associations include hepatitis B, hepatitis C, and antecedent streptococcal infections. Vascular-based tuberculids (erythema induratum, nodular tuberculid) may have histology identical to PAN. The proportion of PAN cases associated with HBV is currently about 5–7% of cases overall, but this percentage is falling with HBV immunization. The identification of associated hepatitis virus infection has therapeutic and prognostic implications.

The skin is involved in up to 50% of patients with the systemic form of PAN, with wide-ranging findings. The most striking and diagnostic lesions (15% of patients) are 5–10 mm subcutaneous nodules occurring singly or in groups, distributed along the course of the blood vessels, above which the skin is normal or slightly erythematous (macular arteritis). These nodules are often painful and may pulsate and, in time, ulcerate (Fig. 35-24). Common sites are the lower extremities, especially below the knee. Ecchymoses and peripheral gangrene of the fingers and toes may also be present. Livedo reticularis in combination with subcutaneous nodules strongly suggests the diagnosis of PAN. Palpable purpura with histologic features of cutaneous LCV may be seen in PAN in 20% of patients. Urticaria is present in 6% of cases of PAN. HBV-associated PAN is associated with cutaneous findings in only 30% of cases.

Fig. 35-24 Polyarteritis nodosa with multiple leg ulcerations.

Classic systemic PAN may involve the vessels throughout the entire body. It has a particular predilection for the skin, peripheral nerves, gastrointestinal tract, and kidneys. Hypertension (due to renal involvement in 80%), tachycardia, fever, edema, and weight loss (>70%) are cardinal signs of the disease. Arthralgia/arthritis (up to 75%), myocardial and intestinal infarctions, and peripheral neuritis (75%) are also seen. Mononeuritis multiplex, most often manifested as foot drop, is a hallmark of PAN. Involvement of the meningeal, vertebral, and carotid arteries may lead to hemiplegia and convulsions. The lungs and spleen are rarely involved. Aneurysms develop, which may result in multiorgan infarcts. A Five Factor Score (FFS) has been validated, with 1 point each for proteinuria, renal insufficiency, gastrointestinal tract involvement, CNS involvement, and cardiomyopathy. The 5-year survival for patients with FFS scores of 0, 1, and >2 are 88%, 75%, and 54% respectively. Prior to the use of systemic immunosuppressives, the mortality for systemic PAN exceeded 90%.

A leukocytosis of as high as 40 000/mm³ may occur, with neutrophilia to 80%; thrombocytosis, progressive normocytic anemia, and an elevated sedimentation rate and C-reactive protein (CRP) may also be found. Hepatitis B and C studies should be performed. Urinary abnormalities, such as proteinuria, hematuria, and casts, are present in 70% of patients. The prevalence of ANCA positivity is related to how one diagnoses PAN as opposed to MPA. ANCAs are more commonly found in MPA than in PAN, and in both diseases p-ANCA is the predominant type. HBV-associated PAN is rarely, if ever, ANCA-positive.

The histology is that of an inflammatory necrotizing and obliterative panarteritis that attacks the small and medium-sized arteries. Focal vasculitis forms nodose swellings that become necrotic, producing aneurysms and rupture of the vessels. Hemorrhage, hematoma, and ecchymosis may result. Obliteration of the lumen may occur, with ischemic necrosis of surrounding tissue. Characteristically, the arteries are affected at their branching points.

The mainstay of diagnosis is the presence of these histologic features and the constellation of clinical findings. The preferable site for biopsy is an accessible area such as skin, muscle, or testis. If these are not involved, angiography may detect

aneurysmal dilations as small as 1 cm wide in the renal, hepatic, or other visceral vessels.

Treatment

Untreated classic PAN can be fatal, death usually being due to renal failure or cardiovascular or gastrointestinal complications. Death generally occurs early in the course of the disease. Patients with HBV- or HCV-associated PAN should be given IFN and other antiviral treatments as their initial therapy. For PAN not associated with HBV or HCV, treatment with corticosteroids and cytotoxic agents has increased the 5-year survival rate to more than 75%. Corticosteroids in the range of 1 mg/kg/day are given initially. Once the disease remits, the dose should be reduced. After an average of 3–6 months, with the patient in remission, the steroids are slowly tapered to discontinuation.

Cyclophosphamide is given with steroids or sometimes as a single agent. Initially, 2 mg/kg/day as a single dose is recommended. Twice this amount may be required for severely ill patients. The oral dose is then adjusted to maintain the white blood cell count between 3000 and 3500/mm³ and the neutrophil count above 1500 cells/mm³. When the disease has been quiescent for at least 1 year, the cyclophosphamide may be tapered and stopped. On average, 18–24 months of therapy are required. Pulsed intravenous cyclophosphamide is associated with a lower incidence of toxicity, especially the long-term risk of malignancy. Plasma exchange may be used for acute crises or treatment failures with corticosteroids and cyclophosphamide. Ulcerations in PAN can be very painful due to the associated neuropathy. They should be managed like nonhealing leg ulcers.

Cutaneous polyarteritis nodosa

About 10% of patients present with PAN localized to the skin and with limited systemic involvement. Neuropathy occurs in 20%. Subcutaneous nodules (80%), livedo (70%), and ulceration (44%) are the characteristic cutaneous features that should lead to suspicion of cutaneous PAN. Atrophic blanche-like lesions around the ankles may be the sole cutaneous manifestation of cutaneous PAN. Plaques on the trunk and proximal extremities expanding slowly and centrifugally are another manifestation. At the periphery of the plaques is a ring of 1–2 cm subcutaneous nodules. Cutaneous PAN has a better prognosis and will require less aggressive therapy, patients rarely suffering the systemic renal, gastrointestinal, and cardiovascular complications of systemic PAN. This form of PAN is the most common childhood pattern of PAN. Whether there are two clear subsets of patients, cutaneous and systemic PAN, or rather a spectrum of disease is controversial. Patients with “cutaneous” PAN must be followed carefully and regularly evaluated to exclude the development of systemic involvement, which may appear as long as two decades after the initial diagnosis.

The diagnosis of cutaneous PAN is made by biopsy of a subcutaneous nodule. An excisional biopsy is recommended, as the vasculitis is focal. The affected arteriole is at the junction of the dermis and subcutaneous tissue or in the subcutaneous fat. Adjacent to the affected vessel there is an inflammatory panniculitis, and inadequate evaluation of the biopsy or too small a sample may lead to the erroneous diagnosis of a panniculitis. Also distal to the affected arteriole, thrombosis usually occurs. If the biopsy is inadequate in depth or size, this bland thrombosis without inflammation is seen and the erroneous diagnosis of a “vasculopathy” will be made. Cutaneous PAN has been associated with HBV surface antigenemia, HCV infection, Crohn’s disease, Takayasu arteritis, relapsing poly-chondritis, streptococcal infections, tuberculosis, and medica-

tions (minocycline). Typically, the only laboratory abnormality is an elevated erythrocyte sedimentation rate (ESR) or CRP. In some cases, a p-ANCA may be present. Most patients respond well to aspirin, NSAIDs, prednisone, pentoxifylline, sulfapyridine, or methotrexate, alone or in some combination. In childhood cutaneous PAN, since streptococcal infection is common, penicillin treatment may be used. In refractory cases, IVIG may be used.

ANCA-positive small-vessel vasculitides

Antineutrophil cytoplasmic antibodies (ANCA) have become an important laboratory finding used in the diagnosis and, in some cases, the prognosis of systemic vasculitis. ANCA occur in three patterns: cytoplasmic (c-ANCA); perinuclear (p-ANCA); and atypical ANCA. c-ANCA is associated with antibodies directed against proteinase 3 (PR3). Antibodies against myeloperoxidase result in the p-ANCA pattern, but antibodies against other antigens may also give this pattern. Atypical ANCA are not directed against myeloperoxidase or

PR3. Most laboratories now perform specific tests to determine whether positive ANCAs are reactive against myeloperoxidase or PR3. Anti-PR3 antibodies are relatively specific for Wegener granulomatosis and microscopic polyangiitis. Antibodies against myeloperoxidase are less specific and can be found in microscopic polyangiitis, Churg–Strauss syndrome, and drug-induced vasculitis. Usually, either anti-myeloperoxidase or anti-PR3 antibodies are found, but not both. If both patterns are found, drug-induced vasculitis should be suspected. ANCAs have been used to delineate a group of small-vessel vasculitides called “ANCA small-vessel vasculitides” or ANCA-SVV. These include microscopic polyangiitis, Wegener granulomatosis, and Churg–Strauss syndrome. These diseases have overlapping features, but characteristically demonstrate pulmonary hemorrhage and/or necrotizing glomerulonephritis (pulmonary–renal syndrome). Conversely, 60% of patients with the pulmonary–renal syndrome will have ANCA-SVV. With ANCA testing, ANCA-SVV can be diagnosed with 85% sensitivity and 98% specificity. While ANCAs are usually negative in Takayasu arteritis, giant-cell arteritis, Kawasaki’s disease, and Behçet disease, positive ANCAs can be found in cryoglobulinemia and other forms of skin-limited vasculitis, in 20% of patients with SLE, and in a higher percentage of patients with RA. ANCAs are used in the setting of vasculitis with systemic features or in situations where the clinical findings suggest ANCA-SVV. ANCA testing does not replace other tests or, more importantly, histologic confirmation of the presence of vasculitis. While the ANCA-SVVs are of unknown etiology, in multiple cases a solid tumor has been identified at the time of the diagnosis of the vasculitis, and Wegener granulomatosis and microscopic polyangiitis are the two most frequent forms of ANCA-positive vasculitis. Thrombophlebitis occurs in about 8% of persons with an ANCA-positive vasculitis.

Microscopic polyangiitis

With the advent of ANCA serologies and clarification of the features of microscopic polyangiitis (MPA), this diagnosis is becoming increasingly more common. There is a north–south gradient in incidence, with southern European countries having 3–4 times as many cases. Most patients with MPA have systemic symptoms, such as fever, weight loss, myalgias, and arthralgias, which can present with an acute flu-like illness or can evolve for months to years before a more explosive phase of their disease. These cases have been termed “slowly progressive MPA.” Most patients with MPA will have or develop segmental necrotizing and crescentic glomerulonephritis (80–90%), with pulmonary involvement in 25–65% of cases. Pulmonary capillaritis, which can be complicated by hemorrhage, occurs in 12–29% of MPA patients. The skin is involved in 44% of cases of MPA. Purpura as papules, macules, or ecchymoses (retiform purpura) is present in 26% of cases and cutaneous ulceration may result. Urticarial lesions occur in 1% of cases. Patients with MPA may present with skin lesions as their initial clinical findings. Livedo is seen in two-thirds of such patients. Skin biopsies of macules, papules, petechiae, or sites adjacent to ecchymoses may reveal a necrotizing LCV in the reticular dermis. Palisading and neutrophilic granulomatous dermatitis was found on a skin biopsy of the elbow of an MPA patient.

Vasculitic neuropathy is common (58%) and eye disease may occur. Eosinophilia and asthma are not seen. ANCAs are positive in 70% of cases, p-ANCA more frequently than c-ANCA. MPA is separated from PAN by the presence of glomerulonephritis, pulmonary symptoms, and the absence of hypertension and microaneurysms. ANCAs are less frequently positive in PAN.

MPA is managed like other forms of ANCA-SVV, with systemic corticosteroids and often cytotoxic agents from the disease onset. If the disease is localized, sulfamethoxazole/trimethoprim with corticosteroids may be considered. In generalized but non-organ-threatening disease, methotrexate may be added to the corticosteroids. Cyclophosphamide is usually used in the early induction phase of treatment (6–12 months) as monthly pulses (as opposed to daily treatment). Lower-toxicity immunosuppressives (methotrexate, azathioprine, mycophenolate mofetil) may be used as maintenance or in milder cases. IVIG and anti-TNF agents (infliximab) may be considered in refractory cases. Relapses are frequent; the 5-year survival is about 75% and 7-year survival is 62%.

Wegener granulomatosis

Wegener granulomatosis is a syndrome consisting of necrotizing granulomas of the upper and lower respiratory tract, generalized necrotizing angiitis affecting the medium-sized blood vessels, and focal necrotizing glomerulitis. By far the most common initial manifestation, present in 90% of patients, is the occurrence of rhinorrhea, severe sinusitis, and nasal mucosal ulcerations, with one or several nodules in the nose, larynx, trachea, or bronchi. Fever, weight loss, and malaise occur in these patients, who are usually 40–50 years of age and more often male than female (1.3:1). Obstruction in the nose may also block the sinuses. The nodules in the nose frequently ulcerate and bleed. The parenchymal involvement of the lungs produces cough, dyspnea, and chest pain. Granulomas may occur in the ear and mouth, where the alveolar ridge becomes necrotic, and ulceration of the tongue and perforated ulcers of the palate develop. The combination of nasal and palatal involvement may lead to saddle-nose deformity. The “strawberry gums” appearance of hypertrophic gingivitis is characteristic, and biopsy from these lesions may be diagnostic (Fig. 35-25).

Cutaneous findings occur in 45% of patients. Nodules may appear in crops, especially along the extensor surfaces of the extremities. The firm, slightly tender, flesh-colored or violaceous nodules may later ulcerate. These may be mistaken for ulcerating rheumatoid nodules. The necrotizing angiitis of the skin may present as a palpable purpura, petechial or

Fig. 35-25 Wegener granulomatosis, strawberry gingiva.

hemorrhagic pustular eruption, subcutaneous nodules, or ulcers. Livedo reticularis is rare in Wegener granulomatosis. Patients may present with pyoderma gangrenosum-like lesions and several patients have been reported presenting with features of temporal arteritis. The condition previously described as “malignant pyoderma” is now felt to represent Wegener granulomatosis.

Limited forms involving the upper respiratory tract without renal involvement may also occur and have a better prognosis. Cutaneous findings can be associated with limited disease. Focal necrotizing glomerulitis occurs in 85% of patients. It may be fulminant from the outset or may become more severe as the disease progresses. Renal failure was the most frequent cause of death before cyclophosphamide treatment. Other organs frequently involved include the joints (arthralgia in two-thirds); eyes (conjunctivitis, episcleritis, and proptosis) in 58%; and CNS and cardiac involvement in 22% and 12% of patients, respectively.

Histologically, the cutaneous lesions may demonstrate an LCV, with or without granulomatous inflammation. Granulomatous vasculitis may be seen. Palisaded granulomas with multinucleated giant cells and a central core of neutrophils and debris are a characteristic finding. Often, if the lesions are ulcerated, they are nonspecific histologically. Biopsy of another affected organ may be required to confirm the diagnosis. The early detection of Wegener granulomatosis has improved with the availability of ANCA testing, as 75–80% of patients are c-ANCA (anti-PR3)-positive.

Untreated Wegener granulomatosis has a mean survival time of 5 months and a 90% mortality over 2 years. Cyclophosphamide therapy has dramatically changed the prognosis. Treatment recommendations are cyclophosphamide, 2 mg/kg/day, and prednisone, 1 mg/kg/day, followed by tapering of the prednisone to an alternate-day regimen. Complete remission is achieved in up to 93% of patients and lasts an average of 4 years for still living patients. In more limited disease, patients may respond to methotrexate alone or methotrexate in combination with prednisone. After initial induction therapy and a remission, methotrexate, azathioprine, leflunomide, or mycophenolate mofetil may be used instead of cyclophosphamide. Treatment should be continued for at least 1 year. Trimethoprim-sulfamethoxazole may decrease the relapse rate and can be considered for long-term treatment of patients with limited upper respiratory tract involvement in remission in combination with conventional immunosuppressive protocols. The benefit of long-term sulfamethoxazole/trimethoprim is due to its reduction of

nasal carriage of *Staphylococcus aureus*, an accepted trigger of Wegener granulomatosis. In refractory cases, IVIG and anti-TNF therapy (infliximab) may be used. Tacrolimus, 0.1 mg/kg/day, was successful in treating a pyoderma gangrenosum-like ulceration in a patient with Wegener granulomatosis.

Churg–Strauss syndrome

Churg–Strauss syndrome (CSS) occurs in three phases. The initial phase, often lasting many years, consists of allergic rhinitis, nasal polyps, and asthma. The average age of onset of the asthma is 35 years in CSS (as opposed to allergic asthma, which often presents in childhood). After 2 to 12 years, a debilitated asthmatic begins to experience attacks of fever and eosinophilia (20–90%), with pneumonia and gastroenteritis (second phase). After a few more months or years, but on average 3 years after the initial symptoms, a diffuse angiitis involves the lungs, heart, liver, spleen, kidneys, intestines, and pancreas. Mononeuritis multiplex is common. Triggers of this third phase have included vaccination, desensitization, leukotriene inhibitors, azithromycin, inhaled fluticasone, or rapid discontinuation of corticosteroids. Renal involvement is less common than in Wegener granulomatosis or microscopic polyangiitis. A fatal outcome is likely in most untreated patients, with congestive heart failure resulting from granulomatous inflammation of the myocardium being the most frequent cause of death. Increased rates of arterial and venous thrombosis are seen in CSS, perhaps related to the dense infiltrates of eosinophils.

Cutaneous lesions are present in two-thirds of patients. Palpable purpura is seen in nearly 50% of patients. Subcutaneous nodules on the extensor surfaces of the extremities and on the scalp are seen in 30%. Firm, nontender papules may be present on the fingertips. These may resemble lesions seen with septic emboli or atrial myxoma, but show vasculitis on biopsy. Urticaria, solar urticaria, and livedo reticularis can occur in CSS. Plaques with the histologic features of eosinophilic cellulitis (Well syndrome) can be seen.

Laboratory studies are significant for a peripheral eosinophilia, which correlates with disease severity. ANCAs are frequently positive (55–70%), most commonly for anti-myeloperoxidase (p-ANCA) and less frequently for anti-PR3 (c-ANCA), and tend to correlate with disease severity.

Histologically, a small-vessel vasculitis is present that involves not only superficial venules, but also larger and deeper vessels. The tissue is often diffusely infiltrated with eosinophils, and granulomas may be present. Palisaded granulomas differ from those in Wegener granulomatosis in that

they generally lack multinucleated giant cells and the core contains eosinophils. In some patients, flame figures, similar to those in Wells syndrome, are noted in the dermis.

Corticosteroids alone may be used in patients with CSS and an FFS (see PAN above) of 0. Cyclophosphamide alone or in combination with corticosteroids should be used in cases of neuropathy, refractory glomerulonephritis, myocardial disease, severe gastrointestinal disease, and CNS involvement. Methotrexate and other immunosuppressives can be used as a steroid-sparing agent, especially to maintain a remission. IFN- α , mycophenolate mofetil, and the anti-TNF agents (infliximab and etanercept) have also been used successfully in CSS.

Cocaine-associated vasculitis

There are numerous reports of various forms of cutaneous vasculitis associated with the intravenous or intranasal use of cocaine. Skin lesions have included typical LCV, as well as larger-vessel vasculitis resembling PAN. Localized nasal lesions with vasculitis resembling Wegener granulomatosis have been observed in patients using inhaled cocaine. This has been termed “cocaine-induced pseudovasculitis” or “cocaine-induced midline destructive lesions” to try to distinguish it from true Wegener granulomatosis. In addition, patients using cocaine may develop more widespread cutaneous and sys-

temic vasculitis affecting kidneys, lungs, and testes. The cutaneous lesions resemble LCV, but ecchymotic lesions and skin necrosis were more prominent in these patients than in the typical LCV patient. Purpura and necrosis of the earlobe were especially common and characteristic. Agranulocytosis, not a typical feature of ANCA-positive vasculitis, was also found. These patients have an elevated c-ANCA (PR3-ANCA), similar to patients with true Wegener granulomatosis. However, the c-ANCA in patients with cocaine-induced vasculitis reacts with human neutrophil elastase (HNE-ANCA). Patients with Wegener granulomatosis and microscopic polyangiitis are negative for HNE-ANCA.

Street cocaine is commonly contaminated with pharmaceutical agents. Surprisingly, levamisole has been found in the cocaine seized by law enforcement in up to 30% of cases in the US and 100% in Italy. Levamisole therapy is associated with ecchymotic purpura and necrosis, with a predilection for the ears. It also causes agranulocytosis and c-ANCA positivity. It is therefore unclear whether the vasculitic lesions seen in recreational cocaine users are due to the cocaine or to the levamisole excipient or both. In every patient presenting with a cutaneous or systemic vasculitis, a detailed history of recreational drug use must be obtained, and toxicology screening should be considered in any patient with vasculitis having the features outlined above, especially agranulocytosis or cutaneous necrosis, or failure to respond to appropriate therapy. In these patients, stopping of the drug may lead to a gradual improvement of the vasculitis, although initial immunosuppressive therapy may be required. Treatment to eradicate nasal *S. aureus* should be considered if there are prominent nasal findings.

Giant-cell arteritis/temporal arteritis

Giant-cell arteritis is a systemic disease of people over the age of 50 years (mean age >70), favoring women (2:1). It is uncommon in African Americans and favors whites. Its best-known location is the temporal artery, where it is known as temporal arteritis, cranial arteritis, and Horton’s disease. It is characterized by a necrotizing arteritis with granulomas and giant cells, which produce unilateral headache and exquisite tenderness in the scalp over the temporal or occipital arteries in 50–75% of patients. Temporal headaches are characteristically constant, severe, and boring. Ear and parotid pain and mastication-induced jaw claudication may occur. Fever, anemia, and a high sedimentation rate (>50) are usually present. Proximal,

Fig. 35-26 Giant cell arteritis with scalp necrosis.

symmetrical, and severe morning and even day-long stiffness, soreness, and pain occur in 50% of patients (associated polymyalgia rheumatica). It is rarely fatal. Blindness may develop and is the most feared complication of the disease. Many patients who develop visual loss have premonitory symptoms allowing for the diagnosis and intervention, which may prevent permanent visual loss.

The cutaneous manifestations may be only inflammatory. The affected artery becomes evident as a hard, pulsating, tender, tortuous bulge under red or cyanotic skin. Another manifestation is necrosis of the scalp (Fig. 35-26). The lesions may first appear as ecchymoses. Later, they may become vesicular or bullous and are followed by gangrene. Urticaria, purpura, alopecia, tender nodules, prurigo-like nodules, and livedo reticularis may be seen. Lingual artery involvement may cause an accompanying red, sore, or gangrenous tongue. Nasal septal perforation may develop. Actinic granuloma may be associated. Actinic damage of the arterial elastic tissue of the temporal artery may be possible due to its superficial location. The elderly Caucasian is at greatest risk, and when lesions are biopsied, at times only the external half of the artery that received solar radiation is involved. Temporal arteritis may be an actinically induced disease.

Polymyalgia rheumatica (PMR) has a significant clinical association with giant-cell arteritis. Prompt treatment may forestall serious disease. About 10% of central retinal artery occlusions are due to giant-cell arteritis. ESRs are elevated in more than 90% of patients with giant-cell arteritis. Temporal artery biopsy is generally diagnostic, provided that at least a 2 cm segment is provided. Even arteries that are normal to palpation may show diagnostic findings. Magnetic resonance angiography is a noninvasive diagnostic method that may aid in confirming the clinical suspicion and identify the best site to biopsy. Not all patients with arteritis of the temporal artery have giant cell arteritis, as temporal arteritis may be a manifestation or part of the systemic vasculitides such as PAN, Wegener granulomatosis, or microscopic polyarteritis. Pathogenically, the presence of TNF polymorphisms in patients with PMR and temporal arteritis suggests a genetic predisposition.

Treatment is usually begun with prednisone, 60 mg/day, and continued for 1 month or until all reversible clinical and laboratory parameters (such as the ESR) have returned to normal. The disease is quite steroid-responsive and tapering to a dose of 7.5–10 mg/day is usually possible. Daily therapy seems to be important and is usually necessary for a minimum of 1–2 years. Most patients achieve complete remission that is often maintained after therapy is withdrawn. Anti-TNF agents may be used in refractory cases, but relapses occur when treatment is stopped, and corticosteroid therapy is usually required.

Takayasu arteritis

Known also as aortic arch syndrome and pulseless disease, Takayasu arteritis is a thrombo-obliterative process of the great vessels stemming from the aortic arch, occurring generally in young women (female to male ratio, 9:1) in the second or third decade of life. It is more common in Japan, Southeast Asia, India, and South America. Radial and carotid pulses are typically obliterated. Most skin changes are due to the disturbed circulation. There may be loss of hair and atrophy of the skin and its appendages, with underlying muscle atrophy. Occasional patients with cutaneous necrotizing or granulomatous vasculitis of small vessels have been reported. Erythematous nodules with or without livedo, simulating erythema nodosum or erythema induratum, may rarely occur. Pyoderma gangrenosum-like ulcerations are well described in Japan. Pyoderma gangrenosum lesions precede the diagnosis of the arteritis by an average of 3 years. These lesions are more commonly generalized and in three-quarters of cases occur on the upper extremities.

Treatment of Takayasu arteritis with prednisone, 1 mg/kg/day tapered in 8–12 weeks to 20 mg/day or less, is recommended. Methotrexate may be used for its steroid-sparing effects. With active medical and surgical intervention, the aggressive course of this disease can be modified. The pyoderma gangrenosum-like lesions are also treated with systemic steroids, but azathioprine, cyclophosphamide, mycophenolate mofetil, cyclosporine, and tacrolimus have also been effective.

Malignant atrophic papulosis

Papulosis atrophicans maligna, also known as Degos' disease, is a potentially fatal obliterative arteritis syndrome. Some affected patients have a long benign course with skin lesions only, while in others, death occurs within a few years. Degos' disease occurs 2–3 times more frequently in men than in women, often presenting between the ages of 20 and 40. Familial kindreds are well reported. In patients with the more aggressive variant, survival averages 2–3 years after the disease has developed.

Skin lesions are usually the first sign of the disease. Clinically, Degos' disease is characterized by the presence of pale rose, rounded, edematous papules occurring mostly on the trunk. Similar lesions may occur on the bulbar conjunctiva and oral

mucosa. Palms, soles, and face are spared, but the penis may be involved. Over days to weeks, the lesions become umbilicated, with a central depression, which enlarges. The center becomes distinctively porcelain-white, while the periphery becomes livid red and telangiectatic. Central atrophy occurs eventually. The eruption proceeds by crops in which only a few new lesions appear at any one time. One patient was reported to develop panniculitis. Lesions characteristic of Degos' disease may be seen in patients with lupus erythematosus, dermatomyositis, scleroderma, and Wegener granulomatosis.

Systemically, ischemic infarcts involve the intestines, producing acute abdominal symptoms, which include epigastric pain, fever, and hematemesis. Death is usually due to fulminating peritonitis caused by multiple perforations of the intestine. Less commonly, death occurs from cerebral infarctions.

Wedge-shaped necroses brought on by the occlusion of arterioles and small arteries account for the clinical lesions. Proliferation of the intima and thrombosis constitute the typical histologic picture. The thrombosing process is usually pauci-inflammatory, although neutrophils or lymphocytes may be found associated with the thrombosis. The overlying dermis, which is infarcted, contains abundant mucin, especially early in the lesion's evolution. Adnexae are typically necrotic and the depressed central portion may be noted histologically.

The etiology of this disease is unknown, but based on the infarctive nature of the lesions and the universal presence of arteriolar thrombosis, a hyperthrombotic state or endothelial abnormality is suggested. While most patients have not had abnormalities identified, abnormal platelet aggregation and abnormal coagulation have been identified in some cases. Antiphospholipid antibodies and anticardiolipin antibodies have been present in some patients, and a Leiden factor V mutation in one patient. Parvovirus B19 infection was associated with a fatal case in an adult.

Administration of immunosuppressives has not been beneficial. IVIG has been of therapeutic benefit in one case, but failed in another. Ingestion of low-dose acetylsalicylic acid alone or in combination with dipyridamole (Persantine) has been effective in some patients. Heparin, as described by Degos, has been helpful, and should be considered if antiplatelet therapy is ineffective. Nicotine patches, 5 mg/day, were effective in one case. In severe crises, fibrinolytic therapy should be considered. The prognosis is guarded in patients with systemic involvement.

Thromboangiitis obliterans (Buerger's disease)

Thromboangiitis obliterans (TAO) is a nonatherosclerotic segmental occlusive disease affecting the arteries of multiple extremities. It is most often seen in men between the ages of 20 and 40 who smoke heavily. Smoking and, rarely, the use of smokeless tobacco are intimately tied to Buerger's disease. Various diagnostic criteria have been proposed. They usually include: age younger than 45 (or 50); history of tobacco use; distal extremity involvement (infrapopliteal segmental arterial occlusion with sparing of the proximal vasculature); frequent distal upper extremity involvement (Raynaud or digital ulcers); consistent angiographic findings; superficial thrombophlebitis; exclusion of autoimmune disease, diabetes mellitus, and hypercoagulable or embolic states.

The vasomotor changes in early cases may be transitory or persistent; they produce blanching, cyanosis, burning, and tingling. Superficial thrombophlebitis in the leg and foot occurs in 38% of cases and 44% of patients may have Raynaud phenomenon. The color of the part may change when it is elevated or lowered below heart level, being red when dependent and white when elevated. Pain is a constant symptom, coming at first only after exercise and subsiding on resting. Instep and foot claudication is the classic complaint. Ultimately, the dorsalis pedis and posterior tibial pulses disappear, followed by others. In TAO, skin supplied by affected arterioles tends to break down, with central necrosis and ulceration, and eventual gangrene (Fig. 35-27). Gastrointestinal involvement has been reported. Exposure to cold may cause exacerbations, and more cases are identified in the winter than any other season.

Arteriography should be carried out to investigate for central atherosclerotic disease, which may be operable, rather than the inoperable distal damage of Buerger's disease. A characteristic tapering and occlusion of the major arteries with "corkscrew" collateral arteries is found in Buerger's disease on angiography. A vasculo-occlusive syndrome similar to Buerger's disease has been reported in cannabis smokers, but venous thrombophlebitis does not occur. The pathogenic mechanism of the vascular occlusion in Buerger's disease is unknown. In one report G20210A prothrombin mutations, the majority homozygotic, were found, but these findings have not been reproduced.

Fig. 35-27 Buerger's disease.

The most important therapeutic aspect is the cessation of smoking. Even one or two cigarettes/day, smokeless tobacco, or nicotine replacement may keep the disease active. Intravenous iloprost (a prostaglandin analog) may help the patient with critical limb ischemia get through an acute episode. Oral iloprost is ineffective. Sympathectomy can provide temporary relief. Autologous transplantation of bone marrow mononuclear cells into the calf muscle has benefited patients with TAO and other forms of limb ischemia. G-CSF-mobilized peripheral blood mononuclear cells have had similar efficacy. In patients who stop smoking and do not have gangrene, major amputations are rare. In continued smokers, at least 43% will require amputations. Implantation of a spinal cord stimulator may be tried.

Arteriosclerosis obliterans

Arteriosclerosis obliterans is an occlusive arterial disease most prominently affecting the abdominal aorta, and the small and medium-sized arteries of the lower extremities. The symptoms are due to ischemia of the tissues. There is intermittent claudication manifested by pain, cramping, numbness, and fatigue in the muscles on exercise; these are relieved by rest. There may be "rest pain" at night when in bed. Also, sensitivity to cold, muscular weakness, stiffness of the joints, and paresthesia may be present. Sexual impotence is common and there is an increased frequency of coronary artery disease.

Impaired to absent pulses (dorsalis pedis, posterior tibial, or popliteal arteries) may be found on physical examination, confirming the diagnosis. The feet, especially the toes, may be red and cold. Striking pallor of the feet on elevation and redness when dependent are compatible findings. Decreased to absent hair growth may be observed on the legs. Ulceration and gangrene may supervene. If present, they usually begin in the toes and are quite painful. Arteriography may be indicated as a preliminary to corrective surgery (arterial grafts). Occasionally, subclavian atherosclerosis may give rise to these signs in the distal upper extremity, producing painful nails and loss of digital skin. Diabetes mellitus, smoking, and hyperlipidemia are risk factors for the development of atherosclerosis.

Claudication and diminished blood pressure in the affected extremity are findings that may lead to earlier diagnosis and thus to curative surgical intervention. Usually, bypass of the affected artery or sympathectomy, or both, are the preferred treatment. Balloon angioplasty or stent placement may also be effective. When critical limb ischemia is present, injection of stem cells into the calf muscle may be beneficial.

Diffuse dermal angiomas

Diffuse dermal angiomas (DDA) is a not uncommon disorder that preferentially affects women. The most common location is the breast, especially the dependent portion. Affected women tend to have large, pendulous breasts, and are usually older than 45 years of age. Patients may have had a reduction mammoplasty (often decades before), and the disease tends to localize adjacent to the scar from that procedure. The clinical lesions may be reticulated groups of telangiectasias, ischemic (retiform) purpura, or ulceration, or some combination. The erythematous/telangiectatic plaques are slightly palpable but not usually indurated. The nipple and areola are spared. The affected patients often have multiple risk factors for a hypercoagulable state or premature atherosclerosis. These include a personal history of atherosclerotic cardiovascular disease, obesity, smoking, hypertension, mutations in the thrombolytic pathway (analogous to those seen in livedoid vasculopathy), and a strong family history for premature atherosclerotic disease-related cardiovascular events. The areas involved are very similar to those affected by other prothrombotic disorders such as warfarin necrosis and heparin necrosis—skin with overly abundant adipose tissue. The breast is most commonly affected, but the abdomen and medial thighs are also sites of predilection. Usually, only one site is affected, but if the breast is involved, the process can be bilateral. Surgical procedures on the affected area may lead to ulceration that is very painful and slow to heal. Because a surgical procedure triggered the ulceration, a mistaken diagnosis of pyoderma gangrenosum may be entertained.

