

HUMAN DISEASES AND CONDITIONS

HUMAN
DISEASES AND
CONDITIONS

Second Edition

Advisors

A number of experts in the medical community provided invaluable assistance in the formulation of this encyclopedia. The advisory board performed a myriad of duties, from defining the scope of coverage to reviewing individual entries for accuracy and accessibility. To them our sincerest appreciation is extended.

LEAD ADVISOR

EUGENE W. STRAUS, M.D.
Emeritus Professor of Medicine
State University of New York Health Science Center at Brooklyn
Downstate Medical Center

LARRY I. LUTWICK, M.D.
Professor of Medicine
State University of New York, Downstate Medical School
Director of Infectious Diseases
Veterans Affairs New York Harbor Health Care System, Brooklyn Campus

STEPHAN L. KAMHOLZ, M.D., M.A.C.P., F.C.C.P.
Chairman, Department of Medicine
North Shore University Hospital and Long Island Jewish Medical Center
David J. Greene Professor of Medicine
New York University School of Medicine
Adjunct Professor of Medicine
Albert Einstein College of Medicine
State University of New York Downstate College of Medicine

PETER H. ROCHELEAU, M.D.

Please Read—Important Information

H*uman Diseases and Conditions, Second Edition*, is a health reference product designed to inform and educate readers about a wide variety of diseases and conditions, nutrition and dietary practices, treatments and drugs, as well as other issues associated with general health. Cengage Learning believes the product to be comprehensive, but not necessarily definitive. It is intended to supplement, not replace, consultation with a physician or other healthcare practitioner. While Cengage Learning has made substantial efforts to provide information that is accurate, comprehensive, and up-to-date, Cengage Learning makes no representations or warranties of any kind, including without limitation, warranties of merchantability or fitness for a particular purpose, nor does it guarantee the accuracy, comprehensiveness, or timeliness of the information contained in this product. Readers should be aware that the universe of medical knowledge is constantly growing and changing, and that differences of opinion exist among authorities. Readers are also advised to seek professional diagnosis and treatment for any medical condition, and to discuss information obtained from this product with their healthcare provider.

Today's Fish

Whenever there is a second edition of a reference work, there is the strong implication that the first edition satisfied important needs and was well received. This is certainly the case with respect to the second edition of *Human Diseases and Conditions*, but there are extraordinary circumstances which make this new work especially important.

First, healthcare has recently emerged as one of the most vital issues of our time. Every informed citizen must now have a general understanding of human diseases and conditions—their cause, diagnosis, treatment, prognosis, and economic consequences—in order to play a role in the crucial reforms that are coming to our society. This is especially true of young adults.

Second, the understanding of human diseases and conditions undergoes evermore rapid change. In the 1,343 years that followed the death of the great physician Galen (c. 130–c. 200) and the declaration of his divinity and the sanctification of his ideas, there were virtually no changes or advances to our thinking about human diseases and conditions until Andreas Vesalius (1514–1564) published his great work, *De humani corporis fabrica*, in 1543. That was in the age of anatomy, when Western medical discovery focused on human dissection. It was followed by the ages of pathology, pathophysiology, microbiology, immunology, and now molecular and regenerative medicine.

The rapid advances in science and technology, including informatics, make it imperative to update and reevaluate the fields of health and human disease frequently. This second edition is fresh and up-to-date; it emphasizes new and very practical conceptualizations like the Metabolic Syndrome and strategies to reduce the epidemics of childhood obesity, Type 2 diabetes, heart disease, and stroke. It discusses important new diseases such as avian influenza (bird flu), and conditions like Internet addiction and bullying, and contains frank discussions of subjects such as body odor, drug addiction, behavioral and school-related disorders, eating and gender difficulties, among many others.

This edition is fresh and new—it is Today's Fish.

Life and health reflect the fluxing equilibriums between organisms and the environment. That is why the most exciting aspect of human diseases and conditions is the way in which they change. When the first edition of this encyclopedia was prepared in 1999, the diagnosis of AIDS was like a death sentence and the treatment section concluded that "...Experts believe that people with AIDS eventually will die from it. ...". Now, only a few years later, AIDS is one of the most treatable chronic diseases. Leading clinical experts currently tell their patients that if they follow their treatment regimens they will not die of AIDS, and there are data to prove that. SARS was virtually unknown. HPV vaccine was not yet available for use. Similarly, the fields of genetics, epi-genetics, and molecular biology are increasingly transforming our understanding of the human condition. In the last few years we have actually begun to engineer diseases, like sickle-cell anemia, out of the human genome.

The second edition of *Human Diseases and Conditions* builds on the solid foundations of the first. It provides updated information on every subject. It includes nearly 90 new and important subjects, many of which are especially timely and of interest to our readership. And throughout there is an emphasis on the new paradigms which are now essential to our understanding and involvement in human biology and healthcare. Thus, the completely rewritten chapter on sickle-cell anemia discusses how Linus Pauling's analysis of the structure of hemoglobin S (Hb S) ushered in the age of molecular biology; how heterozygosis for the Hb S gene provides a survival advantage for individuals living in

endemic-malaria regions, which explains its high prevalence in those areas; and how preimplantation genetic diagnosis and blastocyst selection are now removing Hb S from family genomes. Similarly, new entries on genetic disorders include both generic and specific discussions of the problems and horizons for gene therapy, and entries dealing with regenerative medicine discuss the controversies, promises, and current achievements of stem cell research and their applications.

This *Second Edition* recognizes the many and increasing contributions of women to the theory and practice of medicine. The great achievements of Helen Taussig with respect to the diagnosis and treatment of congenital heart disease; Rosalyn Yalow's revolutionary development of radioimmunoassay (RIA), which advanced all areas of medicine and biology; the astounding cures of childhood leukemias by Gertrude Elion; and Rita Levi Montalchini's discovery of the growth factors that are so essential to stem cell and regenerative medicine. All of their work was developed under trying circumstances but eventually won the highest accolades in science and medicine. These facts are important for the education of young men and women and highlight current changes in medical career opportunities and research directions. The continuing struggles against race, gender, and class bias are essential to progress with regard to human diseases and conditions.

Every attempt has been made to embrace scientific complexities and to express them in authoritative yet readily available prose. By the same token, political and economic issues have not been excluded from this work. In fact, what comes through is the reality that dealing with human diseases and conditions has always been, and will ever be, at the cutting edge of human cultures and their most pressing controversies. This is the place where our values can truly be seen without the camouflage of ideology. It is increasingly difficult to doubletalk around the meaning of millions of men, women, and children being left out of timely diagnosis and treatment for the human diseases and conditions dealt with in this work. It is also clear that being driven into bankruptcy and homelessness by the excessive and unnecessary costs of a health care system that many contend is virtually unique in its waste, inefficiency, and obsolescence is something that should not be excluded from discussions of human diseases and conditions. All conscious members of society should have access to information which enlightens them to what exists, what is changing, and what the choices for improvement really are. In an age of increasing power over human diseases and conditions our society is lagging far behind with respect to inclusiveness, patient satisfaction, cost effectiveness, and healthcare outcomes. These are not controversial statements, they are the conclusions of US government agencies like the General Accountability Office (GAO) and the World Health Organization (WHO).

Let us hope that this second edition of *Human Diseases and Conditions* will provide vital information and contribute to an atmosphere within which medicine and science can flourish and young people can make informed decisions about their lives and their futures.

Emeritus Professor of Medicine
State University of New York
Health Science Center at
Brooklyn
Downstate Medical Center

Eugene Straus is the author of over 200 original scientific publications and the highly acclaimed *Medical Marvels: The 100 Greatest Advances in Medicine* and *Rosalyn Yalow, Nobel Laureate: Her Life and Work in Medicine*. He is Vice-President of the Rosalyn S. Yalow Foundation for Medical Research.

About This Edition

Human Diseases and Conditions, Second Edition is the completely reviewed, revised, and expanded version of Charles Scribner's Sons' well received *Human Diseases and Conditions* (2000) and its two supplements (2001, 2003). Offering in-depth coverage of all areas of human health and disease, *Human Diseases and Conditions, Second Edition* offers current and accurate information on approximately 450 diseases and conditions. The topics covered include tropical diseases (malaria, Chagas' disease), infectious diseases (STDs, HIV/AIDS), many cancers, worrisome conditions (hives, hair loss), psychological conditions (phobias, obsessive/compulsive disorder), and human conditions (addiction, homelessness), as well as public health issues (environmental diseases, bioterrorism, vaccination) and issues of interest to the young adult audience (growth, puberty, suicide, sports injuries, eating disorders).

Originally designed for use by middle and high school students, it soon became apparent that the features of the first edition, which made it appealing to students, also made it appealing and accessible to readers of all ages. Therefore, the editors of this second edition have built on the foundation established by the first edition and its supplements.

Should this book be used to diagnose or treat medical problems? Not at all. This is a reference book. The human body is very complicated. Many medical problems have the same sorts of symptoms, and your doctor is trained to recognize the difference between those that seem alike but really are quite different. If you have medical concerns, do not try to diagnose and treat yourself (or your friends). Ask your doctor or other healthcare practitioner.

Compilation Methods

Each of the 365 entries which appeared in the first edition of *Human Diseases and Conditions* and its supplements was reviewed by a board of medical advisors who made recommendations for its updating. In addition, the board identified 85 topics that were not covered in the first edition or its supplements which they felt needed to be included in the *Second Edition*. These topics include:

- Diseases and conditions which filled out an existing area covered in the first edition, such as brain, ovarian, and thyroid cancers in the cancer field, and menopause in the area of women's health
- Newly identified diseases/conditions including Avian Influenza, Caffeine-related Disorders, Internet Addiction Disorder, Severe Acute Respiratory Syndrome (SARS)
- Conditions made popular by television advertising such as Chronic Obstructive Pulmonary Disease (COPD), Erectile Dysfunction (ED), Human Papilloma Virus (HPV)
- Genetic diseases like Familial Mediterranean Fever and Fanconi Anemia
- General interest articles such as Aging; Conjoined Twins; Gay, Lesbian, and Transgender Health; Sports Injuries
- Public Health Issues including Chemical Poisoning and Toxic Inhalation Disorders

as well as many others.

Once an entry was written or revised by a medical writer, it was reviewed again by the advisor in charge of the original review to assure the entry presented the information clearly, accurately, correctly,

and in an unbiased manner. It was then given a final vetting by a physician to guarantee that the information across entries was correct and solid. The last review was made by a copyeditor who brought the language and grammar into line across entries and made sure that the presentation of the information was consistent.

Anatomy of an Entry

Order of Entries: Entries in *Human Diseases and Conditions, Second Edition* are arranged in alphabetical order, word-by-word.

Each entry has an introductory paragraph of one sentence to three short paragraphs defining the topic with parenthetical guides to pronouncing important and possibly unfamiliar terms.

The body of the entry is defined by headings in the form of questions starting with a story of a person affected by the disease/condition. Typical headings include:

- What is the disease/condition?
- How common is the disease/condition?
- Is the disease/condition contagious?
- How do people know they have the disease/condition?
- How do doctors diagnose and treat the disease/condition (with subheads Diagnosis, Treatment, Complications if needed)?
- Can the disease/condition be prevented?

Each entry concludes with a list of resources and organizations for further information, both in print and on-line. Every effort was made to include at least two articles or books and two organizations in each entry.

Special Features

Sidebars: *Human Diseases and Conditions, Second Edition* offers two types of sidebars. The **main text sidebar** falls within the body of the entry and contains information such as historical data about the disease/condition or biographical information about people involved with the discovery of the disease/condition. The **marginal sidebar** falls in the margin and contains information such as statistics, health hints, and “fun facts.”

Photographs and Illustrations: Every attempt has been made to assure that each entry has appropriate illustrations and photographs to help the reader better understand the topic. New to *Human Diseases and Conditions, Second Edition* is a variety of charts and tables to present key facts at a glance.

Definitions: Terms that are used in an article but may be unfamiliar to readers have been starred in the text and the definition appears in the margin of the page. Definitions include diseases, medical terms, parts of the body, and other terms that may not be familiar to all readers.

Cross-references: A system of cross-references, devised by the advisory board, is in place to inform readers of related entries throughout *Human Diseases and Conditions, Second Edition*. Cross-references may appear at the end of an article as a “see also” reference or as a “blind entry” (“see” reference) in the body of the work.

Index: A comprehensive index of concepts, names, and terms enables readers to locate topics throughout *Human Diseases and Conditions, Second Edition*. Many subjects are not treated in separate entries but within the context of comprehensive entries; the index will guide readers to discussions of these subjects.

New to This Edition

In addition to increasing the number and type of resources, illustrations, and definitions, *Human Diseases and Conditions, Second Edition* contains three new compilations of information found in individual entries brought together into one convenient place. They are:

- **Bibliography:** The bibliography brings together over 800 book, periodical, and on-line resources mentioned in the *Resources* section of the entries.
- **Glossary of Terms:** All the terms defined in the margins of *Human Diseases and Conditions, Second Edition* also appear in the glossary with their definitions.
- **List of Organizations:** The 430 organizations cited in the entries have been compiled into one list. This lists the address and home page URL of the organization and has a short description of the organization if available.

Suggestions Welcome

Comments and suggestions from users of *Human Diseases and Conditions, Second Edition* on any aspect of the product as well as suggestions for a disease or condition to be included or updated in a future edition are cordially invited. Please write:

Abscesses

Abscesses (AB-seh-sez) are localized or walled off accumulations of pus caused by infection that can occur anywhere within the body. Furuncles (FYOOR-ung-kulz), which are also known as boils, and carbuncles (KARBUNG-kulz) are types of abscesses that involve hair follicles* and occur on the skin.*

What Are Abscesses?

An abscess develops when the body's immune system* isolates an area of body tissue that has been infected by an invading microorganism* (usually bacteria) to prevent the infection from spreading further. The body sends infection-fighting leukocytes (LOO-kuh-sites) to the infected area; leukocytes are specialized white blood cells that can destroy infectious microorganisms such as bacteria, parasites, and viruses.

As the bacteria and white blood cells clash at the site of infection, pus begins to form within the involved tissue. As the infection progresses, a wall of tissue develops surrounding the infection site, forming an abscess. A growing abscess on the skin is usually warm, red, painful, and swollen with pus.

Abscesses that grow inside the body are uncommon but can be very serious. Internal abscesses can occur anywhere within the body, but some of the more common areas where they form include surrounding the appendix* (as when someone has appendicitis, ah-pen-dih-SY-tis, an inflammation

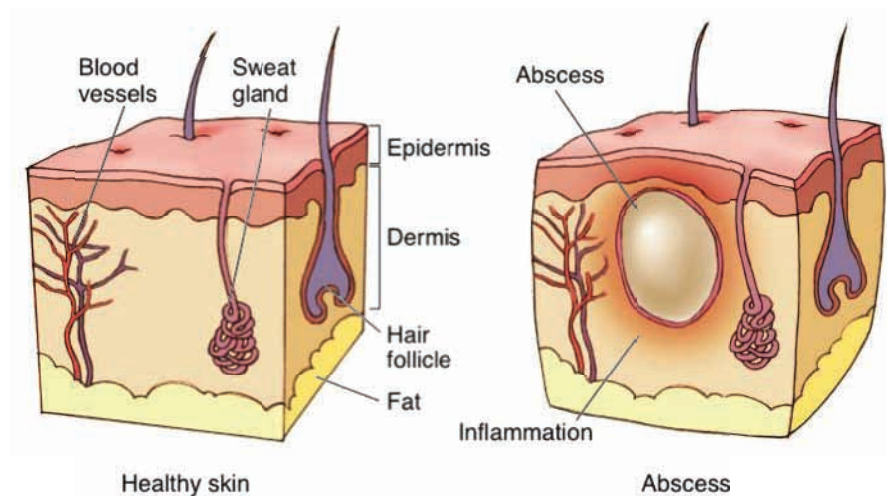

* **pus** is a thick, creamy fluid, usually yellow or ivory in color, that forms at the site of an infection. Pus contains infection-fighting white cells and other substances.

* **hair follicles** (FAH-ih-kulz) are the skin structures from hair develops and grows.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **microorganism** is a tiny organism that can be seen only by using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

* **appendix** (ah-PEN-diks) is the narrow, finger-shaped organ that branches off the part of the large intestine in the lower right side of the abdomen. Although the organ is not known to have any vital function, the tissue of the appendix is populated by cells of the immune system.

◀ An external abscess is an accumulation of pus that results from bacterial infection. Abscesses that form under the skin may go away on their own. Some require drainage (removal of the pus). *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

▲
A carbuncle is a deep seated infection of the skin and underlying tissue that consists of a cluster of boils. There are usually one or more openings draining pus onto the skin.

© Medical-on-Line/Alamy.

* **tonsils** are paired clusters of lymphatic tissue in the throat that help protect the body from bacteria and viruses that enter through a person's nose or mouth.

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

of the appendix), surrounding one of the tonsils* (a peritonsillar, per-ih-TON-sih-lar, abscess), and in the gums or jaw (a dental abscess). They may also form in the liver, around the spinal cord, or on or in the brain. People who have weak immune systems, such as those who need chemotherapy* for cancer or someone with diseases such as longstanding diabetes* or HIV*/AIDS*, are at more risk for developing internal abscesses.

Furuncles (boils) are a type of skin abscess most commonly found on the face, neck, armpit, groin, buttocks, and thighs. Carbuncles are larger areas of skin infection made up of several boils that have formed close together and then joined. They take longer to form and are often located on the back and the nape of the neck. Men are more likely to develop carbuncles than are women. Fever and a general feeling of illness are often associated with carbuncles.

What Causes Abscesses?

Bacteria that are commonly found on the skin, especially *Staphylococcus aureus* (stah-fih-lo-KAH-kus ARE-ree-us) and Group A β -hemolytic* *Streptococcus* (he-muh-LIH-tik strep-tuh-KAH-kus) typically cause most abscesses, furuncles, and carbuncles. People who have staphylococcus bacteria residing in their nose (called staph colonization) may be prone to developing recurrent skin abscesses.

Much of the skin's surface is covered by hair. At the base of each hair is a hair follicle, a sac-like pit in which the hair shaft develops and grows. If the skin around a hair follicle has been damaged in some way, such as with a cut or a nick on the skin from shaving, bacteria on the skin's surface can enter and start to cause an infection. This alerts the body's immune system, which walls off the area around the infected hair follicle. As the body's defenses go to work, the area fills with pus and becomes inflamed. When an area of skin contains infected, inflamed hair follicles, the condition is known as folliculitis (fuh-lih-kyoo-LYE-tis).

A boil usually starts within an area of folliculitis. The growing pus inside the boil creates pressure and swelling around the infected spot, often forming a drainage point at the surface of the skin called a head. A carbuncle typically has many small areas where pus has collected and formed heads.

Abscesses that appear inside the body, such as within the abdomen, may be caused by types of bacteria different from those that cause skin infections. For example, an abscess that forms with appendicitis may be caused by a blockage in the appendix (known as a stone). These abscesses usually contain bacteria normally found inside the intestine and in bowel movements. A liver abscess can occur when an infection in the abdomen spreads or when an infectious agent from somewhere else in the body travels through the bloodstream and is deposited in the liver.

Are Abscesses Contagious?

Abscesses are not contagious, but the bacteria that cause them can spread from person to person and can cause other types of infections. Individuals who touch a boil that is draining pus should wash their hands, and cloths

WHAT ABOUT METHICILLIN-RESISTANT STAPHYLOCOCCAL AUREUS?