Histologically, a diffuse dermal proliferation of endothelial cells and bland blood vessels occupies much of the dermis. Atypical cells and atypical vascular shapes (as seen in angiosarcoma and Kaposi sarcoma) are not seen. The dermal cells stain for markers of endothelial cells. The pathogenesis is felt to be local chronic ischemia, which may either lead to vascular proliferation (angiomas), or if acute and severe, may lead to retiform purpura or ulceration. The fatty areas are poorly oxygenated (worse in the obese patient), and the pendulous nature of the breasts may stretch or tether the vessels, further compromising the circulation. Inherited and acquired hypercoagulable risk factors (smoking, atherosclerosis, and so on) contribute to the pathogenesis.

The treatment involves reversing the contributing factors. This includes stopping smoking, weight reduction, and anti-thrombotic medications such as low-dose aspirin, 81 mg per day, and pentoxifylline, 400 mg BID. Reduction mammoplasty may lead to resolution. Atherosclerosis of the arteries serving the affected area may be found, and vascular surgery to enhance circulation may lead to improvement. One patient has been successfully treated with isotretinoin. Isotretinoin has a fibrinolytic effect, which may be the mechanism by which it improved DDA in this one patient.

Mucocutaneous lymph node syndrome (Kawasaki's disease)

The typical presentation is an irritable, ill-appearing, febrile infant or child younger than 5 years old. Clinical findings (four of which, plus fever for 5 days, are diagnostic of Kawasaki syndrome) include a skin eruption; stomatitis (injected pharynx, strawberry tongue) and fissuring cheilitis; edema of the hands and feet; conjunctival injection; and cervical lymphadenitis. The skin eruption is polymorphous and may be macular, morbilliform, urticarial, scarlatiniform, erythema multiforme-like, pustular, or erythema marginatum-like. An early finding (within the first week) is the appearance of an erythematous, desquamating perianal eruption in about two-thirds of patients. Periorbital edema has been reported. Fifteen to 20% of children with Kawasaki's disease (KD) and fever will not have one or more of the other cardinal features. These cases are termed "incomplete KD." These patients are still at risk for cardiac disease.

Numerous cutaneous and systemic complications have been reported as accompanying or following KD. Pincer nail deformities may appear and resolve spontaneously. Intestinal pseudo-obstruction may occur. Facial nerve paralysis has been described, and a severe peripheral vasculitis with vasospasm, digital ischemia, and gangrene can occur. Numerous children have developed guttate or plaque psoriasis 10–20 days after the KD had begun. The presumed mechanism is the triggering of psoriasis by the superantigens associated with the acute illness.

The acute illness evolves over 10–20 days. A week or two following the acute illness, the fingers and toes desquamate, starting around the nails (Fig. 35-28). Coronary artery aneu-

Fig. 35-28 Desquamation in Kawasaki's disease.

rysms occur in 20–25% of untreated children and 3–5% of treated children. This is the most common cause of acquired cardiac disease in young children. The cardiac involvement, which, in addition to aneurysms, can include decreased left ventricular function, arrhythmias, mitral regurgitation, and pericardial effusion, may lead to immediate cardiac complications, the major cause of morbidity and mortality. In addition, over time, those with aneurysms can develop coronary artery stenosis, and as a result acute cardiac events can occur in young adulthood.

Pathogenesis

A viral or infectious pathogenesis is attractive for the following reasons:

1. Cases were rare before 1950.
2. KD affects children older than 3 months but younger than 8 years.
3. Seasonal peaks occur in the winter and spring.
4. Focal epidemics have been reported.
5. Oligoclonal IgA immune responses are found, suggesting a respiratory portal of entry of an infectious agent.

There are increased superantigens in the stool of children with KD. A KD-like illness has been described with group A meningococcal septicemia. An infectious pathogenesis, therefore, remains the most plausible etiologic hypothesis.

It has long been suspected that there is a genetic basis for KD. The disease is 10–20 times more common in persons from Northeast Asia (Japan and Korea), where rates of up to 1 per 150 children are reported. When these Asians move to the US, they still have this high rate of increased susceptibility. The risk of a sibling developing KD is increased tenfold. Children of parents who had KD in childhood have a twofold increased risk of developing KD. A recent genome-wide search of almost 1000 KD cases and family members found strong linkage to five genes, three of which form a single functional network. The central gene of this network is *CAMK2D*, which encodes a serine/threonine kinase expressed in cardiomyocytes and vascular endothelial cells. These genes are already known to be involved in cardiac and inflammatory pathways. The transcripts of these genes were also markedly suppressed during KD. The previously reported genetic associations for KD were not found in this study, including the *ITPKC* gene mutation.

Coronary arterial disease occurs after day 10 of the illness (subacute phase), in combination with thrombocytopenia (up to 1 million). This combination of an altered endovascular surface and too many platelets, plus abnormal blood flow in

the coronary aneurysms, leads to thrombosis and occlusion of the vessels and the subsequent cardiac events.

Treatment

IVIG is the cornerstone of therapy, given in a single dose of 2 g/kg infused over 10–12 h. Response to treatment is best if given during the first 5–6 days of the illness; however, children with persistent fever beyond this period may benefit from later treatment. Aspirin is used to reduce inflammation and platelet aggregation. The dose is 80–100 mg/kg/day in four divided doses. Once the child has been afebrile for 3–7 days, the aspirin dose is decreased to a single daily dose of 3–5 mg/kg. If the child remains febrile, a second 2 g/kg dose of IVIG should be given. A single dose of infliximab, 5 mg/kg, has been reported to be effective in refractory cases, but response, as with other treatments, is not universal. If there is no response to the second IVIG dose, systemic steroid therapy is commonly given. Angioplasty, thrombolytic therapy, or coronary artery bypass surgery may be required for patients with coronary disease.

Telangiectasia

Telangiectasia are fine linear vessels coursing on the surface of the skin; the name given to them collectively is telangiectasia. Telangiectasia may occur in normal skin at any age, in both sexes, and anywhere on the skin and mucous membranes. Fine telangiectases may be seen on the alae nasi of most adults. They are prominent in areas of chronic actinic damage. In addition, persons long exposed to wind, cold, or heat are subject to telangiectasia. Calcium channel-blockers may lead to telangiectatic lesions in a generalized or photodistribution and contribute to the appearance of photoaging. Telangiectasias may also be found on the legs as a result of heredity, varicosities, pregnancy, and birth control pill use.

Telangiectases can be found in conditions such as radiodermatitis, xeroderma pigmentosum, lupus erythematosus, scleroderma and the CREST syndrome, rosacea, pregnancy,

cirrhosis of the liver, AIDS, poikiloderma, basal cell carcinoma, necrobiosis lipoidica diabetorum, lichen sclerosus et atrophicus, sarcoid, lupus vulgaris, keloid, adenoma sebaceum, Kaposiform hemangioendothelioma, angioma serpiginosum, angiokeratoma corporis diffusum, hereditary benign telangiectasia, Cockayne syndrome, ataxia-telangiectasia, and Bloom syndrome.

Altered capillary patterns on the finger nailfolds (cuticular telangiectases) are indicative of collagen vascular disease, such as lupus erythematosus, scleroderma, or dermatomyositis. They may infrequently be present in rheumatoid arthritis. These disorders are reviewed in Chapter 8.

Generalized essential telangiectasia

Generalized essential telangiectasia (GET) is characterized by the appearance of telangiectasia over a large segment of the body without preceding or coexisting skin lesions. Lesions tend to appear first on the legs and progress caudad. Women are more commonly affected, with the condition starting between age 20 and 50. Characteristic features include:

1. widespread cutaneous distribution
2. progression or permanence of the lesions
3. accentuation in dependent areas and by dependent positioning
4. absence of coexisting epidermal or dermal changes, such as atrophy, purpura, depigmentation, or follicular involvement.

The telangiectases may be distributed over the entire body or localized to some large area, such as the legs, arms, and trunk. They may be discrete or confluent. Distribution along the course of the cutaneous nerves may occur. Systemic symptoms are absent, although conjunctival telangiectasias can also be seen. GET is usually not believed to be associated with an increased risk of epistaxis, but gastrointestinal bleeding has been reported. Families with this disorder, inherited as an autosomal-dominant trait, have been reported. The cause of essential telangiectasia is unknown. Treatment is with vascular lasers, if required.

Collagenous vasculopathy, a condition favoring middle-aged males, is clinically similar to GET but histologically distinct. Histologically, markedly dilated subepidermal vessels are present. These blood vessels have thickened vascular walls and perivascular hyaline. Type IV collagen staining accentuates the superficial vessels.

Unilateral nevoid telangiectasia

In unilateral nevoid telangiectasia (UNT), fine, thread-like telangiectases develop in a unilateral, sometimes dermatomal (or following the lines of Blaschko) distribution. Spider angiomas may also be present. The most common distribution is unilateral or bilateral involvement of the third and fourth cervical dermatomes. The condition is rare in men; in affected women, it starts in adulthood. The familial form (very rare) favors males, is autosomal-dominant, and appears postnatally. UNT is associated with conditions that have increased levels of estrogen: puberty, pregnancy, oral contraceptive use, HCV infection, and cirrhosis. Treatment with pulse dye laser can be effective.

Hereditary hemorrhagic telangiectasia (Osler's disease)

Also known as Osler-Weber-Rendu disease, hereditary hemorrhagic telangiectasia (HHT) is characterized by small tufts of dilated capillaries scattered over the mucous membranes and the skin. These slightly elevated lesions develop mostly on the lips, tongue, palate, nasal mucosa, ears, palms, fingertips, nailbeds, and soles. They may closely simulate the telangiectases of the CREST variant of scleroderma, which may be distinguished by the lack of other features of CREST syndrome and by anticentromere antibodies, which are not found in HHT. Diagnostic criteria have been proposed and include:

1. epistaxis—spontaneous, recurrent nosebleeds
2. telangiectases—multiple at characteristic sites (lips, oral cavity, fingers, nose) (Fig. 35-29)
3. visceral lesions—gastrointestinal bleeding, pulmonary, hepatic, cerebral, or spinal arteriovenous malformation (AVM)
4. family history—one affected first-degree relative.

The presence of three of the four criteria indicates a definite diagnosis, while two of four indicate a possible diagnosis. There are at least three variants, HHT1 and HHT2, and a third associated with juvenile polyposis.

Frequent nosebleeds and melena are experienced because of the telangiectasia in the nose and gastrointestinal tract. Epistaxis is the most frequent and persistent sign. Worsening epistaxis may herald high-output cardiac failure from AVMs. Pregnancy can also exacerbate HHT. Gastrointestinal bleeding is the presenting sign in up to 25% of cases; however, 40–50% develop gastrointestinal bleeding some time during the course of their disease. Chronic persistent anemia requiring iron and

Fig. 35-29 Hereditary hemorrhagic telangiectasia.

blood transfusions is characteristic of severe cases. The spleen may be enlarged. Pulmonary and CNS AVMs may appear later in life. Liver failure can result from diffuse intrahepatic shunting—hepatic artery to vein, bypassing the liver parenchyma. Retinal arteriovenous aneurysms occur only rarely. Other sites of bleeding may be the kidney, spleen, bladder, liver, meninges, and brain. The risk of cerebral hemorrhage from cerebral AVMs, cerebral abscesses, and pulmonary hemorrhage from pulmonary AVMs is probably high enough that asymptomatic patients should be screened for the presence of cerebral and pulmonary AVMs. Because of the risk of cerebral abscess, some have advocated antibiotic prophylaxis for dental and contaminated skin procedures.

The telangiectases tend to increase in number in middle age; however, the first appearance on the undersurface of the tongue and floor of the mouth is at puberty. Pulmonary or intracranial arteriovenous fistulas and bleeding in these areas may be a cause of death.

HHT is inherited as an autosomal-dominant trait. The vascular abnormalities found in HHT consist of direct arteriovenous connections without an intervening capillary bed. Affected patients have mutations in one of three genes, most commonly in two, endoglin (*ENG*) or ALK-1 (*ACVRL1*). They encode a homodimeric integral membrane glycoprotein, which is a transforming growth factor (TGF)- β receptor. HHT1 is associated with *ENG* mutations, and HHT2 with *ACVRL1* mutations. HHT1 patients have a higher prevalence of pulmonary AVMs, while HHT2 patients tend to have a milder phenotype and later age of onset, but increased liver manifestations. Patients with HHT and juvenile polyposis have mutations in the *MADH4* gene, a downstream effector of TGF- β signaling. TGF- β is a potent stimulator of vascular endothelial growth factor (VEGF) production. VEGF leads to disorganized and tortuous vessels, as seen in HHT. VEGF levels are increased in patients with HHT.

Treatment is directed at controlling the specific complication, and identifying and treating AVMs before they become symptomatic. The tendency to epistaxis has been reduced by estrogen therapy and some recommend oral contraceptives for affected postpubertal females. Dermoplasty of the bleeding nasal septum may be performed by replacing the mucous membrane with skin from the thigh or buttock. Repeated laser treatments of the nasal and gastrointestinal mucosa are often required. Topical tranexamic acid has been used to control epistaxis. Bleeding episodes are treated supportively with iron and red blood cell transfusions. Interventional radiology with selective embolization can treat pulmonary and CNS AVMs and episodes of bleeding, avoiding invasive surgeries. In patients with liver failure or high-output heart failure due to liver AVMs, liver transplantation may be required. Blocking

VEGF with thalidomide (or more effectively with lenalidomide) can reduce gastrointestinal bleeding and transfusion dependence. Bevacizumab, a monoclonal inhibitor of VEGF, has dramatically improved some severely ill HHT patients, reducing the size and flow of their hepatic AVMs, reversing heart and liver failure, and reducing transfusion requirement.

Leg ulcers

Leg ulcers are a common medical condition, affecting 3–5% of the population over the age of 65. The cause of chronic leg ulceration is venous insufficiency alone in 45–60% of cases, arterial insufficiency in 10–20%, diabetes mellitus in 15–25%, or combinations in 10–15%. Smoking and obesity increase the risk for ulcer development and persistence, independent of the underlying cause. Defining the cause of the leg ulceration is important in treating the leg ulcer.

The wound healing response is complex, involving intricate interactions between different cell types, structural proteins,

growth factors, and proteinases. Normal wound repair consists of three phases—inflammation, proliferation, and remodeling—that occur in a predictable sequence.

Venous diseases of the extremities

Stasis dermatitis

Stasis dermatitis presents as erythema and a yellowish or light-brown pigmentation of the lower third of the lower legs, especially in the area just superior to the medial malleolus. An associated eczematous dermatitis may occur. The dermatitis may be weepy or dry, scaling or lichenified; it is almost invariably hyperpigmented by melanin and hemosiderin. Varicose veins are usually present, though they need not be numerous or conspicuous. Stasis dermatitis is a cutaneous marker for venous insufficiency. The approach to management should be two-fold: relief of symptoms and treatment of the underlying venous insufficiency. Patients with pruritus and an eczematous component should be treated with emollients and topical corticosteroids. The daily use of elevation and support stockings is strongly recommended.

Venous insufficiency and obesity-associated mucinosis

Localized areas of mucin deposition can be observed directly over the perforators on the lower extremity. These present as blushed, red–blue, partially compressible, agminated papules. On biopsy, deposits of dermal mucin against a background of the changes of venous insufficiency are seen. In the setting of morbid obesity and lower extremity edema, pretibial translucent papules can appear and merge into plaques. The plaques are composed of dermal mucin (hyaluronic acid). The diagnosis of “pretibial myxedema” is usually made, but thyroid functions are normal. With weight loss the lesions improve, suggesting that they were due to the lower extremity edema/venous insufficiency of obesity.

Venous insufficiency ulceration

Stasis dermatitis and venous ulceration result from increased pressure in the venous system of the lower leg. The most common cause is insufficiency of the valves in the deep venous system and lower perforating veins of the lower leg. With each contraction of the calf, blood should be pumped to the heart via this “muscle pump.” Intact valves in the lower leg are required to prevent this “pumped” blood from refluxing out through the perforators into the superficial system. Increased flow through the superficial system results in enlargement of the superficial venous plexus and the appearance of “varicose veins.” Increased pressure on the iliac veins from pregnancy or obesity, or simple inactivity may also result in the appearance of “venous insufficiency,” as well. The valvular insufficiency results in disorder in the venous and capillary circulation in the leg. Valve insufficiency may occur from prior thrombophlebitis or congenital “weakness.” Prolonged standing without walking or contracting the calf muscles, sitting for long periods, anemia, zinc deficiency, and a defective fibrinolytic system may accelerate the process. If a history of thrombophlebitis is present, an evaluation for a hypercoagulable state, such as a deficiency of Leiden factor V, should be considered.

Edema and fibrosis develop in the skin over the medial aspect of the ankle and lower third of the shin (Fig. 35-30). Following minor trauma, a macular hemorrhage appears. This is the premonitory sign of an impending ulceration. Venous

Fig. 35-30 Stasis dermatitis, venous insufficiency.

Fig. 35-31 Venous leg ulcer.

ulcers usually occur on the lower medial aspect of the leg. They may appear on the background of stasis dermatitis with lipodermatosclerosis (Fig. 35-31). Venous ulcerations can be painful, but not as painful as pyoderma gangrenosum or arterial or embolic ulcerations. The ulcer tends to be round or oblong and has a characteristic yellow, fibrinous base. Multiple lesions may occur.

In most cases, the diagnosis of a venous ulceration can be made on clinical grounds. If there is no clear history or physical findings of venous insufficiency, venous rheography can be performed. An ABI (ankle:brachial index, or ratio of blood pressure in the leg to the arm) should be performed, especially in cases where peripheral pulses are diminished and hair on

the lower legs is lost. This will identify coexistent arterial disease. More extensive vascular studies may be necessary to identify the presence and extent of arterial disease or focal venous valvular incompetence or congenital absence. In leg ulcers of the lower medial leg, even if cutaneous findings of venous insufficiency are absent, venous insufficiency will still be the most common cause of the ulcer. Lesions in atypical locations, those that do not respond appropriately to therapy, and those in which venous rheography is normal may require a biopsy to exclude other causes, including a cutaneous neoplasm. Additional workup may also be required to identify other, less common causes of leg ulcers, such as cholesterol emboli, atherosclerotic disease, diabetes mellitus, sickle cell disease, vasculitis, infection, and pyoderma gangrenosum.

Despite extensive research and the marketing of many new products and devices for the treatment of leg ulcers, very little has changed in their management over the last decades. Treatment is primarily to improve venous return and reduce edema. Compression therapy is the mainstay of treatment. This involves the use of pressure wraps, such as Unna boots covered with Coban or elastic wraps. Elevation of the leg above the heart, for as much of the time as is possible (a minimum of 2 h twice a day), is also beneficial. Elastic support of the legs must be continued after the ulcer heals. Other causes of edema, such as cardiac failure, must be addressed. The avoidance of long, cramped sitting (in airplanes or vehicles) or prolonged standing is advisable. Diuretics are overused and not proven to be of benefit. If there is a central cause of fluid retention (cirrhosis, heart failure, renal failure), diuretics may be beneficial, but otherwise they are best avoided. Avoidance of trauma is important. Pentoxifylline, 400–800 mg three times a day, in addition to compression, is beneficial in healing refractory venous ulcerations. A cooperative patient and a patient physician are necessary in the long-term management of venous disease. Topical anti-infectives are usually not necessary (except metronidazole gel to prevent anaerobic overgrowth). There is a high risk of allergic contact dermatitis from other topical antibiotics. Oral antibiotics should only be used to treat associated invasive infection. A rim of erythema commonly surrounds an ulcer. Expanding erythema, an enlarging ulcer, or increasing pain or tenderness may be signs of infection. Surface cultures and Gram stains may demonstrate colonizing, but not pathogenic, bacteria. Biopsy for histology and tissue homogenate culture is the most effective way to demonstrate a true invasive pathogen.

Many treatment options have been developed for chronic ulcers. Unfortunately, conclusive comparative studies between the various treatment alternatives are lacking. All are to be used in combination with compression treatment. Occlusive and semipermeable biosynthetic wound dressings can be very effective when combined with compression. They can speed healing, reduce pain, make dressing changes infrequent, and help debridement. If a hard eschar is present over the ulcer when first seen, a dressing will assist in its removal. Early in the treatment of an ulcer, a highly inflammatory and exudative phase occurs. This will often wash off the semipermeable dressing and may require the use of fenestrated dressings and even the application of absorbent padding over the dressing for the first few weeks. The patient will interpret this increased wound exudate, which is normal and indicates the conversion of a non-healing to a healing wound, as an infection. He/she should be appropriately educated before such dressings are applied. Dressings containing dilute acetic acid or silver may help reduce bacterial overgrowth in the wound, but fail to decrease the time to healing. However, metronidazole gel 0.75% instilled into the wound will help to reduce the amount of wound exudate (by eliminating anaerobic bacteria) and remove the smell of the wound exudate. The smell of achronic

leg ulcer may reduce the patient's quality of life. Becaplermin (Regranex) is expensive, but promotes wound healing. Granulation tissue formation is enhanced. It may be useful in wounds that are unable to develop a granulation tissue base despite local care and conservative debridement. Weekly debridement of the anesthetic dead fibrinous tissue can be useful in stimulating granulation tissue at the base of slow-to-heal venous ulcerations. Injection of granulocyte-macrophage colony-stimulating factor (GM-CSF) into the ulcer base may also stimulate refractory ulcers to heal. It is very expensive. Grafts and skin substitutes should be reserved for refractory ulcers that have failed conservative therapy. In more than 90% of cases, only simple but persistently applied measures are required. Enhanced compliance, longer elevation, and removal of leg edema are the first steps in attempting to heal refractory leg ulcers. If these are not optimized, expensive dressing and medications will not lead to healing. The role of vascular surgery or venous ablation in the healing of leg ulcers is controversial.

Risk factors that predict failure to heal within 24 weeks of limb compression therapy include a large wound area, history of venous ligation or stripping, history of hip or knee replacement, ABI <0.80, fibrin on 50% or more of the wound surface, and the presence of the ulcer for an extended time. For every 6 months of duration, the ulcer healing time doubles.

Arterial insufficiency (ischemic) ulcer

Ischemic ulcers are mostly located on the lateral surface of the ankle or the distal digits. The initial red, painful plaque breaks down into a painful superficial ulcer with a surrounding zone of purpuric erythema. Granulation tissue is minimal, little or no infection is present, and a membranous inactive eschar forms over the ulcer. Patients at risk are those with long-standing hypertension, smokers, diabetics, and those with hyperlipidemia. The presence of an arterial ulceration identifies patients at increased risk for limb loss.

Signs and symptoms indicating that arterial disease is the cause of the ulceration include thinning of the skin, absence of hair, decreased or absent pulses, pallor on elevation, coolness of the extremity, dependent rubor, claudication on exercise, and pain on elevation (especially at night) relieved on dependency. In progressive disease, the diagnosis of thromboangiitis obliterans, or Buerger's disease, should be considered. Patients with arterial insufficiency are also at risk for cholesterol emboli, another arterial cause of lower leg ulceration. Eosinophilia, palpable peripheral pulses, sudden onset, and associated renal insufficiency are clues to the diagnosis of cholesterol emboli.

The diagnosis of arterial insufficiency can usually be confirmed by physical examination and careful palpation of the pulses in the legs. For more accurate evaluation, take the blood pressure in the arm and leg. They should be nearly identical. The ratio of the popliteal to brachial pressure is called the ABI. If it is less than 0.75, arterial insufficiency exists; if less than 0.5, the insufficiency is substantial.

Surgical intervention may be required to heal the ulceration. If the blood supply cannot be improved, little can be done, except to prevent infection by the measures described under venous ulcers. The area should be protected from injury and cold, and smoking and tight socks should be avoided. Hyperbaric oxygen may be of some use, but it is limited by availability and cost.

Neuropathic ulcers

Foot ulcers in diabetics are usually related to sensory neuropathy. Offloading the ulcer is the primary principle of manage-

ment. Necrotic tissue should be debrided back to bleeding viable tissue. As the foot is typically insensate, this can be done in the office without the need for anesthetic. Associated osteomyelitis is best treated by removal of the infected bone. Consultation with or referral to a podiatrist or orthopedic surgeon may be indicated. Various shoes and padded boots can be used to offload different areas of the foot. An orthotics consultation is usually indicated. Clinical infection should be treated, but simple colonization typically does not require treatment. After the ulcer heals, a shoe of appropriate depth and width will help to prevent recurrence. Frequent foot inspections for the presence of "hot spots," as well as debridement of dystrophic nails, are important facets of prevention of leg ulcers in diabetics.

LYMPHEDEMA

Lymphedema is the swelling of soft tissues in which an excess amount of lymph has accumulated. Chronic lymphedema is characterized by long-standing, nonpitting edema. A working classification of lymphedema is shown in Box 35-2.

The most prevalent worldwide cause of lymphedema is filariasis. In the US the most common cause is postsurgical. If lymphedema is long-standing, a verrucous appearance to the affected extremity develops (elephantiasis verrucosa nostra).

Lymphedema of the lower extremity must be distinguished from "lipedema." This syndrome is characterized by bilateral, symmetrical lower extremity enlargement due to subcutaneous fat deposition. The buttocks to the ankles are affected in women, starting at puberty with gradual progression. The feet are spared in lipedema but usually involved in lower extremity lymphedema. Lipedema does not respond to compression therapy. The skin fold at the base of the second toe is too thick to pinch in lymphedema but normal in lipedema (Stemmer's sign). Verrucous changes do not occur in lipedema but do occur in lymphedema. Women with lipedema will have tenderness to pressure on the affected area. There is frequently a family history of lipedema. Magnetic resonance imaging (MRI)

Box 35-2 Classification of lymphedema

Primary lymphedema

- Congenital lymphedema (Milroy's disease)
- Lymphedema praecox
- Lymphedema tarda

Syndromes associated with primary lymphedema

- Yellow nail syndrome
- Turner syndrome
- Noonan syndrome
- Pes cavus
- Phakomatosis pigmentovascularis
- Distichiasis-lymphedema
- Emberger syndrome
- WILD syndrome
- Hypotrichosis-telangiectasia-lymphedema syndrome

Cutaneous disorders sometimes associated with primary lymphedema

- Yellow nails
- Hemangiomas
- Xanthomatosis and chylous lymphedema
- Congenital absence of nails

Secondary lymphedema

- Postmastectomy lymphedema
- Melphalan isolated limb perfusion
- Malignant occlusion with obstruction
- Extrinsic pressure
- Factitial lymphedema
- Postradiation therapy
- Following recurrent lymphangitis/cellulitis
- Lymphedema of upper limb in recurrent eczema
- Granulomatous disease
- Rosaceous lymphedema
- Primary amyloidosis

Complications of lymphedema

- Cellulitis of lymphedema
- Elephantiasis nostra verrucosa
- Ulceration
- Lymphangiosarcoma

will separate the two entities if the diagnosis cannot be confirmed on a clinical basis.

Types

Lymphedema is classified by clinical type (Box 35-2). Primary types include congenital, and early- and late-onset types. Other primary types of lymphedema are associated with characteristic features or syndromes. Some cutaneous disorders are associated with or are a complication of primary lymphedema. Secondary lymphedema can occur from numerous causes, including neoplasia and its treatment, infections, and physical factors.

Lymphedema praecox

Lymphedema praecox develops in females between the ages of 9 and 25. Swelling appears around the ankle and then extends upward to involve the entire leg. With the passage of time, the leg becomes painful, with a dull, heavy sensation. Once this stage has been reached, the swollen limb remains swollen, as fibrosis has occurred. Primary lymphedema is caused by a defect in the lymphatic system. Lymphangiography demonstrates hypoplastic lymphatics in 87%, aplasia in approximately 5%, and hyperplasia with varicose dilation of the lymphatic vessels in 8%.

Nonne-Milroy-Meige syndrome (hereditary lymphedema)

Milroy hereditary edema of the lower legs is characterized by a unilateral or bilateral lymphedema present at birth and inherited as an autosomal-dominant trait. The edema is painless, pits on pressure, is not associated with any other disorder, and persists throughout life (Fig. 35-32). It may involve the genitalia and produce lymphangiectasias superficially. Chylous discharge can occur. The face and arm may also be involved. Most frequently, the lymphedema is unilateral, and females are predominantly affected.

Treatment of this particular type of edema is extremely difficult, since the disease is an anomaly of the lymph-draining vessels. Decongestive physiotherapy can be considered. In some cases, surgical procedures to remove affected tissue can

Fig. 35-32 Milroy's disease. (Courtesy of Lawrence Lieblich, MD)

be performed. This condition may be linked to a mutation in *flt4*, the gene for VEGFR3.

Lymphedema–distichiasis syndrome

The association of distichiasis (double row of eyelashes) and late-onset lymphedema is a form of hereditary lymphedema called lymphedema-distichiasis syndrome, or Meige syndrome. It is an autosomal-dominant syndrome with the appearance of bilateral lymphedema, beginning between the ages of 8 and 10 in affected boys, and 13 and 30 in affected girls. Lymphatic vessels are increased (not hypoplastic or absent, as in other forms of congenital lymphedema) in the affected legs. Associated findings are varicose veins in 50% by age 64; congenital ptosis (31%); and congenital heart disease (6.8%), cleft palate (4%), scoliosis, and renal abnormalities. There may be phenotypic heterogeneity in this syndrome, as different types of mutation may lead to slightly different phenotypes, especially with regard to the ancillary features associated with the syndrome. This syndrome is due to a mutation in the FOXC2 transcription factor. This factor is expressed in developing eyelids, lymphatics, lymphatic valves, and other tissues with abnormalities in this syndrome.

Emberger syndrome

Emberger syndrome is primary lymphedema associated with myelodysplasia. This genetic syndrome presents with lymphedema of one or both lower limbs and often the genitalia between infancy and puberty. Myelodysplastic syndrome and/or acute myeloid leukemia developing in adolescence or childhood are preceded by pancytopenia with a high incidence of monosomy 7 in the bone marrow. Associated features include mild skeletal abnormalities, deafness, and multiple warts.

WILD syndrome (Warts, Immunodeficiency, Lymphedema, anogenital Dysplasia)

Lymphedema appears in early childhood and may progress to involve all 4 extremities and the genitalia. Widespread flat warts appear during childhood resembling the numerous flat warts seen in epidermodysplasia verruciformis. The anogenital region develops numerous warts and anogenital dysplasia. Helper T cells are reduced.

Hypotrichosis-telangiectasia-lymphedema syndrome

Lymphedema appears in childhood. Vascular dilations and telangiectasias appear on the palms and soles. Both autosomal recessive and autosomal dominant patterns of inheritance occur, but both forms are due to mutations in the SOX18 gene.

Primary lymphedema associated with yellow nails and pleural effusion (yellow nail syndrome)

Lymphedema is confined mostly to the ankles and occurs in about 60% of patients with this syndrome. The nails show a distinct yellowish discoloration and thickening. Recurrent pleural effusion or bronchiectasis may be a feature.

Secondary lymphedema

In some malignant diseases, involvement of the axillary or pelvic lymph nodes will produce blockage and lymphedema. Malignant disease of the breast, uterus, prostate, skin, bones, or other tissues may cause such changes. Hodgkin disease and, especially, Kaposi sarcoma (KS) may be accompanied by significant lymphedema well beyond the amount expected from the degree of skin involvement by the KS. Such patients require chemotherapy, as this is the hallmark of lymphatic involvement by the KS. Chronic lymphedema is frequently seen after mastectomy and the removal of the axillary nodes; it may occur after varying lengths of time.

Postmastectomy lymphangiosarcoma (Stewart–Treves syndrome)

This type of vascular malignancy usually arises in chronic postmastectomy lymphedema. The lesions are bluish or reddish nodules arising on the arm. Similarly, primary or secondary lymphedema of the lower extremity may be complicated by angiosarcoma. Angiosarcoma arising in a lymphedematous extremity often presents with multiple lesions. Metastasis and death commonly result. Early aggressive surgical treatment with amputation may be life-saving. The treatment of breast cancer with lumpectomy and local radiation therapy may be complicated by angiosarcoma of the breast with minimal or no associated lymphedema. This is called cutaneous postradiation angiosarcoma of the breast. This form of angiosarcoma also frequently results in metastasis and death.

Postinflammatory lymphedema

The lymphedematous extremity may be caused by and worsened by repeated bacterial cellulitis/lymphangitis. It is these recurrent infectious episodes, when they complicate filariasis, that cause the elephantiasis. Streptococcal cellulitis following venectomy in patients who had undergone coronary bypass surgery is a well-documented cause. However, almost any chronic or recurrent infection can cause this. Chronic antibiotic therapy can halt the progression by preventing the attacks of bacterial cellulitis.

Bullous lymphedema

Commonly misdiagnosed as an immunobullous disease, bullous lymphedema usually occurs with poorly controlled edema related to heart failure and fluid overload. Compression results in healing.

Factitial lymphedema

Also known as hysterical edema, lymphedema can be produced by wrapping an elastic bandage, cord, or shirt around an extremity, and/or holding the extremity in a dependent and immobile state. Self-inflicted causes of lymphedema are usually difficult to prove and may occur in settings of known causes of lymphedema, such as postphlebotic syndrome or surgical injury to the brachial plexus. Factitial lymphedema caused by blunt trauma localized to the dorsum of the hand or forearm is referred to as Secretan syndrome or l'œdème bleu, respectively. It often is unilateral and there may be significant purpura. Effective care of such patients requires psychiatric intervention. Occupational causes must be excluded.

Podoconiosis

Podoconiosis, or mossy foot, is a non-infectious form of lymphedema. It is restricted to tropical regions in Central Africa, Central America, and North India. It occurs in persons walking barefoot in soil of volcanic origin. This soil has high concentrations of aluminum, silicon, beryllium, zirconium, magnesium, and iron. Apparently, colloid-sized particles of the dust penetrate the sole, and migrate to lymph nodes ingested in macrophages. Lymphatic drainage is impaired by fibrosis of lymphatic channels, induced by the microscopic deposits of the substances. Males and females are equally affected, and in endemic areas up to 5% of the population can develop the disease. Moving into an endemic area from a non-endemic area can lead to the condition appearing over the next 5 years. Podoconiosis begins in childhood or adolescence with mild swelling of the feet. Burning of the feet occurs at night. The dorsal surface of the foot itches, and is rubbed and lichenified. Increased skin markings and finally marked hyperkeratosis due to repeated infections result. This closely resembles

elephantiasis verrucosa cutis. The condition is usually asymmetrical. Podoconiosis is prevented by wearing shoes. Elevation, compression, and local wound care all aid in this condition. Extensive surgery, as done for filariasis, has had disappointing results.

Other causes

Occupational persistent hand edema in divers, related to the constrictive action of the divers' suits and pricks from sea urchin spines, can occur.

Evaluation

The diagnosis is usually based on a classic presentation; however, in the early stages the disease may require further investigation. Considerations include isotopic lymphoscintigraphy, indirect and direct lymphography, MRI, computed tomography, and ultrasonography.

Treatment

Most cases are treated conservatively by means of various forms of compression therapy, complex physical therapy, pneumatic pumps, and compressive garments. Chronic antibiotic treatment may be beneficial in patients suffering repeated episodes of erysipelas or cellulitis. In diabetics with insensate feet, the frequency of infection can be reduced by wearing properly fitting shoes. Volume-reducing surgery and lymphatic microsurgery are rarely performed, although a few centers consistently report favorable results. It is best to refer these patients to a center versed in the treatment of these complicated conditions, to optimize patient compliance and customize therapy to the patient's lifestyle.

Disturbances of Pigmentation

The visible pigmentation of the skin or hair is a combination of the amount of melanin, type of melanin (eumelanin versus pheomelanin), degree of vascularity, presence of carotene, and thickness of the stratum corneum. Other materials can be deposited abnormally in the skin, leading to pigmentation. Eumelanin is the primary pigment producing brown coloration of the skin. Pheomelanin is yellow or red, and is also produced solely in melanocytes. Melanin is formed from tyrosine, via the action of tyrosinase, in the melanosomes of melanocytes. There are hundreds of genes expressed only in melanosomes and apparently important in melanin production and delivery. Melanosomes are lysosome-related organelles. Melanosome formation and the end result, pigmentation, require both the adequate manufacture of melanin and the appropriate transport of melanosomes within the melanocyte. The melanosomes are transferred from a melanocyte to a group of 36 keratinocytes called the epidermal melanin unit, to which they provide melanin. The variations in skin color between persons and races are related to the degree of melanization of melanosomes, their number, and their distribution in the epidermal melanin unit. Disorders of loss or reduction of pigmentation may be related to loss of melanocytes or the inability of melanocytes to produce melanin or transport melanosomes correctly. Wood's light examination is often performed to evaluate lesions of hyper- or hypopigmentation. Hyperpigmented lesions that enhance with Wood's light usually have increased epidermal melanocyte number or activity. If the lesions do not enhance, the melanin is located in the dermis. Wood's light will markedly enhance depigmented lesions (complete loss of pigment), but does not enhance lesions with partial pigment loss (hypopigmentation).

Pigmentary demarcation lines

Pigmentary demarcation boundaries of the skin can be classified into six groups, as follows:

1. Group A: Lines along the outer upper arms with variable extension across the chest.
2. Group B: Lines along the posteromedial aspect of the lower limb (Fig. 36-1).
3. Group C: Paired median or paramedian lines on the chest, with midline abdominal extension.
4. Group D: Medial, over the spine.
5. Group E: Bilaterally symmetrical, obliquely oriented, hypopigmented macules on the chest.
6. Group F: Facial pigmentary demarcation lines.

More than 70% of black patients have one or more lines; they are much less common in white patients. Type B lines often appear for the first time during pregnancy.

Pigmentary demarcation lines must be distinguished from the much rarer condition, acquired dermal melanocytosis. This primarily affects Asian and Hispanic women (male to female ratio, 1:17). It often first appears during pregnancy or the therapeutic use of estrogen/progesterone. Lesions present as blue-gray patches, with superimposed brown macules affecting the face, trunk, or extremities. Lesions do not enhance with Wood's light. They may be localized (following trauma) or more diffuse. Biopsy shows melanocytes in the dermis, similar to the findings in Mongolian spot, nevus of Ota, and nevus of Ito.

Abnormal pigmentation

Hemosiderin hyperpigmentation

Pigmentation due to deposits of hemosiderin occurs in purpura, hemochromatosis, hemorrhagic diseases, and stasis dermatitis. Clinically, hemosiderin hyperpigmentation is distinguished from postinflammatory dermal melanosis by a golden brown hue, as opposed to the brown or gray-blue pigmentation of epidermal and dermal melanin, respectively. At times, a biopsy is required to distinguish melanin- from hemosiderin-induced hyperpigmentation. Some medications (including minocycline) deposit in the skin and complex with both iron and melanin, making uniquely colored (usually blue-gray) deposits.

Postinflammatory hyperpigmentation (postinflammatory pigmentary alteration—PIPA)

Any natural or iatrogenic inflammatory condition can result in hyper- or hypopigmentation. Postinflammatory dyspigmentation is more frequent in persons with Fitzpatrick skin types IV, V, and VI, especially those of skin types IV and V. It is equally common in males and females. Hyperpigmentation may result from two mechanisms:

1. increased epidermal pigmentation via increased melanocyte activity
2. dermal melanosis from melanocyte damage and melanin dropout from the epidermis into the dermis.

Wood's light examination will distinguish these two patterns of postinflammatory hyperpigmentation. Lesions of hyperpigmentation tend to be tan to brown (Fig. 36-2), and may have

Fig. 36-1 Pigmentary demarcation lines.

Fig. 36-2 Postinflammatory hyperpigmentation from varicella.

a gray hue (due to dermal melanin). Hypopigmented lesions are prominently lighter than the surrounding area. Histologically, there is melanin in the upper dermis and around upper dermal vessels, located primarily in macrophages (melanophages). The pattern of the dermal melanosis does not predict whether the lesion will be lighter or darker as a result of the prior inflammatory process—hence the tendency of pathologists to provide a diagnosis of “postinflammatory pigmentary alteration” in such cases. Postinflammatory dyspigmentation is addressed initially by treating the underlying skin disease, if possible. The resolution of pityriasis alba with mild topical steroids and moisturizers is an example of resolution of postinflammatory hypopigmentation by treating the cause. This should be the sole approach in hypopigmented lesions after inflammation. For hyperpigmented lesions, hydroquinone may be used in hyperpigmented cases that

enhance with Wood’s light. Tretinoin application may enhance the effect of hydroquinone. Laser treatments and chemical peels must be done with extreme caution, as increased pigmentation may result. For additional management approaches, see the section on melasma below.

Melasma (chloasma)

Melasma is a very common disorder. It tends to affect darker-complexioned individuals, especially East, West, and Southeast Asians, Hispanics, and black persons who live in areas of intense sun exposure and have Fitzpatrick skin types IV and V. Subtle melasma, as identified by ultraviolet (UV) light examination, may be seen in up to 30% of middle-aged Asian females. Men are also affected, especially those from Central America, who may have prevalence rates as high as 35%. Guatemalan men seem to be at greater risk than Mexican men, and speaking a native tongue is also a risk factor, suggesting a genetic component associated with indigenous heritage.

The pathogenesis of melasma is not known. However, many observations strongly suggest that sun exposure is the primary trigger. Melasma affects the face, a sun-exposed area, and worsens in the summer. Melasma patients have lower MED (minimal erythema dose) to UV light, and pigment more easily with UV exposure. There is an association between the number of melanocytic nevi and the development of vitiligo. The number of nevi, in addition to being familial, is also related to sun exposure. The prevalence of melasma increases with age in both men and women. Solar elastosis is more marked in areas of melasma, compared to unaffected facial skin. At the cellular level, areas of melasma have higher levels of inducible nitric oxide synthase and phosphorylated Akt, an element of the nuclear factor kappa B (NF- κ B) pathway. The role of sunlight in inducing melasma may be to cause elevated levels of nitric oxide via the NF- κ B pathway. Inducible nitric oxide stimulates tyrosinase activity of melanocytes, increasing local melanin production. This results in the clinically evident hyperpigmentation in sun-exposed sites.

After sun exposure, the second most important triggers for melasma are female hormones. Melasma is more common and severe in women than men. It occurs frequently during pregnancy, with oral contraceptives use, or with hormone replacement therapy (HRT) at menopause. Discontinuing the use of contraceptives or HRT rarely clears the pigmentation and it may last for many years after the drugs are discontinued. In contrast, melasma of pregnancy usually clears within a few months of delivery. Melasma may be seen in other endocrinologic disorders, and with dilantin therapy.

Melasma is characterized by brown patches, typically on the malar prominences and forehead. The forearms may also be affected. There are three clinical patterns of facial vitiligo: centrofacial, malar, and mandibular. The centrofacial and malar patterns comprise the majority of patients (Fig. 36-3), but most patients have multiple types, making this classification not very useful therapeutically. The pigmented patches are usually quite sharply demarcated. While melasma has classically been classified as epidermal- or dermal-based on the presence or absence of Wood’s light enhancement, respectively, most cases show both epidermal and dermal melanin. Dermal melanophages are a normal finding in sun-exposed Asian skin. Independent of Wood’s light findings, a therapeutic trial of

Fig. 36-3 Melasma of the cheek.

some form of hypopigmenting agent should be recommended if the patient requests it.

A number of topical therapies are available. Exposure to sunlight should be avoided and a complete sunblock with broad-spectrum UVA coverage should be used daily. Bleaching creams with hydroquinone are the gold standard and are moderately efficacious; they contain from 2% (available over the counter) to 4% hydroquinone. Tretinoin cream may be added to increase efficacy. While tretinoin alone may reduce melasma, it may also increase pigmentation via its irritant effect. The combination of hydroquinone and tretinoin, administered in conjunction with a topical steroid, has been called "Kligman's formula" and is excellent. This is available as a commercial product, Triluma, used once a day. The efficacy of this product has been reported to be superior to any combination of two of its ingredients, with a more rapid and complete response with the triple combination. Glycolic acid is at times added to hydroquinone to enhance its efficacy. In some patients with melasma, 4% hydroquinone is insufficient and higher doses of hydroquinone must be compounded. Satellite pigmentation and local ochronosis are potential complications from use of these higher-concentration preparations. Mequinol, azelaic acid, kojic acid, licorice extract, ellagic acid, glucosamine, niacinamide, vitamin C, vitamin E, phytosterol, glycyrrhetic acid, pidobenzon 4%, and arbutin are other therapies with efficacy. Many of these agents are added to cosmetic products for skin lightening, and may be combined, as they act on different steps of melanogenesis.

Various surgical procedures, such as peels and light-based treatments, have been proposed as effective for melasma. Most patients who undergo surgical procedures have been previously treated with hydroquinone, and this therapy is frequently continued or is used in preparation for the surgical treatment. Peels are usually given in a series. It is suggested that repeated peels with glycolic acid, low-concentration TCA, and salicylic acid, when combined with pretreatment with hydroquinone, enhance the improvement obtained with hydroquinone alone, but comparative trials are lacking. The use of surgical modalities for the treatment of melasma should be approached with caution. These products are all irritants and these therapies may be complicated by hyperpigmentation, irritation, hypopigmentation, and even scarring, if not used appropriately. Since these treatments are not standardized from one report to another, the literature is not compar-

able, and the variable results may be in part technique-dependent. Intense pulse light, fractional resurfacing, erbium:YAG resurfacing, 578 nm copper bromide, and Q-switched Nd:YAG have all been reported as effective. However, results are inconsistent, and complications may result.

Pigmented anomalies of the extremities

This group of disorders is linked by the similar clinical features (reticulate pigmented macule) and characteristic histology—adenoid pigmented proliferations of the rete ridges of the interfollicular and infundibular follicular epidermis. Patients may have features of several different syndromes, making classification difficult. They probably represent at least three distinct disorders, but since the genetic cause has not been found for all these conditions, their uniqueness cannot be proven. Interestingly, dermatopathia pigmentosa is due to a mutation in the keratin 14 gene, and Dowling–Degos disease

is due to a similar mutation in keratin 5. Keratin 5 and 14 are a keratin pair highly expressed and required for structural integrity of the basal cell layer. Also the rare EB subtype, EB simplex with mottled pigmentation, is also due to a mutation in keratin 14. These genetic clues can explain how slightly different syndromes can have similar phenotypes, since the genetic defects are in proteins that interact in vivo.

Dyschromatosis symmetrica hereditaria (DSH) (reticulate acropigmentation of Dohi)

Originally described and still reported primarily in the Japanese, acropigmentation of Dohi has been found to affect individuals from Europe, India, and the Caribbean. It is also referred to as dyschromatosis symmetrica hereditaria (DSH) or symmetrical dyschromatosis of the extremities. It is inherited most commonly as an autosomal-dominant trait, although autosomal-recessive kindreds have been reported. Patients develop progressive hyperpigmented and hypopigmented macules, often mixed in a reticulate pattern, concentrated on the dorsal extremities, especially the dorsal hands and feet. The lesions vary in size from pinpoint to pea-sized. Freckle-like macules can present on the face. Lesions appear in infancy or early childhood and commonly stop spreading before adolescence. The pigmentary lesions last for life. The autosomal-dominant form of DSH is due to a mutation in the *DSRAD* gene, which encodes a double-stranded RNA-specific adenosine deaminase, an RNA editing enzyme. There is no association between the site of the mutation in this gene and the clinical phenotype.

Dyschromatosis universalis hereditaria (DUH)

Dyschromatosis universalis hereditaria is a rare autosomal or autosomal-recessive genodermatosis characterized by reticulate hyper- and hypopigmented macules in a generalized distribution (Fig. 36-4). Lesions appear in childhood, often in the first few months of life. The palms, soles, and mucous membranes of the mouth and tongue may be diffusely pigmented, with hypopigmented macules interspersed. Most DUH patients do not show other symptoms and are otherwise well. Uncommonly reported associations include ocular and auditory abnormalities, photosensitivity, developmental delay, and short stature. In different kindreds the causal gene has been reported on chromosome 6 or 12, making this syndrome genetically distinct from DSH and Dowling-Degos disease.

Reticular pigmented anomaly of the flexures (Dowling-Degos disease)

Reticular pigmented anomaly of the flexures is a rare autosomal-dominant pigmentary disorder; it is sometimes called Dowling-Degos disease or dark dot disease. Pigmentation usually appears at puberty or in early adolescence, but may present later in adulthood. The skin lesions primarily affect the axillae, neck, and inframammary/sternal areas. In some cases, the dorsal hands are involved. The pigmentation is reticular; at the periphery, discrete, brownish-black macules surround the partly confluent central pigmented area. In more mildly affected patients the pigmentation is dappled. The pigmentation progresses very gradually. There are frequently acneiform, pitted scars, sometimes pigmented, about the mouth. Comedonal and cystic lesions have been described on the flexures and in the axilla. Hidradenitis suppurativa-like lesions in the groin and axilla may occur. Patients may complain that the condition is worse during hot weather. Squamous cell carcinoma of the buttocks or perianal area has been described.

Histologically, in addition to the typical lentiginous adenoid proliferations of the rete ridges, small horn cysts may be present, so that the pattern resembles that of a reticulated seborrheic keratosis. Comedones may be present. Erbium:YAG laser has treated the pigmented lesions of the chest.

Dowling-Degos disease is caused by mutations in the keratin 5 gene. The reported mutations have been proposed as altering function of the initiation codon, or premature termination of the keratin 5 polypeptide. Similar mutations occur in Galli-Galli disease, suggesting that the two conditions represent variants of the same disorder, rather than separate diseases.

Galli-Galli disease

Galli-Galli disease is now recognized as a variant of Dowling-Degos disease, also caused by mutations in the keratin 5 gene. The skin lesions are 1–2 mm, slightly keratotic, red to dark brown papules, which are focally confluent in a reticulate pattern (Fig. 36-5). The skin lesions favor skinfolds but other skin sites may also be involved. The neck, axillae, upper

Fig. 36-5 Galli-Galli disease.

extremities, dorsal hands, trunk, groin, and even the scrotum and lower extremities may be affected. Histologically, there is prominent digitate downgrowth of the rete ridges, identical to that seen in Dowling-Degos disease. The characteristic histologic feature is a suprabasilar cleft and suprapapillary thinning of the epidermis. There is no dyskeratosis, as is seen in Grover's disease.

Reticulate acropigmentation of Kitamura

Reticulate acropigmentation of Kitamura is a rare autosomal-dominant disease, which initially was recognized in Japan, but now has been seen in many countries, usually in persons of color. The characteristic presentation is pigmented, angulated, irregular, freckle-like lesions with atrophy, arranged in a reticulate pattern on the dorsal feet and hands. Lesions start in the first to second decade, gradually progress, and slowly darken over time. The axillae and groin may be affected, as can the skin of the trunk and more proximal extremities. Linear irregular breaks in the dermatoglyphics of the palms are characteristic and help to distinguish this disorder from the other "reticulate flexural anomalies."

Kocaturk E, et al: Reticulate acropigmentation of Kitamura: report of a familial case. *Dermatol Online J* 2008; 14:7.

Dermatopathia pigmentosa reticularis

Dermatopathia pigmentosa reticularis (DPR) is an autosomal-dominant disorder characterized by the triad of generalized reticulate hyperpigmentation (Fig. 36-6), noncicatricial alopecia, and onychodystrophy. Additional associations include loss of dermatoglyphics, hypo- or hyperhidrosis, pigmented

Fig. 36-6 Dermatopathia pigmentosa reticularis.

Fig. 36-7 Transient neonatal pustulosis.

lesions of the oral mucosa, palmoplantar hyperkeratosis, and nonscarring blisters on the dorsa of the hands and feet. Wiry scalp hair and digital fibromatosis have also been reported. Dental anomalies are not a feature of DPR. Some members of families affected by Naegeli-Franceschetti-Jadassohn syndrome (NFJS) have clinical features identical to DPR. Both NFJS and DPR are due to mutations in the E1/V1 encoding region of the keratin 14 gene, which would lead to premature termination at the translation initiation site of keratin 14. NFJS and DPR are now best considered variants of the same genetic disorder. EB simplex with mottled pigmentation also has a mutation in keratin 14, explaining the presence of blistering in DPR and mottled pigmentation in this unique form of EB.

Tunca M, et al: Early-onset gastric carcinoma in a man with dermatopathia pigmentosa reticularis. *Int J Dermatol* 2008; 47:641.

Transient neonatal pustular melanosis

Also called transient neonatal pustulosis, this disorder is present at birth. Newborns present with 1–3 mm flaccid, superficial fragile pustules (Fig. 36-7). Some of the pustules may have already resolved in utero, leaving pigmented macules.

Lesions affect the chin, neck, forehead, back, and buttocks, but can occur anywhere. In dark-skinned infants, pigmented macules may persist for weeks or months after the pustules have healed, whereas in affected lighter-skinned neonates, dyspigmentation less commonly occurs. The condition is observed in 4.4% of black and 0.6% of white newborns.

Histologically, there are intracorneal or subcorneal aggregates predominantly of neutrophils, but eosinophils may also be found. Dermal inflammation is composed of a mixture of neutrophils and eosinophils. The differential diagnosis includes erythema toxicum neonatorum, neonatal acne, and acropustulosis of infancy.

Van Praag MC, et al: Diagnosis and treatment of pustular disorders in the neonate. *Pediatr Dermatol* 1997; 14:131.

Peutz–Jeghers syndrome

Peutz–Jeghers syndrome (PJS) is characterized by hyperpigmented macules on the lips and oral mucosa, and polyposis of the small intestine. The dark brown or black macules appear typically on the lips, especially the lower lip, in infancy or early childhood (Fig. 36-8). Similar lesions may appear on the buccal mucosa, tongue, gingiva, and genital mucosa; macules may also occur around the mouth, on the central face, and on the backs of the hands, especially the fingers, toes, and tops of the feet. More than two-thirds of patients have lesions on the hands and feet, and 95% have perioral lesions. Skin lesions grow in size and number until puberty, after which they begin to regress. Similar pigmentation may be seen in the bowel.

The associated polyposis involves the small intestine by preference (64%), but hamartomatous polyps may also occur in the stomach (49%), colon (49%), and rectum (32%). The polyposis of the small intestine may cause repeated bouts of abdominal pain and vomiting. Bleeding is common; intussusception is frequent (47%).

Patients with PJS have a 15-fold greater lifetime cancer risk (85–93%) than the general population. The greatest risk is for gastrointestinal malignancy of the colon (39% of patients), stomach (29% of patients), and small intestine (13% of patients). Cancers begin to appear around age 30 years. Cancers occur in both the gastrointestinal tract and extraintestinal sites. Pancreas (36%), breast (can be bilateral, 54%), ovary (21%), lung, cervix, uterus, and thyroid carcinomas may develop. Sertoli–Leydig cell stromal tumors occur in 9% of PJS males,

Fig. 36-8 Peutz–Jeghers syndrome, macular pigmentation of the lower lip.

and sex cord tumors with annular tubules can occur in female PJS patients. Patients with PJS lacking an *STK11/LKB1* mutation have a 40% risk of cholangiocarcinoma.

The syndrome is transmitted as a simple mendelian dominant trait. Between 50 and 70% of families with PJS have a germline mutation of the *STK11/LKB1* tumor suppressor gene on chromosome 19p13. The gene product is a serine–threonine kinase involved in signal transduction in the mTOR pathway. Patients have one inactive copy of this gene. Patients with truncation of the gene rather than a missense mutation are more severely affected, suggesting a phenotype/genotype correlation.

Laugier–Hunziker syndrome and Cronkhite–Canada syndrome should be considered in the differential diagnosis. Laugier–Hunziker syndrome presents with mucosal pigmentation and pigmented nail streaks. Cronkhite–Canada syndrome consists of melanotic macules on the fingers and gastrointestinal polyposis. Also there is generalized, uniform darkening of the skin, extensive alopecia, and onychodystrophy. The polyps that occur are usually benign adenomas and may involve the entire gastrointestinal tract. A protein-losing enteropathy may develop and is associated with the degree of intestinal polyposis. Onset is typically after age 30 in this sporadically occurring, generally benign condition. Hypogeusia is the dominant initial symptom, followed by diarrhea and ectodermal changes. Seventy-five percent of all cases have been reported from Japan. Zinc therapy may improve the hypogeusia and other symptoms.

Riehl melanosis

Riehl melanosis describes the pigmentation that occurs following photoallergic contact dermatitis, usually from fragrances and essential oils in cosmetics. This term is no longer used.

Miyoshi K, et al: Riehl's melanosis-like eruption associated with Sjögren's syndrome. *J Dermatol* 1997; 24:784.

Seike M, et al: Coexistence of Riehl's melanosis and lichen planus. *J Dermatol* 2003; 30:132.

Serrano G, et al: Riehl's melanosis. *J Am Acad Dermatol* 1989; 21:1057.

Tar melanosis (melanodermitis toxica lichenoides)

Tar melanosis is an occupational dermatosis that occurs among tar handlers after several years' exposure. Severe widespread itching develops and is soon followed by the appearance of reticular pigmentation, telangiectases, and a shiny appearance of the skin. In addition, there is a hyperhidrotic tendency. Small, dark, lichenoid, follicular papules become profuse on the extremities, particularly the forearms. Bullae are sometimes observed. This represents a photosensitivity or phototoxicity induced by tar. This condition is rarely observed with current occupational protections.

Lebwohl M, et al: Tar melanosis. *Mt Sinai J Med* 1995; 62:412.

Familial progressive hyperpigmentation

Familial progressive hyperpigmentation (FPH) is characterized by patches of hyperpigmentation, present at birth, which increase in size and number with age. Later, hyperpigmentation appears in the conjunctivae and the buccal mucosa. Eventually, a large portion of the skin and mucous membranes becomes involved. Inheritance is in an autosomal-dominant pattern with variable penetrance. A focus in a small village in Germany has recently been reported. FPH is differentiated from other hyperpigmentations mainly by the presence of bizarre, sharply margined patterns of hyperpigmented skin. A gain-of-function mutation in *c-KIT* has been described in an affected kindred.

Betts CM, et al: Progressive hyperpigmentation: case report with a clinical, histological, and ultrastructural investigation. *Dermatology* 1994; 189:384.

Wang ZQ, et al: Gain-of-function mutation of *KIT* ligand on melanin synthesis causes familial progressive hyperpigmentation. *Am J Hum Genet* 2009; 84:672.

Zanardo L, et al: Progressive hyperpigmentation and generalized lentiginosis without associated systemic symptoms: a rare hereditary pigmentation disorder in south-east Germany. *Acta Derm Venereol* 2004; 84:57.

Periorbital hyperpigmentation

Dark circles around the eyes are not uncommon, often familial, and frequently found in individuals with dark pigmentation or Mediterranean ancestry. Atopic patients may also exhibit periorbital pigmentation (allergic shiners). There are probably multiple pathogenic factors involved, including epidermal hypermelanosis, dermal melanosis, increased vasculature, and normal anatomic variants. Since there are multiple etiologies, treatment is often ineffective.

Metallic discolorations

Pigmentation may develop from the deposit of fine metallic particles in the skin. The metal may be carried to the skin by the bloodstream or may permeate into it from surface applications. Discolorations from medications containing silver and gold are discussed in Chapter 6.

Arsenic

Acute arsenic poisoning is associated with flushing on day 1 of exposure, and facial edema on days 2–5. A morbilliform eruption appears on days 4–6. Hepatic dysfunction occurs simultaneously with the appearance of an eruption of discrete red–brown, erythematous papules in the intertriginous areas (areas of friction) of the lower abdomen, buttocks, and lateral upper chest. It regresses after 2–3 weeks, at times accompanied by acral desquamation. Three months after exposure, Mees's lines, total leukonychia, Beau's lines, and onychodystrophy may be seen. Periungual pigmentation occurs in up to half of acutely poisoned patients at 3 months.

Arsenic is an elemental metal that is ubiquitous, existing in nature as metalloids, alloys, and a variety of chemical compounds. These various forms of arsenic may be deposited into water, soil, and vegetation, producing serious health risks. In West Bengal, India, an estimated 200,000 people have arsenic-induced skin disorders and more than 1 million Indians are drinking arsenic-laced water from contaminated wells. Arsenic-contaminated water sources are a worldwide health concern also affecting countries such as Japan, Chile, Taiwan, and Mongolia. It is not known what are safe levels of arsenic in drinking water.

Industries using arsenical compounds place their workers at risk of exposure. Use of arsenic pesticides and exposure to sodium arsenite, used as a veterinary pesticide exposing sheep-dip workers, has resulted in chronic arsenism. In the US arsenic is used for pesticides, rodenticides, herbicides, insecticides, desiccants, feed additives, and wood preservatives. Pressure-treated lumber, particularly the marine-treated plywood, exposes carpenters and shipbuilders. The largest risk from wood products, however, occurs when pretreated wood is burned and the arsenic fumes are inhaled. Electroplating silver may also require arsenic. Another potential source of exposure during the 1960s was American tobacco, resulting mostly from the use of arsenic-containing insecticides.

The most common form of arsenic exposure worldwide is chronic, from contaminated wells and ground water. In areas of exposure, even young children can demonstrate cutaneous stigmata. Skin lesions occur only when arsenic concentrations are 200 µg/L or more. Two characteristic forms of skin disease occur. Cutaneous hyperpigmentation is the most common and earliest side effect. The hyperpigmentation is usually diffuse, most prominent on the trunk. Patchy hyperpigmentation may be accentuated in the inguinal folds, on the areolae, and on palmar creases. This can simulate Addison's disease. Areas of hypopigmentation may be scattered in the hyperpigmented areas, giving a "raindrop" appearance. Focal melanotic macules may also be present. The pigmentation may resolve or persist indefinitely. Punctate keratoses on the palms and soles are characteristic. Diffuse palmoplantar keratoderma may rarely occur. Blackfoot disease—arsenic-induced peripheral vascular disease that can lead to vasospasm and peripheral gangrene—and a severe peripheral neuropathy can also occur with chronic arsenic ingestion. Risk factors for development of clinically evident arsenic-induced disease include: concentration of arsenic contamination in exposure source (usually water), and malnutrition/low body mass index (BMI). There is significant variation in prevalence of skin disease from arsenic exposure in different racial groups and different individuals. There is evidence that polymorphisms in arsenic-metabolizing (methylation) pathways, specifically converting monomethylarsonic acid to dimethylarsinic acid, may explain these risk differences. Arsenic exposure is also associated with a significant reduction in circulating helper T cells, perhaps contributing to increased cancer risk. One study identified polymorphisms in the *XPD* gene as a risk factor

for arsenic-induced skin lesions. Histologically, the arsenical keratosis on the palms and soles shows hyperkeratosis, parakeratosis, acanthosis, and papillomatosis. Approximately 6–7% of hyperkeratotic skin lesions will demonstrate basilar atypia, and about 1% will show cancer. Arsenic exposure leads to the development of nonmelanoma skin cancers. Bowen's disease represents the majority of arsenic-induced skin cancers and may appear on sun-exposed or sun-protected skin. Basal cell carcinomas are frequent, are usually multiple, are most common on the trunk, and can be in sun-protected sites. Squamous cell carcinoma may also occur. Acitretin may improve "arsenical" keratoses. Arsenic exposure results in increased risk for lung, liver, and renal carcinoma.

Lead

Chronic lead poisoning can produce a "lead hue," with lividity and pallor, and a deposit of lead in the gums may occur: the "lead line" (Fig. 36-9).

Iron

In the past, soluble iron compounds were used in the treatment of allergic contact and other dermatitides. In eroded

Fig. 36-9 Lead line.

areas, iron was sometimes deposited in the skin, like a tattoo. The use of Monsel solution can produce similar tattooing, so aluminum chloride is now preferred. If Monsel is used to minimize tattooing, it is best applied with a cotton-tipped applicator barely moistened with the solution, then rolled across a wound that has just been blotted dry.

Hemochromatosis

Hemochromatosis is a disorder caused by mutations in at least five different genes involved in iron absorption. It is very common in the white European population, where the majority of the mutations are at two genetic loci, C282Y and H63D, allowing for widespread genetic screening. At least four different phenotypes are described. Many of the patients with the most common genetic defects do not develop any disease (perhaps 25% of men and 6% of women). Men are affected more frequently and at an earlier age (usually between 30 and 50 years). With widespread genetic testing, the age of diagnosis has been decreased, and the number of asymptomatic affected females has dramatically increased. The characteristic cutaneous manifestation is gray to brown mucocutaneous hyperpigmentation. This is enhanced in sun-exposed areas of the forearms, dorsal hands, and face, as well as in the inguinal area. The mucous membranes are pigmented in up to 20% of patients. The percentage of affected males with pigmentation is around 30% and in women fewer than 10% of diagnosed patients have skin changes. Other skin changes that can be seen include koilonychia and localized ichthyosis. Alopecia is common and pruritus can occur. Porphyria cutanea tarda may be present due to inhibition of uroporphyrinogen decarboxylase in the liver by iron overload. In patients with chronic venous insufficiency, the risk of lower leg ulceration is increased six-fold in those also carrying the C282Y mutation, leading some to suggest that this test should be ordered in at-risk patients at the initial stages of venous insufficiency. Biopsy of affected hyperpigmented skin shows dermal iron deposition, but the visible pigmentation is actually increased epidermal melanin in the basal cell layer.

The most seriously affected organ is the liver. Hepatomegaly and elevated liver function tests are signs of hepatic iron overload. Cirrhosis and hepatocellular carcinoma may develop, but are now uncommon with early diagnosis and treatment. The endocrine system is also affected, with diabetes mellitus, impotence, and amenorrhea being most common. Arthropathy is seen in about 50% of women and 40% of men. Cardiac abnormalities include heart failure and arrhythmias. Consuming alcohol and smoking, as well as coexistent hepatitis C infection, all make it more likely that persons with genetic predisposition will develop clinical disease.

Laboratory evaluation should be pursued in persons with appropriate clinical findings suggesting the diagnosis of hemochromatosis. Levels of plasma iron and the serum iron-binding protein are elevated. The transferrin saturation (TS = serum iron/total iron-binding capacity) is a useful screening measure. A score of 45 or less is normal, except in premenopausal women when greater than 35 may be considered abnormal. High serum ferritin levels are also present. Genotyping is now performed in persons with a TS greater than 45 and an elevated ferritin, and confirms the diagnosis. Liver biopsy is reserved for persons with elevated liver function tests, a ferritin greater than 1000, or age over 40.

Four different genes cause autosomal-recessive hemochromatosis and one causes autosomal-dominant disease. The most common autosomal-recessive form is due to a mutation in the *HFE* gene, most frequently C282Y, and less commonly H63D. The incidence of homozygosity for C282Y is 5 in 1000 persons of northern European descent, making it ten times more common than cystic fibrosis. Compound heterozygotes (C282Y/H63D) also develop disease. Two autosomal-recessive forms of juvenile hereditary hemochromatosis are described, due to mutations in the *Hemojuvelin* and *Hepcidin* genes, respectively. Mutations in the transferrin receptor 2 gene lead to a form of autosomal-recessive adult-onset hemochromatosis. Ferroportin mutation leads to an adult-onset form of autosomal-dominant hemochromatosis.

All forms of hemochromatosis are treated with phlebotomy until satisfactory iron levels are attained. Vitamin C supplementation must be avoided, as it can worsen the disease. Raw seafood should be avoided because *Vibrio vulnificus* infection may occur. Phlebotomy can prevent cirrhosis. Once cirrhosis is present, phlebotomy does not prevent the development of hepatocellular carcinoma, which occurs in 30% of patients.

Titanium

A titanium-containing ointment caused yellowish papules on the penis in a patient. Titanium screws used for orthopedic procedures, if they come in close proximity to the skin, can cause cutaneous blue-black hyperpigmentation.