While staphylococcus bacteria have long been implicated in abscess formation, a later strain that is resistant to methicillin and other antibiotics was circulating in the early 2000s. This type of infection, called community-associated methicillin-resistant Staphylococcal Aureus (MRSA), was particularly worrisome because it might be more contagious via contact than other forms of staph infections. Groups of people who have close physical contact are vulnerable to this type of infection, for example, children in daycare or other crowded school settings, people participating in contact sports, prisoners, military personnel, homeless people, homosexual men, and intravenous drug users. An abscess caused by this type of bacteria does not respond to the usual types of antibiotics, although some oral antibiotics may be effective. More serious infections due to these organisms require intravenous (IV) antibiotics. An abscess caused by MRSA will probably require incision and drainage, and in some severe cases a wide-excision of all infected tissue is required in order to rid the body of the organism and lower the risk for systemic spread of this virulent organism.

or towels that have touched an open or draining boil or carbuncle should not be shared.

How Are Abscesses Treated and Prevented?

Skin abscesses sometimes need to be drained before they can heal, although most of the time they heal on their own without medical treatment. Skin abscesses are often treated at home by applying warm compresses. The abscess usually comes to a head on its own, then begins to drain and heals soon afterward.

Boils and carbuncles that do not drain on their own should not be squeezed or lanced (cut open) to remove pus by anyone but a healthcare provider. Trying at home to puncture a boil could force the infection deeper into the skin and spread the bacteria. Skin abscesses that do not improve on their own will need to be lanced by a doctor to prevent the infection from becoming worse. The area is thoroughly cleaned before it is lanced, and antibiotics are sometimes prescribed. Most carbuncles require antibiotic treatment.

Internal abscesses are usually treated with surgical drainage and antibiotics. If a dental abscess is not treated with antibiotics it can destroy the root of a tooth, leading to the need for a root canal* procedure or the removal of the entire tooth.

Job Syndrome

The Bible includes a story in which God tests the faith and devotion of Job by allowing him to become afflicted from head to toe with painful boils. Job syndrome is named for this biblical figure's condition. People who have this rare disease experience recurring cases of severe abscesses on the skin and in the lungs, sinuses, and bones.

* **hemolytic** (he-mo-LIT-ik) refers to destruction of red blood cells with the release of hemoglobin into the bloodstream.

* **root canal** is a procedure in which a dentist cleans out the pulp of an infected tooth, removes the nerve, and then fills the cavity with a protective substance.

Keeping the area around a minor skin wound clean and dry, not sharing razors, and using antibacterial soap can help prevent skin abscesses.

Acne

Acne (AK-nee) is a condition in which there are pimples, blackheads, whiteheads, and sometimes deeper lumps on the skin.

Jay's Story

Before he turned 13, Jay's skin was clear. Soon after the start of eighth grade, though, Jay noticed a few pimples on his face. Before long, the problem had gotten much worse. Jay's face was always broken out, and the pimples had spread to his neck, back, and chest.

Jay was willing to try almost anything to get rid of his acne. He had heard that it is caused by dirt or by eating certain foods, so he washed his face several times a day and gave up chocolate, nuts, and french fries. He also tried several acne medicines sold without a prescription. Nothing worked. Finally, Jay went to see the doctor, who prescribed a medicine. Within a few weeks, the acne started to go away. Although Jay had to

Healthy skin (left) has pores, hair follicles, and sebaceous glands that make an oily substance called “sebum.” Sebum helps keep skin and hair healthy by carrying away dead skin cells that have been shed by the follicle linings. If the cells shed too fast and stick together, they may form a plug at the surface of the skin. If the opening to the surface stays partly open, the top of the plug may darken, causing a blackhead (center). If the opening to the surface closes, the follicle may fill up and its wall may start to bulge, causing a whitehead (right). If the follicle wall bursts, the oil, cells, and bacteria spill into the skin. The result is redness, swelling, and pus. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

keep using medicine and seeing the doctor for a while, he felt that his improved appearance was well worth the trouble.

What Is Acne?

Acne is the name for pimples or comedones*: blackheads, whiteheads, and sometimes deeper lumps that occur on the skin, especially on the face, neck, chest, back, shoulders, and upper arms and legs. Almost all teenagers have at least a little acne, and some adults have the problem as well. Although acne is not a serious health threat, it affects the appearance, which in turn can affect how individuals feel about themselves. Severe acne can leave permanent scars on the skin.

Acne occurs when hair follicles (FOL-li-culs) become plugged. The follicle is a tiny shaft in the skin through which a single strand of hair grows. Follicles are connected to sebaceous (se-BAY-shus) glands, which are small structures in the skin that make an oily substance called sebum (SEE-bum). This oil helps keep the skin and hair healthy. To reach the surface of the skin, the oil drains from the glands into the follicles then leaves the follicles through tiny openings in the top of the shaft. As it leaves the follicles, the oil carries away dead skin cells shed by the follicle linings.

What Are Different Kinds of Acne?

Sometimes the cells inside the follicles shed too fast and stick together, forming a white, thick plug at the surface of the skin. If the opening to the surface stays partly open, the top of the plug may darken, causing a blackhead. If the opening to the surface closes, the follicle may fill up and its wall may start to bulge, causing a whitehead. The mixture of oil and cells inside the follicle also aids the overgrowth of bacteria. If the follicle wall bursts, the oil, cells, and bacteria spill into the skin. The result is redness, swelling, and pus*, in other words, a pimple. Ordinary acne is made up of blackheads, whiteheads, and pimples.

At times, large, pus-filled lumps called cysts (SISTS) form deeper in the skin. In this more severe form of acne, the lumps may be painful, and if they are not treated by a doctor, they may lead to permanent scars.

◀

* **comedo** (KOM-e-dones) are acne pimples. Blackheads are open comedones. Whiteheads are closed comedones. Cosmetics that are labeled non-comedogenic (non-kom-e-do-JEN-ik) are less likely to cause pimples.

* **pus** is a thick, creamy fluid, usually yellow or ivory in color, that forms at the site of an infection. Pus contains infection-fighting white cells and other substances.

* **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

How Do Hormones Cause Acne?

Nearly all teenagers have at least an occasional pimple. The problem usually starts between the ages of 10 and 13, and it typically lasts for 5 to 10 years. Acne usually goes away on its own when people reach their early twenties. However, it can last into the twenties, thirties, and beyond. A few people get acne for the first time as adults. Acne strikes boys and girls about equally. However, boys are more likely than girls to have more severe, longer-lasting forms of acne.

During the teen years, both boys and girls go through changes in their hormones*. One group of hormones called androgens (AN-dro-jens) seems to play a role in acne. Among other factors, androgens make the sebaceous glands work harder. The more oil the glands make, the greater the chance that the follicles will become clogged. Teenage boys make ten times as much androgen as teenage girls, so it is not surprising that boys are more likely to get more severe cases of acne.

What Else Causes Acne?

Certain oily kinds of makeup and face cream can clog the openings of the skin and cause mild acne. That may mean that people who try to cover their pimples with makeup actually make the problem worse by causing new pimples. Oil-free products are labeled “non-comedogenic” (non-kom-ee-do-JEN-ik), meaning they should not cause blackheads or whiteheads, or “non-acnegenic” (non-ak-nee-JEN-ik), meaning they should not cause acne.

Several other factors can cause acne or make it worse. These include certain medicines. People who work in fast food restaurants or garages may find that their acne is made worse by the constant contact with grease, motor oil, or chemical irritants. Many girls also find that their pimples get worse around the time of their menstrual periods.

What Does Acne Look Like?

Acne is typically found where the sebaceous glands are most numerous: on the face, neck, chest, back, and shoulders. Blackheads are small round dark spots, whereas whiteheads are spots with a white center. Pimples look like small, red bumps. Some of them have a white center with a ring of redness around it. When pimples occur with no blackheads or whiteheads, they may be a sign of another skin disease or a skin reaction to medication. Cysts are large, red bumps that are often painful. They may leave deep pits and scars after healing.

It is usually easy for a doctor to recognize acne by sight. It is smart to see a doctor whenever the following is the case:

- Acne interferes with a person's life
- Acne spots are large, red, and painful
- Acne causes dark patches to appear on a dark-skinned person
- Acne scars remain when the acne spots heal
- Treatment with nonprescription medication does not work

How Is Acne Treated?

Acne treatments work by stopping new pimples from forming. They do this by cutting back on the amount of oil the sebaceous glands make, the number of bacteria that are present in the skin, or the rate at which dead skin cells are shed. It is important to give an acne treatment enough time to do its job. It may take weeks for the skin to clear up, even if a treatment is working.

Over-the-counter medications Milder cases of acne are often helped by lotions, creams, pads, and gels sold without a prescription. Many of these dry out the skin if used too frequently, however, and it is important to follow label instructions carefully.

Prescription medications A doctor may prescribe stronger medicines than those sold over the counter. These come in cream, gel, or liquid form (tretinoin), or pill form (isotretinoin). These medications carry serious side effects: skin dryness and peeling with tretinoin; and with isotretinoin, chapped lips, itchy skin, nosebleeds, irritation of the eyelids, joint and muscle pain, temporary hair loss, and rash. The doctor can offer advice on how to deal with these side effects.

Women who are pregnant or who may become pregnant during treatment should refrain from using isotretinoin as it may harm the developing fetus*.

Other treatments Doctors may prescribe topical or oral antibiotics* to help fight the overgrowth of bacteria on the skin.

The doctor may open pimples or remove blackheads and whiteheads in the office. A skilled doctor is the best one to do this. People who try to do it themselves may wind up making the acne worse and increasing the risk of scarring.

What Does Not Cause Acne?

Acne is not caused by being dirty. The black core in a blackhead is dried oil and dead skin cells, not dirt. Washing too often may actually irritate the skin and make the acne worse. In general, the following guidelines may help to prevent acne or to reduce its symptoms:

- Do not pop, squeeze, or pick at acne pimples, as this can lead to more redness, swelling, and permanent scars.
- Choose oil-free makeup and face creams labeled “non-comedogenic” or “non-acnegenic.”
- Avoid skin irritants, such as grease, oil, and rough clothes and sports equipment.
- Wash the face gently twice a day with a mild soap, then pat it dry.
- Shampoo hair regularly.
- For men who shave, shave as lightly as possible to avoid nicking any pimples.

▲ Acne is characterized by blackheads, whiteheads, and pustular nodules.

© Medical-on-Line/Alamy.

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

Acne is also not caused by the foods a person eats. Studies have shown that a strict diet alone will not clear up the skin. However, some people are still convinced that certain foods such as chocolate or french fries make their acne worse. It certainly cannot hurt to cut back on junk food. A healthier diet is always a plus, whether it has an effect on acne.

Addiction

Addiction (a-DIK-shun) refers to the abuse of a substance, such as alcohol or another drug, to the point at which a person develops a physical or psychological need for it. The term also may be used to describe a behavior that is out of control, such as gambling or spending too much time on the Internet.*

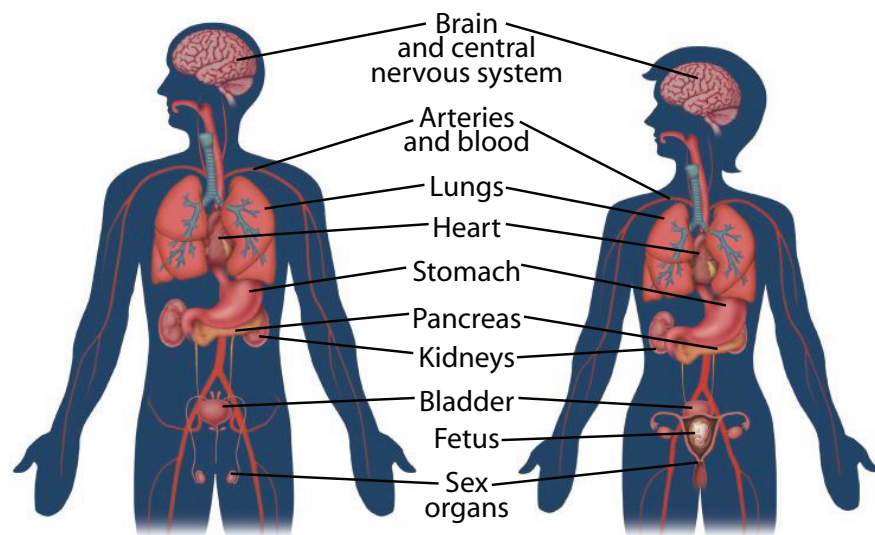

Josh's Story

When friends first told Josh that his drinking and drug use were out of control, he ignored them. He liked to party, he said, but he could stop anytime he wanted. He did not stop, though, no matter how much his grades fell and his soccer game suffered. He still did not stop even after he was kicked off the soccer team and lost many of his friends. Eventually, Josh had to admit that his use of alcohol and drugs had gotten out of control. He had developed an addiction, he now said, and he needed help to fight it.

What Is Drug Addiction?

People who have an addiction are commonly said to be “hooked” on a substance or behavior. It is an apt choice of word, since addicts often feel as if they are dangling like a fish on a hook and that they cannot break free. Fortunately, this is not true. Treatment can help people overcome addiction and regain control of their lives.

Psychological dependence Some people feel as if they have lost control of their drinking or drug use, yet they do not show signs of tolerance* or withdrawal. While these people may not be physically hooked on a substance, they can still have a strong psychological dependence on it.

* **psychological** (SI-ko-LOJ-i-kal) refers to mental processes, including thoughts, feelings, and emotions.

* **tolerance** (TALL-uh-runce) a condition in which a person needs more of a drug to feel the original effects of the drug.

◀ Addiction affects many different parts of the body. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

- * **amphetamines** (am-FET-a-meenz) are stimulants, drugs that produce a temporary feeling of alertness, energy, and euphoria.
- * **cocaine** (ko-KAYN) is a stimulant, a drug that produces a temporary feeling of alertness, energy, and euphoria.
- * **LSD** short for lysergic acid diethylamide (ly-SER-jik A-sid dy-e-thel-AM-eyed), is a hallucinogen, a drug that distorts a person's view of reality and causes hallucinations.
- * **PCP** short for phencyclidine (fen-SY-kle-deen), is a hallucinogen, a drug that distorts a person's view of reality.
- * **withdrawal** a group of symptoms that occurs when a drug that causes physical or psychological dependence is regularly used for a long time and then suddenly discontinued or decreased in dosage.

FROM USE TO MISUSE TO ABUSE TO ADDICTION

Alcohol or drug use by teenagers typically moves through four stages as it goes from occasional use to addiction. The stages are:

- **Occasional use:** Teenagers at this stage typically use beer, marijuana, or inhalants on weekends with their friends. There are few obvious changes in their behavior during the week.
- **Regular misuse:** Teenagers at this stage actively seek the high they get from drinking or using drugs. They may try stimulants (amphetamines* or cocaine*) or hallucinogens (LSD* or PCP*), and they may use drugs four or five times per week, even when they are alone. Grades start to slip, activities fall by the wayside, and old friends are replaced with new ones who also use alcohol or drugs.
- **Frequent abuse:** Teenagers at this stage can have mood swings that go from extreme highs to such lows that suicide becomes a risk. Many start to sell drugs to support their habit. As the drug use continues, lying, fighting, stealing, and school failure become on-going problems.
- **Addiction:** Teenagers at this stage may need alcohol or drugs every day to fend off withdrawal*. They will use whatever drug is handy and do whatever it takes to get high. Drug use is all they think about, and they may feel as if they have lost control. Guilt, shame, and depression are common emotions, and overdoses and medical problems may occur.

Psychological dependence is present when individuals are convinced they cannot manage or enjoy themselves without using. The substance, they believe, helps them cope. Like people with a physical dependence, these individuals feel an intense craving, which leads them to believe that using is necessary.

Physical dependence People with an addiction to alcohol or another drug develop a physical dependence on the substance, which is a strong need to use it no matter how bad the consequences may be. One sign of physical dependence is called tolerance. When individuals develop tolerance for a certain substance, they need more and more of it to get the same effect they originally got with a small amount. If individuals keep using the same amount of the substance, after a while they notice that it does not have the original effect anymore.

Another sign of physical dependence is withdrawal, which means that people who are hooked on a substance can have physical symptoms, including feeling sick if they stop using it. The symptoms are so unpleasant that people may be driven to start using the substance again just so

Addiction is believed to change the brain's pleasure circuits and pathways. A complex cascade of signals within the brain creates the craving that characterizes addiction. Thus, an addiction to a substance may be both psychological and physiological, as the body creates demands that are out of the person's control. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

they can feel better in the present. Withdrawal discomfort explains why addicted individuals come back for more of a substance, even after they realize that they have a serious problem.

People who are dependent on alcohol or other drugs, either psychologically or physically, often spend much of their time finding ways of getting the substance, using it, hiding it, and recovering from its ill effects. Friendships, school, work, sports, and other activities all are negatively affected as a result. As the problems pile up, people may want desperately to give up the substance, yet they find it very hard to do so despite repeated efforts to kick the habit. Often, users will not see the connection between drug use and life problems. They think that the issues in their lives justify their drug and alcohol use and deny that their substance abuse is the underlying problem causing those issues.

What Causes Drug Addiction?

Addiction usually begins with a conscious choice to drink or use drugs. It begins with a small exposure to a drug and repeated exposure to that drug. People often turn to alcohol or other drugs to avoid whatever is bothering them. For teenagers, this may mean pressure from friends, stress at home, or problems at school. Teenagers may also assume that drinking or using other drugs will help them fit in, let them overcome their shyness at parties, or make them look more grown up. Some just like the feeling of being high. In the long run, though, these individuals feel worse. The more they drink and use drugs, the more problems arise, and the harder it is to stop. By this point, however, people may feel as if they no longer have a choice, because the urge to use alcohol or drugs has become so powerful.

To understand how alcohol and drugs can gain such a strong hold on people, it helps to understand how these substances act inside the body. Once a substance is taken in through drinking, smoking, injecting, or

The Tiniest Addicts

Babies who are born addicted to substances their mothers used during pregnancy go through drug withdrawal after birth. Babies born addicted to heroin, for example, sneeze, hiccup, twitch, and cry. They also may have such symptoms as restlessness, shakiness, trouble sleeping and eating, a stuffy nose, vomiting, diarrhea, a high-pitched cry, fever, irregular breathing, and seizures. These symptoms usually start within a few days after birth, and some can last for three months or more. As they develop, these children can experience behavioral problems, learning difficulties, mental retardation, and retarded growth.

- * **heroin** is a narcotic, an addictive painkiller that produces a high, or a euphoric effect. Euphoria (yoo-FOR-ee-a) is an abnormal, exaggerated feeling of well-being.
- * **inhalants** (in-HAY-lunts) are substances that a person can sniff, or inhale, to get high.
- * **marijuana** (mar-a-WA-na) is a mixture of dried, shredded flowers and leaves from the hemp plant that a person can smoke or eat to get high.
- * **morphine** (MOR-feen) is a narcotic, an addictive painkiller that produces a high.
- * **sedatives** (SAID-uh-tivs) are drugs that produce a calming effect or sleepiness.

inhaling, it travels through the bloodstream to the brain, which has its own built-in reward mechanism. When people engage in actions that are important for survival, such as eating, special nerve cells in the brain release chemicals that make people feel pleasure. In this way, the brain's response conditions people to want to repeat these actions in order to feel pleasure.

Substances that are addictive affect the brain's reward system. Instead of teaching people to repeat survival behaviors, though, they "teach" them to take more drugs. The way this happens depends on the substance that is being used. Some drugs, such as heroin* or LSD, mimic the effects of a natural brain chemical. Others, such as PCP, block the sending of messages between nerve cells. Still others, such as cocaine, interfere with the molecules that carry brain chemicals back to the nerve cells that released them. Finally, some drugs cause brain chemicals to be released in larger amounts than normal, such as methamphetamine, a type of amphetamine, also known as "speed." At first, drug use may seem to be fun, because it leads to feelings of pleasure or relaxation. Over time, though, drug use gradually changes the brain so that people need to take drugs just to feel normal.