Canthaxanthin

The orange-red pigment, canthaxanthin, is present in many plants (notably algae and mushrooms) and in bacteria, crustaceans, sea trout, and feathers. When ingested for the purpose of simulating a tan, its deposition in the panniculus imparts a golden orange hue to the skin. Stools become brick red and the plasma orange, and golden deposits appear in the retina. Its use is not recommended, since it may be associated with liver and retinal damage.

Fig. 36-10 Idiopathic guttate hypomelanosis.

Idiopathic guttate hypomelanosis (leukopathia symmetrica progressiva)

Idiopathic guttate hypomelanosis is a very common acquired disorder that affects women more frequently than men. It usually occurs after age 40 and its prevalence increases with age. The lesions occur chiefly on the shins (Fig. 36-10) and forearms, suggesting that sun exposure plays a role. Widespread lesions have occurred in patients receiving UVB therapy. Individual lesions are small (2–5 mm on average), hypopigmented macules. They usually number between 10 and 30, but numerous lesions may occur. Lesions spare the trunk and face. The lesions are irregularly shaped and very sharply defined, like depigmented ephelides. Histologically, there is epidermal atrophy and reduced numbers of hypoactive melanocytes. Cryotherapy can improve the appearance of the lesions.

Vitiligo

Vitiligo usually begins in childhood or young adulthood, with a peak onset between 10 and 30 years. About half of cases begin before the age of 20. The prevalence ranges from 0.5% to 1%. Although females are disproportionately represented among patients seeking care, it is not known whether they are actually more commonly affected or simply are more likely to seek medical care. Vitiligo has developed in recipients of bone marrow transplant or lymphocyte infusions from patients with vitiligo.

Clinical features

Vitiligo is an acquired pigmentary anomaly of the skin manifested by depigmented white patches surrounded by a normal

Fig. 36-11 Localized vitiligo.

Fig. 36-12 Vitiligo, generalized.

or a hyperpigmented border. There may be intermediate tan zones or lesions halfway between the normal skin color and depigmentation—so-called trichrome vitiligo. Blue-gray hyperpigmented macules representing melanin incontinence may be present focally. The hairs in the vitiliginous areas usually become white also. Very rarely, the patches may have a red, inflammatory border. The patches are of various sizes and configurations, but the margins are usually smooth, except in the case of segmental vitiligo.

Six types have been described, according to the extent and distribution of the involved areas: localized (Fig. 36-11); or focal (single or a few macules in one anatomic area, often the trigeminal area, especially in children); segmental; generalized (common symmetric); universal (Fig. 36-12); acrofacial; and mucosal. The generalized pattern is most common. Involvement is symmetrical. The most commonly affected sites are the face, upper part of the chest, dorsal aspects of the hands, axillae, and groin. There is a tendency for the skin around orifices to be affected: namely, the eyes, nose, mouth, ears, nipples, umbilicus, penis, vulva, and anus. Lesions appear at areas of trauma, so vitiligo favors the elbows and knees. Universal vitiligo applies to cases where the entire body surface is depigmented. The acrofacial type affects the distal fingers and facial orifices (lips and tips). Focal vitiligo may affect one nondermatomal site (such as the glans penis) (Fig. 36-13), or

Fig. 36-13 Penile vitiligo.

asymmetrically affects a single region. It is to be distinguished from the segmental form of vitiligo, which is treatment-resistant, has an earlier onset, and is less frequently associated with other autoimmune phenomena. It represents 5% of adult vitiligo and 20% of childhood vitiligo. Segmental vitiligo often has a dermatomal or quasi-dermatomal distribution.

In patients with vitiligo, local loss of pigment may occur around nevi and melanomas, the so-called halo phenomenon. Vitiligo-like leukoderma occurs in about 1% of melanoma patients. In those with previously diagnosed melanoma, this suggests metastatic disease. Paradoxically, however, as the reaction indicates an autoimmune response against melanocytes, patients who develop it have a better prognosis than patients without leukoderma. Lesions of vitiligo are hypersensitive to UV light and burn readily when exposed to the sun. With repeated sun exposure, lesions of vitiligo can tolerate additional UV exposure (photoadaptation), allowing for increasing doses of therapeutic UV phototherapy.

Ocular abnormalities are increased in patients with vitiligo, including iritis and retinal pigmentary abnormalities. Patients have no visual complaints. Eight percent of patients with idiopathic uveitis have vitiligo or poliosis. The conditions most frequently associated with vitiligo are other “autoimmune” diseases. These include type 1 diabetes mellitus, pernicious anemia, Hashimoto thyroiditis, Graves’ disease, Addison’s disease, and alopecia areata, which in total affect 32% of family members of patients with vitiligo. If a family history of autoimmune disease is obtained, the vitiligo patient (except those with segmental vitiligo) should be tested for serum antithyroglobulin and antithyroid peroxidase antibodies, since autoimmune thyroid disease is the most common autoimmune disease to be present in vitiligo patients. Additional screening should be directed by signs and symptoms. Vitiligo occurs in 13% of patients with the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome, caused by mutations in the autoimmune regulator gene (*AIRE*). Polymorphisms in the *AIRE* gene are found more commonly in vitiligo patients than controls.

Although familial aggregation of vitiligo is seen—up to 30% of vitiligo patients have an affected relative—it is not inherited as an autosomal-dominant or recessive trait, but rather seems to have a multifactorial genetic basis. In addition to the autoimmune pathogenic hypothesis, which is most likely, oxidant/antioxidant and neural theories have been proposed. Several of these mechanisms may simultaneously be pathogenic in vitiligo.

The psychologic effect of vitiligo should not be underestimated. Patients are frequently anxious or depressed because of the appearance of their skin and the way it affects their social interactions. This is true for both children and adults. Young adults with childhood vitiligo have persistent health-related quality of life impairment. Referring the patient to a mental health professional or the National Vitiligo Foundation (www.nvfi.org) may be helpful in this situation.

Histopathology

There is a complete absence of melanocytes. Usually, there is no inflammatory infiltrate, but lichenoid or spongiotic inflammation may be detected at the edge of a substantial number of vitiligo lesions. This explains the scaling or hyperpigmentation sometimes observed around lesions of vitiligo.

Differential diagnosis

Vitiligo must be differentiated from morphea and lichen sclerosus, both of which are hypopigmented but associated with a change in the skin texture. Pityriasis alba has a fine scale, is slightly papular, and is poorly defined. Tinea versicolor favors the center back and chest, and has a fine scale; yeast and hyphal forms are demonstrable with potassium hydroxide (KOH) examination. The tertiary stage of pinta might easily lead to diagnostic confusion, but a travel history and serologic testing will help elucidate the diagnosis. Chemical leukoderma (see below) may closely resemble vitiligo.

Treatment

Vitiligo can be a frustrating condition to treat. Spontaneous repigmentation occurs in no more than 15–25% of cases. Response is typically slow, and response rates are low in some anatomic areas. Since vitiligo is common, many studies have been published regarding therapeutic options. However, they are often of poor quality, or have markedly different results when performed at different centers. Persons of different Fitzpatrick phototypes may have different rates of response when facial vitiligo is treated. In addition, some forms of treatment, such as phototherapy, may actually worsen the appearance of the vitiligo initially by pigmentation surrounding skin, accentuating the depigmented areas. This is particularly true in persons of lower Fitzpatrick phototypes (I and II). The anatomic location of the lesion predicts the likelihood of response, independent of the modality used for therapy. Facial vitiligo has an excellent prognosis, with many patients achieving cosmetically significant improvement. The dorsal hands and feet, by contrast, respond to most forms of treatment only about 10–20% of the time. Truncal vitiligo demonstrates an intermediate response.

The major problem for the vitiligo patient is appearance. With regard to vitiligo in persons of low Fitzpatrick phototypes (I and II), non-treatment is an option. These patients are treated with sun protection, supplemented with cosmetic camouflage as required. The newer self-tanning creams are useful for light-skinned and olive-complexioned patients with acral lesions. Phototherapy may more dramatically increase the risk of skin cancer in those with lower Fitzpatrick phototypes, suggesting that alternative approaches should be considered. In addition, mucosal vitiligo (of the lips), and periungual and dorsal hand vitiligo currently have essentially no reproducibly effective form of medical therapy. Camouflage is, therefore, an important therapeutic modality for the vitiligo patient. Dihydroxyacetone is a brown dye that stains the skin. In lower concentrations it can be used in lower phototypes, as it is a

golden or tan color (self-tanning products). In high concentrations it is dark brown and can be used in patients with type V and VI phototypes to camouflage their lesions. As it is a stain, it does not rub off, but needs to be reapplied because it is sloughed off from the epidermis (every 5–10 days). Covermark, Dermablend, Dermacolor, Keromask, Veil Cover, and PerfectCover are trademarks that specialize in cosmetic products for patients with dyspigmentations, including vitiligo. These products can be amazingly effective in making the vitiliginous skin blend completely into the normal surrounding skin. However, it is technically difficult for patients to match their skin color without instruction. In the beginning, vitiligo patients using these products will benefit by consulting an aesthetician trained in medical camouflage. Once applied, the products tend to rub off. Application of Cavilon “No Sting Barrier Film” as a spray over the camouflage cosmetic may prevent the product from rubbing off during daily activities.

Topical treatment is appropriate for limited skin areas (<10–20% body surface area [BSA]). Occlusion of all forms of topical therapy may enhance efficacy. Topical potent to superpotent steroids are used for a 2-month trial. Up to 80% of patients with facial vitiligo will achieve >90% repigmentation. This usually occurs diffusely, not perifollicularly, as occurs on the trunk. On the trunk only 40% of patients achieve >90% repigmentation. Treatment should be limited to 4–6 months and the patient must be monitored for acne, atrophy, and telangiectasias.

Topical pimecrolimus cream and tacrolimus ointment 0.1% have been particularly efficacious in treating facial vitiligo. In some series they have been as effective as superpotent topical steroids and avoid the complications of atrophy and acne induced by topical steroids. Patients who initiate treatment in the summer have a higher rate of response. Continual application may be required, as patients who discontinue treatment may suffer the appearance of new lesions. With topical therapies, new areas of vitiligo appear in untreated areas, suggesting there is no systemic effect. Topical pimecrolimus may enhance the efficacy of narrow-band UVB (NBUVB) in repigmenting facial, but not non-facial vitiligo. Topical calcipotriene and other vitamin D analogs have had variable results. Alone these agents lack efficacy. When they are used in combination with other treatments, some studies have demonstrated additive benefit and others no benefit. Therefore, these agents cannot be recommended.

NBUVB twice weekly has become the preferred form of phototherapy to treat vitiligo. It avoids the need for prolonged eye protection and the occasional psoralen-induced nausea. About half of patients will achieve more than 75% repigmentation of the face, trunk, proximal arms, and legs. Hand and foot lesions repigment in less than 25% of patients. Children may have slightly higher response rates than adults. In patients with >20% BSA involvement, only about 5% will show complete repigmentation with phototherapy. Long courses of treatment may be required. PUVA therapy can also be used to treat vitiligo, but is less effective than NBUVB. Repigmentation from phototherapy may begin after 15–25 treatments; however, significant improvement may take as many as 100–200 treatments (6–24 months). On average, maximum improvement is seen after about 9 months of therapy. If follicular repigmentation has not appeared after 3 months, phototherapy treatments should be discontinued. Known photosensitivity, porphyria, and systemic lupus erythematosus are contraindications to phototherapy.

Topical application of 8-methoxypsoralen at a concentration of 0.01–0.1%, followed by UVA exposure, may lead to repigmentation. Topical PUVA is used for focal or limited lesions. Inadvertent burns with blistering are frequent complications

during treatment in the US, even when the patient is treated by professionals. For this reason, topical PUVA has been very difficult for the patient to carry out at home. Topical PUVA, however, is widely used in India with success, suggesting that, in the right hands, this treatment can be effective.

Excimer laser phototherapy can be as effective as NB-UVB, and the response is more rapid. It can be used on limited areas, avoiding whole-body UV exposure. While 25% of treated patches repigment completely, treatment-resistant areas (elbows, knees, wrists, dorsal hands and feet) have only a 2% rate of at least 75% repigmentation. The addition of topical steroid treatment to excimer laser may enhance efficacy.

In certain situations, the use of systemic immunosuppressives may be appropriate in the treatment of vitiligo. This is usually in the setting of very rapidly progressive disease, with the goal of reducing the total amount of pigment loss. Systemic corticosteroids are usually used and are tapered over several months. Twice weekly dexamethasone, at a dose of 10 mg, is one such regimen. Once the disease is arrested, the patient can be converted to phototherapy. The long-term use of systemic immunosuppressives is not recommended. They initially may control the disease, but with chronic use, unacceptable toxicity often develops.

Surgical treatments can be applied to limited lesions if the above methods do not prove beneficial, but these are time-consuming. They are recommended primarily in patients with treatment-resistant vitiligo. Patients must have stable disease (no new lesions, or expansion of lesions for 1 year). Surgical procedures are not effective in patients who exhibit Koebner phenomenon or have active vitiligo. Given its expense, surgical treatment should be reserved for exposed skin sites covering less than 2–3% of BSA. Minigrafting, transplantation of autologous epidermal cell suspension, and ultra thin epidermal grafts have all been used. UV phototherapy is often given following the surgical procedure.

Systemic immunosuppressives, specifically high-dose corticosteroids, can arrest rapidly progressive vitiligo. However, they cannot be used long-term due to toxicity, so another form of therapy must be sought once the vitiligo has been arrested.

Total depigmentation

If more than 50–80% of the body surface area is affected by vitiligo, the patient can consider depigmentation. This form of treatment should be considered permanent and the goal is total depigmentation. Limited areas (such as those exposed daily) may be treated, but satellite and distant depigmentation may occur, so the action of the medication cannot be limited to the applied area. Monobenzone (monobenzyl ether of hydroquinone) 20% is applied twice a day for 3–6 months to residual pigmented areas. Up to 10 months may be required to complete the treatment. About 1 in 6 patients treated experience acute dermatitis, usually confined to the still-pigmented areas, but this rarely limits treatment. Once the patient achieves a uniform depigmented appearance, he/she is very satisfied. Topical 20% 4-methoxyphenol cream (mequinol, monomethyl-ether of hydroquinone) can also be used for depigmentation. The Q-switched laser selectively destroys melanocytes and can also achieve depigmentation. It can be combined with a topical depigmenting agent for added efficacy.

Chemical leukoderma (occupational vitiligo)

Chemical leukoderma is an acquired, depigmented dermatosis caused by repeated exposure to chemicals. It is frequently misdiagnosed as vitiligo. Patients with vitiligo or a family history of vitiligo are at much greater risk of developing chemical leukoderma. The diagnostic criteria are:

1. acquired vitiligo-like depigmented lesions
2. history of repeated exposure to a specific chemical compound
3. patterned vitiligo-like macules conforming to site of exposure
4. confetti macules.

The majority of cases are caused by exposure to aromatic or aliphatic derivatives of phenols and catechols, including paratertiary butylphenol (adhesive in shoes), amylphenol, butylcatechol, and alkyl phenols. However, sulfhydryls, mercurials, arsenics, cinnamic aldehyde, p-phenylenediamine, chloroquine, and azelaic acid have also been incriminated. Some of these compounds have a structure similar to tyrosine and may be converted by tyrosine-related protein-1 to compounds toxic to the melanocyte. This process is considered to be different from depigmentation following allergic contact dermatitis. The clinical pattern may be very similar to idiopathic vitiligo, but lesions tend to be concentrated in areas of repeated contact with the incriminated substance. The first recognized cases of occupational vitiligo occurred in individuals who worked in rubber garments or wore gloves that contained monobenzyl ether of hydroquinone. This compound may still contaminate some rubber products. Phenolic antiseptic detergents used in hospitals and in industrial cleaners have caused chemical leukoderma in janitorial and housekeeping employees. Adhesives and glues containing incriminated chemicals may be found in shoes, wristbands, adhesive tape, and rubber products used in brassieres, girdles, panties, or condoms. Self-sticking bindis (the cosmetic used by many Indian women on the forehead) have been reported to induce leukoderma from the adhesive material. Also, electrocardiograph electrodes may cause similar round hypopigmented spots at the site of contact.

The most common location for chemical leukoderma is the face (40% of cases), followed by the hands and feet. The scalp is rarely affected. Hair dye (at the rim of the scalp but not on the scalp), deodorant (axilla), detergent, adhesives (face, bindis), rubber sandals (feet), black socks and shoes (feet), and rubber condoms (penis) are the exposures associated with lesions in various anatomic regions. Pruritus occurs in more than 20% of patients (a rare complaint in vitiligo patients). The clinical lesions are sharply marginated macules and patches, often with confetti or pea-sized macules seen at the periphery. This clinical pattern is atypical for idiopathic vitiligo and should suggest the diagnosis of chemical leukoderma. More than 25% of patients have lesions outside the area of contact with the incriminated chemical. In about 10% of patients, new vitiliginous lesions will continue to develop, even after exposure to the chemical is stopped. Treatment is avoidance and measures used for idiopathic vitiligo (see above). Chemical leukoderma in a person without vitiligo has a good prognosis, with repigmentation in up to 75% of cases. If a person with vitiligo develops a chemical leukoderma, repigmentation only occurs in 20% of cases. Histologically, the vitiliginous areas of a chemical leukoderma show an absence of melanocytes identical to lesions of true vitiligo.

Vogt–Koyanagi–Harada syndrome

Vogt–Koyanagi–Harada syndrome (VKHS) is a disease complex affecting the eyes, skin, auditory system, and central nervous system (CNS). It affects primarily pigmented races and is rare in white persons. It is more common in females, and affects all ages. The disease occurs in four phases. First is the prodromal phase or meningoencephalitic phase, with fever, malaise, headache, nausea, and vomiting. The CNS involvement can include meningismus, headaches, mental status changes, cerebrospinal fluid pleocytosis, tinnitus, and dysacusis. Recovery is usually complete. The second stage, the uveitic phase, is characterized by anterior and/or posterior uveitis and inflammation of many other parts of the eye. The third or convalescent phase begins 3 weeks to 3 months after the uveitis appears, usually as it begins to improve. This stage is characterized by frontal non-cicatricial alopecia, vitiligo, and poliosis of scalp, eyebrows, eyelashes, and hairs of the axillae. The skin lesions must begin after the ocular symptoms to be considered diagnostic. The fourth phase is one of recurrent attacks of uveitis. Most ocular complications occur as a result of this stage of the disease, and include permanent decreased visual acuity, cataracts, and glaucoma.

VKHS is a cell-mediated autoimmune disease with the autoantigen(s) felt to be solely expressed in melanin-containing cells. The target antigens may be the tyrosinase family proteins, as immunization of mice with several of these proteins can induce a syndrome similar to VKHS. Supporting this hypothesis are the rare observations that vitiligo, erythroderma, interferon therapy for hepatitis C, and melanoma can all be associated with the appearance of VKHS. Aggressive immunosuppressive therapy with systemic steroids and immunomodulatory medications (cyclosporine, azathioprine, mycophenolate, tacrolimus, infliximab) may preserve ocular function and prevent ocular complications. Th17 CD4+ cells stimulated by high levels of interleukin (IL)-23 and secreting IL-17 are present in VKHS patients with active uveitis. IL-23 is important in the production and maintenance of autoimmune diseases, and IL-17 is one of the most important effector cytokines in autoimmune diseases. At least four patients with psoriasis and VKHS have been reported.

Alezzandrini syndrome

Alezzandrini syndrome is a very rare condition characterized by a unilateral degenerative retinitis, followed after several months by ipsilateral vitiligo on the face and ipsilateral poliosis. Deafness may also be present.

Hoffman MD, Dudley C: Suspected Alezzandrini's syndrome in a diabetic patient with unilateral retinal detachment and ipsilateral vitiligo and poliosis. *J Am Acad Dermatol* 1992; 26:496.

Leukoderma

Postinflammatory leukoderma may result from many inflammatory dermatoses, such as pityriasis rosea, psoriasis, herpes zoster, secondary syphilis, and morphea. Sarcoidosis, tinea versicolor, mycosis fungoides, scleroderma, and pityriasis lichenoides chronica may all present with hypopigmented lesions (only rarely are these actually depigmented), as may Hansen's disease. Burns, scars, postdermabrasion, and intralesional steroid injections with depigmentation are other examples of leukoderma.

Friedman SJ, et al: Perilesional linear atrophy and hypopigmentation after intralesional corticosteroid therapy. *J Am Acad Dermatol* 1988; 19:537.

Oculocutaneous albinism

Oculocutaneous albinism (OCA) is an autosomal-recessively inherited trait with reduction or absence of melanin in skin, hair, and eyes. Eye problems are frequently present, including moderate to severe impairment of visual acuity, nystagmus, strabismus, and photophobia. The cutaneous phenotype of the various forms of albinism is broad, but the ocular phenotype is reasonably constant in most forms. Genetic disorders of pigment cells can now be defined as caused by:

1. disruption of melanoblast migration to target tissues during development (Waardenburg syndrome and piebaldism)
2. disruption of melanin synthesis (oculocutaneous albinism)
3. disruption of melanosome formation (Chédiak–Higashi and Hermansky–Pudlak syndromes)
4. disruption of melanosome transport and melanin transfer to keratinocytes (Griscelli syndrome).

The most serious sequelae of albinism are gross visual disturbances and the increased risk for the development of skin cancer. A number of syndromes associated with albinism can also cause premature mortality due to impairment of the functioning of other involved organs and systems.

Disorders of melanin synthesis

The four genetic forms of non-syndromal OCA are all caused by disruption of melanin synthesis and all autosomal-recessive disorders. Their prevalence varies widely around the world, but is estimated to be about 1 in 17000. That means that about 1 in 70 persons carries a gene for OCA. Given the phenotypic overlap of the various forms of OCA, genetic testing is recommended to establish the diagnosis. Since both parents are obligate carriers and two-thirds of healthy siblings are at risk for being carriers, genetic counseling is recommended. Carriers are asymptomatic. All persons with OCA and their parents should be educated regarding aggressive sun protection with sunscreens, appropriate clothing, and sun avoidance. Vitamin D supplementation may be required. As adults, patients should be examined for skin lesions suspicious for melanoma and nonmelanoma skin cancer.

Oculocutaneous albinism 1

OCA1 results from mutations in the tyrosinase gene and accounts for approximately 40% of OCA worldwide. It is the most severe form of albinism, and is the most common type of albinism in Japanese, non-Hispanic Caucasians, and a mixed race European population, with a prevalence of about 1 in 40000. Affected patients are homozygous for the mutant gene or are compound heterozygotes for different mutations in the tyrosinase gene (*TYR*). OCA1 is divided into two forms: OCA1A and OCA1B. At birth these are indistinguishable. OCA1A is the most severe form, with complete absence of tyrosinase activity and complete absence of melanin in the skin and eyes. Visual acuity is decreased to 20/400. The hair, eyelashes, and eyebrows are white, and the skin is white and does not tan. Irises are light blue to pink and fully translucent. Amelanotic nevi may be present. In OCA1B, tyrosinase activity is greatly reduced but not absent. Affected patients may show an increase in skin, hair, and eye color beginning at age 1–3 years, and can tan. Iris color may also darken over time. OCA1B was originally called “yellow mutant” albinism. Temperature-sensitive OCA (OCA1-TS) is considered a variant of OCA1B; it results from mutations in the tyrosinase gene that produce an enzyme with limited activity below 35°C (95°F) and no activity above this temperature. Affected patients have white hair, skin, and eyes at birth. At puberty, dark hair develops in cooler acral areas. Visual acuity is not as severely affected in OCA1B.

Oculocutaneous albinism 2

OCA2 has a prevalence of 1 in 36000 in white Europeans, but as much as 1 in 4000 in some parts of Africa. It is the most common form of OCA, accounting for approximately 50% of OCA worldwide. OCA2 was formerly called “tyrosinase-positive” albinism, or “brown OCA.” Inheritance is autosomal-recessive and results from mutations in the OCA2 gene, formerly known as the P gene. The OCA2 gene encodes an integral melanosomal protein that is important for normal biogenesis of melanosomes and for normal processing and transport of melanosomal proteins such as tyrosinase and tyrosinase-related protein 1 (TYRP1). The cutaneous phenotype of OCA2 patients is broad, ranging from nearly normal pigmentation to virtually no pigment. Newborns have pigmented hair. Nevi and ephelides are common. Pink irises are usually not seen. Visual defects are not as severe as in OCA1. Pigmentation increases with age and visual acuity improves from infancy to adolescence. Prader–Willi and Angelman syndromes are caused by deletions in the chromosomal region contiguous to and sometimes including the OCA2 gene. One percent of patients with these syndromes also have OCA2.

Oculocutaneous albinism 3

OCA3 is caused by mutations in the *TYRP1* gene. TRYP1 protein is an enzyme in the melanin biosynthesis pathway that oxidizes dihydroxyindole carboxylic acid (DHICA) monomers into melanin. Mutations in this enzyme result in delayed maturation and early degradation of tyrosine. This form of OCA has been most commonly found in African patients and was called “rufous” or red OCA. It has also been seen in a large Pakistani family and a Caucasian patient. Patients have red hair and reddish-brown skin. Visual abnormalities may not be detectable.

Oculocutaneous albinism 4

OCA4 is due to mutations in the *MATP* gene encoding a membrane-associated transporter protein, predicted to span the membrane 12 times and to function as a transporter. Patients are hypopigmented to a variable degree, and are phenotypically identical to patients with OCA2. Visual acuity is decreased and nystagmus is found in many but not all patients. This has also been reported in a Turkish patient, as well as German, Japanese, and Korean OCA patients.

Disorders of melanosome formation

These are multisystem syndromes that are associated with albinism. These syndromes are caused by genes that function in intracellular organelle formation and movement in a variety of specialized cell types, such as melanocytes, neurons, immune cells, monocytes, platelets, and type II epithelial cells in lungs. The silver hair of some of these syndromes may demonstrate pigment clumping, allowing the diagnosis to be suspected.

Chédiak–Higashi syndrome

Chédiak–Higashi syndrome (CHS) is a progressively degenerative, fatal disease characterized by partial oculocutaneous albinism (decreased skin, eye, and hair pigment), giant intracellular granules, pigment clumping in hair shafts, and a bleeding diathesis due to absent or reduced platelet-dense bodies. It presents in childhood, usually with life-threatening infections of the skin and lungs. Common pathogens are *Staphylococcus aureus*, streptococcus, Gram-negative organisms, *Candida*, and *Aspergillus*. Immunoglobulins, antibody production, and phagocytosis are normal, but neutropenia is common and leukocytes display impaired migration. Natural killer cells are decreased in function. The hair of these patients is blond and sparse. The ocular albinism is accompanied by nystagmus and photophobia. In darker-skinned races, affected patients are lighter-skinned than their parents and siblings, and may have speckled hyper- and hypopigmentation.

CHS results from mutations in the *SHS1* gene, the exact biological function of which is unknown. The gene must be important in lysosome and lysosome-related organelle trafficking or size regulation. Melanosomes are giant, and platelets, eosinophils, basophils, and monocytes have giant intracellular granules that are azurophilic.

In 85% of cases a lymphohistiocytosis syndrome occurs, referred to as the “accelerated phase.” It is fatal and caused by the unfettered proliferation of lymphocytes creating a lymphoma-like situation with fever, anemia, neutropenia, hepatosplenomegaly, and lymphadenopathy. Liver function tests and serum ferritin may be elevated. Bone marrow transplantation (BMT) prior to the onset of this phase may be life-saving, and also prevents the infections. Unfortunately, even with BMT, if CHS patients survive into adulthood they develop progressive neurological involvement.

Hermansky–Pudlak syndrome

Hermansky–Pudlak syndrome (HPS) is an autosomal-recessive disorder consisting of oculocutaneous albinism, a hemorrhagic diathesis secondary to the absence of dense bodies in platelets, and accumulation of a ceroid-like material in the reticuloendothelial system, visceral organs, oral mucosa, and urine. Patients with this disorder have a history of easy bruising, epistaxis, gingival bleeding, hemoptysis, and bleeding after various surgical procedures and childbirth. Major bleeding occurs in 40% of HPS patients. The hypopigmentation is due to impaired melanosome formation, trafficking, or transfer to keratinocytes.

Currently, eight human genes (*HPS1–8*) have been identified, which, when independently mutated, lead to a clinical picture consistent with HPS. It is anticipated that more HPS genes will be identified in humans, since in mice there are at least 14 non-allelic genes that, when singly defective, give rise to HPS. While the HPS subtypes 1–8 all share the clinical signs and symptoms noted above, a few subtypes either lack some of or have additional unique features that serve to distinguish them from the other HPS subtypes. Seven of the eight genes causing HPS (not *HPS2*) are parts of distinct complexes that are called biogenesis of lysosome-related organelle complexes, or BLOCs. Mutations in any member of a BLOC tend to create a similar clinical phenotype. There are three known BLOCs, and mutations in most of the BLOC subunits cause a variant of HPS.

The most common subtype is HPS1, which, together with HPS4, comprises 50% of the known worldwide cases of HPS. One in 21 Puerto Ricans has a mutation (usually a 16-base pair [bp] duplication) in the *HPS1* gene. HPS accounts for 80% of albinos in Puerto Rico, and 1 in 1800 Puerto Ricans in the northwest region of the country has HPS. HPS1 and HPS4 are clinically very similar, since they together form the BLOC3 complex (Fig. 36-14). These are the two most severe forms of HPS. Skin pigmentation can vary from total lack to lighter hair and skin coloring than in other members of the family. Ocular changes similar to those of OCA can occur, including iris transillumination, hypopigmented retina, visual impairment, horizontal nystagmus, and strabismus. Atypical nevi, acanthosis nigricans-like lesions in the axillae and neck, and trichomegaly also occur. Solar damage, as evidenced by solar lentigines, actinic keratoses, and nonmelanoma skin cancers, occurs in 80% of patients with the 16-bp duplication in HPS1. Interstitial pulmonary fibrosis, inflammatory bowel disease, renal failure, and cardiomyopathy are late complications, and can cause premature mortality between the ages of 20 and 50 years. Sixty percent of patients with HPS have pulmonary symptoms, starting at a mean age of 35 years. Pirfenidone, an antifibrotic

Fig. 36-14 Hermansky–Pudlak syndrome, freckling of the “V” of the neck and a basal cell carcinoma in a Puerto Rican man.

agent, can slow the progression of pulmonary fibrosis in HPS1 patients with significant residual lung function (initial forced ventilatory capacity >50%). Lung transplantation can be considered.

HPS2 is caused by a mutation in the gene (*AP3B1*) coding for the β A subunit of AP3, a molecule necessary for normal protein trafficking to the lysosome. HPS2 is notable for immunodeficiency and persistent neutropenia, with patients suffering recurrent bacterial infections of the upper respiratory system and middle ear, possibly due to the lack of antigen presentation by the CD1b molecule, since CD1b fails to gain access to the lysosome. Initially, patients may be misdiagnosed as having CHS due to pigment dilution and recurrent infections. However, the large intracellular granules of CHS are absent. Mild pulmonary fibrosis and a mild hearing defect can be associated with HPS2.

HPS3, HPS5, and HPS6 have mild clinical findings, without reported pulmonary or gastrointestinal involvement. They are due to mutations in three proteins that make up BLOC2.

HPS 7 and 8 are very rare and present with a phenotype of oculocutaneous albinism and a bleeding tendency due to platelet dysfunction. The HPS7 gene (*DTNBP1*) encodes dysbindin; the HPS8 gene is *BLOC1S3*.

Disorders of melanocyte transport

Griscelli syndrome

Griscelli syndrome (GS) is a rare autosomal-recessive disorder with mild skin and hair hypopigmentation, immunological impairment, lymphohistiocytosis, or defects in the central nervous system. Patients do not have a bleeding tendency. There are three forms of GS. GS1 is caused by mutations in the *MYO5A* gene encoding the actin-associated myosin Va motor protein. Patients have primary neurological dysfunction but no immunological disease. They have silver hair. GS1 and Elejalde syndrome are felt to be the same disease. GS2 is due to mutations in the *RAB27A* gene. Patients have silver hair, infections, and lymphohistiocytosis. Leukocytes infiltrating the brain can cause secondary neurological disease, but patients have no primary neural defects. GS3 is caused by mutations in *Melanophilin* and results only in cutaneous hypopigmentation. The three genes responsible for GS all form a protein complex essential for the capture and local movement of melanosomes in the actin-rich periphery of melanocytes.

Disorders of melanoblast migration and survival

These disorders cause “spotting,” i.e. patches of white hair and/or unpigmented skin.

Waardenburg syndrome

Four genotypic variants of Waardenburg syndrome exist, with overlapping phenotypic features; all are autosomal-dominant. Types 1 and 3 are caused by mutations in the *PAX3* gene, encoding a transcription factor. Type 2 is caused by mutations in the *MITF* gene, also encoding a transcription factor, and type 4 is due to either a heterozygous mutation in the *SOX10* gene (encoding a transcription factor), or homozygous mutations in the endothelin-3 (*EDN3*) or the endothelin B receptor (*EDNR3*) gene. These mutations impair the ability of melanoblasts to reach their final target sites (inner ear, eye, skin) during embryogenesis.

Patients with this syndrome have features of piebaldism, with a white forelock, hypopigmentation, premature graying, and other characteristic findings including synophrys, congenital deafness, dystopia canthorum (broad nasal root), and ocular changes, including heterochromia iridis (Fig. 36-15). Types 1 and 3 are both characterized by dystopia canthorum; in type 1, white forelock and depigmented skin patches are more frequent; while in type 3, limb anomalies occur. In type 2, no dystopia canthorum is observed, but hearing loss and heterochromia iridis are more frequently found. Type 4 Waardenburg’s syndrome is identical to type 3, except that it is associated with Hirschprung disease.

Piebaldism

Piebaldism is a rare, autosomal-dominant syndrome with variable phenotype, presenting at birth. The characteristic clinical features are a white forelock and patchy absence of skin pigment (Fig. 36-16). The depigmented lesions are static and characteristically occur on the anterior and posterior trunk, mid-upper arm to wrist, mid-thigh to mid-calf, and shins. A characteristic feature of piebaldism is the presence of hyperpigmented macules within the areas lacking pigmentation and also on normally pigmented skin. The depigmented lesions may repigment spontaneously, or especially after injury. The white forelock is a triangular or diamond-shaped midline white macule on the frontal scalp or forehead, and is the only

Fig. 36-15 Waardenburg syndrome with heterochromia iridis.

Fig. 36-16 Piebaldism, vitiligo-like depigmentation.

manifestation in 80–90% of patients. The medial portions of the eyebrows and eyelashes may be white. Histologically, melanocytes are completely absent in the white macules.

Piebaldism is caused by mutations in the *KIT* gene (gene product kit proto-oncogene), encoding a cell surface receptor for the steel factor, an embryonic growth factor. The phenotypic differences between families are caused by different locations of mutations in the gene. A mild phenotype occurs in cases associated with mutations in the ligand-binding region, whereas more severe phenotypes occur from mutations in the tyrosine kinase region of the receptor. The white lesions may respond to camouflage cosmetics or surgical corrections (see discussion under *vitiligo*). Hirschprung disease and neurofibromatosis type I have rarely been associated with piebaldism.

Cross–McKusick–Breen syndrome

Also known as Cross syndrome, oculocerebral hypopigmentation syndrome, or hypopigmentation and microphthalmia,

this extremely rare disorder is characterized by white skin, blond hair with a yellow–gray metallic sheen, small eyes with cloudy corneas, jerky nystagmus, gingival fibromatosis, and severe mental and physical retardation.

Dermatology has always been a surgically oriented specialty. While procedures such as curettage, biopsy, destruction, and excision have been key components of the field, the practice has evolved to include a greater number and extent of surgical procedures. This progression can be attributed to a variety of factors. Dermatologists have a greater understanding of cutaneous pathology, which places them in a unique role to manage complex surgical procedures. In addition, outpatient dermatologic surgery has been shown to be cost-effective, safe, and efficacious, and to deliver a greater degree of patient convenience, particularly when compared to other fields. With this in mind, the American Board of Dermatology mandates certain surgical exposure and experience for all residents in dermatology residency programs. Furthermore, with the recent Accreditation Council for Graduate Medical Education (ACGME) accreditation of Procedural Dermatology fellowships, dermatologic surgery has become recognized as a mainstream medical option for patients. While the practice of dermatologic surgery can be the subject of entire textbooks, the following chapters provide a survey of procedures, indications, and appropriate management within the spectrum of the field.

Preparation for surgery

A thorough and complete preoperative evaluation is required prior to performing any surgical procedure. A detailed medical history must be obtained, including information on drug allergies, current medications (including herbal or natural supplements), presence of a pacemaker or implantable cardioverter/defibrillator, recently implanted prosthetics, history of prior wound infection or perioperative bleeding, and history of endocarditis, or cardiac valvular or congenital malformation.

Anticoagulants

Much has been written regarding the role of antiplatelets and/or anticoagulants and surgical bleeding. Dermatologists are frequently presented with the dilemma of whether to discontinue blood thinners in the setting of surgery. Data and multiple reviews have shown that continuous treatment with blood thinners perioperatively in patients undergoing Mohs and cutaneous surgery is not associated with an increase in surgical complications leading to significant morbidity. In contrast, discontinuation of these medications may increase the risk of catastrophic cerebral and cardiovascular complications. Kovich and Otley reported a series of thrombotic complications in a group of patients who had discontinued aspirin or warfarin prior to surgery; these included stroke, transient ischemic attack, myocardial infarction, pulmonary embolus, and death. Multiple authors feel that the potential adverse effects of discontinuing essential medical blood thinners far outweigh the potential side effects of surgical bleeding (i.e.

managing a postoperative hematoma). In fact, despite some surgeons' claims to the contrary, several studies have demonstrated that blinded surgeons are unable to identify intraoperatively which patients are taking anticoagulation medication based on the subjective amount of surgical oozing. As such, it is recommended that patients be maintained on all medically necessary blood thinners during cutaneous surgery. Patients taking aspirin for primary prevention may discontinue use 2 weeks prior to any surgical procedure.

Herbal supplements are becoming increasingly popular with patients who are looking for a "natural" option to traditional medication. Patients may not readily volunteer the fact that they are taking these supplements, either because they do not characterize them as medication or out of fear that physicians will not be accepting of alternative treatments. Therefore, it is important to ask patients specifically if they are taking any supplements. Ginkgo, garlic, ginseng, ginger, and vitamin E may increase the risk of perioperative bleeding. As these herbal supplements are not medically necessary, patients should discontinue them for several weeks prior to undergoing dermatologic surgery.

Antibiotic prophylaxis

Dermatologists performing cutaneous surgery are often faced with the decision of whether to prescribe prophylactic antibiotics. The main issues surrounding antibiotic prophylaxis are prevention of surgical site infections and reduction of the risk of endocarditis or contamination of prosthetic devices in high-risk patients. While there is a trend in medicine towards evidence-based approaches, this is often overlooked by many dermatologists when it comes to antibiotic prophylaxis. While

reducing infection is one objective in the use of antibiotics, dermatologists must take into consideration the risks of such treatment, including adverse drug reaction, serious drug reactions, drug interactions, development of resistant strains of bacteria, and increased cost.

Surgical site infection

Determining the indications for antibiotic prophylaxis for surgical site infections requires an understanding of the various types of wound that the dermatologist may encounter. Wounds are categorized into four groups:

1. Clean wounds (class I) are created on normal skin using clean or sterile technique. Examples include excision of neoplasms, noninflamed cysts, biopsies, and most cases of Mohs surgery. The majority of dermatologic surgery falls into this category. The infection rate of these wounds is less than 5%. Of note, this incidence is based on general surgery cases, which are often of longer duration and a greater extent than most dermatologic procedures. This explains the lower actual infection rate in dermatologic surgery, which is in the 1–3% range.
2. Clean-contaminated wounds (class II) are created on contaminated skin or any mucosal or moist intertriginous surface, such as the oral cavity, upper respiratory tract, axilla, or perineum. The infection rate of these wounds is 10%.
3. Contaminated wounds (class III) involve visibly inflamed skin with/without nonpurulent discharge and have an infection rate of 20–30%. Examples included inflamed cysts or traumatic wounds.
4. Infected wounds (class IV) have contaminated foreign bodies, purulent discharge, or devitalized tissue. Examples included necrotic tumors, ruptured cysts, or active hidradenitis suppurativa. These wounds have an infection rate of 40%.

Clean (class I) wounds, which constitute the vast majority of dermatologic surgery procedures, do not require antibiotic prophylaxis.

Although antibiotic prophylaxis in clean-contaminated (class II) wounds is not a clear issue, most cases do not require routine antibiotics. It is preferable to treat infections should they arise (as they are not a common occurrence, even in class II wounds), rather than expose all patients to antibiotics and the increased rate of drug-related adverse events. The exception to this would be those surgery cases that violate mucosal membranes (i.e. oral, nasal, or anogenital mucosa), and patients with heavily colonized skin (i.e. atopic dermatitis or infected skin), as well as those patients in whom a wound infection would result in significant morbidity.

In contaminated (class III) and infected (class IV) wounds, antibiotics serve a therapeutic, rather than a prophylactic, role and should be used routinely in these cases.

Antibiotic selection and timing

In order to achieve optimal prophylaxis, antibiotics ought to be in the bloodstream, and thus at the surgical site, at the time of incision. Antibiotics given at the conclusion of the procedure are not as effective in preventing infection, as they are not incorporated into the coagulum of the wound. Once the surgical wound is closed, the risk of infection decreases significantly. As the majority of dermatologic procedures are of short duration, a single preoperative dose of antibiotics 1 h before the start of the case is sufficient. In rare cases with an extended dermatologic procedure, a second dose of antibiotics can be administered 6 h postoperatively.

The choice of antibiotic is based on the surgical site's most likely causative organism (Table 37-1). *Staphylococcus aureus* is the most common wound infection in cutaneous surgery.

Table 37-1 Antibiotic prophylaxis for heavily colonized or high-risk patients

Situation	Antibiotic	Regimen (1 h preoperative dose)
Skin	Cephalexin	1 g orally
	Dicloxacillin	1 g orally
	Clindamycin	300 mg orally
	Vancomycin	500 mg IV
Oral/respiratory mucosa	Cephalexin	1 g orally
	Amoxicillin	1 g orally
	Clindamycin	300 mg orally
Gastrointestinal/genitourinary mucosa	Cephalexin	1 g orally
	Trimethoprim/sulfamethoxazole	1 double-strength tablet orally
	Ciprofloxacin	500 mg orally

Other pathogens that need to be considered in some situations include *Streptococcus viridans* (oral mucosa) and *Escherichia coli* (perineal and genital location).

First-generation cephalosporins are an ideal initial choice for the treatment of wound infection because of their coverage of staphylococcal organisms, common Gram-negative organisms such as *E. coli*, and certain *Proteus* species. They are rapidly absorbed when taken orally and have good tissue penetration. The estimated cross-reactivity in penicillin-allergic patients is 5–10%.

Isoxazolyl penicillins, such as dicloxacillin and nafcillin, can also be used as they provide coverage for most strains of streptococci and β -lactamase-producing bacterial strains such as *S. aureus*. Aminopenicillins, such as ampicillin and amoxicillin, have better Gram-negative, enterococcal, and group A streptococcal coverage. However, they are not effective against β -lactamase-producing bacteria, and thus are more commonly used in procedures involving oral mucosa.

Clindamycin, macrolides (i.e. erythromycin or azithromycin), trimethoprim-sulfamethoxazole, and ciprofloxacin can all be considered in patients with a penicillin or cephalosporin allergy, with the specific choice based on the site of surgery and thus the presumed causative organism. Vancomycin is generally limited to those cases where methicillin-resistant *S. aureus* (MRSA) is suspected, as it requires intravenous administration and adjustment in patients with impaired renal function.

Treatment of wound infection

Postoperative surgical site infection is quite uncommon in dermatologic surgery procedures, with an incidence of 1–3%. Infections typically present 4–7 days after surgery with increased erythema, tenderness, warmth, and purulent drainage. Sutures can be removed to allow for drainage of exudate. In cases where infection leads to dehiscence, the wound can be packed or allowed to heal by second intention. Scar revision can be performed at a later date. A culture should be performed prior to initiating empiric antibiotics to determine sensitivities.

S. aureus is the most common pathogen, and cephalexin or dicloxacillin is an appropriate first-line treatment. Those patients with a penicillin allergy can be treated with clindamycin. Although this antibiotic has been associated with colitis, the short courses that are typically used with surgical site infection generally do not present a problem. In those communities or institutions with a high incidence of MRSA, antibiotic choice can be modified based on community sensitivities (e.g. doxycycline or trimethoprim-sulfamethoxazole). Ciprofloxacin can be used for those infections with a higher likelihood of Gram-negative or *Pseudomonas* organisms (e.g.

ear). Antibiotic choice should be modified based on culture results.

Endocarditis prophylaxis

The American Heart Association (AHA) updated its recommendations on infective endocarditis (IE) prophylaxis in 2007. The overall conclusions were that bacteremia from daily activities is much more likely to cause IE than bacteremia associated with dental procedures, and that far fewer patients are now recommended to have antibiotic prophylaxis. Antibiotic prophylaxis has been limited to patients with the conditions listed in **Box 37-2**. All other cardiac conditions, including mitral valve prolapse and other forms of congenital heart disease, no longer require prophylaxis for any procedure.

Antibiotic prophylaxis is reasonable when procedures involve manipulation of gingival tissue, perforation of oral mucosa, or incision or biopsy of the respiratory mucosa, or are performed on infected skin, but only in patients with underlying cardiac conditions associated with the highest risk of adverse outcome, as outlined in the box below. Antibiotic prophylaxis solely to prevent infective endocarditis is not recommended for gastrointestinal or genitourinary procedures. The AHA reaffirmed its 1997 statement regarding medical procedures, including incision or biopsy of surgically scrubbed skin, that do not require antibiotic prophylaxis. Antibiotic pro-

phylactic regimens for those selected high-risk patients should be a single dose of antibiotic administered 1 h before the procedure (Table 37-3).

There are no formal guidelines regarding the use of antibiotics in patients with orthopedic prosthetic devices undergoing dermatologic surgery. However, guidelines for dental procedures in patients with joint replacement can be extrapolated to certain procedures. Patients with joint replacement probably do not need prophylactic antibiotics for clean wounds. If mucosa is invaded, prophylaxis may be appropriate and reasonable in the small number of patients who might be at high risk of joint infection. Consultation with orthopedic surgery is appropriate in determining whether antibiotic prophylaxis is necessary.

Box 37-2 Cardiac conditions associated with the highest endocarditis risk

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
- Previous infectious endocarditis
- Congenital heart disease (CHD)*
 - Unrepaired cyanotic CHD, including palliative shunts and conduits
 - Completely repaired congenital heart defect with prosthetic material or device, during the first 6 months after the procedure
 - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

*Except for conditions listed above, antibiotic prophylaxis is not recommended for any other form of CHD. Adapted from Wilson et al. (2007)

Preoperative antisepsis

Many surgical preparations are available. Alcohol is commonly used for minor clean procedures, such as biopsies. However, since it has only weak antimicrobial activity, it is not recommended for more extensive procedures.

Chlorhexidine has a broad spectrum against Gram-positive and Gram-negative organisms, a rapid onset of activity, sustained residual activity even after being wiped off, and is nonstaining. Chlorhexidine has been reported to cause both

Table 37-3 Endocarditis prophylaxis regimen (single dose 1 h prior to procedure)

Situation	Agent	Adults	Children
Able to take oral medication	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin	2 g IM/IV	50 mg/kg IM/IV
	or Cefazolin or ceftriaxone	1 g IM/IV	50 mg/kg IM/IV
Allergic to penicillins or ampicillin and able to take oral medication	Cephalexin*	2 g	50 mg/kg
	or Clindamycin	600 mg	20 mg/kg
	or Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone*	1 g IM/IV	50 mg/mg IM/IV
	or Clindamycin	600 mg IM/IV	20 mg IM/IV

*Cephalosporins should not be used in patients with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin. Adapted from Wilson et al. (2007)

ototoxicity and keratitis from direct tympanic or ocular contact. However, this is mainly in patients under general anesthesia who cannot respond to immediate irritation associated with ocular contact, a problem that is avoided in most dermatologic procedures performed under local anesthesia.

Betadine and all iodine-containing preparations have an excellent bactericidal activity within several minutes of application. However, they are often irritating to the skin, leave a residual color, can be absorbed in premature infants, and must dry before the procedure if they are to act as an effective antimicrobial agent.

Hexachlorophene is not bactericidal against many Gram-negative organisms. It has the potential for neurotoxicity in children and teratogenicity in pregnancy. Hydrogen peroxide has no significant antiseptic properties, and thus it is not suitable for sterile skin preparation.

If hair must be removed prior to surgery, this should be done in a manner that does not leave open skin (i.e. cuts or scratches), which can serve as a conduit for infection. Preoperative shaving has been associated with a higher rate of bacterial infection secondary to cutting of the skin surface.

Anesthesia

Anesthetics work by blocking sodium influx into neurons and preventing depolarization and blockage of action potential. Small unmyelinated C-fibers, which carry pain and temperature sensation, are more easily blocked than larger myelinated A-fibers, which carry pressure sensation and motor function. This difference translates clinically, with patients under local anesthesia not experiencing pain from the sharp incision, but still maintaining the sensation of pressure during the procedure.

All local anesthetics have a similar structure, consisting of three parts: an aromatic hydrophobic ring, an intermediate chain, and an amine end. The aromatic hydrophobic portion is lipophilic and facilitates diffusion through nerve cell membranes, correlating to the potency of the anesthesia. The hydrophilic amine end contributes to the aqueous solubility of the anesthetic and is involved in binding of the molecule to the sodium channel. The intermediate chain consists of either an amide or an ester. Amides are metabolized by hepatic microsomal enzymes, while esters are metabolized in plasma by pseudocholinesterase and excreted by the kidney.

The choice of anesthetic is based on a variety of factors, including patient allergy, renal or hepatic impairment, and type of procedure being performed. The workhorse anesthetic of dermatologic surgery is lidocaine, due to its rapid onset of action and intermediate duration of action. Longer-acting anesthetics, such as bupivacaine, have a delayed onset of action, but can be used in special procedures or in combination with lidocaine to maximize duration of anesthesia.

All local anesthetics, with the exception of cocaine and prilocaine, cause vasodilatation due to relaxation of smooth muscle. As a result, patients experience increased surgical bleeding and shorter duration of action as the anesthesia is cleared from the surgical site due to vasodilatation. Epinephrine, which causes vasoconstriction, is often added to local anesthetics to decrease bleeding, increase duration of anesthesia, and reduce systemic side effects due to systemic absorption. Concentrations of 1:100,000 to 1:400,000 are typically used, with lower concentrations having fewer side effects while still maintaining clinical efficacy. As the vasoconstrictive effect of epinephrine takes 15 min for onset, the surgeon must allow adequate time prior to starting the procedure. Epinephrine is a strong α - and β -adrenergic receptor agonist, and has an absolute contraindication

in hyperthyroidism and pheochromocytoma. Large amounts of epinephrine must be used cautiously in patients with severe hypertension or narrow-angle glaucoma, and in pregnancy. Patients taking β -blockers, monoamine oxidase inhibitors, tricyclic antidepressants, and phenothiazines are more sensitive to epinephrine. While the subject of much controversy, epinephrine is safe to use in well-vascularized areas, such as the ear, nose, and genitals. Reports of necrosis are likely due to excessive volume being placed, which can cause a physical tamponade of vessels, rather than being a direct result of epinephrine.

Sodium bicarbonate (8.4%) can be added (1:10 ratio) in order to reduce the pain and burning associated with the lower pH of lidocaine with epinephrine. However, sodium bicarbonate can reduce epinephrine activity with time, thus requiring freshly mixed preparations on a regular basis.

Side effects

The most common side effect of local anesthetic is injection site pain. Buffering with sodium bicarbonate, using a small-gauge needle (i.e. 30 gauge), using ice or vibratory distraction at the injection site, injecting slowly into the subcutaneous tissue (rather than the dermis), warming the anesthesia, minimizing the number of injections, and placing subsequent injections in an already anesthetized location can minimize the pain associated with local anesthesia. Vasovagal reactions are common during anesthesia administration. Patients should lie flat during the injection to reduce this occurrence. Cold compresses and placing the patient in a Trendelenburg position can help if symptoms occur.

Maximum dosage of anesthesia has traditionally been accepted as 5 mg/kg of 1% plain lidocaine and 7 mg/kg of 1% lidocaine with epinephrine. These numbers have been based on old industry-based studies, not found in the medical literature. Experience with tumescent liposuction has taught that dosages up to 55 mg/kg are well tolerated and safe in certain clinical situations. Bupivacaine has a greater risk of cardiac toxicity than lidocaine, because of its longer duration of action.

Most true allergic reactions to local anesthetics have been reported with esters. The metabolite *p*-aminobenzoic acid (PABA) is responsible for ester allergies. There is no cross-reactivity between ester and amide classes of anesthetics, so allergy to one type does not preclude the use of the other. True systemic amide allergy is extremely rare. Thorough questioning of patients who report allergy often reveals a vasovagal reaction or epinephrine sensitivity. If local anesthetic use is precluded, intradermal injection with diphenhydramine can be used. Drowsiness can be a side effect when large doses of this agent are used. Bacteriostatic saline, with the benzyl alcohol preservative acting as the anesthetic agent, is often sufficient to provide the brief anesthesia needed to perform small procedures.

Topical anesthetics can be effectively used for many laser procedures, as well as decreasing pain associated with pin-pricks of local anesthesia. These products require an extended time of application and/or occlusion in order to penetrate the stratum corneum and work effectively. The level of anesthesia obtained with these topical agents is often inconsistent. They are more effective on mucosa, due to the absence of the corneal barrier. There are numerous lidocaine-containing products in a variety of preparations. Eutectic mixture of 2.5% lidocaine and 2.5% prilocaine (EMLA, AstraZeneca, Wilmington, DE) has also been used extensively. Prilocaine-induced methemoglobinemia has been reported in children due to the increased systemic absorption of prilocaine from certain topical products.

Direct application of ice can reduce injection site pain. Ethyl chloride spray rapidly chills the skin and can be used for small

curettage procedures or needle insertion. Refrigerated forced air or water-chilled sapphire crystals can help reduce pain associated with laser procedures. Ophthalmic solutions of proparacaine 0.5% or tetracaine 0.5% can provide rapid anesthesia and are useful when placing corneal shields.

Anatomy

A thorough understanding of anatomy is critical when performing dermatologic surgery. The vascular supply, sensory

and motor innervation, and muscles of facial expression all play a role in the successful surgical outcome (Figs 37-1 to 37-3; Box 37-4).

Several key danger zones are worthy of mention. The temporal branch of the facial nerve is at greatest risk for injury when it runs superficial to the deep temporalis fascia as it crosses the zygomatic arch. Care must be taken to undermine bluntly in a plane above the SMAS (superficial muscular aponeurotic system). Injury to the temporal nerve results in brow ptosis and inability to raise the eyebrow. The danger zone for the marginal mandibular nerve lies where it crosses over the body of mandible, just anterior to the masseter muscle. Injury to the marginal mandibular nerve causes asymmetrical ipsilateral lip elevation and inability to show the lower teeth.

Fig. 37-1 Arterial supply of the face. Light pink designates arteries derived from the internal carotid artery; dark pink, from the external carotid artery. With permission from Bologna JL, Jorizzo JL, Rapini RP (eds): *Dermatology*. 2nd edn. London: Mosby, 2008.

The spinal accessory nerve is at risk in a region of the neck delineated by the clavicle inferiorly, the sternocleidomastoid muscle anteriorly, and the trapezius muscle laterally and posteriorly. Damage to the nerve causes a winged scapula, inability to shrug the shoulder, difficulty abducting the shoulder, shoulder drop, and chronic shoulder pain.

Equipment

The choice of instruments and suture depends on the procedure being performed. Most simple, in-office biopsies are performed in a “clean” rather than sterile manner, and

require minimal instrumentation. More complex excisional and reconstructive surgery is generally performed with sterile technique and employs a surgical tray with a wider range of instruments (Box 37-5). For procedures requiring sutures, absorbable material is used for deeper, layered closures, whereas surface sutures are generally nonabsorbable or fast-absorbing (Box 37-6). The large number of suture choices relates to both the type of procedure performed and the anatomic location treated. Choices include absorbable and nonabsorbable, synthetic and nonsynthetic, monofilament and braided. There are a variety of other characteristics one must consider when choosing which suture to use. Memory is the ability of the suture to return to its original shape after

Box 37-5 Cutaneous surgical instruments and supplies

- Scalpel handle (flat No. 3)
- Blade (No. 15)
- Needle holder (appropriate size)
- Sharp curved iris scissors, tissue-cutting scissors
- Blunt undermining scissors
- Skin hook (dull-tipped, 2–4-prong)
- Hemostats
- Forceps (1 × 2 teeth, with suture platform)
- Skin preparatory scrub in sterile basin
- Sterile towels
- Sterile gauze and cotton-tipped swabs
- Hyfrecator cover
- Suture
- Suture scissors
- Blade remover

deformation, which results in poor handling and decreased knot security. Plasticity is the ability of the suture to retain its new shape after it has been stretched. Elasticity is the ability of a suture to return to its original length and shape after stretching, an important factor to consider in relation to the resulting edema associated with surgery. The coefficient of friction is the ease with which the suture slides through tissue and is directly related to knot security. Capillarity is the ability of the suture to wick away fluid, with braided sutures having an increased tendency to trap fluid and bacteria. All have appropriate applications and a detailed discussion is beyond the scope of this chapter.

In general, for procedures requiring buried suture, a synthetic braided suture is a common choice. The 50% tensile strength for this class of suture is about 3 months. Additionally, it is less palpable under the skin. For procedures on the trunk and extremities (i.e. areas under tension), a monofilament absorbable suture may be a better choice, as the tensile strength may last for a greater length of time. The thicker skin in these areas may hide the palpability of this class of suture, making it more acceptable to patients. Epidermal approximation in more delicate areas is more appropriately closed with smaller 5-0 or 6-0 sutures. Absorbable sutures (e.g. gut) may be considered in sensitive areas where suture removal may be painful or difficult (e.g. eyelids) or in children. Facial sutures are often taken out in 4–7 days to decrease the chance of forming track marks from epithelialization of the suture puncture site, whereas sutures on the scalp, neck, and body are often left in for approximately 2 weeks. Running subcuticular sutures can

Fig. 37-4 Shave biopsy. Lesion is pinched up with thumb and finger and biopsy performed with sweeping strokes.

be left in for 3 weeks to add tensile strength to wounds without the risk of suture marks.

Biopsies

When performing a skin biopsy, the clinician should consider the lesion characteristics, reason for biopsy (i.e. diagnostic versus cosmetic), and site. Shave biopsies can range from a superficial scissor snip of an epidermal growth to deep shave excisions of papillary dermal processes. Punch biopsies are most often used for dermal lesions, sampling deeper than shave biopsies, but requiring sutures. Excisional biopsies remove an entire clinical lesion and are the biopsy of choice for pigmented lesions suspicious for melanoma. Incisional biopsies remove a portion of a clinical lesion and are often performed on larger plaques or patches when an excisional biopsy is not cosmetically acceptable or feasible. A wedge biopsy is a deep incisional biopsy that can sample pathologic tissue and adjacent normal tissue, and is especially useful for pathologic diagnosis of certain inflammatory conditions (e.g. panniculitis, fasciitis).

Shave biopsies are best suited to pedunculated, papular, or otherwise exophytic lesions. Using a deep or rolled shave, samples can also be obtained of macular or indurated lesions, provided the necessary histologic changes reside in the epidermis or papillary dermis. Infiltration of local anesthesia distends and elevates the lesion, increases skin turgor, affords greater resistance to the blade, and facilitates undercutting the lesion. Using either a 15-blade scalpel or a razor blade, which can be flexed to achieve the desired depth, a horizontal incision is made and the lesion removed with sweeping strokes (Fig. 37-4). Hemostasis is attained with 35% aluminum chloride solution.

Sharp scissor biopsy is best suited to pedunculated lesions. Iris or Gradle scissors are used to snip the base of the lesion. In many cases, this can be done without anesthesia. Chemical hemostasis, electrocautery, or simple pressure can be used to control bleeding.

The dermatologic punch is commonly used for both excisional and incisional biopsies (Fig. 37-5). When performing a punch biopsy, the skin should be stretched perpendicular to the relaxed skin tension lines. The elliptical wound resulting from the release of the tension can be suture-closed in a linear fashion without redundancy or puckering associated with circular wounds. The punch is placed on the skin perpendicular to the surface. While the surgeon applies gentle pressure, it is

Fig. 37-5 Punch biopsy. A, Lesion to be removed. B, Skin stretched perpendicular to relaxed skin tension lines and punch inserted with twisting motion. C, Specimen is carefully grasped and removed. D, Resultant elliptical defect. E, Sutures in place.

rotated back and forth and advanced to the hub. The specimen is carefully grasped to avoid crush artifact and the base is cut. Sutures are typically placed to achieve hemostasis, but punch sites that are allowed to heal by second intention have been shown to heal with a similar cosmetic outcome.

A variation of the punch biopsy can be used to remove larger subcutaneous nodules. Narrow-hole extrusion is a surgical technique that uses a punch biopsy to make a small cutaneous portal through which larger benign growths (e.g. lipoma) can be extruded (Fig. 37-6). This technique allows the evacuation of large subcutaneous growths with a relatively small surface incision.

Suture technique

Proper suture placement is essential to obtain the desired final result. Sutures are used to close any dead space, reduce bleeding, provide tensile strength and minimize tension to facilitate wound healing, and achieve epidermal wound approximation to maximize cosmetic outcome. Instrument-tied knots are the most common sutures used in dermatologic surgery. Various suturing techniques can be employed, based on factors such as size, anatomic location, and thickness of the surgical wound.

Buried subcutaneous sutures are used for larger or deeper wounds to reduce the chance of wound dehiscence. Proper placement is key to achieving eversion of the wound edges

and decreasing tension (Fig. 37-7). The stitch is in the dermis and fat, with the knot cut short and buried to reduce tissue reaction and “spitting” sutures.

Simple epidermal interrupted sutures are one of the most versatile stitches used in dermatology. They are best used for closure of small punch biopsies, or for larger layered excision or flap repairs. They are especially useful in high-tension wounds, as a single suture can be removed and the surgeon can assess the wound for any dehiscence. For wound edges with a step off the opposing epidermal edges, the surgeon places the suture more superficially at the higher side and deeper on the lower side to even the edges (Fig. 37-8).

The vertical mattress suture is useful for reducing tension, closing dead space, and achieving wound eversion (Fig. 37-9). It can function as both the buried and the superficial suture. As this suture has a high tendency to leave track marks and strangulate the skin, it must be used strategically and removed sooner than traditional sutures. The horizontal mattress suture reduces tension and can be used as a retention suture when attempting to close larger wounds (Fig. 37-10). It can cause strangulation and necrosis of poorly vascularized tissue and should be used with caution when closing flaps.

Running sutures can be used for epidermal closure in wounds under little tension and with closely approximated wound edges. Placement is much faster than simple interrupted sutures, as knots are only used at each end of the wound. The running locked suture is a variant of the simple

running suture and involves passing the needle through the previous loop (Fig. 37-11). This technique creates pressure along the wound edge and can be used in highly vascularized regions for additional hemostasis.

Running subcuticular sutures typically use a non-absorbable suture and are used for trunk and extremity closures where sutures are left for 2–3 weeks. Since the suture is buried, it can be left in place for a longer period of time without developing cross-hatch marks (Fig. 37-12). A single loop coming out in the middle of larger wounds can help facilitate removal of the suture. Alternatively, absorbable suture can be used and eliminate the need for removal.

Cryosurgery

Cryosurgery is used for the treatment of numerous benign, premalignant, and malignant skin lesions. This modality is extensively employed by almost every dermatologist, owing to its ease of use, cost-effectiveness, and versatility. Postoperative wound care is relatively simple and complica-

Fig. 37-10 Horizontal mattress suture. A, To place this suture, begin with a widely spaced simple interrupted suture (1) (2). Numbers indicate entry points of the needle. tions are infrequent. Although a number of cryogens have been used (including ethyl chloride, CO₂, and NO), liquid nitrogen, with a boiling point of –195.6°C, is most widely utilized.

The mechanism of injury in cryosurgery is the result of multiple factors, including mechanical damage to cells resulting from intracellular and extracellular ice crystal formation, exposure to high electrolyte concentrations in surrounding non-frozen or thawing fluid, recrystallization patterns during thaw, and ischemia caused by vascular stasis and damage. Rapid freezing causes intracellular ice crystals that are more destructive than the extracellular crystals formed during slow freezing. Tissue damage is maximized with a slow thaw time, which causes increased solute gradients and greater cell destruction. Multiple freeze-thaw cycles can further increase damage to the target lesion.

There are several techniques for cryosurgery. The simplest is the use of a cotton-tipped applicator. Varying the amount of pressure applied and the length of contact of the applicator to the skin can control the depth of freeze. Additionally, the volume of liquid nitrogen can be increased or decreased by

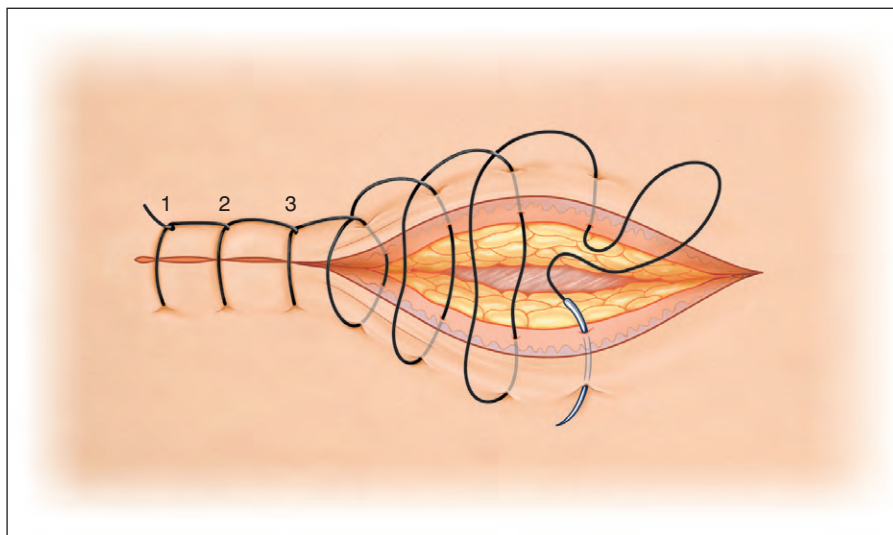

Fig. 37-11 Running block suture. A running simple suture is placed, passing the needle through the loop created by the last suture. This locking suture facilitates hemostasis. adding or removing cotton from the applicator tip. As viruses have been shown to survive in liquid nitrogen, cotton-tipped applicators should never be reintroduced to the storage container. Rather, a small amount of liquid nitrogen should be transferred to an individual container and discarded after use.

Spray application is one of the most commonly used methods of cryosurgery. This technique uses a hand-held liquid nitrogen spray unit with an adjustable nozzle to vary the size of the stream delivered. An insulating cone or a disposable otoscope speculum can be used to focus the delivery of liquid nitrogen, resulting in a deeper freeze and finer control with less damage to uninvolved skin (Fig. 37-13).