Who Is at Risk of Addiction?

Addicts come in all shapes, sizes, and ages. The homeless man sleeping on the street may have an addiction, but so may the captain of the high school soccer team. Any person who abuses alcohol or other drugs is at risk of becoming addicted. For some people, however, the risk is especially high. For example, problems with drinking and drug use, just like heart disease or cancer, often run in families. Children whose parents are addicted to alcohol may be more likely than other people to have an alcohol or drug problem themselves.

People who have certain mental disorders also have a higher than average risk of addiction. This is not surprising, because it is thought that many mental disorders are caused in part by an imbalance in the same kinds of brain chemicals that drugs affect. People who suffer from depression, for example, may find that a certain drug lifts their mood for a while. The "self-medication" theory of addiction asserts that people learn to cope with a particular mood by taking a drug, in a misplaced effort to relieve their mental pain.

What Are Some Addictive Drugs?

People can become addicted to a wide range of substances, including alcohol, amphetamines, cocaine, heroin, inhalants*, LSD, marijuana*, morphine*, tobacco, PCP, and sedatives*, just to name a few commonly abused drugs.

Marijuana addiction Some people believe that marijuana use is relatively safe, because it does not lead to addiction. However, regular marijuana users may become psychologically dependent on the drug. Some longtime, heavy users also can experience mild signs of physical dependence, including tolerance and withdrawal. Some studies suggest that marijuana affects the brain's reward system in much the same way as other addictive drugs.

Alcohol addiction Alcoholism (AL-ko-hall-i-zm) is the common name for an addiction to alcohol. Some people with alcoholism develop a tolerance that lets them drink large amounts of alcohol without seeming drunk or passing out. Others have severe withdrawal symptoms if they stop drinking. Delirium tremens (de-LEER-ee-um TRE-munz) is the name given to the most severe withdrawal symptoms seen in people who have alcoholism. These symptoms include confusion, disordered thoughts, and hallucinations*.

Tobacco addiction Cigarette smoking is a difficult habit to break, because tobacco contains nicotine, a highly addictive substance. Smokers can build up a tolerance for nicotine, as shown by the fact that most smokers increase the number of cigarettes they smoke as they continue to use tobacco. They also go through withdrawal when they are unable to smoke, which explains why many smokers rush to light up as soon as they leave a place where smoking is not allowed.

Caffeine addiction Caffeine (ka-FEEN), a substance found in coffee, tea, colas, and many nonprescription medicines, is a widely used mind-altering chemical. It is no accident that coffee, a potent source of caffeine, is the favorite wake-up drink in so many homes. People often use caffeine for the temporary surge of energy it produces, much like the “buzz” that comes from some other drugs. Owing to tolerance, however, it eventually takes more and more caffeine to get this feeling. When daily coffee drinkers stop using caffeine, they may have withdrawal symptoms, such as headaches, fatigue, and irritability.

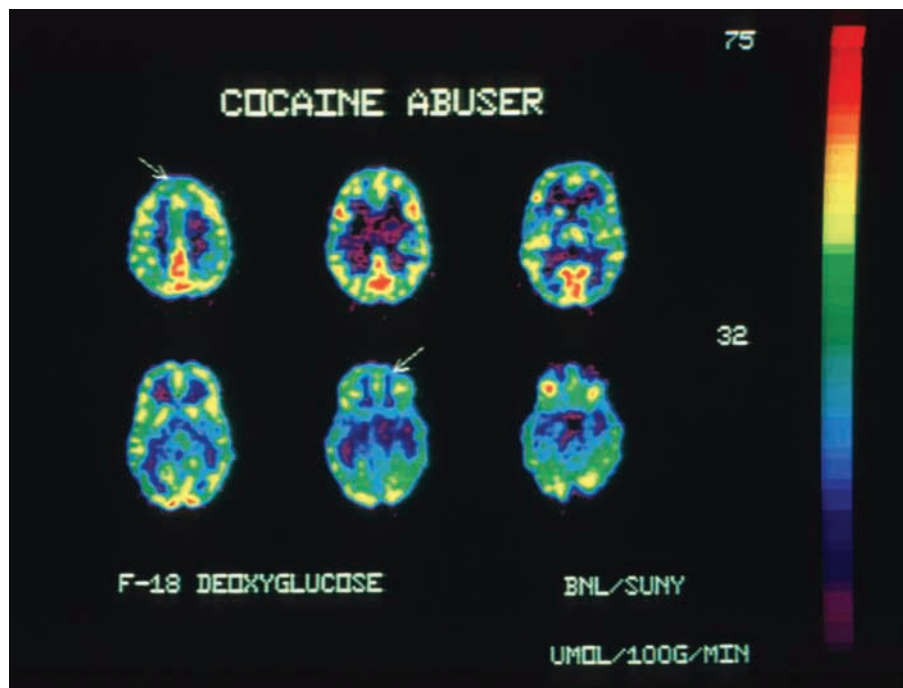

What Is an Addictive Disorder?

People may also develop harmful behavior patterns that share many of the same traits as dependence on alcohol or other drugs. Such behaviors sometimes are referred to as addictions although the abuse of a substance is not involved. Among the types of behavior that can be taken to an unhealthy extreme are gambling, sexual activity, and Internet use. When people say they have an addiction to gambling, for example, they mean that they have trouble controlling their desire to gamble, even when they experience harmful consequences, such as losing a lot of money.

Experts disagree about whether this kind of out-of-control behavior should be termed an addiction. Many doctors prefer to call it an impulse control disorder. People with an impulse control disorder are unable to curb their urge to do something that is harmful to themselves or others, even though they may try to resist and feel guilty for failing to do so. In everyday conversation, though, people often refer to excessive gambling, promiscuous and risky sexual activity, and Internet use as addictions, because people with these problems act much like people who are addicted to alcohol or other drugs. Rather than responding to outside chemicals, however, such people may be responding in part to natural chemicals released inside the brain. Exciting activities, such as gambling and certain risky sexual behavior, can trigger the release of brain chemicals

* **hallucinations** (ha-LOO-sin-AY-shuns) occur when a person sees or hears things that are not really there. Hallucinations can result from nervous system abnormalities, mental disorders, or the use of certain drugs.

People who use cocaine often feel smart and powerful. Actually, a brain impaired by cocaine use is less active than a healthy brain. These positron emission tomography (PET) scans show areas of high brain activity in red and yellow. Note that brain activity is reduced in the cocaine user, especially in the frontal lobes (arrows) where ideas, thoughts, plans, and memories are created. *Pascal Goetgheluck/Photo Researchers, Inc.*

* **pornography** (por-NAH-gra-fee) refers to any material, such as magazines or videos, that shows sexual behavior and is meant to cause sexual excitement.

that have an arousing effect. This is similar to the effect that people get from taking cocaine or amphetamines.

Gambling addiction Gambling addiction, also sometimes called pathological (pa-tha-LAH-ji-kal) gambling, refers to out-of-control gambling with harmful consequences. Like people addicted to substances, gambling addicts may need to risk ever-increasing amounts of money to feel the same excitement they got from gambling a small amount the first time. They may also become restless or cranky if they try to cut down or stop gambling, which makes it hard for them to quit. The continued gambling causes trouble at home, school, or work. Yet gambling addicts use their habit as a way to escape problems, much the way someone else might use alcohol or drugs as a form of escape. They may find that much of their time is spent thinking about their next bet or scheming to get more money. They also may start lying to friends and family to hide how much they are gambling, or they may need to borrow money to cover their losses. As their financial situation gets worse, they may even turn to stealing. Despite increasing problems, such people find it nearly impossible to stop gambling.

Sexual addiction Sexual feelings and desires are normal, but some people take these natural feelings to an unhealthy extreme, to the point where they are unable to control their sexual behavior. Some people might spend hour after hour looking at pornography*, whereas others might have casual sex with partner after partner. In either case, there can be serious negative consequences. People who spend too much time looking at

WITHOUT DRUGS = WITHDRAWAL

When long-term or heavy drug use suddenly stops, people experience a number of unpleasant and sometimes dangerous symptoms. These symptoms vary, depending on the substance involved. Some addictive substances and the common withdrawal symptoms that follow their abuse are:

- **Alcohol and sedatives:** shaking hands, upset stomach, vomiting, anxiety, sweating, rapid heartbeat, restlessness, trouble sleeping, seizures, and hallucinations
- **Amphetamines and cocaine:** bad mood, tiredness, vivid nightmares, increased appetite, and sleeping too much or too little
- **Caffeine:** tiredness, sleepiness, depression, anxiety, upset stomach, vomiting, and headache
- **Heroin and morphine:** bad mood, upset stomach, vomiting, muscle aches, runny nose or eyes, sweating, diarrhea, yawning, fever, and trouble sleeping
- **Nicotine:** bad mood, depression, trouble sleeping, crankiness, anger, anxiety, short attention span, restlessness, slower heartbeat, increased appetite, and weight gain

sexual pictures or videos may lose friends or drop out of other activities. Those who have numerous sex partners risk an unwanted pregnancy or a sexually transmitted disease (an infection, such as herpes or HIV, that can be passed from person to person by sexual contact).

Internet addiction A problem of the computer age is seen among people who are unable to control their online behavior. Some people feel driven to “surf” websites or play computer games for hours on end, to the point where they lose interest in offline activities. Others spend so much time “chatting” with online buddies that they have no time for real-world friends. Still others who already have trouble controlling their desire to gamble or look at pornography spend a lot of time at websites that cater to their pre-occupations. Like other drug abuse, Internet addiction isolates people and erodes their face-to-face relationships with family members and friends.

What Are the Signs of a Drug Addiction?

It is not easy for others to tell when individuals whom they know have an alcohol or drug addiction, because addicted people work hard to hide the addiction. Addicts themselves may have difficulty recognizing the signs of their addiction. Nonetheless, certain signs do suggest that something is wrong. Typical warning signs in young people include:

- Getting drunk or high on a regular basis
- Having to use more alcohol or drugs to get the same effect

- Wanting to quit but being unable to do so
- Lying about or hiding the alcohol or drug use
- Avoiding friends in order to get drunk or high
- Giving up responsibilities and activities, such as homework or sports
- Pressing others to drink or use drugs
- Taking risks, including having unsafe sex
- Driving under the influence of alcohol or drugs
- Getting into trouble with the law
- Being kicked out of school for a reason related to alcohol or drugs
- Thinking that the only way to have fun is to drink or use drugs
- Being unable later to remember actions while drunk or high
- Feeling run-down, hopeless, or depressed

What Are the Signs of an Addictive Disorder?

People with an addictive disorder may act much like those with alcohol or drug addiction. Typical warning signs include:

- Taking part in the behavior more often or intensely than intended
- Having to increase the behavior to get the same effect
- Wanting to quit but being unable to do so
- Feeling restless or cranky if the behavior stops
- Continuing the behavior despite knowing that it causes real problems
- Giving up other responsibilities and activities, such as homework or sports
- Thinking about or planning for the behavior all the time
- Spending a lot of time on the behavior and its aftereffects

How Is an Addiction Diagnosed and Treated?

An addiction is a tough problem to beat, but it can be done. The first step is to seek professional help. To make a diagnosis, a physician or mental health professional, such as a psychologist, social worker, or counselor, asks the addicted person about past and present alcohol and drug use. If possible, the doctor or mental health professional will also talk to the person's family or friends. In addition, a physician can perform a full medical checkup and may order tests to check for diseases that are more common among addicts. For example, a person who injects drugs might be tested for HIV infection, which can be contracted by sharing needles with an infected person.

Once a diagnosis has been made, there are several treatment options. Medications can help control drug cravings and relieve withdrawal symptoms. These are not the same kinds of drugs that are involved in the addiction but rather medications that help lessen the addiction problem. Talk therapy can help people with addictions understand their own behavior, develop improved self-esteem, and cope better with stress. For most people, a combination of medication and talk therapy

TWELVE-STEP PROGRAMS

Founded in Akron, Ohio, in 1935, Alcoholics Anonymous (AA) is a self-help group with a 12-step program that addicts work through to become free of their addiction. AA had grown to nearly 2 million members in more than 99,000 groups worldwide as of 2009. Not surprisingly, dozens of other self-help groups have copied its model.

A generic version of the 12 steps follows.

1. We admitted we were powerless over our addiction—that our lives had become unmanageable
2. Came to believe that a Power greater than ourselves could restore us to sanity
3. Made a decision to turn our will and our lives over to the care of God as we understood God
4. Made a searching and fearless moral inventory of ourselves
5. Admitted to God, to ourselves and to another human being the exact nature of our wrongs
6. Were entirely ready to have God remove all these defects of character
7. Humbly asked God to remove our shortcomings
8. Made a list of all persons we had harmed, and became willing to make amends to them all
9. Made direct amends to such people wherever possible, except when to do so would injure them or others
10. Continued to take personal inventory and when we were wrong promptly admitted it
11. Sought through prayer and meditation to improve our conscious contact with God as we understood God, praying only for knowledge of God's will for us and the power to carry that out
12. Having had a spiritual awakening as the result of these steps, we tried to carry this message to other addicts, and to practice these principles in all our affairs

works best. Talk therapy can be done one-on-one with a therapist or in a group.

Many people do quite well being treated at a clinic while living at home, but others may need to spend a short time in a hospital or other controlled setting. These may be appropriate for individuals who have other mental disorders, are not motivated to change, have friends who still use alcohol or drugs, or have failed in past treatment efforts. Peer group self-help programs, such as Alcoholics Anonymous or Narcotics Anonymous, are cornerstones of treatment for addiction problems.

Medications Some medications block the effects of addictive drugs and relieve withdrawal symptoms. For example, methadone (METH-a-don) is a medication used to treat heroin withdrawal, whereas naltrexone (nal-TREK-zone) blocks the effects of heroin and related drugs. Other medications discourage the use of addictive drugs. For example, disulfiram (dy-SUL-fi-ram) works against alcohol use by causing severe nausea and other unpleasant symptoms when a person who is using it drinks alcohol.

Various forms of therapy Several kinds of talk therapy (psychotherapy) are used to treat addiction. Cognitive (COG-ni-tiv) therapy targets the faulty thinking patterns that lead to alcohol and drug use. For example, people who think that alcohol protects them from pain may be helped to recognize the pain alcohol has caused them (such as loss of friends, work, and self-esteem, along with physical pain such as hangovers). People who use drinking as the only way to cope with problems may be helped to identify other ways to cope with problems. They are then helped to reconsider their old beliefs that alcohol is the only way to cope or that it protects them from pain. By discovering that old beliefs are false, individuals can decide what beliefs are more accurate. In this way, with time and effort, thinking patterns and false beliefs can change.

Behavioral (bee-HAV-yor-al) therapy takes aim at negative forms of behavior, often by using a system of rewards and punishments to replace harmful behaviors with more positive ones. A teenager, for example, might get movie tickets for having a drug-free urine sample or lose the privilege of driving the car as a result of a relapse. Behavioral therapy may also focus on identifying behaviors that keep a drug or alcohol problem in place (such as going to bars for recreation or spending time with friends who drink) and choosing behaviors that help beat the problem (such as going to the gym instead of a bar).

Family therapy works on problems at home that may play a role in alcohol or drug abuse, such as conflict between family members. Family members may be taught to communicate better or to solve problems more effectively.

Self-help groups Self-help groups can be helpful to people who are trying to deal with an addiction and to their family members. Many are 12-step groups, patterned on the 12 steps that are the guiding principles of Alcoholics Anonymous. Those who attend group meetings receive personal support from peers who are fighting the same addiction and trying to solve their problems responsibly.

A partial list of self-help groups follows:

- Chemically Dependent Anonymous, P.O. Box 4425, Annapolis, MD 21403. Telephone: 800-CDA-HOPE. <http://www.cdaweb.org>

Addison's Disease

Addison's disease is a chronic condition that results when the adrenal cortex, the outer layer of the adrenal glands, is damaged, destroyed, or otherwise functioning incorrectly, and the glands are unable to produce enough of certain important hormones. This condition can lead to fatigue, low blood pressure, loss of appetite, and darkening of the skin. While Addison's disease is highly treatable with daily oral medication, it can be fatal if care is inadequate or lacking.

JFK's Story

Many people knew that U.S. president John F. Kennedy (1917–1963) suffered from back pain most of his life. Only after he died from an assassin's bullet in 1963, however, did the public learn that the president also had Addison's disease, a rare condition that results when the body fails to produce enough of certain hormones*.

What Is Addison's Disease?

The adrenal glands are thin triangular groups of cells about the size of an adult thumb. One adrenal gland is located above each of the two kidneys. Among other functions, the glands release hormones known as cortisol and aldosterone. In people with Addison's disease, the adrenal cortex is damaged or destroyed, and the glands no longer release enough cortisol and aldosterone to keep the body working normally.

Cortisol and aldosterone Cortisol helps the body respond to stresses such as diseases and infections. It also helps the body use sugars, proteins, carbohydrates, and other substances in food for energy. Aldosterone helps

signal the kidneys to regulate the amount of salt and water retained in the body, which is important because, without the proper concentrations of salt and water, blood pressure can drop to dangerously low levels.

Autoimmunity Normally, the immune system releases antibodies to fight foreign substances in the body, such as viruses. The cause in about 70 percent of Addison's disease cases is a faulty immune system that turns against the body—a situation known as autoimmunity—and targets the adrenal cortex. Specifically, the antibodies and cells of the immune system destroy the adrenal cortex and cause the glands to release inadequate amounts of cortisol and aldosterone. As of 2009, scientists were not sure why this response occurs.

Other causes The disease also can result from conditions that affect the pituitary gland, which is located at the base of the brain. Normally, this gland secretes a hormone called adrenocorticotropin, which stimulates the production of cortisol in the adrenal glands. When the pituitary is compromised, cortisol levels can drop and cause Addison's disease. In this case, levels of aldosterone are not affected.

A similar condition can occur in patients who have been medicated with daily high doses of cortisol-like drugs usually for a serious disorder involving the immune system. In these patients, the sudden cessation of the medication, or a sudden increase in stress, such as major surgery or a serious infection, can produce symptoms and threats to health that are similar to many of those associated with Addison's disease. These patients should always wear an identification bracelet indicating their drug usage and carry with them a supply of extra medication to meet any needs that arise.

Incidence Addison's disease is rare in the early 21st century. It strikes only about one of every 100,000 persons.

What Are Those Puzzling Feelings?

The first signs of Addison's disease can be puzzling to patients and their doctors. The lack of hormones in the body causes individuals to feel tired and weak. Patients also can feel dizzy due to low blood pressure. Appetite

THOMAS ADDISON

The 19th-century British physician Thomas Addison (1793–1860) was the first to connect the symptoms of Addison's disease to problems with the adrenal glands. At that time, the disease was more common because tuberculosis was widespread, and people with tuberculosis may develop Addison's disease if the infection involves and destroys the adrenal glands.

Autoimmunity

Addison's disease is one of many diseases that are considered autoimmune disorders. Normally, the immune system protects the body from foreign substances, such as viruses. Sometimes, however, it attacks the body's own cells, tissues, and/or organs, causing a wide variety of medical conditions. AIDS, lupus, type 1 diabetes mellitus, and rheumatoid arthritis are just a few of the more than 80 known autoimmune disorders. Together, autoimmune diseases affect an estimated 5 to 7 percent of the human population.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

drops, and they start to lose weight from not eating as much. Because salt levels are out of balance in the body, people with Addison's might also feel hungry for salty foods, such as potato chips.

Sometimes people get sick to their stomachs and vomit, and they can develop dark areas on the skin, as if they are tanning. They also can seem unreasonably upset in response to certain circumstances or become depressed.

Addison's usually develops slowly over many years. The symptoms might be noticed but ignored or explained away as the result of working too hard or not exercising enough. About 25 percent of people with Addison's disease do not seek medical help until an accident or other illness triggers a sudden worsening of their symptoms. Without medical help, the sudden worsening can be fatal.