Basal cell carcinomas (BCCs) can be treated effectively with cryosurgery. Freezing to reach a target temperature of approximately -50°C , as measured by a thermocouple, is appropriate for management of these tumors. This translates to a thaw time of approximately 60 sec, with a freeze margin of approximately 5 mm (Fig. 37-14). It is important to recognize that the

pain associated with such treatment requires local anesthesia. In a review of published data, Kokoszka et al found a recurrence rate of less than 10% for primary small, noninfiltrating (i.e. superficial and nodular) BCC treated with cryosurgery. Some have suggested that initially treating the tumor with curettage, followed by cryosurgery, can lead to cure rates consistent with curettage and electrodesiccation. However, Kuijpers et al have suggested that standard excision provides higher cure rates than curettage and cryosurgery, and recommend that excision be used as the preferred treatment for BCC, due to the higher cure rate, better cosmetic outcome, and faster healing rates.

Side effects of cryosurgery are similar to those of other ablative procedures (e.g. curettage and electrodesiccation), and include blistering, crusting, pain, a 3–4-week healing period, and scarring. As melanocytes are more susceptible to thermal damage than keratinocytes, hypopigmentation can often be seen, especially in individuals with darker skin tones. While

pigment alterations are more frequently seen with longer freeze-thaw times, these changes can be observed even with very brief treatment cycles. A self-limited hyperplastic or pseudoepitheliomatous healing response may occur approximately 2–4 weeks after freezing. Nerve injury can occur during cryosurgery. Anatomic locations with superficial nerves (e.g. lateral aspects of the fingers, ulnar groove of the elbow, pre- and post-auricular skin) are especially susceptible to this complication. Techniques to limit this risk include tenting the skin up and away from the nerve, ballooning the skin with lidocaine, or sliding the skin back and forth over the underlying fascia during treatment to limit exposure to the underlying nerve. Alopecia can occur when treating hair-bearing areas.

Both atrophic and hypertrophic scars can be seen following cryosurgery.

Curettage

The curette has long been a standard tool in the dermatologist's surgical management of neoplasm. This round, semi-sharp knife is available in sizes from 0.5 to 10 mm, allowing for the removal of a variety of lesions. Since it is not as sharp as a scalpel, the curette does not easily cut through normal skin. Therefore, it is best suited for use on soft or friable lesions, such as warts, seborrheic and actinic keratoses, the papules of molluscum contagiosum, or selected basal and squamous cell carcinomas. The proper selection of lesion, location, and the size of the curette, combined with the surgeon's technique, all play a role in both the therapeutic and cosmetic outcome.

The skin should be stabilized with the nondominant hand while the curette is held like a pencil. Curettage should be performed in a centripetal manner (from the outside in) to avoid stripping sun-damaged skin and creating a larger wound. To ensure complete destruction, curettage should be performed in multiple directions to produce symmetrical wound margins. A large curette is used for initial debulking, followed by a smaller curette to remove any residual foci or extensions. Curettage is complete when the "gritty," firm sensation of normal dermis is felt and slight punctate dermal bleeding occurs.

Curettage, combined with electrodesiccation (C&E), is widely used for the treatment of BCC and squamous cell carcinomas (SCC) (Fig. 37-15). Silverman et al reviewed the cure rates of primary BCC treated with C&E over a 27-year period at New York University. The result of the study stratified low-, middle-, and high-risk anatomic locations and the risk of recurrence following C&E of primary BCC. Low-risk anatomic sites (neck, trunk, and four extremities) had a 5-year recurrence rate of 3.3%. Middle-risk sites (scalp, forehead, pre- and post-auricular, and malar areas) had an overall recurrence rate of 12.9%, but this was reduced to 5% when limited to noninfiltrative carcinomas of less than 1 cm. High-risk sites (nose, paranasal, nasolabial groove, ear, chin, mandibular, perioral, periocular areas) had an overall recurrence rate of 17.5%, but a more acceptable 5% recurrence rate was achieved when treatment was limited to lesions of less than 6 mm.

In addition to size and anatomic location, the histologic subtype is an important factor in the effectiveness of C&E. Infiltrative and micronodular BCC are not appropriate for C&E, while it can be considered a therapeutic option in superficial and nodular subtypes. SCC in situ may be appropriately treated with C&E, while in most circumstances invasive SCC would not typically be amenable to this modality.

There is little agreement regarding the requisite number of cycles of C&E. Indeed, treating all lesions identically with a particular number of cycles may lead to overtreatment of some lesions and undertreatment of others. In general, accepted therapy employs three cycles to treat most malignant lesions. However, smaller superficial malignancies may be treated with fewer cycles; the rationale is to improve cosmetic outcome, while still achieving acceptable cure rates. None the less, the success of C&E relies on the surgeon's ability to identify by feel and appearance the tissue to be ablated. Finally, C&E should be replaced by excision if curettage extends into subcutaneous tissue. As such, lesions that have been previously biopsied using a punch that has extended into the subcutaneous fat may be less amenable to C&E.

Electrosurgery

Electrosurgery comprises a variety of surgical techniques, applications, and apparatus. In general, the tissue effect is created by heat delivered to or generated in the tissue as a result of an electrical current. Various forms of electrosurgery are routinely used by dermatologists for applications such as destruction, hemostasis, excisions, and cosmetic procedures. An understanding of the different modalities and their applications can improve surgical outcome (Fig. 37-16).

Electrocautery

Electrocautery is most often performed today with battery-powered, hand-held, disposable units. Direct current is passed through a metal treatment tip. Resistance to the flow of current causes heat to be generated, which can be adjusted by the intensity of the current. Hemostasis is achieved by direct heating of the tissue; no electrical current passes through the patient. As such, this device may be considered in patients with implantable cardiac devices sensitive to electric current.

Fig. 37-16 Electrosurgery waveforms.

Electrodesiccation and electrofulguration

Electrodesiccation (from the Greek desiccate, meaning “dry”) and electrofulguration (from the Greek fulgur, meaning “lightning”) represent the most commonly employed uses of electrosurgery in dermatology. In electrodesiccation, the electrode tip is in contact with the tissue; with electrofulguration, a 1-2 mm separation between the tip and the tissue produces a spark. Electrodesiccation causes a deeper wound, while electrofulguration is more superficial.

A highly damped (decreasing amplitude) waveform of high voltage and low amperage is produced by a spark-gap generator. As this is a monoterminal current, a grounding electrode on the patient is not required. Electrodesiccation/fulguration produces superficial destruction, as the carbonization on the treated surface limits damage to deeper tissue.

This type of electrosurgery has numerous applications in the daily practice of dermatology. Superficial, small dermal tumors, such as syringomas or seborrheic keratoses, may be treated with electrodesiccation. Insertion of the fine epilating needle into the tumor is followed by the application of low current until a surface bubbling occurs. The small amount of char is then removed with a curette, resulting in a smooth surface appearance. In addition, skin tags, warts, and fine telangiectases may all be effectively removed by this technique. Electrodesiccation or fulguration is commonly employed in treatment of many BCCs and SCCs (see above section on [curettage](#)). It is also useful in excisional surgery to obtain hemostasis. The field must be dry, since the destruction by this current is superficial and will not be transmitted through blood.

Electrocoagulation

Electrocoagulation employs moderately damped current with a lower voltage and higher amperage. The patient is incorporated into a biterminal circuit. Electrocoagulation causes

greater tissue damage and deeper penetration than electrodesiccation or electrofulguration.

Electrosection

Electrosection employs an undamped, low-voltage, high-amperage current in a biterminal fashion. This technique has the advantage of cutting with simultaneous hemostasis. As such, it is used for bloodless excisional surgery of protuberant masses and growths, such as rhinophyma. There is vaporization of tissue with little heat spread. Care must be taken with this technique, as maintaining an appropriate depth can be difficult, given the ease with which the device can cut through skin. When the device is properly used, fine surgical excisions can be produced, with minimal trauma to surrounding tissue and excellent hemostasis. Various handpiece attachments, including scalpels, needles, wire loops, and balls, can further adapt the instrument to the specific procedure.

Care must be taken when using electrosurgery in a patient with a pacemaker or implantable cardioverter-defibrillator, especially if the procedure is performed within a few centimeters of the device. Although modern devices are better shielded and less likely to respond to external electrical interference, it is always prudent to deliver current in short bursts. Additionally, consideration should be given to the use of electrocautery (heat only, no electrical transmission) or a bipolar device (current transmitted between two tips) when treating these patients. Yu et al recently reviewed the use of electrosurgery in patients with cardiac devices and offer a complete discussion of the subject.

Excisional technique

The fusiform or elliptical excision is the workhorse procedure used to treat invasive skin cancers, as well as benign skin lesions needing extirpation (Fig. 37-17). The basic principle of

Fig. 37-17 Elliptical excision. A, Ellipse is designed along relaxed skin tension lines with a 3:1 length to width ratio. B, Incision made into subcutaneous tissue. C, Removal using tissue scissors in even plane. D, Blunt undermining of skin edges using skin hook. E, Buried interrupted tension-bearing absorbable sutures placed. F, Epidermal approximation using nonabsorbable running subcuticular sutures, with interruption in center of wound for easier removal.

the fusiform ellipse is excision of a specimen oriented with its longest axis along skin tension lines and its width not exceeding one-third of its length. The ellipse can be curved in a crescentic or "lazy S" pattern to align the final scar better with skin tension lines. If the procedure is performed with the correct dimensions (usually a length to width ratio of 3:1) and a 30° angle at each pole, standing cutaneous cones at the two extremes of the excision are generally avoided. Standing cutaneous cones represent excess tissue bunching at the poles of a skin closure and should be "sewn out" or excised by triangulation or M-plasty if needed. Undermining, using sharp or blunt dissection of the skin from underlying subcutaneous tissue, reduces wound tension and helps with wound edge eversion.

Skin flaps and grafts

Choosing whether to close a wound by linear closure, local skin flap, or skin graft, or allowing it to heal by second intention can be complex. Important considerations include patient concerns, local tissue movement, adjacent anatomic structural preservation and function, and cosmesis.

Second intention

Second intention wound healing yields excellent results in appropriate clinical settings. As there is contraction in wound

healing, wounds that are adjacent to a free margin may result in a pull and distortion. This may affect surrounding anatomic structures (e.g. pull on a nasal rim or eyelid). The wounds may heal with hypertrophic or pigmentary changes. However, there are areas and situations where allowing a wound to heal by second intention is appropriate. These include superficial wounds in concave areas (e.g. medial canthus, conchal bowl, and junction between the nose and cheek), partial thickness wounds involving the mucosa of the lip, or certain clinical situations, such as elderly or frail patients with decreased cosmetic concerns (Fig. 37-18). Wound care is simple and post-operative restrictions are minimal.

Flaps

Local skin flaps are geometric segments of tissue contiguous with a skin defect that are advanced, rotated, or transposed to close a wound. Advantages of flaps include better approximation of skin texture and color, hiding incision lines, redirecting tension vectors, and covering exposed cartilage and bone. Flap survival is based on the preservation of the random blood supply along the pedicle. Consideration of both the primary movement of the flap (the actual movement of the flap into the defect) and secondary movement (movement of surrounding tissue in reaction to the flap movement) is critical when designing the repair (Fig. 37-19).

Fig. 37-18 Second intention. A, Mohs defect. B, Final result 9 months later.

Fig. 37-19 Advancement flap movement.

Fig. 37-20 Single arm advancement flap. A, Advancement flap designed on nasal sidewall. B, Final wound closure.

Fig. 37-21 Island pedicle flap. A, Mohs defect. B, Final wound closure. C, 6 weeks postoperatively.

Advancement flap

An advancement flap moves almost entirely in one linear direction (Fig. 37-20). The classic advancement flap involves the creation of a rectangular pedicle, which slides into position over the primary surgical defect. The key suture advances the flap and closes the primary defect. Tissue redundancies at the base of the flap can be removed by triangulation. As survival of the distal tip of the flap depends on blood supply from the base, a maximum length: width ratio of 3:1 should be designed.

If insufficient movement is obtained with a single advancement flap, a bilateral advancement (O-H) can be employed, such that each flap advances to cover half the defect. This repair can be used in eyebrow or helical rim repairs. Single arm advancement flaps (O-L) and bilateral single arm advancement flaps (O-T) are similar to classic advancement flaps, except that only a single incision is made and the standing cone is removed by triangulation. These flaps have the advantage of a larger pedicle providing blood supply and allow a linear portion of the flap to be hidden in an existing rhytid for better cosmetic outcome. Common sites for single arm advancement flaps include the nasal sidewall, helical rim, upper lip, forehead, and eyebrow.

The island pedicle flap is a specific variant of an advancement flap (Fig. 37-21). This flap depends on a subcutaneous vascular pedicle for its blood supply and has all of the epidermal connections severed by incisions. Care must be taken in designing island pedicle flaps as the incision lines surrounding the flap can result in a patch-like appearance in the final

outcome. The best cosmetic results are achieved when at least one of the incision lines can be hidden in an existing rhytid or anatomic boundary.

Rotation flap

The rotation flap can conceptually be considered a variation of the advancement flap, in that it slides into position in much the same way, albeit in an arcuate manner. Tension vectors from this pulling action are directed along the arc of rotation in reverse fashion (Fig. 37-22). Rotation flaps are often used to close large defects when there is insufficient tissue laxity (Fig. 37-23). The flap has the advantage of good survival secondary to the large pedicle and the ability to recruit skin from a great distance. A back cut can be used to reduce pivotal restraint and provide greater tissue movement, but may compromise the vascular pedicle. Variations include bilateral rotation flap (O-Z) (Fig. 37-24) or dorsal nasal rotation flap (Fig. 37-25).

Transposition flaps

In the case of the transposition flap, the flap is elevated, transposed over intervening tissue, and sutured into the primary defect (Fig. 37-26). The tension vector is redirected across the closure of the secondary defect (i.e. the area originally occupied by the flap). This is especially helpful for defects that are adjacent to anatomic free margins. The key suture closes the secondary defect, and the flap is then lifted

Fig. 37-26 Transposition flap movement.

and transposed into position over the primary defect. The prototype of this flap is the rhombic flap (Fig. 37-27). Other examples include bilobed flaps (Fig. 37-28), nasolabial/melolabial flaps, banner flap, Z-plasty, and Webster's 30° flap (Fig. 37-29).

Choice of a particular type of flap must take multiple factors into consideration, including location of defect, availability of tissue movement, surrounding structures, effects of tissue movement, and blood supply. Full discussion of flaps is beyond the scope of this chapter and is available in multiple referenced texts. The successful design and execution of flap repairs can be complex, and requires appropriate and extensive training.

Skin grafts

Skin grafts are employed when primary closure or flap closure is not an available option. By definition, a graft is completely excised from the donor site and is devitalized (i.e. no intrinsic blood supply). Success is predicated on the reattachment of vascular supply to the graft from the defect. Grafts offer the advantage of fewer incision lines, as compared to local flaps. However, the lack of color and texture match due to the remote donor location of grafts is a potential disadvantage.

Grafts can be categorized as full, split, or composite. Choice of when to use each of these depends on the depth of the defect, vascular supply, and concern about skin cancer recurrence. Full-thickness skin grafts have a full dermis and are the most common grafts used in dermatologic surgery. The graft is defatted, trimmed to fit the defect, anchored in place with peripheral and basting sutures, and secured with a tie-over dressing. Common donor sites include pre-auricular cheek, post-auricular crease, conchal bowl, upper eyelid, upper inner arm, or clavicle. Full-thickness grafts can produce an excellent cosmetic result if executed properly (Fig. 37-30). However, the increased skin thickness results in an increased metabolic demand and a higher rate of necrosis and failure.

Imbibition occurs during the first 24–48 h after graft placement. The graft is sustained by passive diffusion of nutrients from the wound bed during this stage. It becomes edematous, and the fibrin network attaches the graft to the bed. Inosculation is the next stage, with revascularization from linkage of dermal vessels in graft to wound bed. Neovascularization occurs from capillary ingrowth to the graft from recipient base and sidewalls. Full circulation can be restored in 7 days and depends on the graft thickness and vascularity of the wound bed.

Fig. 37-27 Transposition flap. A, Mohs defect. B, Final wound closure. C, 3-month follow-up.

Fig. 37-28 Bilobed flap. A, Mohs defect. B, Final wound closure. C, 6-week follow-up.

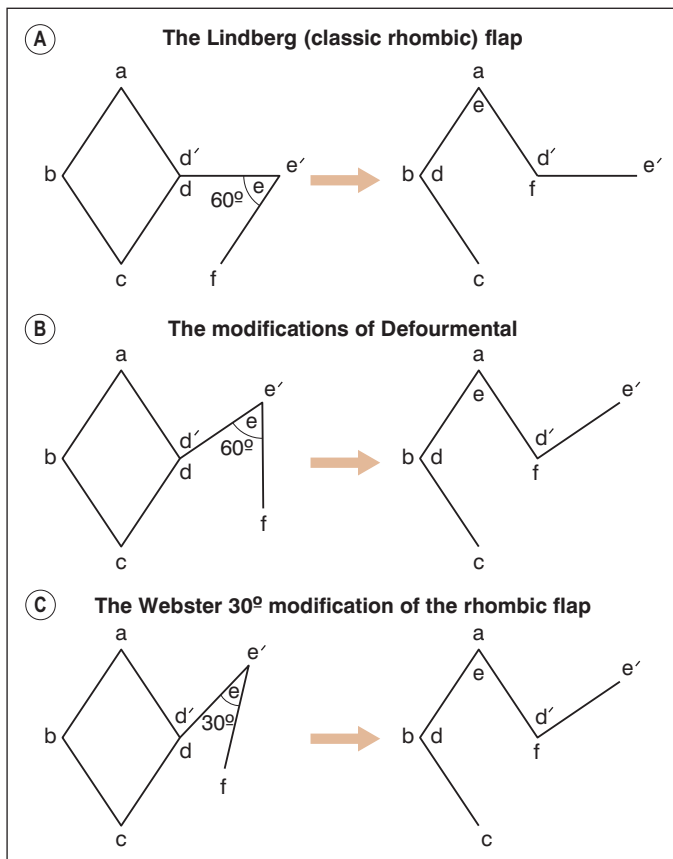

Fig. 37-29 Variations of transposition flap.

Split-thickness skin grafts have only a partial dermis and are useful for covering large areas or for improved surveillance in tumors with a high risk of recurrence. Small grafts can be harvested freehand with No. 15 blade or with a hand-held Weck blade using various guards to determine graft thickness (Fig. 37-31), while larger grafts can be obtained using a power dermatome (Fig. 37-32). Grafts can be meshed in order to provide coverage for larger defects. In comparison to full-thickness skin grafts, split-thickness grafts have a higher rate of survival and shorter healing time, do not require repair of the donor site, and are a good choice for poorly vascularized areas due to lower metabolic demand. However, they have a higher degree of contraction, lack skin appendages, and provide a poorer cosmetic match.

Composite grafts most commonly consist of skin and underlying structure (e.g. cartilage), and are predominately used to repair such wounds as full-thickness alar rim defects. These grafts have an increased nutrient requirement and thus are more likely to fail. Free cartilage grafts can be used for reconstruction of the ear and nasal ala or tip.

Mohs micrographic surgery

Frederic Mohs initially developed this technique at the University of Wisconsin in the 1930s as a means for margin control during surgical excision of skin cancer. The original technique used zinc chloride paste to fix tissue *in vivo*, followed by surgical excision. Drs Theodore Tromovitch and Samuel Stegman modified this technique in the 1970s to a fresh-frozen tissue variant that continues to be used today. While the basic surgical principles in Mohs micrographic surgery are similar to those used in standard excision, there are unique challenges encountered with Mohs surgery. A complete understanding of pathology, anatomy, cutaneous oncology, advanced surgical reconstruction, and management of surgical complications is critical to a successful patient outcome. Any dermatologist performing Mohs micrographic surgery should be well trained in this technique and all the accompanying challenges of surgical and postoperative care.

Mohs micrographic surgical excision is a tissue-sparing technique that employs frozen-section control of 100% of the surgical margin. This evaluation of the entire surgical margin using horizontal sections (not vertical, as used in standard sectioning), combined with precise mapping, allows for the highest cure rate of cutaneous neoplasms (Fig. 37-33). In addition, the sparing of normal adjacent tissue can improve cosmesis and decrease the risk of functional defects in a sensitive anatomic location. Any tumor that has a contiguous growth pattern would be a candidate for Mohs micrographic surgical excision. Immunohistochemical stains can be used in specific cases to help identify residual tumor.

There are multiple indications for Mohs micrographic surgical excision (Box 37-7, Fig. 37-34). Mohs surgery provides cure rates of 99% for primary BCCs, and 95% for recurrent BCCs. SCCs on the skin and lip treated with Mohs surgery have a 5-year recurrence rate of 3.1% (versus 10.9% for other modalities). SCC on the ear treated with Mohs surgery has a 5-year recurrence rate of 5.3% (versus 18.7% for other modalities). Locally recurrent SCC also had a reduced recurrence rate when treated with Mohs surgery, as compared to other modalities (10% versus 23.3%). Other tumors that can be successfully

Fig. 37-32 Harvesting of split-thickness skin graft with powered dermatome.

Box 37-7 Indications for Mohs surgery

- Recurrent or incompletely excised nonmelanoma skin cancer
- Tumors with aggressive histologic subtypes (i.e. infiltrative, morpheaform, micronodular, perivascular, or perineural involvement)
- Tumors with poorly defined clinical margins
- High-risk location >0.4 cm (H-zone of the face, eyes, ears, nose)
- Large tumors (>1.0 cm on face; >2.0 cm on trunk or extremities)
- Cosmetically and functionally important areas, including genital, anal, perianal, hand, foot, and nail units
- Tumors arising in immunosuppressed patients
- Tumors arising in previously irradiated skin or scar
- Genetic conditions with increased risk of neoplasms (i.e. basal cell nevus syndrome or xeroderma pigmentosa)

treated by Mohs surgery include dermatofibrosarcoma protuberans, atypical fibroxanthoma, and microcystic adnexal carcinoma. Mohs micrographic surgical excision of melanoma continues to be debated. Bricca et al demonstrated comparable 5-year local recurrence rates, metastasis rates, and disease-specific survival rates in head and neck melanomas treated with Mohs micrographic surgery, as compared to standard excision. In contrast, Walling et al showed that staged excision for melanoma resulted in lower recurrence rates and similar-sized defects compared to Mohs surgery.

Photodynamic therapy

Photodynamic therapy (PDT) involves the activation of a photosensitizer by visible light in the presence of oxygen, resulting in the creation of reactive oxygen species, which selectively destroy the target tissue.

The first requirement for PDT is delivery of either a systemic or a topical photosensitizing drug. Systemic photosensitizing molecules are large, lipophilic molecules that require intravenous administration to reach the target site. One of the major disadvantages of these systemic drugs is the prolonged period of phototoxicity. Examples include porfimer sodium and hematoporphyrin derivative. The benzoporphyrin derivative monoacid ring A (verteporfin) has a shorter period of photosensitivity (<72 h) compared to other systemic agents.

Topical agents offer the advantage of limiting photosensitivity to the application site and have become widely used in dermatology. Delta-aminolevulinic acid (ALA) is the most commonly used photosensitizing agent used in dermatology. It is applied and left on the skin for a sufficient period of time to allow for accumulation within the target cells. ALA is subsequently converted to the photosensitizer, protoporphyrin IX (PpIX), which can then be stimulated through the controlled use of a light source. Tumor cells are thought to be selectively targeted by increased penetration of ALA through the abnormal epidermis overlying the tumor cells. In addition, the iron-deficient, rapidly proliferating tumor cells have an increased production of PpIX as compared to normal epidermal cells, resulting in selective photosensitivity and damage to the target site. Methyl aminolevulinate (mALA) is also used as a topical photosensitizing agent. Gentle scraping or curettage prior to application is performed to increase penetration. Once absorbed, mALA is converted to ALA within the target tissue.

The second requirement of PDT is an appropriate light source to activate the photosensitizer. The light source must match the absorption peak of the photosensitizer. Lasers, intense pulsed light devices, or an incoherent light source can be used. Red light uses the 630 nm peak of PpIX as its target, and has a deeper penetration, which is appropriate for dermal processes. Blue light targets the 417 nm peak and has a more superficial penetration, making it an appropriate choice for the treatment of epidermal lesions like actinic keratoses.

Following absorption of light, the photosensitizer is converted from a stable ground state to an excited triplet state. The excited triplet state electrons interact with tissue oxygen, creating singlet oxygen. Singlet oxygen causes oxidative damage to cellular membranes (i.e. mitochondria and other cellular organelles) and direct cell death, the key mechanism of action in topical PDT. This entire process occurs over the course of microseconds. In comparison, PDT using systemic photosensitizers predominantly causes destruction of target sites via vascular injury that leads to tissue ischemia.

Actinic keratosis

Numerous studies have demonstrated the efficacy of PDT in the treatment of actinic keratoses, with overall clearance rates ranging from 50 to 70% for a single treatment, and up to 90% with additional treatment sessions. Facial lesions tend to respond better than acral or extremity lesions. Initial studies have demonstrated that topical ALA applied for 14-18 h, followed by activation with a variety of light sources (i.e. blue light, red light, pulsed dye laser, intense pulsed light, and so on), is an effective treatment for actinic keratoses on the scalp and face. More recent studies have shown that short incubation periods of 1-3 h with ALA are an effective protocol for the treatment of actinic keratoses, vastly improving the convenience of this therapy. Kurwa et al demonstrated similar reduction in actinic keratoses with a single ALA PDT and red light treatment, as compared to a 3-week course of twice a day topical 5-fluorouracil (5-FU) (70% versus 73% reduction).

mALA may offer several advantages over ALA, including improved skin penetration due to its increased lipophilic quality, greater selectivity for neoplastic cells, and possibly less pain and discomfort associated with treatment. However, there are no comparative studies for ALA and mALA PDT in the treatment of actinic keratosis. Pariser et al showed that mALA, applied for 3 h followed by noncoherent red light, resulted in an almost 90% response rate in the treatment of actinic keratosis. Szeimies et al demonstrated a similar response rate for mALA PDT compared to cryotherapy, but PDT gave better cosmetic results and had a higher degree of patient satisfaction.

Given the absence of stratum corneum on the lips and the increased penetration of topical ALA, PDT has been used effectively for the treatment of actinic cheilitis. This may be an option in patients with recalcitrant disease. Alexiades-Armenakas et al demonstrated about a 70% clearance with an excellent cosmetic result using ALA PDT activated by the long-pulsed dye laser in patients with refractory actinic cheilitis.

Basal cell carcinoma

Studies suggest that topical PDT for the treatment of BCC can have initial clearing and excellent cosmetic results, with cure rates ranging from 64 to 97%. However, despite the initial success, BCCs treated with PDT often have a higher recurrence rate with long-term follow-up. In addition, comparative studies of PDT and traditional surgical treatments (e.g. excision or Mohs surgery) are limited or lacking.

Superficial BCC tends to have better response rates than nodular BCC, likely due to the limited penetration of both ALA and the activating light into the deeper portion of the dermis for nodular tumors. Pre-treatment with curettage for thicker lesions may help to facilitate penetration of ALA and may result in improved cure rates. Infiltrative tumors have an even higher recurrence rate, suggesting that PDT should not be considered a first-line treatment for this histologic subset of BCC.

Subsets of patients with numerous and extensive BCC (e.g. basal cell nevus syndrome) may be unique cases where PDT can be considered for nodular or more extensive tumors, due to the tissue-sparing and chemopreventative advantages over traditional surgical treatments.

Squamous cell carcinoma in situ

SCC in situ is quite responsive to PDT. Multiple studies demonstrate an initial cure rate in a range of 54–100%, with quite a variable long-term efficacy. Red light should be used over blue light, as it penetrates more deeply and thus more effectively treats adnexal extensions. In a randomized study, Salim et al compared topical ALA PDT with 5-FU. At 1-year follow up, PDT achieved an 82% clinical response rate compared to 48% with 5-FU. Varma et al showed initial clearing in 88% of Bowen's disease lesions using ALA PDT with red light; however, at 12-month follow-up, complete response decreased to 69% (compared to initial response of 95% and 12-month response of 82% for superficial BCC).

There are few reports of the use of PDT for invasive cutaneous SCC. Given the limited success in treating these tumors and potential for metastatic spread, PDT is not recommended as standard therapy for invasive SCC.

Radiation therapy for skin cancer

Radiation therapy (XRT) has a long history of use for treatment of both benign and malignant skin conditions. The use of ionizing radiation in dermatologic therapy of benign conditions has decreased markedly, owing to highly effective medical therapies and the potential genetic and somatic hazards of radiation. However, XRT for malignant skin conditions remains an important primary and adjuvant therapeutic modality. When used in the proper clinical situation, XRT can provide effective treatment while sparing normal tissue and eliminating the need for surgical reconstruction.

XRT is an appropriate primary treatment for skin cancer in patients who refuse surgery or are poor surgical candidates. In contrast, patients who are relatively young should not be candidates for XRT due to the increased risk of developing additional primary tumors within the radiation field and the long-term cosmetic complications associated with this therapy. Tumors located on the eyelids, nose, ears, and lips do well with XRT, while lesions on the extremities are better treated by surgical excision. Treatment of primary BCC with XRT can produce cure rates of more than 90%, while primary SCC may have slightly lower cure rates. It is important to stress that Mohs micrographic surgical excision of primary tumors can achieve cure rates of 97–99%, often with excellent long-term cosmetic outcomes.

XRT may also be considered if margins show microscopic evidence of residual tumor following surgical excision. Recurrent BCC and SCC that had been treated previously by nonradiologic methods can be treated by radiation, although not with the same success as primary tumors. Caccialanza et al demonstrated an 84% 5-year cure rate for recurrent BCC and

SCC in a group of nearly 250 recurrent tumors, with almost all having an acceptable cosmetic result. Locke et al showed that primary tumors treated with radiation had a response rate of 93%, as compared to 80% for recurrent neoplasms. Mohs micrographic surgical excision of recurrent nonmelanoma skin cancer produces higher cure rates (95%).

Several studies indicate that recurrence of nonmelanoma skin cancer after primary XRT may be more aggressive and invasive than recurrence after primary surgical treatment. Smith et al demonstrated that BCCs that recurred following primary radiation therapy had deeper subcutaneous tissue invasion and larger percentage increase between clinical preoperative tumor area and final postoperative defect area, as compared to recurrent tumors that had initially been treated with other modalities.

XRT offers a valuable adjunctive treatment option for particularly aggressive perineural SCC and BCC. Detection of single-cell tumor spread may be particularly difficult following excisional surgery. In addition, perineural carcinoma may spread more rapidly along nerve sheaths than by contiguous growth. Given the increased risk of metastasis and recurrence in this group of tumors, adjuvant XRT should be considered as prophylactic treatment following surgical excision.

Almost no area of dermatology is changing as rapidly as that of cutaneous laser surgery. Development of new lasers, as well as improvements in existing lasers, continues to advance the field. As a result of this progress, laser surgery has become an effective therapeutic modality for a variety of dermatologic conditions.

Laser principles

“Laser” is an acronym for light amplification by stimulated emission of radiation. The first laser, a ruby laser, was operated in 1960 by Theodore Maiman. Medical applications were quickly recognized, and Leon Goldman pioneered their dermatologic use.

While technology has advanced through the years, several distinctive characteristics have remained in all lasers. As compared to other light sources, laser light is defined as monochromatic (only one wavelength), collimated (i.e. nondivergent), and coherent (i.e. in phase, with peaks and troughs of the light all aligned) (Fig. 38-1). Laser energy is measured in joules (J). Fluence is defined as the amount of energy delivered per unit

Fig. 38-1 Laser characteristics. In contrast to A, B demonstrates laser light that is both collimated and coherent.

Table 38-1 Dermatologic lasers

Laser	Wavelength (nm)	Color	Applications
Argon	488–514	Blue–green	Vascular lesions
Intense pulsed light (IPL)	515–1200	Green–red and infrared	Vascular lesions, pigmented lesions, epilation, photodamage
Potassium titanyl phosphate (KTP)	532	Green	Vascular lesions, pigmented lesions
Q-switched Nd:YAG (frequency-doubled)	532	Green	Vascular lesions, pigmented lesions, tattoo—red
Copper vapor	578/511	Yellow–green	Vascular lesions, pigmented lesions
Flashlamp pumped pulsed dye (PDL)	585–600	Yellow	Vascular lesions
Q-switched ruby	694	Red	Deep and superficial pigmented lesions; tattoo—black, blue, green
Long pulsed ruby	694	Red	Epilation
Q-switched alexandrite	755	Infrared	Tattoo—blue, black, green
Long pulsed alexandrite	755	Infrared	Epilation
Diode	810	Infrared	Epilation
Q-switched Nd:YAG	1064	Infrared	Deep and superficial dermal pigment; tattoo—black, blue
Long pulsed Nd:YAG	1064	Infrared	Epilation, vascular lesion
Er:YAG	2940	Infrared	Superficial skin resurfacing and destruction of superficial growths
Carbon dioxide	10600	Infrared	Skin resurfacing and destruction of warts, keloids, superficial cancers, and benign growth

Fig. 38-2 Laser penetration.

area (J/cm^2). Power is the rate at which energy is delivered and is measured in watts (1 watt is defined as 1 J/sec).

The wavelength is determined by the active medium of each particular laser. Active medium can consist of a gas (e.g. argon or CO_2), liquid (e.g. dye), or a solid (e.g. ruby or yttrium-aluminum-garnet crystal) (Table 38-1). The choice of wavelength is determined by the target tissue and depth of penetration required (Fig. 38-2).

Continuous wave lasers emit a constant beam of light with long, constant exposure. Quasi-continuous wave lasers shutter the continuous beam into short segments, producing interrupted emissions of constant laser emission. Pulsed lasers produce short, high-energy pulses of light. Q-switched (quality-switched) lasers are able to generate extremely high-energy pulses over very short (i.e. nanoseconds) pulse durations and are used primarily for treating pigmented lesions.