How Do Doctors Diagnose and Treat Addison's Disease?

Generally, doctors first suspect Addison's disease following a careful review of a given patient's medical history and symptoms, which may be as innocuous as darkened patches of skin or a desire for salt. Various tests can be used to check for the proper levels of the hormones involved in Addison's disease. In addition, doctors can use an abdominal x-ray or other diagnostic tests to obtain an image of the adrenal glands to see if they look damaged or if they reveal calcium deposits that are a sign of tuberculosis. If necessary, they may also employ another tool, called a computerized tomography* scan, to look at the pituitary gland.

People with Addison's disease need to take prescription hormones to do the work of the missing cortisol and, if necessary, aldosterone. Most of the time, taking the prescribed hormones allows people with Addison's to avoid the disease's symptoms.

Individuals might experience a return of severe symptoms, such as low blood pressure or elevated potassium levels, if they become ill with another condition. Because these symptoms can be fatal, doctors recommend that people with Addison's wear a medical identification bracelet that explains their condition. The bracelet is especially helpful if the individual suddenly becomes sick and is unable to communicate with those trying to help.

With treatment, however, people with Addison's disease can live as long and as well as people without the disease typically do.

Agenesis of the Corpus Callosum

Agenesis of the corpus callosum is a medical term used to describe the partial or complete absence of the corpus callosum during the development of a fetus. Because the corpus callosum fails to develop normally, the two hemispheres of the brain are functionally disconnected resulting in a wide spectrum of medical consequences.

The disconnected hemispheres of a brain affected with agenesis of the corpus callosum. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

* **white matter** a group of nerve fibers insulated with a material known as myelin that affects the speed of nerve impulse transmissions and has a white appearance

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

* **chromosomes** (KRO-mo-somz) are threadlike chemical structures inside cells on which the genes are located. There are 46 (23 pairs) of chromosomes in normal human cells. Genes on the X and Y chromosomes (known as the sex chromosomes) help determine whether a person is male or female. Females have two X chromosomes; males have one X and one Y chromosome.

* **prenatal** (pre-NAY-tal) means existing or occurring before birth, with reference to the fetus.

* **insomnia** abnormal inability to get adequate sleep.

What Is Agenesis of the Corpus Callosum?

The corpus callosum is a bundle of nerve fibers that connect the right and left hemispheres of the brain. It is made up of 200 to 300 million fibers of the type known as white matter*, which is a group of nerve fibers covered in a substance called myelin that affects the speed of nerve impulse transmission. The corpus callosum is located in a band right down the midline of the brain. Its function affects the sensory systems, motor function (movement), learning, memory, and thought processes. Different parts of the band have an effect on specific functions.

Agenesis of the corpus callosum (ACC) is a medical term used to describe the partial or complete absence of the corpus callosum during the development of a fetus*. Sometimes the terms hypogenesis or dysgenesis are used instead of agenesis, specifically when the corpus callosum is only partially absent or malformed, respectively. Because the corpus callosum failed to develop normally, the two hemispheres of the brain are functionally disconnected. The varying degrees of agenesis lead to a wide spectrum of medical consequences. The occurrence of ACC is often associated with other physical abnormalities. The frequency of ACC in the United States is low at 0.7 to 5.3 percent.

Causes of Agenesis of the Corpus Callosum

The corpus callosum develops in the fetus around the 10th and 11th week of pregnancy. If fetal development is disrupted during this period, the corpus callosum may be negatively affected. The exact cause of ACC is unknown, but multiple factors may be involved. ACC may be caused by errors in the chromosomes* or the inheritance of some unknown genetic factor. Disruption of corpus callosum development may also be due to prenatal* infections, injuries, or exposure to toxins. The corpus callosum may be kept from forming properly when blocked by cysts that form in the developing brain.

Signs and Symptoms of Agenesis of the Corpus Callosum

Abnormalities of the corpus callosum can occur as in isolation. However, abnormalities in corpus callosum development often occur with other medical problems. The number or type of medical complications an individual has in association with the degree of corpus callosum agenesis determines what the individual's symptoms are. There are some medical signs that appear in most people with ACC, in various degrees of severity. The range can be from slight to seriously disabling.

Physical and structural defects Many individuals with ACC may have the following problems: vision defects such as nearsightedness or difficulty with depth perception; difficulty feeding as a baby, gastric reflux problems, or problems chewing and swallowing; low muscle tone and weakness; sleep problems such as insomnia* or bed-wetting; abnormal facial features; seizures; hearing defects; chronic constipation; low perception of

pain. Less often seen are heart problems, defects in the skeletal system, or genetic conditions.

Developmental defects Many children with ACC do not develop normally or reach standard developmental milestones in the expected time. Milestones associated with movement are known as motor milestones. They may be delayed in ACC and include general coordination, walking, and riding a bike. Other potentially delayed developmental abilities include speech and toilet training.

Behavioral defects Children with ACC tend to have a lack of self-awareness and consequently tend to be socially immature. They may have difficulty interpreting and responding appropriately to other people. These children may have increasing social difficulty with age, due to the increasingly complex nature of social interactions. Children with ACC may be hyperactive and have difficulty paying attention for long periods of time. Obsessive compulsive behaviors and timidity may also be seen.

Cognitive defects Cognitive* defects are problems with communication, thought processes, language usage, and judgment. Individuals with ACC may have explicit mental retardation*, or they may seem to have normal intelligence if the ACC is partial and an isolated medical incident. However, even those with seemingly normal intelligence are thought to have some form of more subtle cognitive difficulties. Individuals with ACC may have difficulty interpreting people's facial expressions or verbal cues. Tasks requiring problem-solving skills such as finances or scheduling events may prove difficult. Unfortunately, individuals with ACC are often not aware of their limitations and may attempt to perform tasks beyond their abilities, with poor awareness of the consequences. Abstract language concepts such as the use of slang or sarcasm may not be understood by people with ACC. Confabulation*, making up information that is not true while convincing oneself that it is true may also occur in ACC.

How Is Agenesis of the Corpus Callosum Diagnosed?

ACC can be diagnosed using medical tools that perform brain scans. Brain scans can be performed using a variety of techniques that provide an image of the brain for physicians to analyze and search for missing structures. Prenatal ultrasound* or MRIs* may be performed to look for a defective corpus callosum. CT scans* are also used to view the structures of the brain, but MRIs provide the most detailed information.

Treatment and Prognosis of Agenesis of the Corpus Callosum

No medical treatment as of the early 2000s was available to rectify the defective development involved in ACC. Some treatment may be available to relieve symptoms associated with ACC, such as constipation or seizures.

* **cognitive** associated with thinking, learning, perception, awareness, and judgment

* **mental retardation** is a condition in which people have below average intelligence that limits their ability to function normally.

* **confabulation** filling in gaps in memory by making up or fabricating facts. The gaps occur because the memory function is impaired.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **MRIs** a procedure in which magnetic resonance imaging is used.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

However, behavioral therapies, educational programs, and support groups may assist an individual with ACC in leading a more satisfying life.

The prognosis for ACC varies with the type and degree of corpus callosum abnormality and associated medical conditions. The corpus callosum cannot regenerate or degenerate, meaning that once formed it cannot regrow or continue to deteriorate. Some individuals with ACC may seem to have average intelligence and lead normal lives, but they cope at least with slight deficiencies in cognition in contrast to individuals without ACC.

Aging

Aging is the accumulation of changes in a living organism over time. Most organisms have a predictable pattern of development and an easily established life expectancy. However, with humans, the patterns of development and life expectancy itself have been throughout the ages subject to a wide range of threatening environmental and social conditions that came under some control only in the 19th and 20th centuries. Disease has always been one of the greatest environmental threats. Military action, slavery, and other forms of physical cruelty affect life expectancy. As disease is eradicated, diet is improved and the social threats are ameliorated, human life expectancy tends to increase proportionately. Nevertheless, new environmental and social threats continue to evolve. Diseases such as AIDS, Ebola virus, avian flu, and epidemic metabolic syndrome, along with climate change*

The faces of aging from child to senior.
 Frank Schwere /Stone+/Getty Images.

and habitat reduction forcing hostilities over diminishing resources, are 21st-century threats to human life expectancy. In the early 2000s, the refusal of nuclear powers, including the United States, to seriously limit the deployment of nuclear weapons while continuing to use military force to exercise global strategies in the interest of their perceived needs represents another real threat to human longevity.

Jerry and Saba at 32

Since grade school, Jerry was always the best athlete among his peers. Even in his mid-20s, when most of his friends gave up the weekly softball game, he was still the best pitcher, best hitter, and best runner. Now at

- * **prenatal** (pre-NAY-tal) means existing or occurring before birth, with reference to the fetus.
- * **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.
- * **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.

age 32, he is losing his love for the game. Not only are the younger players better athletes, but he is having difficulty in coming close to his best game. In previous years, he was always getting better at the game, but now he realizes that he cannot take age-related improvement for granted. He recognizes that his wife Saba is beginning to gain weight even as she makes effort to retain her figure. But she looks much younger than her younger sister, who smoked for many years and now has dry skin and the beginnings of wrinkles. Saba's work requires her to update her skills through yearly training exams. During these trainings she realizes that her memory skills are not as strong as they used to be, yet she still is able to do very well on the training assessment. Jerry and Saba enjoy the company of their friends, but now their reciprocal relationship as a married couple has replaced outside friendships and the importance those once held in their lives. On the threshold of middle-age, Jerry and Saba are experiencing the changes that come with more advanced aging.

Humans accumulate change in three different domains: biological, psychological, and social. As people grow older, their bodies first grow stronger and then begin to deteriorate. Their psychological characteristics also change over time as they exhibit shifting personality traits and use different intellectual abilities. Aging in the social domain is marked by the changing expectations that others have of people as they age.

Aging and Child Development

Biologically, aging begins with prenatal* development. The fetal period is the time when the developing fetus* gradually becomes a viable human being that will be able to survive outside of the uterus*. The accumulated successes of the prenatal period make it likely that a healthy infant will be delivered and will grow in strength, mass, and physical ability for the next 25 to 30 years.

The first years of life are important for growth and the development of vital functions. The changes that mark the first two years are rapid, and they are of such importance that any delay in any area of growth or development can be detrimental. The pediatricians who care for the newborn encourage regular monthly check-ups to make sure that the baby's growth and attainment of developmental milestones are normal. Because the baby changes so much from week to week, aging in infancy is measured in months (as compared to years in older children and adults). Some childhood behavioral assessments, such as the Revised Gesell Developmental Schedules, use months as the benchmarks for children under five years of age. The developers of these schedules note the maturational changes in abilities and behaviors that occur each month in the first five years.

Changes in a child's psychological profile are first noted in the initial months of a child's life. As the physical senses become more acute and the perceptions of sensory stimuli become more accurate, the child begins to make better sense of the world. One milestone taking place at around eight months is the development of depth perception. A baby needs

about one month of crawling experience to understand that the world is three-dimensional. A seven-month-old baby who has just started crawling will take some risks with stairs or other possibilities for a tumble that an eight-month-old is likely to avoid. Around 15 months, the baby develops some self-awareness, as noted by the baby's recognizing that the image in the mirror is a reflection of self. Communication skills begin long before the first words, with cries, gestures, and babbling. After two years of age, the baby makes rapid strides with respect to language proficiency.

The social expectation in infancy is the bonding between the baby and the primary caregiver who is usually the mother. This bonding, known as attachment, is very important for the child's psychosocial development. It begins with the mother's responding to the infant's needs in a way that assures the infant that life is meaningful and that the world is predictable.

Childhood, as a period of aging, extends from age two until puberty*. During this time the child grows continuously. Before the growth spurt associated with puberty, an average child will achieve about 85 percent of adult height. During childhood, the child becomes more adept at gross motor skills (such as those used in sports) and fine motor skills (such as those used in drawing or writing).

Psychologically, childhood is the time during which a person begins to develop self-reliance. The child also recognizes similarities and differences between self and others and begins to develop a self-concept. New mental abilities enable the child to learn what is taught at school and in other social settings. What is taught and what is seen as important to the child's development and education are culturally and environmentally determined.

In the social domain, children begin spending time outside the home and, therefore, have to learn to make friends. As they grow, their concept of friendship evolves. Preschool children accept any playmate as a friend, but as children grow older, they become selective. They also have to learn rules of society. As children generally like to experiment with new surroundings and new opportunities, they inevitably come to realize that their actions and choices have consequences.

Adolescence is a time of rapid change in all three domains. Physically, the adolescent is changing from a child to an adult. The onset of puberty, accompanied by a growth spurt (coming a little earlier for girls than for boys), is the time at which the physical body first becomes capable of sexual reproduction. In addition to changes in reproductive organs and reproductive functions, the secondary sexual characteristics, the traits that distinguish the two sexes, begin to appear.

In the psychological domain, there is exploration of all kinds, as the adolescent works to develop a sense of identity. It is important that adolescents have positive exploratory experiences, and the hoped-for outcome is that they have acquired a vocational goal, individual values, and a mature personality. Adolescents are aided in this exploration by their more advanced

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

* **dementia** (dih-MEN-sha) is a loss of mental abilities, including memory, understanding, and judgment.

and more sophisticated cognitive abilities. In comparison to children, adolescents are more capable of abstract thinking. For the first time in life, they think about the future in a serious way. Young people at the threshold of adult life are likely to be idealistic.

Socially, adolescents try to break away from the influence of their parents. Peers become more important as adolescents tend to value their perceptions and want their opinions and reactions. Adolescents are required to maneuver in increasingly difficult environments. Their social life can be especially rewarding at this time. However, it also can be difficult and fraught with anxieties and conflict.

Aging after Young Adulthood

After adolescence, the physical body continues to grow stronger, reaching a peak or plateau between 25 and 30 years of age. Starting in one's thirties, the slow degeneration of the physical body that is part of the aging process begins. While adults gradually lose physical abilities, overall mental abilities tend to increase through middle age. In general, overall mental abilities do not diminish until the age of 65, the common age for retirement. Whether the reduction in overall mental abilities owes more to physical changes in the brain or to reduced mental exercise was still debated as of 2009. The social effects of aging are often seen in how adults draw satisfaction from their unique experiences rather than from novelty and excitement, which the young often crave and regard as essential.

Many people like to think they can minimize the decline in physical ability by maintaining a positive mental outlook. However, professional athletes, for example, cannot deny that in middle age there is a sharp decline in physical ability, agility, and endurance when compared to their earlier peak performance. At the same time, there are middle-aged athletes who perform better than younger people who have not made a habit of daily exercise. Exercise and health patterns throughout life play an important role in the maintenance of physical vigor in the years after the late 20s. After age 35, female reproduction capability decreases more sharply, but men of comparable age do not have an equivalent decline in their likelihood of becoming fathers. However, there is a distinct decline in the number and quality of their sperm cells. Around the age of 50, women enter menopause, which marks the end of their childbearing years.

While middle-aged people who maintain their health may reduce the impact of age-related physical degeneration, the decline in sensory acuity is unavoidable. Vision decline is slow between the ages of 30 and 70 years of age, but after 70 it is more rapid. There is a similar trend for the sense of smell where there is virtually no decline in middle age but a sharp decline in the late 60s. Hearing has a steady decline every ten years from age 30 to 60 when the decline becomes steeper. The body begins responding less effectively to stress. The risk of many diseases starts to increase.

In the elderly, there is a higher incidence of dementia*. In many elderly people, dementia is attributable to brain injury. The dementia may

represent the accumulated effects of alcoholism, the presence of mini-strokes, or a brain tumor*. A common form of dementia is Alzheimer's (ALTS-hy-merz) disease*.

From middle age onward, human neural processing starts slowing down, and in particular, people's reaction time, perceptual accuracy, and ability to perform memory tasks. Brain size changes with age, so that an 80-year-old's brain is on average about 10 percent smaller than it was at age 20. The areas of the brain most affected by this loss are the ones associated with memory. However, it appears that being mentally active can counter this trend as it is likely that mental activity encourages the growth of new neurons and synaptic connections. There is evidence that maintaining a physical exercise regimen throughout one's life, just as it contributes to one's physical agility, contributes to one's mental agility later in life.

One popular assumption in the United States is that growing older is negative and that it is associated with increased difficulties and decreased intelligence. Conclusive evidence for reduced overall intelligence as part of the aging process has not been established. When a group of people take an intelligence test at the same time, the younger test-takers tend to do better than the older ones, which suggests an inverse relationship between age and test-taking ability. This would seem to suggest that as people age, they tend to lose intellectual capabilities. However, in longitudinal studies, where the same people are given intelligence tests many times over a long period of time, there is no decrease in intelligence. In fact, there appears to be an increase in intellectual functioning in middle age, which only starts to decline at around age 65.

There is some decline in the ability to perform memory tasks for older people, particularly in recall tasks. If an older person and a younger person are asked to repeat the name of someone they both just met, the older person is less likely to remember than a younger person is. However, in recognition tasks, there is little difference between old and young. Therefore, if the older and younger persons are given a list of names and asked which one was the name of the person just met, they are equally likely to recognize the name. What has been called crystallized memory stays strong throughout the life of a healthy person. This memory involves recalling facts and knowledge accumulated over the years. However, fluid memory declines with age. This kind of memory pertains to quick decision-making and logic tasks. This decline is slowed, however, in people who practice logic problems regularly.

With regard to the social aspect of midlife aging, one misconception needs dispelling: the midlife crisis. Many people expect that middle age will be a period of bigger problems and less satisfaction. However, there is no scientific justification for such an expectation. On average, there is no increased emotional instability in midlife. Also, there is no decrease in the measure of life satisfaction associated with middle age and old age.

According to the psychologist Erik Erikson (1902–1994), much psychosocial development continues in adulthood and late life. Typically,

Alzheimer's disease

Alzheimer's disease is a progressive degenerative (progressively worsening or becoming more impaired) condition characterized by decreasing memory and brain functions and the gradual loss of identity and life memories. The cause of Alzheimer's disease was not fully understood as of 2009; however, there seemed to be a strong genetic component in the early-onset form of the illness, but a smaller genetic influence in the normal or late-onset form. It was theorized that those who are at risk for Alzheimer's disease (based on family histories) are able to delay the onset of the disease through mental exercises.

* **tumor** (TOO-mor) is an abnormal growth of body tissue that has no known cause or physiologic purpose. A tumor may or may not be cancerous.

* **Alzheimer's (ALTS-hy-merz) disease** is a condition that leads to gradually worsening loss of mental abilities, including memory, judgment, and abstract thinking, as well as changes in personality.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

CURRENT RESEARCH IN HUMAN AGING

Each species has a predictable life expectancy, and there is a definite relationship between genes* and lifespan. Researchers at the National Institute of Aging identified individual fruit flies with a "longevity gene," and through selective breeding doubled the lifespan of the fruit fly in their laboratory. This experiment led many to hope that a similar gene that exerts control over the rate of the aging process may be found in humans to help regulate the rate of the aging process.

Some gerontologists (medical doctors researching the causes and effects of aging) believe that aging should be regarded as a "treatable" condition. While it is impossible to prevent aging altogether, these professionals work to delay the effects of aging for as long as possible. The goal is to increase the productive lifespan of humans and not to merely stretch out their number of years.

young adults are focused on finding a mate; middle-aged adults, on leaving something behind for future generations; and people in late life, on seeking validation that their lives have been meaningful. Those who marry and have children eventually experience an empty nest, when the children grow up and begin separate lives of their own. For many people, this transition is happy, as a new milestone is being passed.

Death is the ultimate effect of aging. People tend to accept death in different ways based on their personal, religious, and cultural views. Grief is an individual experience; there is no model for grief that all individuals follow.

Aging Populations in Modern Times

While more people enjoy longer, more productive lives in the 21st century, there are problems associated with an aging population. Due to better living conditions, better medical treatments, and more nutritious eating habits in modern times than in previous ages, the elderly populations of many countries are increasing. At the same time, the birth rates for many of these countries are decreasing. For the first time in human history, in the United States and elsewhere as of the early 2000s, the population of people over age 65 is greater than the population of children under the age of five. It was anticipated that as middle-aged persons begin to retire there will not be enough younger workers to take their places. Many national social insurance systems, including the U.S. Social Security system, rely on a relatively large working population to support a relatively small retirement generation. The trend at the beginning of the 21st century suggests the advent of a challenge to these systems. One benefit of better health among the elderly is that workers may postpone retirement for many years. However, the elderly will continue to need more health care,

and this burden on the healthcare systems of affected nations will increase as the elderly live longer. As of 2009, many industrialized nations were working on restructuring their healthcare and retirement systems to meet anticipated increased demand.

Agoraphobia

Agoraphobia (a-go-ra-FO-bee-a) is an anxiety disorder that involves intense fear of having a panic attack and avoidance of situations that a person fears may trigger a panic attack, such as leaving the home or being in a crowd. The effort to avoid such situations may greatly limit a person's activities.*

What Is Agoraphobia?

In Greek, the word agoraphobia means “fear of the marketplace.” In English, the term is used to describe a disabling disorder that often leads people to fear being in crowds; standing in lines; going to shopping malls; or riding in cars, buses, or subways. In its most extreme form, the disorder can make people afraid of traveling beyond their neighborhoods or even stepping outside their homes. Put simply, agoraphobia is a fear of fear.

* **panic attack** is a period of intense fear or discomfort with a feeling of doom and a desire to escape. The person may shake, sweat, be short of breath, and experience chest pain.

CHARLES DARWIN, AGORAPHOBIC

Charles Darwin (1809–1882), who developed the theory of evolution, is one of the best-known figures in the history of modern science. Many people do not know, however, that Darwin suffered throughout adulthood from an array of physical symptoms that greatly limited his social activities and later caused many physicians to speculate about what might have been the problem. Thomas Barloon and Russell Noyes, Jr., writing in the *Journal of the American Medical Association*, suggested that Darwin may have suffered from agoraphobia. This interpretation would partly explain Darwin's secluded lifestyle and his resistance to meeting people and speaking before groups.

Agoraphobia refers to an intense, unreasonable, and long-lasting fear (a phobia) of panic attacks and avoidance of situations in which a panic attack might arise. A panic attack is a sudden surge of overwhelming terror that occurs unexpectedly and without logical reason. The person is actually in no real danger. Although it is harmless, a panic attack can cause upsetting psychological symptoms, such as a feeling of unrealness and a fear of losing control, as well as unpleasant physical symptoms, such as a racing heart, sweating, trembling, shortness of breath, chest pain, upset stomach, and dizziness. People with agoraphobia have experienced panic attacks and are fearful about experiencing more attacks.

People with agoraphobia may limit themselves to being in places they think of as safe. Any movement beyond this safety zone leads to mounting worry and nervousness. They may worry about whether they could escape quickly from a certain place if they should begin to have a panic attack there. People with agoraphobia often avoid being on busy streets or in crowded classes or stores for fear that they might feel trapped if they start to have a panic attack. Gradually, fewer and fewer places feel “safe.” Some people reach the point where they are too frightened to leave their homes. Others still go out, but doing so causes great distress, and they may insist that family members or friends go with them. Such self-imposed limits can make it difficult for people to get on with their lives at school and work.

What Causes Agoraphobia?

Typically people with agoraphobia experience the disorder after first having one or more panic attacks. Panic attacks usually strike unexpectedly, making it difficult for people to predict which situations will trigger them. This lack of predictability prompts people to worry about when the next attack will occur. It also conditions them to fear situations in which attacks have happened, even if this fear is unreasonable. As a result, people may begin avoiding such situations. Over time, avoidance actually can reinforce the person's phobia, making the condition worse.

What Are the Symptoms of Agoraphobia?

Agoraphobia typically starts between the ages of 18 and 35. Two-thirds of those affected are women. Most people with agoraphobia also have panic disorder, which means that they have repeated, unexpected panic attacks. A few do not have full-blown attacks, but they have similar symptoms of panic. Individuals with agoraphobia may catastrophize (imagine the worst) about what could happen to them if they left home. For example, they may be afraid to leave home because they fear becoming dizzy, fainting, and then being left helpless on the ground. Without treatment, agoraphobia can cause misery for years.

How Is Agoraphobia Treated?

About one-third to one-half of people with panic disorder eventually go on to have agoraphobia. Treatment of panic disorder can help prevent agoraphobia. Once agoraphobia has set in, people still may be helped by the same kinds of medications and therapy used to treat panic disorder. People with agoraphobia may be helped by exposure therapy (a type of behavior therapy*), in which they gradually are put in situations that frighten them until the fear begins to fade. Some therapists go to people's homes for the first few sessions because individuals with agoraphobia may not feel able to get to a therapist's office. Therapists who do exposure therapy also teach coping skills to help with anxiety. Exposure therapy may involve taking patients on short trips to shopping malls or other places that the patients have been avoiding. As people begin to spend more and more time in feared situations, using coping skills instead of avoidance, they may learn that they can handle their feelings after all.

AIDS and HIV Infection

AIDS—acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome—is the condition caused by infection with HIV, the human immunodeficiency virus. HIV attacks the body’s immune system, leaving one susceptible to life-threatening illnesses. Spread primarily through unprotected sexual activity or needles contaminated with infected blood, HIV/AIDS had become a worldwide epidemic* by the end of the 20th century.*

Carl’s Family: How Could This Happen?

Carl could not have been more shocked when his mother informed him that she was HIV-positive. After all, she worked full time, kept house, volunteered at church, and was raising Carl alone. Ever since Carl’s father had died of brain cancer, she had not even been out on a date. And she

was the last person in the world he could imagine shooting up drugs. How could she have contracted HIV? But Carl had not been told the whole story of his father's death. Yes, it had been cancer, but it was a type of cancer—lymphoma of the brain—that strikes HIV-infected people. Carl's father had died of AIDS.

"I didn't know it until your father got sick," Carl's mother told him, "but when he was your age, he and his friends injected cocaine and heroin. He stopped after a couple of years and got his life together. By the time we met, he believed that was all behind him. He didn't realize he carried HIV until he became sick." By that time he had infected Carl's mother. Carl was lucky: His mother had not passed the virus on to him when he was born. But Carl did not feel lucky. His mother now took five different medicines—19 pills every day—to prevent her from developing full-blown AIDS. Sometimes the drugs made her sick. They cost about \$15,000 per year, and she will have to take them for the rest of her life. But she will stay alive, and unlike millions of children in Africa, Carl will not be orphaned by AIDS.

What Is HIV/AIDS?

HIV HIV is a retrovirus that attacks the human immune system by disabling and destroying a type of white blood cell called a CD4-positive (CD4+) T-cell or T-lymphocyte (Tee-LIM-fo-site), sometimes called a T-helper cell. CD4+ T-cells play a central role in the immune response. HIV enters CD4+ cells and uses the cell's machinery and energy to make new HIV particles. When HIV destroys CD4+ cells more rapidly than the body can replace them, the immune system becomes less effective at fighting cancers and infections caused by bacteria, viruses, parasites, and fungi, and AIDS develops. HIV can also attack some organs directly, including the brain, kidneys, and heart.

There are two major types of HIV. HIV-1 is the cause of the current epidemic. Different subtypes of HIV-1 occur in different parts of the world. HIV-2 is found in parts of West Africa and causes a milder form of AIDS.

HIV attacks T-helper cells, or CD4+ cells, by fitting itself into the cell like a key in a lock. Once it has invaded, it can use its own RNA as a template to make copies of itself, multiplying and traveling through the body. This process destroys the body's own T cells over time; as the T-cell count falls, the body's resistance to germs and disease declines. *Illustration by Molly A. Moore Blessington. Reproduced by permission of Gale, a part of Cengage Learning.*

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **enzyme** (EN-zime) is a protein that helps speed up a chemical reaction in cells or organisms.

* **opportunistic infections** are infections caused by infectious agents that usually do not produce disease in people with healthy immune systems but can cause widespread and severe illness in patients with weak or faulty immune systems.

HIV can mutate (change its genetic characteristics) with amazing speed, so that a single individual may be infected with different strains of the virus. Furthermore, HIV can quickly become resistant to antiretroviral medications (ARVs), rendering them ineffective. These are among the reasons that no vaccine or cure for HIV had been found as of the early 2000s.

AIDS It can take 5 to 15 years for HIV infection to develop into full-blown AIDS. During most of this period, people usually look and feel healthy. Unless they have been tested for HIV, they may not know that they are infected. However, if their condition is left untreated, most people with HIV eventually develop AIDS.

AIDS occurs when HIV has destroyed so many CD4+ cells that a person's T-cell count falls below a critical level, and the immune system can no longer fight off common infections. Many of these are opportunistic infections* (OIs) that rarely occur in people with healthy immune systems but which can be life-threatening in AIDS patients. People with AIDS often repeatedly contract the same OI. AIDS patients are also more likely to develop certain cancers.

WHAT IS A RETROVIRUS?

Viruses are tiny particles, much smaller than bacteria. They are made up mostly of genes*—either DNA (deoxyribonucleic acid) or RNA (ribonucleic acid)—that code for a few proteins. Retroviruses such as HIV have RNA as their genetic material, which means that they reproduce themselves in a backward or “retro” manner.

When HIV enters the human bloodstream, it attaches to receptors on the surface of the CD4+ lymphocyte. It fuses with the cell membrane and injects its RNA into the cell. With the help of an HIV enzyme* called reverse transcriptase (RT), the HIV RNA is copied into DNA. Drugs called RT inhibitors prevent this copying of the viral RNA. The HIV enzyme called integrase inserts the HIV DNA in the host cell's genes, where it may remain hidden for some time.

When the CD4+ cell is activated by the immune system, cellular enzymes make RNA “copies” of the HIV DNA and long chains of HIV proteins. An HIV enzyme called a protease (PRO-tee-ace) cuts the large viral proteins into smaller pieces for making new HIV particles. Drugs known as protease inhibitors interfere with this cutting of the viral proteins.

New HIV particles are released from the lymphocyte and travel through the body, destroying other CD4+ cells. HIV reproduces itself very rapidly and several billion new viral particles may be produced every day. In addition, the HIV RT makes many mistakes, which results in different strains or variants of HIV in a single individual.

OPPORTUNISTIC INFECTIONS

Opportunistic infections (OIs) associated with AIDS can be caused by viruses, bacteria, parasites, or fungi, and they can affect every system in the body:

- Tuberculosis (TB), caused by the bacterium *Mycobacterium tuberculosis*, is a very common OI. TB is 100 times more likely to cause illness in an HIV-infected person than in a healthy person. Worldwide, TB kills as many as one in three people with AIDS. Of particular concern is the rapidly increasing incidence of multi-drug-resistant TB (MDR-TB), which is very hard to treat.
- *Pneumocystis* (nu-mo-SIS-tis) pneumonia (PCP) is a very common life-threatening complication of AIDS. It is a fungal infection of the lungs that can spread to the liver, spleen, and bone marrow.
- Oral hairy leukoplakia is caused by the Epstein-Barr virus. Often the first OI to appear in HIV-infected men, it is characterized by white lesions on the tongue.
- *Herpes simplex* virus infections, including genital herpes, are common AIDS-related OIs.
- Cytomegalovirus (syeh-tuh-meh-guh-lo-VY-rus) (CMV) is a herpes virus that is very common in people with low T-cell counts. CMV can attack almost any organ and can cause blindness in AIDS patients.
- Human papillomavirus (HPV) can cause genital warts or cervical cancer.
- Disseminated *Mycobacterium avium* complex are bacteria found in food, water, and soil. Although they are usually harmless in healthy people, they can cause fever, night sweats, diarrhea (dye-uh-REE-uh), weight loss, and lung disease in people with HIV/AIDS.
- Salmonella or common food poisoning is an OI in AIDS patients.
- Bacillary angiomatosis or “cat scratch disease” is a bacterial OI contracted by AIDS patients from cats.
- Histoplasmosis (his-toh-plaz-MO-sis) is a fungal infection that normally does not require treatment. In some areas of the United States, especially in the South and Southwest, almost 80 percent of the population tests positive for histoplasmosis. However, in people with AIDS histoplasmosis can spread from the lungs throughout the body, causing rash, skin sores, nausea and vomiting, and joint pain, and requiring ongoing treatment.
- Cryptosporidiosis (krip-toh-spo-rid-e-O-sis) and isosporiasis (eye-so-spuh-RYE-uh-sis) are gastrointestinal conditions caused by parasites.
- Cryptococcal meningitis (krip-toh-KAH-kul meh-nin-JY-tis), caused by a yeast-like soil fungus, is an infection of the membranes lining the brain and spinal cord. It can lead to coma and death in people with AIDS.
- Cerebral toxoplasmosis (suh-REE-brul tox-oplaz-MO-sis) can destroy parts of the brain and often paralyzes one side of the body.
- Progressive multifocal leukoencephalopathy (loo-co-en-SEF-fal-op-a-thee) is caused by a virus that infects brain cells in late-stage AIDS and is usually fatal.

How Common Is HIV/AIDS?

Although effective measures for preventing HIV infection have been known since the early 1980s, HIV/AIDS continued in the early 2000s to spread throughout the world. Education about the disease and its prevention has played a crucial role in slowing the epidemic. However, changing human behavior to prevent HIV infection proved to be a more intractable problem. New treatments for slowing or preventing the onset

▲ A single HIV virus, seen under an electron microscope, escaping from the body cell (CD4 lymphocyte) that it had invaded. ©NIAID/NIH/Peter Arnold, Inc.

How Did the AIDS Epidemic Begin?

AIDS was first described in the United States in 1981, when gay men in California and New York began developing unusual infections and cancers, similar to illnesses in children born with weak immune systems. However, as early as 1978 cases of what would later be called AIDS were showing up in gay men in the United States and Sweden and in heterosexuals in Tanzania and Haiti. In Africa and the Caribbean, AIDS appeared to be spread primarily through heterosexual contact and sometimes babies were born with it. AIDS also seemed to strike people who had received blood transfusions and drug addicts who shared needles. HIV was identified as the causative agent of AIDS in 1983, the same year that the Centers for Disease Control and

of AIDS in HIV-infected people led to some complacency about HIV/AIDS prevention.

The United States Between 1981 and 2006 there were 982,498 diagnosed cases of AIDS in the United States and 545,805 deaths; thus, by 2006 there were 436,693 Americans living with AIDS. The CDC estimates that there were approximately 56,300 new HIV infections in the United States in 2006. This rate is higher than previous estimates, not because the number of new infections increased but because the technology for tracking new infections improved. The CDC suspected that the number of new HIV infections in the United States remained relatively stable between the late 1990s and the early 2000s.

In the United States, in the early 2000s, gay and bisexual* men remained the population that was most severely affected by HIV/AIDS. Although men accounted for 73 percent of new infections in 2006, women of color infected through heterosexual activity constituted the fastest-growing group of HIV-infected Americans. Young people between the ages of 13 and 29 accounted for more new infections than any other age group. The CDC estimated that new infections in 2006 were contracted in the following ways:

- 53 percent resulted from male-to-male sexual contact
- 31 percent resulted from high-risk heterosexual contact
- 12 percent resulted from injected drug use.

As of the early 2000s African Americans were disproportionately and more severely affected by HIV/AIDS than any other racial or ethnic group in the United States. Blacks accounted for almost half of all Americans living with HIV/AIDS, and they did not survive as long as patients in other racial and ethnic groups. In 2006 black men accounted for 41 percent of all male Americans living with HIV/AIDS, and black women accounted for 64 percent of all female Americans with HIV/AIDS. Blacks accounted for 45 percent of new infections in 2006, seven times the rate among white Americans. Hispanic Americans had three times the rate of new HIV infections as white Americans.

The HIV/AIDS Epidemic Worldwide The HIV/AIDS epidemic is far worse in other parts of the world than in the United States. In 2007 an estimated 2.1 million people died of AIDS-related causes and another 2.5 million became infected with HIV. Globally about 33.2 million people were living with HIV/AIDS in 2007, up from fewer than 10 million in 1990. More than 20 million of these people were in sub-Saharan Africa where, in 2007, 6 percent of the population between the ages of 15 and 49 was infected with HIV. In 2007 sub-Saharan Africans accounted for 67 percent of all people living with HIV and 72 percent of all AIDS deaths. By 2007 more than 12 million children in sub-Saharan Africa had been orphaned by AIDS. Worldwide 50 percent of adults with HIV are female, the vast majority having contracted the infection through heterosexual relations.

The number of new HIV infections worldwide declined from 3 million in 2001 to 2.7 million in 2007. Although the epidemic had stabilized or begun to decline in most sub-Saharan countries, in many countries outside Africa, HIV infection was on the rise.

Two million children under age 15 were living with HIV in 2007, almost 90 percent of them in sub-Saharan Africa. An estimated 370,000 children under age 15 became infected in 2007. However, new HIV infections and AIDS deaths among children declined between 2002 and 2007 due to better control of mother-to-child transmission and increased access to treatment. By 2007 nearly 35 percent of HIV-positive pregnant women worldwide were receiving anti-retroviral (ARV) treatment.

People in developing countries have had far less access to HIV/AIDS medications. However, by the end of 2007, the number of people in low- and middle-income countries who were receiving ARV medications had increased 10-fold in six years, to some 3 million people.

How Does HIV Spread?

Sexual intercourse, either homosexual (between men) or heterosexual (between men and women), is responsible for most HIV infections. Although there are documented cases of transmission of the virus as a result of sexual contact between two women, the incidence of transmission by this means is exceedingly small and close to zero. HIV can be transmitted through vaginal*, anal, or oral intercourse. The virus also spreads among people who share needles when they inject drugs. Infected mothers may pass HIV to their babies during pregnancy, childbirth, or breastfeeding. People can infect others with HIV before they have developed any symptoms or are aware that they are HIV-positive.

Having another sexually transmitted disease, such as syphilis*, genital herpes*, chlamydial infection*, gonorrhea*, or bacterial vaginosis*, appears to increase one's susceptibility to HIV infection during sex with an infected person.

HIV is spread through the mixing of body fluids, including the following:

- Blood
- Semen*
- Vaginal fluids
- Mucous membranes*
- Breast milk
- Any other body fluid containing blood

HIV can be transmitted through any blood-to-blood contact. Because it can be difficult to see small breaks in the skin such as hangnails, precautions should be taken when coming into contact with any cut or wound on someone who could be infected with HIV. Medical personnel are at risk through accidental injuries with medical instruments—such as needles and scalpels—that have been contaminated with the blood of an

Prevention (CDC) warned that the blood supply might be at risk. Within just a few years HIV/AIDS had become one of the worst epidemics in human history.

Where Did HIV Come From?