Light can interact with incident targets in one of several ways: reflected, scattered, transmitted, or absorbed (Fig. 38-3). Approximately 5% of the laser light is reflected from the epidermis and not absorbed. Transmitted light passes unaltered through the tissue. Light is scattered by the various skin structures, molecules, and cells, thus limiting its depth of penetration and effect on tissue. In these first three cases, the light has no effect on the target tissue. However, when absorbed, the light energy is transformed into heat. In most cases of laser therapy, it is the heat generated by absorption that produces the desired effect. One notable exception is photodynamic therapy (see Chapter 37).

The concept of selective photothermolysis was originally promoted by Parish and Anderson, and is the basis for all laser tissue interactions. Lasers in cutaneous surgery are selected by matching their particular wavelength with the absorption spectrum of a desired target. The target structures that absorb laser light are defined as chromophores, with the most common in the skin being water, hemoglobin, and melanin (Fig. 38-4). The goal is to deliver a wavelength that is specifically absorbed

Table 38-2 Pulse durations and targets of selective photothermolysis

Chromophore	Diameter	TRT	Typical laser pulse duration
Tattoo ink particle	0.1 μm	10 ns	10 ns
Melanosome	0.5 μm	250 ns	10–100 ns
PWS vessels	30–100 μm	1–10 ms	0.4–20 ms
Terminal hair follicle	300 μm	100 ms	3–100 ms
Leg vein	1 mm	1 s	0.1 s

PWS, port-wine stain; TRT, thermal relaxation time.

by the chromophore, inducing heat build-up and destruction of that target.

In an ideal situation, that wavelength would have little or no absorption by surrounding structures. By controlling exposure times and energy delivered (fluence), the amount of heat build-up can be confined to the desired target with minimal or no damage to surrounding structures from heat dissipation (a property defined as thermal relaxation). A target's thermal relaxation time is defined as the time required for the heated tissue to dissipate half the absorbed heat, and is related to the size and shape of the target structure. Selective photothermolysis is achieved by ensuring that the laser pulse duration is equal to or less than the thermal relaxation time of the target tissue. Thus, larger structures (e.g. hair follicles) have a longer thermal relaxation time and are best treated with longer pulse widths, as compared to smaller structures (e.g. melanosomes), which have a shorter thermal relaxation time and can be treated with much shorter pulse durations (Table 38-2).

The beam diameter of the laser, or spot size, is a factor in depth of penetration of the laser. Small spot sizes produce

Fig. 38-3 Laser interaction with skin.

significantly more scatter of the laser outside of the effective beam, thus resulting in smaller effective treatment areas. In contrast, larger spot sizes produce more photons that remain within the beam diameter, resulting in higher fluences at a given depth. Therefore with any given wavelength, a larger beam diameter results in a deeper level of penetration (Fig. 38-5).

Epidermal melanin and heat transfer from dermal structures can result in inadvertent epidermal heating and injury. By selectively cooling the overlying skin, while still maintaining sufficient dermal heat to damage the target, the laser surgeon can reduce the chances of epidermal injury. Precooling, parallel cooling, and postcooling have all been used to protect the skin. Dynamic cooling devices use a cryogen spray to cool the skin before and after laser exposure. Contact cooling with a chilled sapphire tip can be used throughout the treatment, and is especially useful for parallel cooling. Forced cooled air provides less effective cooling as compared to other methods, but can be useful in reducing pain associated with laser treatment. Direct application of ice can also be used for postcooling.

The laser is a technologically advanced instrument. However, as with any surgery, side effects can occur. Hypertrophic scar-

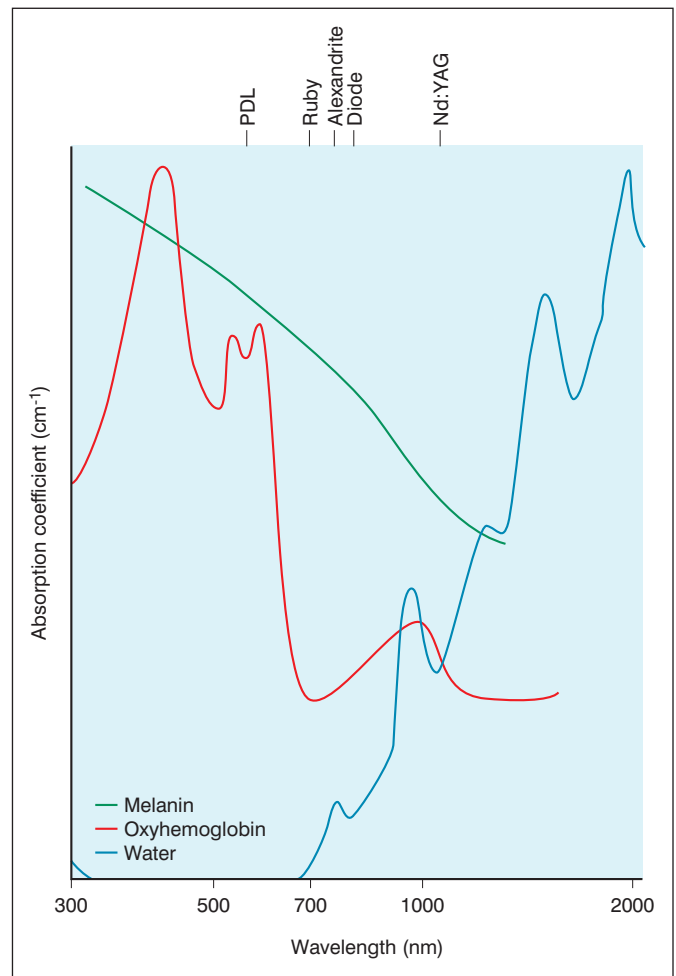

Fig. 38-4 Absorption spectra. The heterogeneous absorption spectra of chromophores allow selective photothermolysis to work. Modified with permission from Bologna JL, Jorizzo JL, Rapini RP, et al (eds): *Dermatology*, 2nd edn. London: Elsevier, 2008.

Fig. 38-5 The effects of spot size on scattering. The larger spot size allows more photons to remain within a beam's diameter, whereas with a smaller spot size a greater fraction of photons scatters outside the beam and is ineffective. Thus, a beam of a given wavelength penetrates to a deeper level with a larger spot size. Reproduced with permission from Bologna JL, Jorizzo JL, Rapini RP, et al (eds): *Dermatology*, 2nd edn. London: Elsevier, 2008.

ring and pigmentary changes are the most common, but infection, pain, and lack of efficacy are possible. Appropriate instruction and supervision in the use of lasers must be obtained by dermatologic surgeons in order to ensure optimum safety and surgical outcome.

Laser treatment of vascular lesions

A number of congenital and acquired vascular lesions can be effectively treated with laser. Given the variety of choices available, the laser surgeon must have a complete understanding of the inherent differences in wavelengths, pulse durations, and the vessel size of the particular lesion being targeted. Over the years, lasers have become more selective and treatment of vascular lesions is more effective.

Argon laser

The argon laser was one of the first lasers used for the treatment of vascular and pigmented lesions. Because its wavelengths (488 and 514 nm) do not precisely correspond to absorption peaks of either hemoglobin or melanin, and also because of its continuous wave nature, thermal damage to surrounding tissue may be significant (Fig. 38-6). Other lasers have been developed that have largely replaced the argon laser, due to their greater efficacy and improved side effect profile (i.e. less scarring and dyspigmentation). In addition, the newer technology has resulted in smaller and more reliable laser devices.

Copper vapor/copper bromide laser

These devices, with wavelengths of 578 and 511 nm, were effective in treating vascular and pigmented lesions. Due to technical concerns regarding size of the device, reliability, and cost of maintenance, they have been replaced by several of the lasers discussed below.

Pulsed dye laser

The pulsed dye laser (PDL) was the first laser developed specifically to take advantage of the theory of selective photothermolysis. The laser medium is a rhodamine dye, which initially was developed to deliver a wavelength of 577 nm,

coinciding with a specific hemoglobin absorption peak. Older lasers used a wavelength of 585 nm, but for various technical and clinical reasons, the wavelength has evolved in the current generation of PDL to be 595 nm. Initial pulse durations were of the order of 500 μ s/pulse. This was based on calculations that the target, hemoglobin, had a thermal relaxation time of 1 ms or less. These parameters resulted in immediate postoperative purpura lasting up to 2 weeks.

Newer configurations of the laser allow for pulse durations from 0.45 to 40 ms, based on newer understandings of thermal relaxation times in the context of the size of the target (e.g. capillaries vs. larger vessels) and clinical effects (purpuric vs. nonpurpuric treatments). By using longer pulse durations, more gentle and uniform heating results in reduced or absent post-treatment purpura (more acceptable to patients) than the earlier PDL configurations, while still maintaining clinical efficacy.

The PDL is an extremely useful instrument for the treatment of vascular lesions. These lasers have traditionally been used for port wine stains, telangiectasias, erythematotelangiectatic rosacea, and hemangiomas. The risk of scarring and pigment change is very slight, and infants as young as a few weeks old can be treated. The newer long pulsed and longer wavelength lasers allow for treatment of larger and deeper vessels. By associating these treatments with surface cooling devices, the epidermis can be protected, which allows for the delivery of greater energy in a safer and less painful manner.

PDL is the treatment of choice for port wine stains. A series of treatments every 4–6 weeks is required for maximum benefit, with gradual improvement after each session. While most patients will show improvement, total clearance of lesions is extremely rare (Fig. 38-7). Rate of improvement is related to anatomic location, with lesions on the extremity having less of a response than facial lesions. Size also plays a role in the response rate of port wine stains. Smaller lesions have greater rate of improvement as compared to larger lesions. Treatments are typically performed with short pulse durations, with resulting purpura lasting for 10–14 days. When the treatment is performed with proper cooling and appropriate technique, the risk of atrophic scarring and pigmentary alterations is extremely low. Redarkening of treated port wine stains following treatment with PDL has been shown over time, and may necessitate repeat treatments years later.

Ulcerated hemangiomas have been successfully treated by PDL. In addition, following spontaneous resolution of infantile hemangiomas, PDL can be used for any persistent telangiectasias. However, PDL has a limited depth of penetration and thus is not effective in the treatment of deeper components of hemangiomas that are likely to continue to proliferate despite laser therapy. The use of PDL for treatment of superficial hemangiomas in the proliferative phase remains controversial. Some studies have demonstrated that early treatment with PDL results in improved clearing. However, others have advocated that the natural course of hemangiomas is of regression, and that potential risk of ulceration and atrophy from PDL treatment is not warranted for uncomplicated lesions.

Erythematotelangiectatic rosacea is a common condition characterized by persistent facial erythema, telangiectasias, and flushing. PDL has been shown to be an effective and safe treatment option (Fig. 38-8). The long pulsed PDL has the advantage of purpura-free treatment, which is better tolerated by patients desiring cosmetic improvement.

PDL has been effectively used for the treatment of warts, producing similar cure rates as traditional therapy. Several reports address the use of PDL for hypertrophic scars. Manuskiatti and Fitzpatrick demonstrated that PDL, intralesional corticosteroid, and 5-fluorouracil (5-FU) produced similar beneficial effects in the treatment of hypertrophic sternotomy scars. The mechanism of action in both incidences

Fig. 38-7 Port wine stain. A, Prior to treatment. B, After eight treatments with the pulsed dye laser.

Fig. 38-8 Rosacea. A, Prior to treatment. B, After two treatments with subpurpuric pulsed dye laser.

is not clear. It may be related to injury to vessels supporting the lesions or simply to heat-related injury. As with other treatment modalities for these two conditions, results are variable.

KTP (potassium titanyl phosphate) laser

The KTP laser produces a visible green beam of 532 nm. Since there is significant hemoglobin and melanin absorption of this wavelength, KTP can be used to treat both vascular and superficial pigmented lesions (see below). The KTP laser is actually an Nd:YAG laser that emits a wavelength of 1064 nm. The beam is passed through a crystal of KTP that reduces the wavelength by 50%, producing the 532 nm wavelength.

Pulsed KTP lasers have pulse durations ranging from 1 to 100 ms. The advantage of these lasers is the strong absorption of their wavelength by hemoglobin. In addition, purpura is not present with the longer pulse widths. The 532 nm wavelength has a limited depth of penetration, making it an excellent choice for the treatment of fine facial vessels. However, it can be absorbed by epidermal pigment to a greater degree

than other longer wavelength vascular lasers, which increases the possibility of pigmentary complications. KTP lasers can be quite compact, allowing for easy transport between various locations. With few moving parts they are relatively maintenance-free.

These lasers are best suited to treatment of individual telangiectasias of the face, cherry angiomas, and small spider angiomas. Since individual vessels must be traced out using a narrow beam diameter, there are limitations to the number of vessels treated in any given session.

Long pulsed infrared lasers

Lasers are now being used to take advantage of the broad oxyhemoglobin absorption band in the near-infrared range. Long pulsed lasers include the alexandrite (755 nm), diode (800 nm, 940 nm), and neodymium:yttrium-aluminum-garnet (Nd:YAG; 1064 nm). These lasers are best used for larger and deeper vessels, such as large-vessel venous malformations, vascular blebs in port wine stains, blue reticular veins, and lower extremity spider veins (Fig. 38-9).

Fig. 38-9 Venous lake. A, Prior to treatment. B, After two treatments with the long pulsed Nd:YAG laser.

Intense pulsed light

The intense pulsed light (IPL), while technically not a laser, is a device that uses a flashlamp that emits a noncoherent broad spectrum of light (from 400 to 1200 nm) at various pulse durations and intervals. By employing filters to eliminate the lower wavelengths, light from 560 nm and above can be used to treat various cutaneous conditions. This technology has the advantage of treating more than one specific chromophore at a time and is especially useful in improving both vascular and pigmentary changes commonly seen in photodamaged skin (see below). In addition, it has a relatively large beam size and rapid pulse rate, allowing for the treatment of a large area in a relatively short amount of time.

IPL has been used for the treatment of facial telangiectasia and rosacea. There is generally no purpura when appropriate settings are used, but care must be taken to avoid dyspigmentation and blistering in darker skin types. As with other light sources, a series of treatment sessions spaced out every 4–6 weeks are typically required for maximum improvement.

Laser treatment for pigmented lesions

Highly pigment-selective Q-switched lasers are used extensively in the treatment of both epidermal and dermal pigmented lesions. In most cases, the target chromophore is the melanosome. These tiny structures have a very short thermal relaxation time (250–1000 nsec), and the development of Q-switching allows for production of extremely high energies and short nanosecond pulse durations. As a result, these lasers can produce damage to the selected target while minimizing injury to surrounding tissue.

Q-switched lasers are used to treat epidermal pigmented lesions and tattoos. The delivery of tremendous amounts of energy over a very short period of time produces pressure waves. This photoacoustic effect results in shock waves that shatter the larger ink particles into smaller fragments. Repeated treatments are necessary for complete response. Q-switched lasers include the ruby (694 nm), alexandrite (755 nm), and Nd:YAG, in both a frequency doubled (532 nm) and standard (1064 nm) mode (Table 38-3). Because of the longer wavelength, the Nd:YAG laser penetrates much more deeply and therefore is more useful in treating more deeply seated or thicker lesions compared to shorter wavelength Q-switched lasers.

Less pigment-selective lasers can be used in some clinical settings. The variable pulsed KTP laser can be used to treat epidermal pigmentation, such as lentigines, ephelides, thin seborrheic keratoses, and dermatosis papulosis nigra. As the KTP laser has a limited depth of penetration, it is not effective in the treatment of deeper dermal lesions. Long pulsed ruby, alexandrite, and Nd:YAG lasers can also be used to treat

pigmented lesions; however, they are not as effective as their Q-switched counterparts.

Non-pigment-specific ablative lasers have been used in the treatment of pigmented lesions and tattoos. Carbon dioxide (10600 nm) and erbium:YAG lasers (2940 nm) target water. They non-selectively remove the entire epidermis and a variable level of dermis tissue, and any associated pigment present.

Epidermal pigmented lesions

Lentigines are hyperpigmented macules composed of an increased number of basal melanocytes. These lesions can be

effectively treated with a variety of laser and light sources owing to their superficial position in the skin. Q-switched lasers can be used to treat solar lentigines and those associated with syndromes (e.g. Peutz-Jeghers) (Figs 38-10 and 38-11). Variable pulsed KTP provides effective treatment. IPL is an excellent choice for patients with widespread photodamage consisting of both vascular and pigmentary changes.

Café-au-lait macules and Becker's nevus can be treated with Q-switched lasers. Unfortunately, treatment often results in variable clinical efficacy. Short-term lightening or clearing with multiple treatments is frequently seen, but recurrence is common.

Dermal pigmented lesions

Nevus of Ota and nevus of Ito are dermal melanocytoses that can be effectively treated with Q-switched lasers. A series of treatments can significantly improve or even clear the lesion (Fig. 38-12). These treatments are generally well tolerated and the results are long-lasting.

Melasma is an acquired hypermelanosis that is often associated with sun exposure, pregnancy, and oral contraceptives. First-line treatment includes strict sun protection, discontinuing any offending systemic medication, and the use of topical agents such as hydroquinone and retinoids. Laser treatment is

Table 38-3 Q-switched lasers

Laser type	Wavelength	Pulse duration
QS Nd:YAG (frequency doubled)	532 nm	5–7 nsec
QS ruby	694 nm	25–40 nsec
QS alexandrite	755 nm	50–100 nsec
QS Nd:YAG	1064 nm	5–7 nsec

Fig. 38-12 Nevus of Ota. A, Prior to treatment. B, After treatment with a Q-switched ruby laser.

Fig. 38-13 Tattoo. A, Prior to treatment. B, After six treatments with Q-switched ruby and Q-switched Nd:YAG laser.

often ineffective, and recurrence is commonly seen in those cases with initial improvement.

Post-inflammatory hyperpigmentation does not generally respond to Q-switched laser. Recurrence or worsening is typically seen due to additional epidermal injury associated with laser treatment.

Tattoos

Pigmentation to mark the skin for decorative purposes has been used by humans for thousands of years and remains a popular practice today. As a result of the increasing number of people with tattoos, it should come as no surprise that many patients desire removal. Regardless of the type of tattoo (i.e. cosmetic, medical, and traumatic), effective treatment can be frequently offered.

In the past, tattoos were removed by a variety of non-selective destructive techniques, including excision, dermabrasion, cryosurgery, and ablative laser. While effective in

eliminating the ink, these techniques produced significant scarring. With the advent of newer technology that is more specific and less traumatic, these destructive modalities are not generally employed today.

Currently, Q-switched lasers are the first-line treatment for tattoo removal. The delivery of high energy in very short pulse durations causes fragmentation of the tattoo ink particle, which is then eliminated from the body via phagocytosis of macrophages and lymphatic drainage. Repeat treatments are required to achieve maximum benefit (Fig. 38-13).

Patients frequently inquire as to the number of treatment sessions needed for maximum improvement. Unfortunately, a precise answer is difficult to provide and depends on the amount of ink, size of tattoo, location, and color being treated. Amateur tattoos typically have less ink and generally have a better response to laser treatment. In contrast, multicolored professional tattoos have a more unpredictable response and require more treatments (sometimes 10–15 or more) to achieve maximum benefit. The choice of which laser to use is dependent on the specific tattoo color being targeted (Table 38-4).

Tattoo complications

Textural changes can occur as a result of the repetitive injury associated with laser treatment (Fig. 38-14). Epidermal injury can be seen with excessive fluences and with short treatment intervals. By spacing out treatment sessions, lowering fluences, and using longer wavelengths to protect the epidermis, this can often be avoided.

Hypopigmentation is sometimes seen in patients with darker skin types (Fig. 38-15). Much like textural changes, pigmentary changes are more common with shorter wavelengths (i.e. ruby and alexandrite), which can cause more epidermal damage. Similar precautions can be used to minimize these changes.

Paradoxical darkening of flesh, brown, or white tattoos (with red and yellow ink less frequently) can occur immedi-

ately following treatment with Q-switched lasers. The reduction of rust-colored ferric oxide to black-colored ferrous oxide or the white-colored titanium⁴⁺ dioxide to blue titanium³⁺ dioxide is felt to be responsible for the color change. This reaction is typically seen in cosmetic tattoos used for lip liners, eyebrows, etc. However, as many brightly colored tattoos have some white in them, caution must be taken in these circumstances (Fig. 38-16). Test treatment should be done if there is a potential for paradoxical darkening. The darkened tattoo can be treated with the appropriate QS wavelength, but response is unpredictable and requires numerous treatments.

Despite appropriate treatment, tattoos may not respond completely. This may be due to the color, ink density, anatomic location, age of tattoo, etc. Appropriate preoperative counseling is required before embarking on any treatment course.

Table 38-4 Tattoo colors and pigments and lasers used for treatment

Color/Etiology	Pigment	Laser
Traumatic	Lead, asphalt, carbon, gunpowder	QS ruby; QS alexandrite; QS Nd:YAG (1064 nm)
Amateur black	India ink, carbon	QS ruby; QS alexandrite; QS Nd:YAG (1064 nm)
Professional black	Carbon, iron oxide, logwood extract	QS ruby; QS alexandrite; QS Nd:YAG (1064 nm)
Blue	Cobalt aluminate (azure blue)	QS ruby; QS alexandrite; QS Nd:YAG (1064 nm)
Green	Chromium oxide (casalis green), hydrated chromium sesquioxide (guignet green), malachite green, lead chromate, ferro-ferric cyanide, curcumin green, phthalocyanine dyes (copper salts with yellow coal tar dyes)	QS ruby; QS alexandrite
Red	Mercury sulfide (cinnabar), cadmium selenide (cadmium red), sienna (red ochre; ferric hydrate and ferric sulfate), azo dyes	QS Nd:YAG (532 nm)
Yellow	Cadmium sulfide (cadmium yellow), ochre, curcumin yellow	QS Nd:YAG (532 nm)
Brown	Ochre	Tan/light brown: QS Nd:YAG (532 nm) Dark brown: QS ruby; QS alexandrite; QS Nd:YAG (1064 nm)
Violet	Manganese violet	QS Nd:YAG (532 nm)
White	Titanium dioxide, zinc oxide	QS Nd:YAG (532 nm)
Flesh	Iron oxides	QS Nd:YAG (532 nm)

Laser hair removal

Laser hair removal is widely used for the permanent reduction of hair and is one of the most popular laser procedures performed. Hair removal lasers target the melanin within the follicle and, given the size of the target chromophore, longer pulse durations are required to generate enough heat to damage the bulbar stem cells. Patients with dark hair and

Fig. 38-17 Epidermal burns secondary to laser hair removal performed by an unlicensed provider at a medi-spa.

lightly pigmented skin are the best candidates for treatment, while white, blond, and gray hairs generally respond poorly.

In order to maintain a target, patients must avoid waxing, electrolysis, or plucking of hairs prior to laser treatment. Shaving prior to laser treatment is acceptable (and is mandatory immediately prior to treatment to avoid epidermal injury); it will not interfere with efficacy. Only hairs in the anagen growth phase are permanently injured. Therefore, sufficient time must elapse between treatments for hair to regrow and provide an appropriate chromophore for subsequent laser treatment, generally 6–8 weeks.

Currently used devices for hair removal include the long pulsed ruby, alexandrite, diode, and Nd:YAG lasers, and the IPL. Multiple treatments are required for maximum benefit. In addition, these longer pulsed lasers can produce a significant reduction in both hair and papules/pustules in patients with pseudofolliculitis barbae and folliculitis decalvans.

Complications are rare with proper patient selection and treatment parameters. Excessive fluences or insufficient cooling can result in epidermal injury (Fig. 38-17). Caution must be employed in treating patients with increased skin pigmentation due to sun tanning, as pigmentary changes and cutaneous burns can occur. As melanin is the target for these lasers, care must be taken in treating more darkly pigmented patients to avoid epidermal damage. In this patient

population, the longer pulsed Nd:YAG laser has allowed safe treatment with fewer complications, owing to the deeper penetration and reduced melanin absorption of this wavelength. Paradoxical hypertrichosis as a result of laser hair treatment has been reported. The etiology is unclear, but the condition seems to occur more frequently in darker skin types.

Ablative laser resurfacing

Both CO₂ and erbium:YAG (Er:YAG) lasers are absorbed by water. Since water makes up 72% of the skin, they effectively ablate the skin to varying depths depending on the energy delivered. They can be used therapeutically to treat conditions such as warts, adnexal tumors, and skin cancers. In addition to these medical indications, ablative lasers can also be employed to remove very superficial external layers and resurface the skin for cosmetic enhancement (i.e. photorejuvenation, acne scarring, etc.). Despite all the efforts to produce non-ablative resurfacing technology, ablative lasers remain unparalleled in producing meaningful and dramatic rejuvenation.

Early systems employed a continuous wave mode of emission, which led to a greater degree of thermal damage and risk of scarring. Newer, high-energy, ultra-pulsed and computerized scanning systems have allowed a greater degree of control with laser ablation, resulting in more predictable outcomes.

Carbon dioxide lasers

The CO₂ laser emits an invisible infrared beam of 10600 nm and can be used in continuous-wave or super-pulsed mode. Water nonselectively absorbs laser energy, turning it instantly into steam, and producing ablative and thermal damage. Used in the super-pulsed mode, the laser beam can be delivered in short bursts, allowing thermal destruction of the epidermis and papillary dermis while limiting deeper thermal damage. Delivery in this mode is more uniform and markedly faster when the optomechanical scanner is employed. Super-pulsed CO₂ lasers are extremely effective for the treatment of actinic damage and photoaging. The thermal injury causes conformational changes within the collagen, leading to clinical tightening. As such, ablative laser resurfacing produces significant improvement in wrinkling, scarring, and skin tone.

Side effects include postinflammatory pigmentary changes, especially in patients with Fitzpatrick skin types III–VI.

Treatment with hydroquinone at the first sign of hyperpigmentation can effectively reduce the hyperpigmentation. Hypopigmentation is frequently seen following resurfacing and is often due to the contrast between treated and untreated skin. In order to minimize the aesthetic impact, the entire face should be treated or, if this is not possible, regional subunits to avoid a clear line of demarcation. Scarring and textural changes can rarely be seen. Prolonged erythema can last from 3 to 10 months. Infections (bacterial, viral, and fungal) have all been reported with resurfacing. Prophylactic antiviral agents are typically started on the day of the procedure, even in patients with no history of orolabial herpes simplex virus (HSV) infection. Antibiotic and antifungal treatment can be started if patients develop infection. Given the morbidity of the postoperative course and prolonged recovery associated with ablative resurfacing, patients must be properly counseled during the preoperative visit.

Used in the quasi continuous-wave mode, the CO₂ laser is an excellent therapeutic choice for very large plantar and periungual warts that have failed to respond to routine office modalities. Both a cutting mode and a defocused ablative mode can be used with these systems to excise the visible verrucae effectively and to treat any residual human papillomavirus in surrounding skin.

The CO₂ laser is also a treatment option for earlobe keloids. Other benign lesions amenable to CO₂ laser ablation include xanthelasma, rhinophyma, and syringomas. Various malignant and premalignant lesions are also effectively treated by laser ablation, including actinic cheilitis and superficial basal and squamous cell carcinomas.

Erbium:yttrium-aluminum-garnet laser

The Er:YAG laser emits an invisible near-infrared beam of 2940 nm, resulting in significantly more efficient absorption by water (16 times) and a more explosive ablative effect, as compared to the CO₂ laser. As such, the Er:YAG laser results in tissue ablation with less surrounding thermal damage. In addition, this wavelength is close to a collagen absorption peak, thus allowing for greater collagen ablation than the CO₂ laser. The decreased thermal injury and collagen ablation is an advantage for treatment of scars, photodamaged skin, rhytids, and rhinophyma (Figs 38-18 and 38-19). Some maintain that healing may be slightly faster, with less risk of prolonged erythema and scarring. None the less, the depth of injury produced (regardless of technology used) is the primary determinant for the healing process and incidence of side effects, not the laser used.

As compared to the photocoagulation effects of the CO₂ laser, the decreased thermal damage produced by the Er:YAG can result in poor hemostasis. To address this limitation, certain Er:YAG systems have a coagulation feature to limit the amount of intraoperative bleeding. In addition, the collagen-tightening effect may not be as pronounced as with the CO₂ laser. However, when similar clinical injuries and depth are achieved, studies have shown that the Er:YAG and CO₂ lasers have comparable photorejuvenating effects, and similar postoperative healing times and complication profiles.

Fractional resurfacing

Fractional photothermolysis is a technique whereby an ablative laser is administered in a pixilated pattern over a grid. These lasers created small columns of thermal injury, or microthermal zones (MTZ), which are separated by areas of untreated skin. As only 15–25% of the skin surface is typically ablated during a treatment session, this technology allows for more rapid re-epithelialization, as compared to the confluent

Fig. 38-18 Er:YAG ablative resurfacing. A, Prior to treatment. B, Six months following full-face resurfacing. (Courtesy of Roy Grekin, MD)

Fig. 38-19 Rhinophyma. A, Prior to treatment. B, Immediately following treatment with an Er:YAG laser. C, Final result 3 months later, with marked improvement in shape and appearance.

patch of laser-induced injury typically created with traditional ablative resurfacing. The injury created by MTZ results in the stimulation of collagen synthesis and cutaneous remodeling, much in the same manner as traditional resurfacing but to a proportionately lesser degree.

Fractional resurfacing has been used for the treatment of photoaging, with the advantage of more rapid healing, reduced erythema and swelling, and fewer side effects. An additional advantage is the ability to treat any anatomic location, including hands, chest, neck, and arms. However, patients often need multiple treatment sessions in order to achieve maximum benefit and the final result is not nearly as impressive as with traditional ablative resurfacing. In addition, the cumulative down time required with multiple treatments may exceed that of a single ablative resurfacing treatment, thus negating the perceived benefit of fractional resurfacing.

Dermatologists have been leaders in the field of cosmetic surgery. Many procedures, products, and technologies in cosmetic dermatologic surgery have been developed and researched by dermatologists. Patients are increasingly turning to dermatologists for the management of cosmetic issues. As a result, the specialty must continue to be at the forefront of cosmetic procedures and remain committed to advancing the field through innovation and scientific progress.

Soft-tissue augmentation

Soft-tissue augmentation has been gaining in popularity in recent years as patients seek cosmetic improvement without undergoing invasive procedures. There are numerous fillers available to correct soft-tissue contour abnormalities and provide cosmetic enhancement. While they provide numerous advantages over surgical techniques, the temporary nature of most fillers requires repeated treatment to maintain a desired outcome. While some patients find the temporary nature of these agents to be less than ideal, one must also consider that undesired outcomes of treatment are also temporary. In the last few years, there has been an increase in the number of available agents. In Europe there are as many as 30 different filler choices. In contrast, in the US the Food and Drug Administration (FDA) has approved fewer, although recently several new products have become available.

Bovine collagen

Bovine-derived collagen has been used for over 20 years and is the gold standard against which all filler substances are compared. There are currently three FDA-approved products for use in soft-tissue augmentation: Zyderm I[®], Zyderm II[®], and Zyplast[®] (Allergan, Irvine, CA). The source for all three types is a closed herd in the US, and there have been no cases of bovine spongiform encephalopathy associated with these products. All are composed of 95% type I collagen and the remainder type III collagen, suspended in buffered saline and 0.3% lidocaine.

Zyderm I[®] consists of 35 mg/mL of collagen, while Zyderm II[®] has a higher concentration of 65 mg/mL of collagen. Zyplast[®] is cross-linked with glutaraldehyde, making it more resistant to proteolytic degradation, which provides longer duration. All three products come preloaded into syringes and are stored at 4°C.

Bovine collagen hypersensitivity occurs in about 3% of the population, making skin testing a requirement prior to using these products. Additionally, 1–2% of patients with a negative skin test will subsequently develop an allergic reaction following treatment. Therefore, many dermatologists recommend a second skin test after an initial negative test. Patients may

also develop allergy after multiple treatments. Therefore, in patients with a span between treatments of more than 2 years, repeated skin testing is indicated.

Zyderm I[®] and Zyderm II[®] are injected into the superficial dermis, while Zyplast[®] is placed deeper. A combination of threading, fanning, and serial puncture injection techniques with a 30-gauge needle can be used. Anesthesia may not be required, as the product already contains lidocaine, although regional nerve blocks may be helpful in sensitive patients or when injecting the lips. Slight overcorrection is recommended with bovine collagen, as it tends to reduce in volume due to the amount of water in the product.

Patients can expect 2–5 months of improvement, depending on the location of placement. Dynamic rhytids (e.g. due to muscular activity) have a shorter duration of correction, as opposed to more static conditions (e.g. acne scars). Zyplast[®] may have a longer duration due to its relative protection from enzymatic degradation. However, it must be placed deeper in the dermis to avoid a beaded surface appearance and is therefore less useful for correction of superficial rhytids.

Complications with bovine collagen include delayed hypersensitivity reactions. Although this is extremely rare, allergic reactions can occur in 1% of patients who have had two negative skin tests. This presents as swollen granulomas or sterile abscesses at the treatment site. While self-limiting, these reactions can take up to a year to resolve. Intralesional steroid injections, antibiotics, and systemic anti-inflammatory drugs can be considered for treatment. Zyplast[®] placed in the glabellar complex has resulted in vascular occlusion and necrosis. This may be due to the deeper placement required with this product and the associated adverse pressure-related effects on cutaneous vasculature.

Human collagen

One of the main shortcomings of bovine collagen is the risk of hypersensitivity reaction. Synthetic human collagen has been developed as an alternative that does not require multiple skin testing and can be administered immediately. There has been no documented cross-reaction between bovine and bioengineered human collagen, allowing patients with a documented allergy to bovine collagen to be treated safely with human collagen.