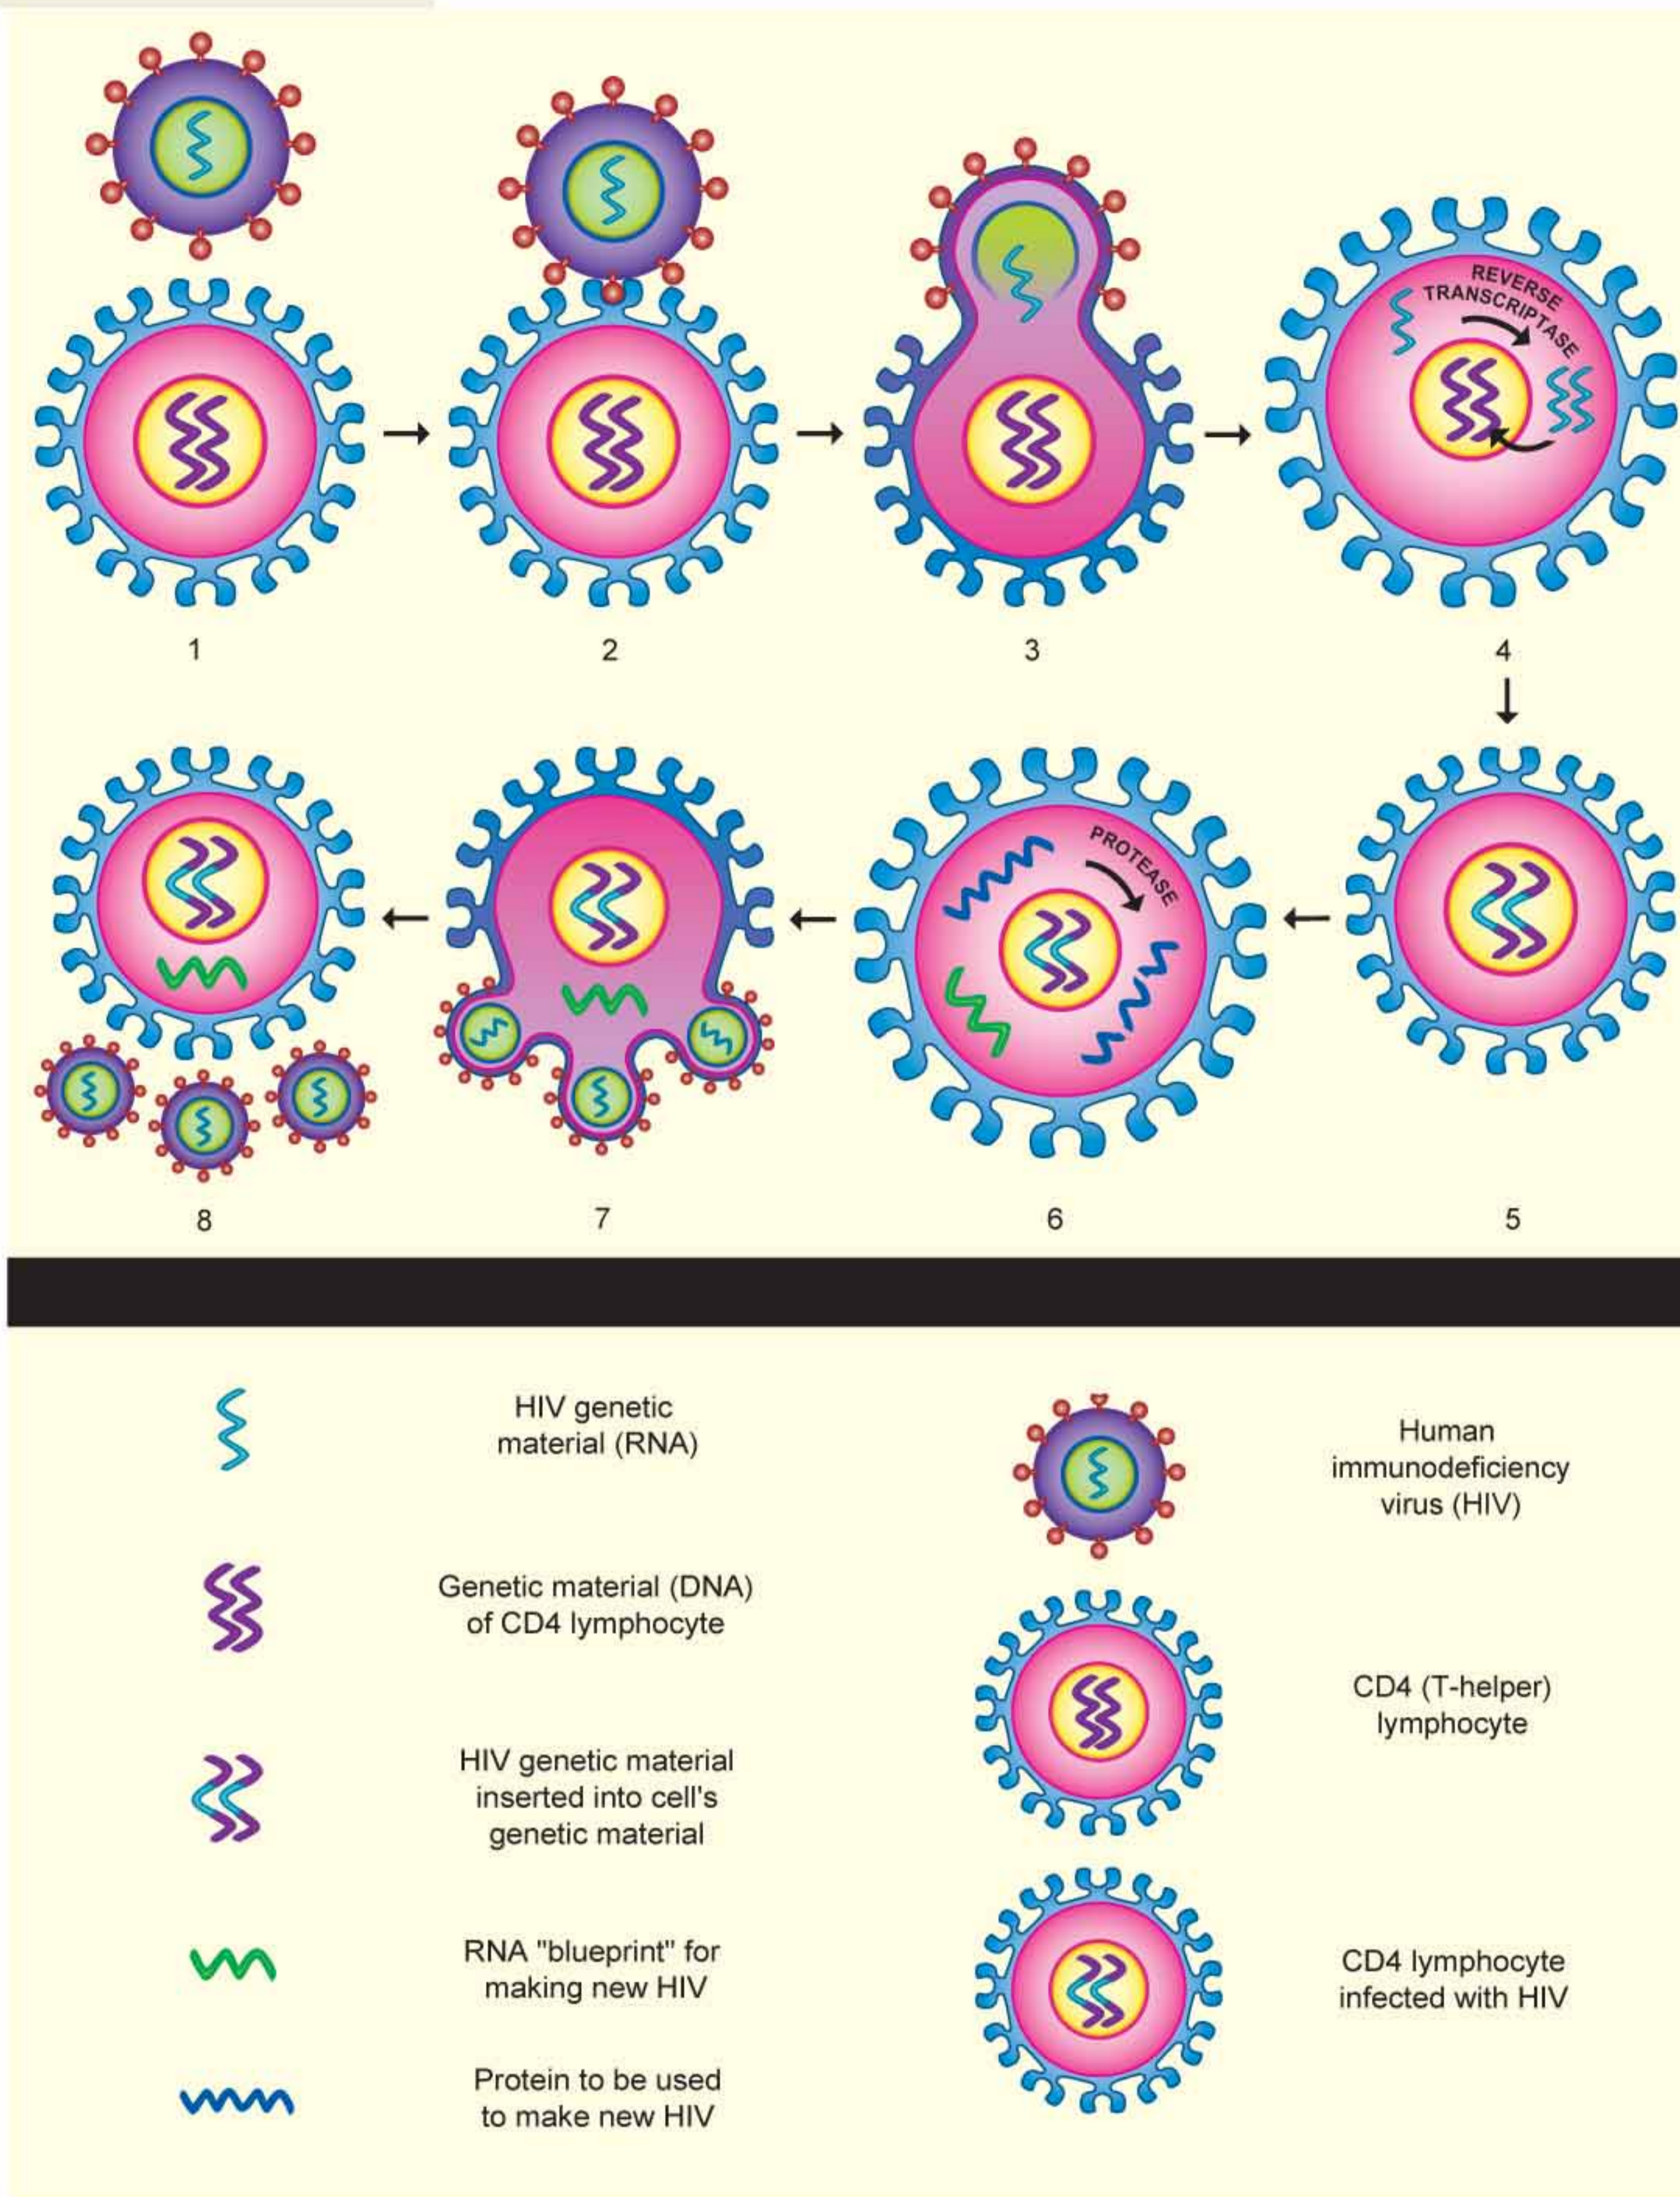

Scientists suspected that HIV arose in Africa from a monkey virus known as SIV (simian immunodeficiency virus). The oldest known HIV was found in a blood sample taken from an African man who died in 1959. In 1999 an international team of researchers found a virus that appeared to be a genetic blend of HIV and SIV in a subspecies of chimpanzee, *Pan troglodytes troglodytes*. Researchers suspected that humans first became infected with SIV in the 1950s while hunting chimpanzees for food. Once in humans, the virus mutated into the deadlier HIV.

* **bisexual** (bi-SEK-shoo-al) means being sexually attracted to both sexes.

* **vaginal** (VAH-jih-nul) refers to the canal in a woman that leads from the uterus to the outside of the body.

* **syphilis** (SIH-fih-lis) is a sexually transmitted disease that, if untreated, can lead to serious life-long problems throughout the body, including blindness and paralysis.

* **genital herpes** (GEN-eh-tal her-PEES) is a viral infection transmitted by intimate contact with an infected person. The herpes simplex type 2 virus enters the mucous membrane and settles in nerves near the spinal column. When an infected person has an outbreak, the virus causes blisters at the infection site.

(1) The human immunodeficiency virus (HIV) particle (top) travels through the bloodstream and (2) attaches to the receptor on the surface of a lymphocyte (bottom), an immune system cell involved in fighting infections. (3) Genetic material (RNA) from the virus enters the lymphocyte and, (4) with the help of an enzyme called *reverse transcriptase*, makes copies of itself to be inserted into the genetic material of the host lymphocyte. Drugs known as *reverse transcriptase inhibitors* act at this step to block the virus' genetic material from copying itself. (5) Copies of the virus' genetic material are inserted into the genetic material of the lymphocyte. (6) This new genetic material in the cell causes the lymphocyte to make the "blueprint" needed for manufacturing new HIV particles. This blueprint contains the code for making virus proteins. An enzyme known as a *protease* acts to clip the large virus protein molecules into smaller pieces so they can be used to make new HIV particles. Drugs known as *protease inhibitors* work at this step by interfering with the processing of virus protein. (7,8) New HIV particles are produced and released from the lymphocyte, which is destroyed. These viruses can then travel through the body and enter and destroy other cells. *Illustration by Molly A. Moore Blessington. Reproduced by permission of Gale, a part of Cengage Learning.*

HIV-infected patient. Although blood transfusions can spread HIV, blood donations and blood products in the United States have been screened for HIV since 1985, and the blood supply was considered to be safe in the early 2000s.

HIV is much less contagious than many other infections such as chickenpox or flu. HIV does not spread through air, water, food, or objects such as doorknobs, eating utensils, clothes, or toilet seats. It is not spread by mosquitoes or other insects. A person cannot “catch” HIV through casual contact such as hugging, shaking hands, playing with, going to school with, or even living with an infected person. There is no evidence that HIV can be transmitted through saliva, sweat, tears, urine*, or feces*.

What Are the Symptoms of HIV/AIDS?

HIV infection Within two months after becoming infected with HIV, most people develop flu-like symptoms, including a fever, sore throat, muscle aches, swollen glands or lymph nodes*, fatigue, and sometimes a measles-like rash. During this period people are very infectious and the genital fluids contain large amounts of HIV. The illness usually disappears within a few weeks, and other symptoms may not appear for 5 to 15 years. Other people have no initial symptoms after contracting HIV. However, the virus can be transmitted to others even in the absence of symptoms.

Although some people have no symptoms of HIV infection until they develop AIDS, over the few years following HIV infection individuals may experience the following occasional symptoms:

- Fevers
- Dry cough
- Night sweats
- Headaches
- Depression
- Swollen glands
- Fatigue
- Skin rashes
- Rapid weight loss
- Persistent diarrhea
- Minor infections such as thrush, a yeast infection (candidiasis) of the mouth characterized by white spots or patches on the tongue or throat
- Shingles, a skin infection caused by the virus that causes chickenpox
- Pneumonia
- Memory loss

Children, especially those infected before birth, generally develop symptoms more quickly than adults. Often these individuals are sick from birth or may fail to grow and develop at a normal rate.

* **chlamydial infection** (kla-MIH-dee-ul) infection can occur in various forms in which the bacteria can invade the urinary and genital systems of the body, as well as the eyes and lungs. One of its most common forms is a sexually transmitted disease (STD), usually passed from one person to another through unprotected sexual intercourse.

* **gonorrhea** (gah-nuh-REE-uh) is a sexually transmitted disease (STD) spread through all forms of sexual intercourse. The bacteria can also be passed from an infected mother to her baby during childbirth. Gonorrhea can affect the genitals, urethra, rectum, eyes, throat, joints, and other tissues of the body.

* **bacterial vaginosis** (back-TER-i-all vag-in-OH-sis) is a condition of the vagina caused by an overgrowth of normal bacteria. Symptoms include an abnormal discharge and fishy odor. This condition is treated with oral antibiotics and vaginal gels.

* **semen** (SEE-men) is the sperm-containing whitish fluid produced by the male reproductive tract.

* **mucous membranes** are the thin layers of tissue found inside the nose, ears, cervix (SER-viks) and uterus, stomach, colon and rectum, on the vocal cords, and in other parts of the body.

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

* **feces** (FEE-seez) is the excreted waste from the gastrointestinal tract.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

- * **sarcoma** (sar-COHM-ah) one of a group of tumors that occur in connective tissue and are mostly malignant.
- * **bone marrow** is the soft tissue inside bones where blood cells are made.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

AIDS The onset of AIDS is usually characterized by the appearance of OIs or cancers that commonly occur in people with severely weakened immune systems. Many of these conditions are considered to be AIDS-defining, meaning that they can constitute a diagnosis of AIDS. Although these illnesses may be treatable or preventable, they tend to recur repeatedly in AIDS patients. Most people who are said to have “died of AIDS” actually die from one of these illnesses.

The most common AIDS-related cancer is Kaposi's (kuh-POE-zees) sarcoma* (KS). KS is characterized by purplish nodules on the skin and is much more common among gay and bisexual men than among other HIV-infected groups. Other cancers associated with AIDS are non-Hodgkin's lymphoma (the uncontrolled growth of lymphocytes), which can involve the central nervous system, liver, and bone marrow*. Lymphoma of the brain can occur in very late-stage AIDS. Invasive cervical cancer in women is also AIDS-associated.

AIDS dementia (dih-MEN-sha) complex is one of the few conditions that is caused directly by the effect of HIV on the brain. Dementia affects concentration, memory, and thinking.

How Is HIV/AIDS Diagnosed and Treated?

The HIV Test Doctors may suspect HIV infection from the symptoms, especially if a person has an OI. However, HIV infection can only be diagnosed by a blood test. The CDC has called for routine HIV screening of all adults and adolescents. In 2008 the American College of Obstetricians and Gynecologists called for routine HIV screening of all women aged 19 to 64 regardless of risk factors, with targeted screening for high-risk women outside that age group and annual retesting depending on a woman's risk factors. Testing is recommended for all pregnant women and for newborns whose mothers are HIV-positive or were not tested during pregnancy. HIV testing is essential for anyone who may have been exposed to the virus or who has had multiple sexual partners or other risk factors.

The most common test for HIV is a blood test to look for antibodies* to the virus. Some tests measure antibodies to HIV in specially collected oral fluid (not saliva) or in urine. Rapid HIV tests give results in about 20 minutes. A positive HIV test is followed by a different test to confirm the positive result. Confirmatory results may take from a few days to a few weeks. With a home HIV test, which is available in pharmacies, a pinprick of blood is dripped onto a specially treated card and sent to a laboratory for testing.

Antibodies to HIV are usually detectable within two to eight weeks following infection. In rare cases it can take up to six months for antibodies to be detected. Therefore, if an initial HIV test following possible exposure is negative, the test should be repeated within a few months. A test that directly detects HIV RNA in the blood can be performed as early as 9 to 11 days after exposure.

Diagnosis of AIDS The onset of AIDS in an HIV-positive individual is diagnosed by the appearance of one of about 26 AIDS-defining OIs or conditions. A blood test that measures the level of CD4⁺ lymphocytes in the body is performed periodically on HIV-infected people. AIDS is diagnosed if there are fewer than 200 CD4⁺ T-cells per cubic millimeter of blood, compared with 1,000 or more in healthy people.

Diagnosis in Newborns About one in four infants born to untreated HIV-infected mothers are HIV-positive. Sometimes infants who are not infected test positive for HIV antibodies for more than a year after birth, due to their mother's antibodies that passed through the placenta*. Therefore, additional tests are performed to determine whether an infant is in fact infected with HIV.

Treatment Treatment with ARV medications begins as soon as possible after a person tests positive for HIV. Initiating treatment immediately, before symptoms appear, increases the likelihood that an HIV-infected person will remain healthy and live longer. ARVs have improved steadily since the 1990s, dramatically increasing the life expectancy of people with HIV, and new drugs are being developed all the time. With proper treatment most patients with HIV/AIDS can live and thrive as well as people with most other chronic medical conditions. However, ARVs do not prevent a person from transmitting HIV to others, and because there is no cure for HIV infection, drug treatment must continue for the remainder of the infected person's life.

A combination of different types of drugs are prescribed in a treatment called HAART (highly active antiretroviral therapy). As of 2009 there were some 30 drugs approved by the Food and Drug Administration (FDA) for treating HIV/AIDS:

- Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) are the oldest class of ARVs. These drugs are faulty DNA building blocks. When they are incorporated into HIV DNA, the RT stops copying HIV RNA into DNA.
- Non-nucleoside reverse transcriptase inhibitors (NNRTIs) bind to RT and prevent it from converting HIV RNA into DNA.
- Protease inhibitors interfere with the protease that HIV needs to make new viral particles.
- Entry and fusion inhibitors interfere with the virus's ability to fuse with the CD4⁺ cell's membrane, preventing the viral RNA from entering the cell.
- Integrase inhibitors block the enzyme that integrates the HIV DNA in the host cell's DNA.
- Multidrug combination products are different classes of drugs combined in a single product.

Regular blood tests measure the amount of HIV in the body (called the viral load) and the CD4⁺ cell count. If the viral load rises above its

* **placenta** (pluh-SEN-ta) is an organ that provides nutrients and oxygen to a developing baby; it is located within the womb during pregnancy.

Protease Inhibitors

Protease inhibitors have proven to be particularly effective in slowing the spread of HIV in the body. HIV uses its protease to cut the new long strands of viral protein into the smaller pieces needed to assemble new viral particles. Protease inhibitors interfere with the cutting action of the protease. Many of the new HIV copies are defective because they contain improperly cut pieces. These defective copies cannot infect other cells.

* **cesarean section** (si-ZAR-ee-an SEK-shun) is the surgical incision of the walls of the abdomen and uterus to deliver offspring in cases where the mother cannot deliver through the vagina.

* **formula** is a prepared, nutritious drink or a dry drink mix designed specifically for infants.

* **hepatitis** (neh-puh-TIE-tis) is an inflammation of the liver. Hepatitis can be caused by viruses, bacteria, and a number of other noninfectious medical conditions.

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

lowest point or the CD4+ count falls, the medications may be adjusted or changed. A given drug regimen or “AIDS cocktail” may fail for the following reasons:

- The person is infected with a strain of HIV that is resistant to the drug(s).
- HIV has mutated in the body to become resistant to one or more of the drugs.
- The drugs are not strong enough to prevent the HIV from multiplying.
- The medications are not being adequately absorbed by the body.
- The patient is unwilling or unable to take the medications as prescribed.

HAART can reduce HIV to nearly undetectable levels in the bloodstream and enable the immune system to recover and fight off illness. However, the virus remains in the brain, lymph nodes, retina of the eye, and elsewhere in the body. HAART can also cause severe side effects and interactions with other medications.

If an HIV-infected woman is treated with particular ARVs during pregnancy and delivery and the newborn is treated immediately after birth, the baby’s risk of HIV infection drops from about 25 percent to about 6 percent. If mothers are treated with ARVs during pregnancy and deliver by cesarean section*, the risk of HIV infection in the newborn drops to about 1 percent. HIV-infected mothers are advised to feed their infants formula* to prevent transmitting the virus through their breast milk.

Complications of HIV/AIDS In addition to AIDS-related OIs and cancers, HIV-infected people often have chronic hepatitis* B, caused by a virus. Viral hepatitis C infection, which can lead to severe liver damage and death, is very common among HIV-infected intravenous drug users. Complications of syphilis are also common with AIDS.

Various medications are used to treat or prevent OIs. For example, adults whose CD4+ cell counts drop below 200 and HIV-infected children whose T-cell counts are below normal are treated to prevent PCP. Following an episode of PCP the treatment is continued indefinitely. AIDS-associated cancers are treated with chemotherapy*, radiation, or alpha interferon.

Living with HIV/AIDS As a result of HAART, a 20-year-old diagnosed with HIV in 2008 who begins treatment immediately can expect to live to age 63, or 13 years longer than the same person diagnosed in 1996. However, it is crucial that HIV-infected people do the following:

- Take all medications exactly as prescribed to prevent the development of HIV drug resistance
- Maintain good general health

- Have adequate exercise and rest
- Follow a nutritious diet
- Refrain from smoking and drug use
- Have regular medical check-ups and tests, preferably by physicians experienced in treating HIV/AIDS

How Can HIV/AIDS Be Prevented?

The best means of HIV/AIDS prevention is to avoid all contact with the bodily fluids of an infected person. Guidelines for preventing HIV infection include the following:

- Avoiding multiple sexual partners
- Avoiding anal sex or other sexual practices likely to cause breaks in the skin
- Avoiding sexual contact with anyone who may be at risk of HIV infection, including anyone who has ever shared needles for injecting drugs, had many sexual partners (promiscuity), or ever had a sexual partner who shared needles or engaged in promiscuity
- Avoiding drugs and alcohol that can prevent people from making good decisions about protecting themselves and others from HIV
- Obtaining prompt treatment for any sore or blister in the genital area through which HIV could enter the body
- Avoiding intravenous drug use and never sharing needles for drugs, steroids, medications, tattooing, or body piercing

Avoiding sexual contact (abstinence), both homosexual and heterosexual, is the only sure way of preventing HIV infection by sexual transmission. The safest sexual relationship is between two uninfected people who have sex only with each other; however, people with HIV may seem completely healthy and often do not know they are infected. Practicing safer sex by always properly using a male latex condom or a female polyurethane condom for vaginal, anal, or oral sex reduces—but does not eliminate—the risk of HIV infection. Other forms of birth control such as spermicides, birth-control pills, or diaphragms offer no protection against the HIV virus.

Unfortunately the availability and effectiveness of ARV drugs in the developed world have led to complacency among some people with regard to safe sex and other practices for preventing the spread of HIV. Meanwhile intensive research in the United States and elsewhere continues to focus on finding an effective vaccine to protect against HIV and substances called microbicides to prevent transmission of the virus.

Albinism

Albinism is an inherited condition in which a person lacks the usual amount of the pigment melanin, which is the substance that gives color to skin, hair, and eyes.

Many people with albinism have skin and eyes much lighter than that of their family members. People with albinism often have vision problems and must take care to protect their skin from sunburn. *Ken Welsh/Alamy.*

What Is Albinism?

Albinism (AL-bi-niz-im) is a group of disorders that occur when a person inherits various genes* that are defective in their ability to make the pigment melanin (MEL-a-nin). Melanin is the main substance that determines a person's skin, hair, and eye color. In the United States, albinism affects approximately one in 17,000 people, although certain types of albinism are more prevalent among specific groups of people. In some parts of Africa, for instance, about one in 1,000 people experience the condition.

The outward signs of albinism vary depending on the amount of pigment a person has, and many people with albinism have skin much lighter than that of their family members. Caucasians with albinism may have white to light-blond hair, pinkish-white skin, and blue eyes, while people who are black may have yellowish hair, skin with a cream-colored tint, and hazel or green eyes. In some people with albinism, the eyes look pink because they contain no pigment to mask the red of the blood vessels in the retina*.

Albinism always affects vision to some degree. The genes responsible for albinism cause abnormal development of the nerve connections between the eyes and the brain. The retina and the iris (the colored portion of the eye) are also affected by albinism.

What Causes Albinism?

Albinism refers to a group of inherited disorders that are often divided into two major categories: oculocutaneous albinism, or OCA, which involves eye, hair, and skin color; and ocular albinism that mainly affects the eyes. Some of these disorders and their causes are:

- **OCA type 1:** This form of albinism, which is characterized by almost no pigmentation, is caused by a defect in a gene for an enzyme* called

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **retina** (RET-i-na) is the tissue that forms the inner surface of the back of the eyeballs; it receives the light that enters the eye and transmits it through the optic nerves to the brain to produce visual images.

* **enzyme** (EN-zime) is a protein that helps speed up a chemical reaction in cells or organisms.

Albinism and the Eyes

Vision is always affected by albinism. Vision problems that can affect people with albinism include:

- sensitivity to bright light
- crossed eyes or “lazy” eyes
- back-and-forth movement of the eyes
- farsightedness
- nearsightedness
- blurry vision

* **chromosome** (KRO-mo-zom) is a unit or strand of DNA, the chemical substance that contains the genetic code to build and maintain a living being. Humans have 23 pairs of chromosomes, for a total of 46.

tyrosinase that normally is involved in producing melanin. OCA type 1 is more common among Caucasians than among people of African descent. Overall, it affects about one in 40,000 people.

- **OCA type 2:** This form of albinism, which is characterized by some pigmentation, is caused by a defect in what is called the “P” gene. It affects about one in 15,000 people overall but is especially prevalent among African and African-American populations, in which it affects approximately one in 10,000 individuals.
- **Hermansky-Pudlak syndrome (HPS):** This form of albinism, which is characterized by easy bruising and bleeding and by a susceptibility to lung and bowel disease, is caused by a different defective gene. Skin, hair, and eye color vary from person to person with HPS. Although this form of albinism is rare overall, it is much more common in Puerto Rico, where it occurs in about one in 1,800.
- **Ocular (eye) albinism:** This form of albinism, which affects mainly the eyes, includes several disorders that are also gene-related. People with ocular albinism often have no loss of pigmentation in the hair or skin.

Most people with albinism are born to parents without the condition, but both parents must carry a copy of the defective gene, and both must pass on that copy to their child. Albinism is a recessive trait, meaning that if a person inherits even one good copy of the gene, he or she will not have the condition. Parents who both carry the trait have a 25 percent chance that each of their newborn children—either boy or girl—will have albinism. Ocular albinism is the exception because most of these cases are caused by a sex-linked genetic defect, which means that the defective gene is carried by the X chromosome*, which is one of two chromosomes that determine a person’s sex. Sex-linked diseases occur most often in males.

Living with Albinism

Vision and skin care are major considerations for people with albinism. The lack of pigment makes eyes and skin very sensitive to sunlight and the skin prone to sunburn. The latter, a feature of people with oculocutaneous albinism, can lead to premature aging of the skin and skin cancer. The use of sunscreen, hats, and/or protective clothing can help prevent overexposure to the sun. Similarly, people with oculocutaneous and with ocular albinism should use sunglasses to shade their eyes and should take care to avoid direct and bright indoor lights, as well as glare from shiny surfaces both indoors and outdoors. Some people with albinism find that their vision problems can be corrected with glasses, but others may require surgery. While many people with albinism can see well enough to drive a car, many others are legally blind. All people with albinism need consistent and continuing eye care.

While people with most forms of albinism have a normal life expectancy, they may face social and emotional hurdles as they learn to live with being different. Support from family and friends is especially important to helping a child with albinism build self esteem.

Alcoholism

Alcoholism (AL-ko-ha-li-zum) is a condition or progressive disease in which people crave alcohol and keep drinking it even though doing so causes repeated problems in many parts of their life.

Jennifer's Story

Jennifer had her first glass of champagne at a family wedding when she was 11. By the time she was 13, she was drinking beer with her friends on Saturday nights. At 15, she was locking herself in her room and drinking alone during the week, when she was supposed to be getting ready for

◀ Alcoholism affects many different parts of the body. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

Campus Life and Alcohol Abuse

Campus fraternity houses have long had an image as places where the alcohol flows freely. Although not all fraternities deserve this reputation, when it is present, this hard-partying lifestyle has taken a terrible toll:

- At Wabash College in October 2008 an 18-year-old student died at a fraternity drinking party. Reports indicated he choked on his own vomit after drinking.
- At the University of New Hampshire, a fraternity was closed in November 2008 when an underage drinking party sponsored by the fraternity caused two students to be sent to the hospital for near-fatal alcohol poisoning (sudden excessive consumption of alcohol).

A study conducted by the Harvard School of Public Health found that binge drinkers in college are 7 times as likely to miss classes and 10 times as likely to damage property as light drinkers. To combat these problems among students, some universities and colleges established alcohol-free fraternities, sororities, and dorms. But the problem of alcohol abuse on campuses continued. According to research summarized in 2005 by the National Institutes of Health, alcohol use nationwide by students between the ages of 18 and 24 was responsible annually for 1,700 deaths; 599,000 injuries; and 97,000 reported cases of sexual assault and acquaintance rape. The report stated that about 25 percent of students have academic trouble (such as poor grades, missing class, and falling behind) linked to alcohol use.

school or doing her homework. At first, drinking seemed exciting. Before long, though, it became something she had to do just to get through the day. Jennifer was not old enough to get a driver's license, but she was already alcohol-dependent.

What Is Alcoholism?

Alcohol is a drug. Alcoholism, also known as alcohol dependence, is a drug addiction (a-DIK-shun), in which people have a strong craving to keep using alcohol even though it causes repeated problems at home, school, or work. Some people call alcoholism a disease because risk factors may be inherited. For certain individuals, often called alcoholics, any use of alcohol predisposes them to use more and more of the substance at the expense of their health and ability to function at work or school. The key traits of alcoholism are:

- Craving: a strong need to drink
- Loss of control: the inability to limit drinking
- Tolerance: the need for ever-increasing amounts of alcohol in order to feel its effects
- Withdrawal: physical symptoms that occur when alcohol use stops after a period of drinking

Alcoholism has little to do with what kind of alcohol people drink, how long they have been drinking, or even how much they drink. What is important is the person cannot control the craving for alcohol, which explains why it is so hard for alcoholics to stop drinking. They may feel the need for alcohol as strongly as other people feel the need for food and water. Although some people are able to break the grip of this powerful craving on their own, most need help to do so.

What Is Alcohol Abuse?

Alcohol abuse refers to overuse of alcohol that can lead to alcoholism. Alcoholics recognize they cannot drink any amount of alcohol and limit the amount they consume. If they begin drinking, they cannot stop. By contrast, alcohol abusers can limit their drinking, but they choose to drink to excess on certain occasions. Thus, when they abuse alcohol, they can get into as serious trouble as any other drunk person can. The distinction between alcohol abuse and alcoholism is a matter of degree, both in behavior and dependence. Abusers of alcohol can experience loss of control and physical signs of tolerance, but if they choose to stop drinking they do not experience painful withdrawal symptoms. Generally speaking, alcohol abuse is a less serious problem than alcoholism, but it still can have very serious consequences. Some symptoms of alcohol abuse are as follows:

- Failing to meet responsibilities at home, school, or work; for example, neglecting chores at home or skipping classes due to drinking
- Drinking in situations that are physically dangerous; for example, just before or while driving a car

- Getting into alcohol-related trouble with the law; for example, being arrested for underage drinking, disorderly conduct, or driving under the influence (DUI)
- Continuing to drink despite relationship problems that are caused or made worse by alcohol; for example, getting into arguments with parents or physical fights with friends or siblings

Alcohol abuse can follow different patterns. Some people are binge drinkers, which means they drink only on certain days, such as on the weekend, and they drink to excess (five or more drinks at one time). Binge drinkers often have accidents that hurt themselves or others or engage in activities while they are drunk that they regret later when they are sober. They are at risk for becoming heavy drinkers (five or more drinks at one time, occurring five or more days per month). Heavy drinkers, in turn, are at risk for becoming alcoholics, because alcohol abusers are at high risk for developing alcoholism.

What Are the Short-Term Risks?

Alcohol dulls the senses, slows reaction time*, decreases coordination, and impairs judgment. It is little wonder that alcohol use is a major risk factor in accidents and injuries. Death by injury is the leading cause of death among individuals from 15 to 20 years of age, and underage drinking is often involved. About two of every five traffic deaths in this age group involve alcohol. Individuals who begin drinking before the age of 15 are seven times more likely to be involved in an alcohol-related car accident in their lifetime, and they are five times more likely to develop alcoholism as an adult.

Alcohol robs people of their ability to think clearly. As a result, people are more likely to engage in risky sexual activity when they are drinking. Thus, they are at higher risk of unwanted pregnancy or sexually transmitted disease*. In addition, some boys believe that it is okay to force a girl to have sex if she is drunk. As a result, girls who drink are at greater risk of being raped* by someone they know. Alcohol is involved in many cases of date rape. Finally, the inability to think clearly causes people who are drinking to take dangerous risks, such as driving under the influence or engaging in daredevil stunts.

What Are the Long-Term Risks?

Alcoholism not only disrupts people's lives but also destroys their health. Long-term, heavy drinking affects almost every organ in the body. The physical risks caused by alcoholism include:

- Liver* disease. More than 2 million Americans have an alcohol-related liver disease. Alcoholic hepatitis (he-pa-TY-tis) is inflammation of the liver, whereas alcoholic cirrhosis (si-RO-sis) is scarring of the liver. Alcohol-related liver disease can cause chronic illness and death.
- Heart disease: Long-term, heavy drinking raises the risk of high blood pressure, heart disease, and some kinds of stroke*.

* **reaction time** is the time it takes a muscle or some other living tissue to respond to a stimulus.

* **sexually transmitted disease** is an infection, such as the human immunodeficiency virus (HIV) or herpes, that can be passed from person to person by sexual contact.

* **rape** is when a person forces another person to have sexual intercourse, or engage in other unwanted sexual activities.

* **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.

* **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

▲ Nathaniel Currier's lithograph *The Drunkards Progress: From the First Glass to the Grave* was published in 1846. *The Library of Congress.*

* **esophagus** (eh-SAH-fuh-gus) is the soft tube that, with swallowing, carries food from the throat to the stomach.

* **larynx** (LAIR-inks) is the voice box (which contains the vocal cords) and is located between the base of the tongue and the top of the windpipe.

* **pancreas** (PAN-kree-us) is a gland located behind the stomach that produces enzymes and hormones necessary for digestion and metabolism.

- **Cancer:** Long-term, heavy drinking increases the risk of cancer of the mouth, throat, esophagus*, larynx*, stomach, pancreas*, liver, and possibly the colon* and rectum*. In addition, women who have two or more alcoholic drinks per day have a slightly higher than average risk of breast cancer.
- **Disease of the pancreas.** Pancreatitis (pan-kree-a-TY-tis) is inflammation of the pancreas. It can cause severe abdominal pain, weight loss, and death.
- **Mental disorders:** Long-term, heavy use of alcohol can cause or worsen several mental disorders, especially depression and anxiety disorders.

Alcohol can also interfere with the body's ability to absorb and use vitamins, especially the B vitamins. Vitamin deficiency can damage the brain and cause problems with thought and memory. In severe cases, it can lead to Wernicke-Korsakoff (VER-ni-kee-KOR-sa-kof) syndrome, the early symptoms of which include double vision, repetitive movements, and loss of coordination. If left untreated, this syndrome leads to irreversible mental impairments.

How Are Women Affected?

Women get drunk more easily than men, even when differences in body weight are taken into account. The reason is women's bodies contain less water per pound than men's bodies. Since alcohol mixes with body water, alcohol is closer to its undiluted strength in women than in men. Women appear more vulnerable than men to alcohol-related organ damage and trauma. Women tend to have more legal and interpersonal problems associated with alcohol use.

Women who drink during pregnancy can have children with a wide range of physical, mental, and behavioral problems. Fetal alcohol syndrome (FAS) is the most severe set of birth defects caused by alcohol. Children with FAS may have problems with eating, sleeping, vision, and hearing. They may grow poorly and have birth defects of the heart, kidneys, skeleton, and other parts of the body. As children with FAS get older, they may have trouble following directions, learning to do simple skills, and paying attention in school. They may also find it hard to get along with others and control their behavior. Because no one knows exactly how much alcohol it takes to cause birth defects, it is best not to drink any alcohol at all during pregnancy.

How Are Families Affected?