Cosmoderm 1[®] and 2[®], and Cosmoplast[®] (Allergan, Irvine, CA) are FDA-approved bioengineered human collagen derived from neonatal foreskin. Synthetic human collagen has a very similar formulation to its bovine counterpart and is packaged in similar concentrations. Cosmoderm 1[®] has a concentration of 35 mg/mL and is in phosphate-buffered saline with 0.3% lidocaine. Cosmoderm 2[®] has a concentration of 65 mg/mL and Cosmoplast[®] has 35 mg/mL of human-derived collagen and is cross-linked with glutaraldehyde.

All products have the same indications, are injected in a similar manner to their bovine counterparts, and have similar cosmetic results and longevity.

Porcine collagen

Porcine collagen (Evolence[®], Ortho-McNeil-Janssen Pharmaceuticals, Titusville, NJ) is now FDA-approved in the US. It consists of porcine collagen composed of 35 mg/mL type I collagen that was derived from porcine tendons with ribose used as a cross-linker. Since porcine-derived collagen is similar to human collagen, there is no significant risk of allergy, and skin testing is not required prior to treatment. The product is stored at room temperature and injected into the mid-dermis with a 30-gauge needle. Initial studies suggest that it has a longer duration than either bovine or human collagen. At the time of publication, the manufacturer announced that it was discontinuing the production and marketing of the product.

Hyaluronic acid

Hyaluronic acid, a polysaccharide, is a natural component of human connective tissue. A member of the family of glycosaminoglycans, hyaluronic acid is composed of repeating disaccharide units. This molecule has the advantage of being identical across all species. As such, hypersensitivity reactions should not occur and skin testing is not required prior to treatment. However, Friedman et al demonstrated a local hypersensitivity reaction in 1 in every 1400 patients treated, although the incidence has declined with the introduction of a more purified product.

Hyaluronic acid avidly binds water and patients may experience redness, swelling, and bruising in the first few days after treatment. Most of the volume is maintained following placement, making overcorrection unnecessary when injecting. Hyaluronic acid products consist of a clear gel and most contain no lidocaine, often necessitating the use of local anesthesia and regional blocks for patient comfort. Recent preparations of hyaluronic acid now include lidocaine, thus eliminating the need for adjuvant anesthesia and making them significantly more comfortable for patients. Hyaluronic acid fillers can produce a more durable aesthetic improvement as compared to collagen, often lasting from 5 to 8 months (Fig. 39-1).

There are two types of hyaluronic acid filler substance. Streptococcal-derived is the most common, and includes Restylane[®] and Perlane[®] (Medicis, Scottsdale, AZ), Juvederm[®]

(Allergan, Irvine, CA), and Prevelle[®] (Mentor, Santa Barbara, CA). An alternative source is the rooster comb, which includes Hylaform[®] gel (Inamed, Santa Barbara, CA), although its use is fading in comparison to other products with greater longevity. These fillers come in prepackaged syringes and do not require refrigeration.

The characteristics and viscosity of the different products are largely determined by the size and concentration of the molecule within each preparation. Restylane[®] contains 20 mg/mL of hyaluronic acid with a particle size of 100 000/mL and is injected with a 30-gauge needle. Perlane[®] also has a concentration of 20 mg/mL, but a much larger particle size of 8000/mL, and requires a larger 27-gauge needle. Juvederm[®] is available in two formulations, Ultra and Ultra Plus. Both have a concentration of 24 mg/mL, with Ultra Plus have more cross-linkage, making it more appropriate for deeper folds. The denser products are effective for the treatment of deeper contour abnormalities.

Hyaluronic acids tend to produce more swelling and bruising than collagen. Proper preoperative consultation is necessary to ensure that the patient understands this and does not have upcoming social engagements. Improper placement of hyaluronic acid too superficially can result in a blue discoloration or nodule on the skin surface. An incision with a large-gauge needle or number 11 blade and expression of the product can be performed. Hyaluronidase injections can dissolve the product if either a reaction or unevenness results, a considerable advantage over other filler substances.

Poly-L-lactic acid

Microparticles of poly-L-lactic acid (Sculptra[®], Sanofi Aventis/Dermik, Bridgewater, NJ) are used as an injectable implant to replace diffuse volume loss, rather than the small-volume injections of other fillers. This product is currently FDA-approved for correcting facial lipoatrophy in patients with human immunodeficiency virus (HIV) and more recently for aesthetic treatment of lines and contour deficiencies.

Poly-L-lactic acid is a biodegradable, biocompatible, and immunologically inert product that does not require skin testing. Polylactic acid has been used as absorbable suture material (e.g. Vicryl[®]). Polylactic acid is absorbed gradually in the skin, inducing a fibroblastic response and de novo collagen synthesis. Multiple treatment sessions at 4–6-week intervals are often required to achieve the final result (Fig. 39-2). Since correction is dependent upon the formation of new collagen, patients must be counseled that an immediate effect does not occur with this product. Results can last for up to 2 years.

Fig. 39-1 Hyaluronic acid filler, nasolabial fold. A, Prior to treatment. B, Immediately following placement of hyaluronic acid with marked improvement and reduction of rhytids.

Fig. 39-2 Poly-L-lactic acid for HIV lipoatrophy. A, Prior to treatment. B, Following five treatments.

Poly-L-lactic acid comes packaged as a freeze-dried powder and must be reconstituted for a minimum of 4 hours prior to injection to ensure adequate hydration of the particles. Lidocaine can be added to the vial to reduce injection pain. The product is injected using a 25-gauge needle at the level of the deep dermis and subcutaneous junction in a fanning or cross-hatch fashion. Post-injection massage for several days can help reduce nodules.

Side effects include delayed foreign body granulomas at injection sites. Intralesional 5-fluorouracil (5-FU) or triamcinolone, 10 mg/mL, may be used for the treatment of these papules.

Calcium hydroxylapatite

Calcium hydroxylapatite (Radiesse[®], BioForm, San Mateo, CA) consists of fine particles (25–45 μm) of material traditionally used to reconstruct bone. Once injected into the dermal-subcutaneous junction, the particles act as a scaffolding for autologous collagen synthesis. The ensuing fibrotic reaction results in soft-tissue correction that can last for 9–12 months. It is FDA-approved for correction of moderate to severe folds and wrinkles such as nasolabial folds, and for HIV facial lipoatrophy.

Injections can be quite painful and local anesthesia is generally used. Calcium hydroxylapatite is injected into the deep dermis and subcutaneous junction with a threading technique using a 27-gauge needle. It comes prepackaged in syringes and can be stored at room temperature.

Nodules are more commonly seen when calcium hydroxylapatite is injected into the lips, thereby discouraging its use in the treatment of hypolabium. Experience with this product is limited and long-term risks are not well known. Caution must be exercised, as any product that requires a fibrotic reaction in order to be effective can result in a granulomatous reaction and an untoward result. As calcium is radiopaque, the product may be detected and interfere with radiological imaging.

Autologous fat transplantation

Autologous lipotransfer allows for soft-tissue augmentation without the risk of allergy, rejection, or infectious transmission. Unlike other filler techniques, fat transfer is truly a grafting procedure. As such, its success is predicated on the survival of the transferred adipocytes. Fat is harvested from a choice of

donor sites, typically the abdomen, buttock, thigh, or knee. There is no consensus as to the advantages of harvesting with a liposuction cannula, syringe extraction with a large-bore needle, or open surgical method. The fat is then separated from anesthetic fluid and blood, and injected through a large-bore needle (16- to 18-gauge) into the desired location. Any remaining fat can be frozen at -70°C for use at a later time, with varying claims regarding loss of efficacy.

The variable rate of graft survival, the recipient site reaction (i.e. bruising, swelling), and the added morbidity of a donor site are limiting factors in patient satisfaction with this technique. In some instances, partial survival results in uneven correction that may require additional treatments. Some argue that multiple smaller-volume injections spaced out over 2–3 treatments are more effective than single large-volume lipotransfer. If the fat survives, it can provide a very natural correction. However, local factors such as motor activity and gravitational effects will mitigate against permanent correction. This technique is not useful for the correction of superficial rhytids, and mainly corrects deeper defects such as nasolabial folds, hypolabium, buccal depression, and deep scars.

Silicone

Silicone has been used in the past for soft-tissue augmentation by dermatologists. This product was never FDA-approved and issues of purity and safety limited its widespread use. In 1994 it was removed from the market by the FDA. Recently, 1000 centistoke liquid silicone (Silikon 1000[®], Alcon Labs, Fort Worth, TX) has been approved by the FDA for the treatment of retinal detachment. It is currently being used off-label as a permanent filler for HIV-associated facial lipoatrophy, scars, and rhytids.

The potential for delayed and severe complications with this permanent filler, as well as legal concerns and restrictions, has limited its use. Adverse reactions associated with silicone injections include granuloma formation and migration of the product, which are compounded by the permanent nature of the product. Many of the past reported complications of silicone injection were the result of using either an impure and nonmedical-grade substance or an improper technique with large-volume injections. A multisession, microdroplet technique, placing multiple depot injection of 0.01 mL of product into the deep dermis in 1–3 mm intervals, significantly reduces the complication rate. An additional consideration is that the

current FDA-approved product is more concentrated than the previous silicone products. Further study is needed to evaluate the long-term safety and efficacy of silicone oil injections for correction of soft-tissue contour deficiencies.

Polymethylmethacrylate

Artefill® (Suneva Medical, San Diego, CA) is an FDA-approved suspension containing 20% polymethylmethacrylate (PMMA) microspheres of 30–40 microns in diameter suspended in 80% bovine collagen for soft-tissue augmentation. The carrier collagen provides initial correction and is degraded over several months, leaving the PMMA microspheres. PMMA serves as a permanent framework for connective tissue deposition and can produce long-term correction.

Technique is critical to successful outcomes. If injected too deeply, the implant is ineffective, while superficial placement can cause prolonged erythema. Granuloma formation and hypertrophic scarring can occur and have been reported as a delayed reaction. Intralesional triamcinolone can be used for treatment of these reactions. One patient who developed a delayed foreign body granuloma 6 years after injection with PMMA was successfully treated with a 24-week course of 600 mg/day of allopurinol. Since the product contains bovine collagen, skin testing is required prior to use.

Expanded polytetrafluoroethylene

Expanded polytetrafluoroethylene (ePTFE) is a synthetic solid material that is soft and pliable, is not degraded, and has the advantage of being permanent. The material is placed through a small skin incision and positioned in the desired location. Areas commonly treated with this include lip margins or the muscular portion of the vermilion for enhancement, nasolabial folds, and soft-tissue depressions. Some complications associated with ePTFE include extrusion, migration, shrinkage, and hardening.

Botulinum toxin

The use of botulinum toxin (BTX) in dermatology has increased rapidly over the years, and at present is the most common cosmetic procedure performed in the US. In 2002, the FDA approved BTX for the treatment of dynamic glabellar frown lines. Although BTX is most commonly approved for relaxation of dynamic rhytids in the upper third of the face, advanced treatment techniques for additional anatomic sites have been developed and are currently used off label.

Produced by *Clostridium botulinum*, there are seven different serotypes of BTX: A, B, C1, D, E, F, and G. These serotypes inhibit the release of acetylcholine from the presynaptic motor neuron, resulting in chemodenervation and paralysis of the treated muscle. Over time, new nerve terminals form and create new neuromuscular junctions with the muscle fibers, which gradually restore motor function.

BTX type A (Botox Cosmetic® (onabotulinumtoxinA), Allergan, Irvine, CA; Dysport® (abobotulinumtoxinA), Medicis, Scottsdale, AZ) is the most commonly used serotype. Its mechanism of action is via the cleavage of SNAP-25, a presynaptic membrane protein required for fusion of neurotransmitter-containing vesicles. Effect is generally noted 2–5 days after treatment with BTX-A, but the delay can be as long as 2 weeks in some cases. Results can last from 3 to 6 months. For dosing purposes, 1 U of Botox® is equivalent to about 3–5 U of Dysport®. There has been a paucity of studies that directly compare Botox® and Dysport®.

The only other serotype that is currently available commercially is BTX type B (Myobloc® (rimabotulinumtoxinB), Solstice Neurosciences, Malvern, PA). Its mechanism of action is via the cleavage of a vesicle-associated membrane protein (VAMP), also known as synaptobrevin. This serotype has more rapid onset of effect than BTX-A. In addition, differences in potency suggest that approximately 100 U of Myobloc® are equivalent to 1 U of Botox®.

Given the efficacy, experience and safety profile of Botox[®], it has emerged as the leading choice of botulinum toxin amongst practitioners and all further discussion of BTX-A will refer to Botox[®]. BTX-A is distributed in vials as a vacuum-dried powder, which is reconstituted with 1.0–5.0 mL of saline. Many physicians feel that the dilution of BTX does not make a significant difference in patient outcome and studies appear to confirm this notion. Others argue that higher concentrations with smaller injection volumes reduce the amount of unintended diffusion. It is more important to use the same dilution every time to ensure that the physician does not have to do “mental math” and to reduce confusion with each new vial of BTX.

Despite package insert recommendations, experience suggests that there is little loss of potency over several weeks following reconstitution with preserved saline. The use of preserved saline for reconstitution reduces the burning and pain associated with injection due to the anesthetic properties of the benzyl alcohol in preserved saline.

BTX-A is predominantly used in dermatology for treatment of dynamic rhytids on the upper third of the face. The key to successful treatment is understanding the anatomy involved in facial expression, rather than performing the procedure by

rote. Having the patient frown, squint, and raise their brows prior to treatment helps identify the active target muscles and serves as a guide for proper placement.

Glabellar frown lines

Currently, treatment of glabellar frown lines is the only FDA-approved cosmetic indication for BTX-A. These lines result from contraction of the corrugator supercilii, which pulls the brows medially, and the procerus, which pulls the brow inferiorly. In addition, by inactivating the brow depressors, unopposed action of the brow elevators (e.g. frontalis) can result in a slight but noticeable brow lift.

Approximately 20–35 U of BTX-A are typically injected into the corrugators and procerus in a five-point injection method (Figs 39-3 and 39-4). Male patients and those with larger muscle mass may require a higher number of units (i.e. 40–60). By having the patient furrow the brow, one can identify the origin and insertion of the corrugator supercilii. By grasping with the thumb and index finger, the physician can isolate the muscle and ensure accurate toxin placement.

If toxin diffuses through the orbital septum into the orbit, weakening of the levator palpebrae can result in upper lid

Fig. 39-3 Botulinum toxin injection technique for glabellar complex. A, Patient frowns and muscle is grasped between thumb and index finger; the injection is placed directly into the belly of the corrugator supercilii. B, Injection into the procerus muscle.

ptosis. Care should be taken to inject 1 cm above the superior bony orbital rim to reduce risk of diffusion of toxin and the resulting complication. The use of α -adrenergic agonist eye drops, such as apraclonidine 0.5% or phenylephrine 2.5%, can stimulate Müller's muscles in the lid, providing some relief until the effects of the BTX dissipate.

Horizontal forehead lines

Horizontal forehead lines are caused by contraction of the frontalis muscle, which produces elevation and movement of the eyebrows. Care must be taken when treating this area with BTX-A to avoid ptosis or "heaviness" of the brow. Extra caution should be used in men with low-set brows or older patients who use their frontalis to raise their eyebrows to assist with vision.

Since the lower portion of the frontalis is primarily responsible for brow elevation, injections are often limited to the upper half or two-thirds of the muscle. Between 10 and 25 U, delivered in multiple superficial injections across the forehead, are typically used for this area.

If upper lateral fibers of the frontalis remain totally untreated, the increased resting muscle tone will raise the lateral edge of the eyebrow, creating a quizzical look (Fig. 39-5). Injecting a small amount of BTX-A in the upper lateral brow can help correct this.

Crow's feet

Crow's feet are rhytids that extend radially from the lateral canthus and are produced by contraction of the lateral orbicularis oculi. Even with successful treatment with BTX-A, rhytids may still persist due to upward motion of the cheek when the patient smiles. Proper preoperative counseling is required to prevent frustrated patients.

Superficial blebs are raised approximately 1 cm lateral to the lateral canthus (Fig. 39-6). Between 8 and 12 U of BTX-A are placed around each orbit. Care should be taken to orient the needle away from the globe as a safety precaution, in case the patient moves unexpectedly.

Bruising is common in this location due to the thin nature of the skin and the presence of numerous periorcular superficial veins. Purpura can be minimized by injecting superficially, ensuring proper illumination and stretching of the skin to help identify the veins, and limiting the total number of injections. Diffusion into the zygomaticus major and minor, leading to ipsilateral lip ptosis and asymmetric smile, can occur with

overzealous treatment of the inferior portion of the orbicularis oculi.

Other locations

Other sites that can be treated with BTX-A include platysmal bands, diagonal creases along the nasal sidewall (i.e. "sniff lines" or "bunny lines"), mental crease, and depressor anguli oris (for frowning of the lateral corners of the mouth). Care must be taken when treating the lower third of the face to avoid complications with mouth and lip control. Excessive or misplaced BTX-A in the platysmal bands can cause dysphagia, dysphonia, and neck weakness.

Hyperhidrosis

In addition to cosmetic uses, BTX-A is FDA-approved for the treatment of axillary hyperhidrosis. Prior to treatment, a Minor's starch-iodine test is used to document both the severity and location of excessive sweating (Fig. 39-7). Effective treatment can be achieved with doses of 50 U/axilla. Intradermal injections are spaced in a grid 1 cm apart over the entire area. Anhidrosis is achieved within 1 week and typically lasts for 6-12 months. Side effects are generally limited to injection site bruising.

Fig. 39-6 Botulinum toxin injection technique for crow's feet, superficial injection approximately 1 cm from the orbital rim.

Fig. 39-5 Botulinum toxin complication. "Quizzical" brow look.

Fig. 39-7 Starch-iodine test, developing positive test with darkening in areas of hyperhidrosis.

Fig. 39-8 Starch-iodine test, partial response to botulinum toxin.

Treatment of palmar hyperhidrosis with BTX-A is more complicated than treating the axilla. Higher doses, typically 100–150 U/palm, are required due to the greater surface area involved and the limited diffusion of the toxin in acral skin. Pain is more significant when treating the palm and typically requires the use of wrist nerve blocks. Lastly, a slight muscle weakness of the hands, manifested by the loss of fine motor movement, is typically seen for several weeks following treatment.

Frequently, there are focal areas of activity following treatment for hyperhidrosis. However, as the sweat diffuses over the entire surface, patients often describe a false sensation of severe sweating and complain that the treatment “didn’t work.” By repeating the starch-iodine test, the focal areas of activity can be identified and directed touch-up can be performed (Fig. 39-8).

Varicose and telangiectatic veins

Sclerotherapy

Patients frequently seek treatment of telangiectasias and reticular veins in the lower extremities. The treatment of choice for telangiectatic and reticular veins is sclerotherapy (Fig. 39-9). Despite recent technologic advances, laser treatment for lower extremity telangiectasias should be reserved for those vessels which cannot be cannulated with a needle. In addition, laser therapy can be considered in patients who have failed to respond to sclerotherapy or had significant complications from sclerotherapy.

Sclerotherapy solutions

There are three broad classes of sclerosing agent available to dermatologists: hyperosmotic agents, detergents, and chemical irritants (Table 39-1). Hyperosmotic agents cause endothelial cell damage via dehydration, and detergents disrupt the cellular membrane, while chemical irritants act as a corrosive and lead to endothelial injury.

Hypertonic saline is an FDA-approved agent that is commonly used in sclerotherapy. Used at concentrations of 10–30%, this agent has the advantage of a complete lack of allergenicity when used alone. The disadvantage of hypertonic saline is pain associated with injections and ulcerogenic potential. Often, anesthetic agents such as lidocaine are added to the mixture to minimize the discomfort involved, both by decreasing the concentration of the saline and by the direct anesthetic effect.

Hypertonic saline (10%) mixed with dextrose (25%) is another hyperosmolar agent that has been used in vein sclerosing. This agent has the advantages of low allergenicity and decreased pain compared to higher concentrations of plain hypertonic saline. However, this mixture is currently not FDA-approved and is a relatively weak sclerosant as compared to other options available.

Sodium tetradecyl sulfate (STS) is a detergent sclerosant that has been FDA-approved for over 50 years. Typical concentrations used for superficial telangiectasias are 0.1–0.2% and for

Table 39-1 Sclerotherapy agents

Agent	Class	FDA-approved	Comments
Hypertonic saline	Hyperosmotic	Yes	No allergenicity, painful
Hypertonic saline (10%) + dextrose (25%)	Hyperosmotic	No	Lower allergenicity, painful
Sodium tetradecyl sulfate	Detergent	Yes	Can be used as foam, painless except with extravascular injection
Polidocanol	Detergent	Yes	Painless, can be used as foam
Sodium morrhuate	Detergent	Yes	High risk of allergic reaction
Chromated glycerin	Chemical irritant	No	Weak agent
Polyiodinated iodine	Chemical irritant	No	Highly caustic

**Fig. 39-10** Sclerosing foam, sodium tetradecyl sulfate foam made by mixing air with liquid using a three-way stopcock and two syringes.

reticular veins 0.2–0.5%. One advantage of STS is the lack of pain with injections; however, extravascular injection can be painful. Also, as with all detergents, STS can be made into a foam. This is typically done with a three-way stopcock and a syringe filled with air (Fig. 39-10). Foam can increase contact between the agent and the vessel wall, can result in more effective sclerosis at a lower concentration, and allows treatment of larger-caliber vessels. One disadvantage is the isolated reports of anaphylaxis and death associated with STS.

Polidocanol (Asclera[®] Merz Aesthetics, San Mateo, CA), a detergent, has recently gained FDA-approved for use in sclerotherapy. It possesses many of the same advantages as STS, including lack of pain with injection and the ability to be used as a foam. Goldman demonstrated comparable efficacy and a similar adverse event profile between polidocanol and STS.

Sodium morrhuate is a detergent approved by the FDA for treatment of varicose veins. However, this sclerosing agent is not generally used for the treatment of cutaneous telangiectasias due to its highly caustic nature and higher anaphylaxis potential.

Glycerin and polyiodide iodine are chemical irritants used as sclerosing agents. Though not FDA-approved for sclerotherapy, these act as corrosive agents and cause a direct injury to the vessel endothelium. Leach and Goldman report a significant decrease in bruising, swelling, and post-procedural hyperpigmentation with glycerin as compared to STS.

Sclerotherapy complications

Side effects and complications can be associated with all types of sclerotherapy agent. Ulceration can occur despite the meticulous technique of the dermatologist and regardless of the

sclerosing agent used. Extravasation of sclerosing solution from the vein may occur, or injection into a dermal arteriole or arteriovenous anastomosis may result in cutaneous necrosis. If it is suspected that extravasation has occurred, injection of normal saline to dilute the sclerosing agent may prevent ulceration. Alternatively, application of 2% nitroglycerin ointment may prove beneficial. If ulceration does occur, conservative wound management should be undertaken until healed.

Hyperpigmentation along the course of treated veins has been reported to occur in 10–30% of patients. This pigmentation is due to hemosiderin deposition and has been reported with a variety of sclerosing agents, including hypertonic saline, polidocanol, and STS. Pigmentation often improves with time, with approximately 70% improvement over a 6-month period. Treatment options include trichloroacetic acid, hydroquinone, retinoic acid cream, intense pulsed light, and laser treatments. Tafazzoli et al report excellent results with the Q-switched ruby laser.

Telangiectatic matting is the appearance of fine telangiectatic blush at the site of previously treated veins. This has been reported in 10–15% of patients treated with sclerotherapy. Risk factors associated with this include estrogen therapy, obesity, and a family history of telangiectasia. Low injection pressures and limiting the amount of sclerosant per injection site may help reduce the incidence of telangiectatic matting. Spontaneous resolution often occurs within 3–12 months. Treatment options include intense pulsed light, pulsed dye laser, and injection of sclerosant into the matted vessels.

Arterial injection of sclerosant is the most feared complication of vein sclerosing. While extremely rare, it has considerable associated morbidity and necessitates timely action. Classically, the patient reports significant pain immediately following injection, accompanied by pallor and cyanosis. If arterial injection occurs, the physician should immediately apply ice and attempt to dilute the vessel with injections of normal saline. Procaine can be used to inactivate STS. Intravenous heparin and thrombolysis should be considered.

Ambulatory phlebectomy

Ambulatory phlebectomy is an outpatient procedure used to remove varicose veins employing skin hooks via a series of stab incisions made along the course of the varicosity. Tumescence anesthesia is commonly used during this technique and has the added benefit of compression of the vein and reduction of blood loss. Various hooks and clamps are used to remove the vein (Fig. 39-11).

Incision sites heal with minimal scarring. Adverse effects are generally quite limited and consist of minor pain and bruising. Infection and nerve damage are extremely rare.

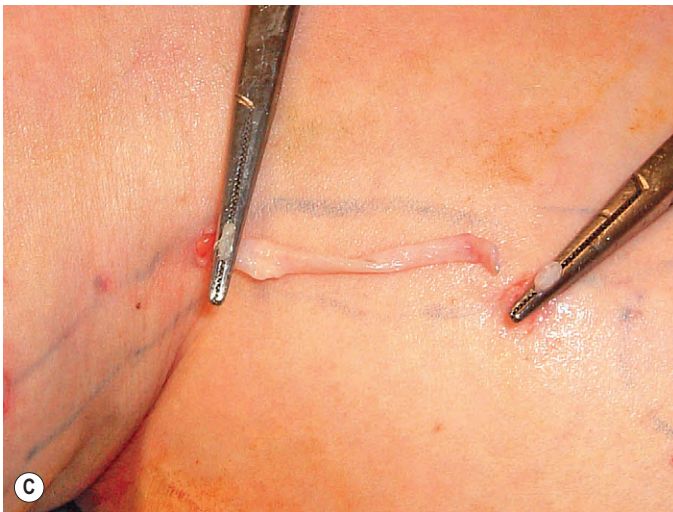

Fig. 39-11 Ambulatory phlebectomy. A, Hook used to secure the vein. B, Vein is clamped on either side and severed. Clamp is then used to remove the vein using a rolling and pulling technique. C, Removed vein segment. The distal end can be tied off using absorbable suture, or additional segments can be removed using the same technique.

Endovenous ablation

Endovenous ablation should be considered in patients with greater saphenous incompetence and is rapidly replacing traditional vein stripping. In patients with lower extremity tel-

Fig. 39-12 Endovenous ablation, a radiofrequency catheter with deployable electrodes at the tip causes thermal destruction of the vein wall.

angiectasia and reticular veins, prior assessment of underlying saphenous reflux is necessary to prevent recurrence following treatment of the visible varicosities.

Radiofrequency or laser (using 810 nm or 1320 nm) can be used to heat and damage veins (Fig. 39-12). Either method results in vein wall shrinkage and subsequent vessel thrombosis and occlusion. Tumescent anesthesia allows the procedure to be performed painlessly, surrounds and compresses the vein for greater contact between the catheter and vessel wall, and distends the skin away from the heat source, preventing cutaneous damage. A catheter is placed under ultrasound guidance and guided to the sapheno-femoral junction. The catheter is slowly withdrawn along the length of the vein, and the thermal injury leads to vessel occlusion.

The most frequent complications include ecchymosis and pain. Thermal burns of the skin are infrequently seen when tumescent anesthesia is properly used. Nerve injury is uncommon and paresthesias are often temporary. Deep vein thrombosis has been documented, but pulmonary embolism is extremely rare when the technique is performed properly.

Liposuction

Liposuction is used for the removal of local areas of adipose and to improve body contour. It is not a treatment for obesity and should not be used as a weight loss mechanism. The most common areas treated are the abdomen and thighs, neck, jowls, knees, ankles, and breasts (Fig. 39-13). Additional conditions, such as gynecomastia, buffalo hump, lipoma, lipodystrophy, and axillary hyperhidrosis, can be treated by liposuction.

The most common technique employed by dermatologists involves infiltrating the treated area with dilute anesthesia and aspirating the fat via cannulas attached to a vacuum. The choice of cannula can determine the amount of fat aspirated, with more aggressive cannulas having a larger bore, being more pointy, and having multiple, larger holes placed near the tip. Tumescent anesthesia typically consists of 0.05–0.1% lidocaine with 1:1000000 epinephrine and sodium bicarbonate. The total safe concentration of lidocaine that can be used is 55 mg/kg. The benefits of tumescent anesthesia are the ability to perform the procedure comfortably under local anesthesia, hemostasis, and hydrodissection of adipocytes, which facilitates aspiration.

Much discussion has been raised regarding the safety of office-based liposuction. It is important to stress that the serious complications seen in liposuction are associated with general anesthesia, and not with procedures performed with local tumescent anesthesia. While there have been reports of deaths occurring during liposuction, no reports have occurred when patients were treated with tumescent anesthesia alone. Office-based tumescent liposuction performed by dermatologic surgeons is safe and has a lower complication rate than hospital-based procedures.

Chemical peels

Superficial peel

Peels are categorized by the level of injury they cause. Superficial peels cause wounding to the epidermis and may reach the papillary dermis. These peels are well tolerated by patients who require limited “down time” after treatment. Superficial peels are used in the treatment of photoaging, actinic keratoses, solar lentigines, and pigmentary dyschromias. Given the limited nature of the injury induced by these peels, patients often need multiple treatments on a weekly or monthly basis to reach a desired result. However, patients need to be properly counseled regarding the limited benefit of superficial peels, as they cannot provide the improvement in wrinkles and deep furrows that may be possible with deeper injury peels.

Alpha-hydroxy acids (AHA), such as glycolic acid and lactic acid, are naturally occurring agents found in foods. The depth of injury is determined by the pH, the concentration of the acid, the amount applied, and the length of treatment time. Glycolic acid, in concentrations up to 70%, is commonly used for melasma, acne, and photoaging. Following rapid application to the entire face, it must be neutralized with sodium bicarbonate or plain water. Glycolic acid has been used in combination with 5-FU for the treatment of actinic keratoses.

Salicylic acid, a beta-hydroxy acid, can be used in concentrations of 20–30% for the treatment of acne and mild photoaging. It is especially useful as an adjunctive treatment for acne due to both the keratolytic and comedolytic properties of salicylic acid. It is also used in combination with other agents as part of the Jessner’s solution. Following application, patients experience some mild stinging and discomfort. A whitening of the skin, termed frosting, from the precipitation of salicylic acid crystals is noted within several minutes of application. Salicylic acid does not require neutralization, although cool compresses after application can soothe the skin.

Trichloroacetic acid (TCA) in concentrations of 10–25% is used extensively as a superficial peel. The depth of injury is related to the concentration and the number of applications, with repeated coats of a low-concentration TCA leading to greater penetration. The agent is applied, and erythema and a white frost are noted within 1 minute. Patients experience a burning sensation. Hand-held fans and post-procedure cool compresses can reduce discomfort. TCA does not require neutralization after application.

Fig. 39-13 Tumescent liposuction. A, Prior to treatment of abdomen. B, Following treatment.

Table 39-2 Jessner's solution

Resorcinol	14 g
Salicylic acid	14 g
85% lactic acid	14 g
95% ethanol qs ad	100 mL

Jessner's solution combines resorcinol, salicylic acid, and lactic acid in ethanol (Table 39-2). This superficial peel has keratolytic activity and is commonly used for acne or hyperkeratotic lesions. It is self-neutralizing, and multiple applications can be performed to obtain a deeper injury.

Solid CO₂ (dry ice) has been used alone and in combination with TCA to obtain a deeper peel. It has been proposed as an effective treatment for acne scars and as a way to potentiate the effect of TCA to achieve a deeper peel.

Medium-depth peel

Medium-depth chemical peeling is defined as a controlled wound to the epidermis and deep papillary dermis, often with some extension into the upper reticular dermis. In contrast to the multiple treatments that are often performed with superficial peels, medium-depth peels are generally done as a single procedure due to the more significant injury produced. These peels cause epidermal necrosis and dermal injury, which results in increased collagen production during the wound healing process over the next several months. Medium-depth peels are indicated for the treatment of mild to moderate photodamage, rhytids, pigmentary dyschromias, actinic keratoses, solar lentiginos, and other epidermal growths. Lawrence et al demonstrated a similar efficacy with Jessner's/35% TCA medium-depth peel as compared to 5-FU in the treatment of widespread facial actinic keratoses.

The classic medium-depth peel is 50% TCA. However, it is generally not used as a single-agent peel due to the unpredictable results and increased incidence of complications: namely, scarring and dyspigmentation. Rather, combining 35% TCA with an initial application of another agent, such as Jessner's solution or glycolic acid, can produce a medium-depth injury without the complications associated with higher concentrations of TCA alone. As a result of the damage to the epidermis produced with the initial peel, the TCA is able to penetrate deeper and produce a more significant and even result.

Deep peel

Deep chemical peels are defined as those that cause an injury down to the mid-reticular dermis. These peels are indicated for patients with moderate to severe photodamage and advanced rhytids. These peels produce significant injury and patients have an extended period of healing following treatment.

Baker-Gordon formula phenol peel is the traditional deep peel (Fig. 39-14). Undiluted 88% phenol does not produce a deep or consistent injury because it causes complete coagulation of epidermal keratin proteins, thus blocking further penetration. The Baker-Gordon formula (Table 39-3) reduces the concentration of phenol to 55%; the croton oil acts as a keratolytic and potentiates the depth of penetration of the phenol. Cardiac monitoring is required since phenol can produce arrhythmias. Intravenous fluids are given before and during

Fig. 39-14 Baker-Gordon phenol peel, white frosting following application. (Courtesy of Richard G. Glogau, MD)

Table 39-3 Baker-Gordon formula

Tap water	2 mL
Septisol® liquid soap	8 drops
Croton oil	3 drops

the peel to limit the serum concentrations of phenol. In addition, the face is divided into smaller cosmetic units which are treated individually. An approximately 15 minute wait is required between treating each subunit, spreading the entire procedure over 1-2 hours, and further limiting the systemic concentration of phenol. Following application, occlusive tape can be applied if a deeper wound is desired.