Living with or caring about a person with alcoholism can be very stressful. This is especially true for the 11 million children under age 18 in the United States who have an alcoholic parent. Alcohol use can lead to frequent arguments in the home, and it plays a role in the breakup of many marriages. In addition, alcohol use is a factor in more than half of all cases of family violence. It is not surprising that children of alcoholic parents are more likely to show signs of depression, anxiety, and low self-esteem than are other children. As they get older, they may have trouble in school, and they may tend to score lower on tests that measure verbal skills. They may also be more likely to have alcohol and drug problems of their own.

However, all children of alcoholic parents are not doomed to have problems with alcohol themselves. Many do well and thrive, particularly if they have positive relationships with other people, such as friends in school, teachers, or neighbors. Support groups for family members and friends, such as Al-Anon and Alateen, also can help people learn to cope with someone else's drinking.

What Causes Alcoholism?

Millions of adults drink alcohol occasionally without any trouble. Yet as many as one in every 13 adults in the United States come to abuse alcohol or become alcohol-dependent. Alcohol problems are more common in men than in women, and they occur most often among young adults between the ages 18 and 29. Yet anyone of any age and either sex can be affected.

Young People and Alcohol Use

- Young people who start drinking before age 15 are five times more likely to become alcohol-dependent than those who delay drinking until age 21.
- The number of young people ages 12 through 17 who say they have drunk alcohol in the past month dropped dramatically after the mid-1980s, from 66 percent in 1985 to 31 percent in 2007.
- Heavy or binge drinkers ages 12 to 17 are five times as likely to drop out of school compared to non-drinkers. Heavy drinkers in high school are disproportionately likely to fail or receive below average grades compared to other students.

* **colon** (KO-lin), also called the large intestine, is a muscular tube through which food passes as it is digested, just before it moves into the rectum and out of the body through the anus.

* **rectum** is the final portion of the large intestine, connecting the colon to the outside opening of the anus.

Don't Get Even. Get MADD.

Mothers Against Drunk Driving (MADD) is one of several national nonprofit groups that aim to stop drunk driving and prevent underage drinking. MADD was founded by a group of California women in 1980 after a hit-and-run drunk driver killed a 13-year-old girl who was walking along a residential sidewalk. The driver had been out of jail on bail for only two days for another hit-and-run crash, and he had three previous arrests (and two convictions) for drunk driving. The concerned women started a crusade to get drivers such as this one off the road. In the early 2000s, MADD had more than 600 chapters nationwide.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

Many young people first start drinking as a way to escape their problems, feel accepted, or feel better about themselves. Those youngsters who move on to frequent or heavy drinking are more likely to be depressed, have low self-esteem, or feel as if they do not fit in. Pressure from friends and easy access to alcohol may make it more likely that drinking will get out of control. Alcoholism also may tend to run in families, a pattern that may have psychological and genetic causes. Children of alcoholic parents can be at risk for several reasons. They often live in stress-filled homes where heavy drinking is commonplace. In addition, the genetic* makeup of these children may increase their risk of alcoholism.

What Are the Signs of Alcoholism?

Warning signs include:

- Being preoccupied with drinking: People with alcoholism are always thinking about their next drink.
- Viewing alcohol as a cure-all: People with alcoholism may drink to steady their nerves, treat a hangover, or “fix” almost any problem.
- Needing to drink increasing amounts to feel high: People with alcoholism must drink ever-increasing amounts to get the desired effect.
- Losing control over drinking: Although they may try, people with alcoholism cannot limit themselves to one or two drinks.
- Drinking alone: Social drinkers enjoy the company of others. People who are alcohol-dependent enjoy the alcohol itself.
- Needing to drink to feel normal: People with alcoholism usually feel as if they must drink just to cope with everyday concerns.
- Feeling guilty and making excuses: People with alcoholism often blame their drinking on other people or on outside events.
- Having blackouts: People with alcoholism may be unable to remember what happened while they were drinking, which is sometimes called “alcohol amnesia.”

How Is Alcoholism Treated?

Alcoholism is a treatable disease. Treatment often begins with detoxification, the process of safely getting all the alcohol out of a person's body. During the first days after drinking is stopped, people may be given medication by a physician to replace the alcohol and then gradually be weaned off the medication. The goal is to reduce withdrawal symptoms and restore good health. Rest, a balanced diet, and plenty of fluids also are stressed.

Medications Once detoxification is complete, some people take medications to help prevent a return to drinking. Disulfiram (dy-SUL-fi-ram; Antabuse) can help deter alcohol use by causing several unpleasant symptoms when a person drinks alcohol, including severe nausea, vomiting,

hot flushing, headache, and anxiety. Naltrexone (nat-TREK-zone; ReVia) is another medication that is sometimes given to people with alcoholism. Scientists think it may block the craving for more alcohol that these people usually feel after taking a first alcoholic drink. The problem is that often times the desire to drink again makes the alcoholic stop taking these medications.

Therapy Various kinds of therapy are used to treat alcoholism. Therapy can help people identify the feelings and situations that trigger their drinking. It also can help them find new ways to cope that do not involve using alcohol. Therapy can be provided individually or in a group, and it can take place in a mental health center, a hospital, or other setting. Social skills training teaches people to handle social situations better. Behavioral therapy helps people learn to control harmful behavior and the impulse to drink. Family therapy focuses on problems among family members, which are made worse by alcohol consumption.

Self-help groups Most treatment programs include meetings of Alcoholics Anonymous or other self-help groups. People who take part in such groups get support from peers who face the same problems and are trying to solve their problems by applying positive steps. Membership is open to anyone with a desire to stop drinking. Alcoholics Anonymous has more than 50,000 groups with more than 1 million members in the United States alone.

How Well Does Treatment Work?

Alcoholism can be a tough addiction to beat, but treatment can be very helpful. Studies have shown that 7 of 10 alcohol-dependent people who get treatment have stopped or cut back on their drinking and improved their health within six months, but relapse is common. The goal of treatment is for the alcoholic to quit drinking entirely and permanently, but most people have at least one or two relapses before they reach this goal. Such slips are common, and they do not mean that people have failed. They just mean that people must stop drinking again and get whatever help they need to give up the habit. The longer people go without drinking, the more likely it is that they will stay sober permanently.

Allergies

Allergies are abnormal or hypersensitive responses by the body's immune system to substances that are usually harmless.*

What Are Allergies?

When Latrell plays outside in the fall, he sneezes and his throat itches. When Melinda pets her friend's cat, her eyes start to water. When Annie puts on her nickel-plated bracelet, her arm breaks out in hives. When Mrs. Garcia feeds her baby formula* containing milk products, the baby cries as if he has a stomachache. After Ben was stung by a bee, he suddenly had trouble breathing.

These are all examples of allergic reactions. For most people playing outside, petting a cat, touching metal, or drinking milk cause no problems. A bee sting hurts but is not life-threatening. However, for millions of people with allergies, these substances and hundreds of others can cause the immune system to leap into action. The result can be as mild as a stuffy nose or as severe as death.

Common allergens A substance that triggers an allergic reaction by some people's immune systems is called an allergen*. Most allergens fall into one of four main categories:

- Substances that are inhaled from the air, such as pollen, dust, mold spores, or pet dander*
- Substances that come in contact with the skin, such as nickel in costume jewelry, chemicals in cosmetics, or latex*
- Foods, such as milk, eggs, wheat, shellfish, or peanuts or other nuts
- Substances that are injected, such as penicillin or other medications or the venom from an insect sting.

Allergic responses do not occur with the first exposure to an allergen. The immune system must first become “sensitized” by at least one previous exposure to the allergen or to a very similar substance. For example, a person who is allergic to one type of penicillin will probably have an allergic reaction to other types of penicillin.

The Immune System

The human body's immune system consists of specialized cells and organs that are finely tuned to fight off disease-causing microorganisms*, abnormal cells such as cancer cells, and toxins and other harmful substances. Allergies result from immune-system responses to otherwise harmless substances. Because allergies involve the immune system, they are distinguished from hypersensitivity* to a substance or intolerance* for a food.

The immune system recognizes and responds to foreign substances called antigens*. Antigens can be molecules (usually proteins) on the surfaces of viruses, bacteria, parasites, fungi, or abnormal cells. Toxins, drugs, chemicals, and foreign particles can also be antigens.

Humoral immunity refers to large proteins called antibodies* or immunoglobulins* (im-mune-o-GLOB-u-linz), which are produced by immune-system cells called B-lymphocytes. The immune system can produce millions of different antibodies that circulate in the blood and are present in almost all bodily fluids. Allergies are caused by a specific type of antibody called immunoglobulin E or IgE. One end of an IgE antibody has two antigen-binding sites that recognize and bind to a specific allergen like two puzzle pieces fitting together. The other ends of all IgE antibodies are the same and bind to the surface of connective-tissue cells called mast cells. People with allergies have much higher levels of IgE in their bodies than people without allergies. They may only have IgE antibodies that bind to one allergen such as ragweed pollen that causes hay

* **allergens** are substances that provoke a response by the body's immune system or cause a hypersensitive reaction.

* **pet dander** refers to microscopic parts of the pet's skin that flake off and get into the air people breathe.

* **latex** (LAY-tex) is a substance made from a rubber tree and is used in such things as medical equipment (especially gloves), toys, and other household products.

* **microorganisms** are tiny organisms that can only be seen using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

* **hypersensitivity** being excessively sensitive or abnormally susceptible physically to a specific agent such as a drug.

* **intolerance** lacking an ability to endure exposure to some environmental feature, such as sunlight, or an exceptional sensitivity, for example to milk, so that the food cannot be properly metabolized, as in glucose intolerance.

* **antigens** (AN-tih-jens) are substances that are recognized as a threat by the body's immune system, which triggers the formation of specific antibodies against the substance.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **immunoglobulins** (im-mune-o-GLOB-u-linz) are types of antibodies.

Medic Alert Tags

Medic Alert tags or bracelets can be life-saving for people with drug allergies. In the event of an accident or loss of consciousness, the tag or bracelet alerts medical personnel to the allergy.

Some companies offer medical alert tags that have a unique identification number. In the event of an accident, a doctor anywhere can retrieve the patient's medical history.

* **humoral** (HUM-eh-ral) relating to a hormone, relating to or part of an immune response that involves antibodies secreted by B cells and circulating in bodily fluids.

* **cellular** (cell-U-lar) relating to or consisting of cells, cell-mandated, as in cellular immunity.

fever. Or they may have many different types of IgE antibodies and are, therefore, allergic to many different substances.

Cellular or cell-mediated immunity refers to the specialized cells of the immune system that directly attack foreign substances. These include cells that engulf and destroy the antigen, such as macrophages, and white blood cells called T-lymphocytes, which have receptors for specific antigens and also help B cells to produce immunoglobulins.

Immediate hypersensitivity The most common form of allergy is immediate hypersensitivity or Type I. It depends on both humoral* and cellular* immunities.

Upon first exposure to an allergen such as ragweed pollen, the immune system of a susceptible person becomes sensitized, which means it goes through the following actions:

- The pollen molecules bind to receptors on the surfaces of specific B-lymphocytes.
- Macrophages engulf and break the pollen grain up into tiny pieces that are displayed on the surfaces of the macrophages, a process called “antigen presentation.”
- Antigen presentation activates T-lymphocytes, which stimulate B-lymphocytes to produce large amounts of IgE that specifically bind to the pollen.
- The IgE antibodies migrate through the body and bind to receptors on mast cells and similar cells called basophils. There are a great many mast cells in the nose, eyes, lungs, stomach, and intestines, each with tens of thousands of IgE antibodies on their surfaces.

The next time the person inhales ragweed pollen, pollen molecules attach to their specific IgE antibodies on mast cells and basophils, causing the cells to explode and release histamines and other inflammatory substances. These substances produce symptoms of an inflammatory allergic reaction and recruit other types of inflammatory immune-system cells to the site, increasing the allergic response.

Whereas an allergen-IgE reaction in the respiratory system may cause hay fever, in the skin it may cause a rash or hives. Food and some drug allergies cause reactions in the digestive tract. These allergic reactions happen within a few minutes after exposure to the allergen.

Delayed hypersensitivity Delayed hypersensitivity occurs with some skin allergies. Delayed hypersensitivity does not involve humoral immunity or antibodies. Rather T-lymphocytes that have been previously sensitized by exposure to the allergen upon subsequent exposure release chemicals called lymphokines. Lymphokines call up macrophages to engulf and digest the allergen and any cells containing traces of it. They also cause swelling, redness, tenderness, and rashes. These symptoms may take up to 72 hours to appear after exposure to the allergen.

How Common Are Allergies?

Allergies affect more than 50 million Americans and more than half of all Americans test positive for one or more allergens. Approximately 36 million Americans have seasonal allergies, with allergic rhinitis (ry-NI-TE-is) or hay fever affecting 20 percent of all adults and up to 40 percent of children. In addition, the following allergies occur frequently:

- Skin allergies or allergic contact dermatitis* is the most common skin condition in children under age 11, and hives affects up to 20 percent of all people at some point in their lives.
- An estimated 2 percent of American adults and 8 percent of children have food allergies.
- Allergic reactions account for 5 to 10 percent of all adverse drug reactions. Penicillin is the most common drug allergen.
- About 15 percent of adult Americans have mild, localized allergic reactions to insect bites.

The incidence of allergies among American children increased dramatically in the last decades of the 20th century. Some of this increase can be attributed to better diagnosis and reporting. However, much of it may be due to lifestyle and environmental factors.

Why Do People Develop Allergies?

Although many factors play a role in the development of allergies, heredity appears to be particularly important. If neither parent has allergies, a child has about a 10-percent risk of developing them. If only one parent has allergies, the child has a 30 to 50 percent chance of developing them. If both parents have allergies, the child's risk jumps to 60 to 75 percent. However, the child will not necessarily have the same allergies as the parents. Because people with allergies tend to produce more IgE than those without allergies, it may be this propensity that is inherited. High levels of IgE also increase the likelihood of having many different allergies.

Repeated exposure to an allergen or prolonged exposure to a strong allergen increases the risk of becoming allergic to that substance. Other factors that increase the likelihood of childhood allergies include:

- Low weight at birth
- Being born during a high-pollen season
- Not being breastfed
- Growing up in a home with tobacco smoke
- Having a family pet
- Having a lower socioeconomic status.

How Do People Know If They Have Allergies?

Allergic rhinitis The most common allergy is seasonal allergic rhinitis or hay fever—although it has little to do with either hay or fever. It is caused by pollen from weeds, especially ragweed, which happen to bloom

Allergies and Asthma

Asthma is a chronic disease that causes inflammation of the airways, making it difficult to breathe. Almost 9 million American children suffer from asthma, a leading cause of school absences. Many allergens can trigger asthma attacks and an estimated 50 percent of adults and more than 80 percent of children with asthma have associated allergies. Allergic asthma is an allergen-IgE response in the lungs, and the majority of people with asthma also suffer from allergic rhinitis.

* **dermatitis** is a skin condition characterized by a red, itchy rash. It may occur when the skin comes in contact with something to which it is sensitive.

* **dust mites** are tiny insects that live in dust and in materials such as carpets, pillows, mattresses and furniture.

at the same time as hay is harvested. Rhinitis means inflammation of the nose. Symptoms include:

- Runny nose
- Watery eyes
- Sore throat
- Sneezing
- Coughing
- Wheezing
- Swelling

Oral allergy syndrome is itching and mild swelling around the mouth. It occurs because some fresh fruits and vegetables—such as melons, cucumbers, zucchinis, and sunflower seeds—contain proteins that are similar to the allergens in ragweed.

Some people suffer from perennial allergic rhinitis. They are bothered by airborne allergens all year long, not just during pollen season. Perennial rhinitis is commonly caused by dust mites*. Household mold spores and pet dander are also major causes of perennial rhinitis.

Skin allergies Skin allergies usually cause a rash or itch. However, contact urticaria causes welts or hives on the skin. Various plants—especially poison oak, poison ivy, and poison sumac—cause allergic reactions in the majority of people. Other skin allergens include:

- Nickel
- Formaldehyde in clothing and building materials
- New clothing that has been treated with hydroquinone

Doctors sometimes use skin tests to diagnose allergies. The reactions shown here demonstrate allergic response.
Custom Medical Stock Photo, Inc.
Reproduced by permission.

- Cosmetics, including perfume and hair dye
- Cleaning products, including laundry and dish soaps
- Medications, including antibiotic creams containing penicillin or sulfonamides, anesthetics, antihistamines*, and antiseptics
- Workplace chemicals

Photoallergic contact dermatitis is caused by a combination of contact with an allergen and sunlight. Aftershaves, perfume, sunscreens, and topical medications can contain photoallergens.

With the increased use of latex gloves in the healthcare and food industries, latex allergies have become a growing concern. It is estimated that 5 to 10 percent of healthcare workers are sensitized to latex. Natural latex rubber is also used in a variety of common products, including balloons and condoms. Symptoms are usually similar to other types of allergic contact dermatitis. However, latex can also trigger whole-body allergic reactions, ranging from hives and swelling to asthma attacks and even anaphylaxis.

Food allergies Most adverse reactions to food are caused by intolerances rather than allergies. More than 90 percent of all food allergies are caused by the following:

- Shellfish, including crab, lobster, and crayfish
- Fish

* **antihistamines** (an-tie-HIS-tuh-meens) are drugs used to combat allergic reactions and relieve itching.

ANAPHYLAXIS AND EPINEPHRINE

Whereas most allergic reactions affect only one part of the body, anaphylaxis is systemic—affecting many areas of the body—and is a medical emergency. The throat and airways to the lungs can swell, making it difficult to breathe. Blood pressure may drop. The person may feel nauseated and have diarrhea and stomach cramps. Without immediate medical treatment, the patient can lose consciousness and die:

- Latex causes more than 200 episodes of anaphylaxis annually in the United States.
- Foods—especially peanuts and shellfish—result in an estimated 150 deaths annually in the United States.
- Anaphylactic reactions to penicillin cause about 400 deaths annually.
- About 3 percent of adults and less than 1 percent of children have systemic reactions to insect bites. Insect stings are responsible for about 40 deaths annually, primarily in adults over age 45.

The most common treatment for anaphylaxis is epinephrine (ep-i-NEF-rin), also known as adrenaline. People who have experienced anaphylactic shock often carry injectable epinephrine.

“Peanut-Free” Zones

Some schools have “peanut-free” zones—an area where no peanuts or peanut products can be served or eaten—or have banned peanuts altogether. They are reacting to reports of an increasingly dangerous allergy to that lunchroom staple, peanut butter, as well as to other foods made with peanuts.

Peanuts and other nuts are among the most common foods that cause allergic reactions—and sometimes anaphylaxis. Accidental exposure is difficult to avoid, because some people react to just the smell of peanuts. Avoiding food allergens requires carefully reading the labels on processed foods. Food manufacturers sometimes change ingredients, so even familiar foods and brand names may not remain peanut-free.

- Eggs and egg products
- Nuts from trees, including walnuts
- Peanuts
- Wheat and wheat products
- Milk and milk products
- Soy and soy products.

The most common allergic skin reaction to food is hives. Atopic dermatitis or eczema—patches of itchy, scaly, red skin—can also be triggered by a food allergy. Gastrointestinal symptoms of food allergies can include itching in the mouth and throat, stomach cramps, nausea, vomiting, or diarrhea. Food allergies can also trigger asthma attacks. However, children often outgrow allergies to milk, eggs, wheat, and soy.

How Do Doctors Diagnose Allergies?

Allergy symptoms vary a great deal and can be very similar to symptoms of other conditions, including colds, flu, skin irritations, and food sensitivities or intolerances. Thus allergies can be difficult to diagnose. A physician usually first determines whether there is a family history of allergies and also tries to rule out other causes of the reaction. If possible, the best diagnostic for a suspected allergy is to remove or avoid the allergen and see if the symptoms disappear.

Skin tests Skin tests are performed to determine which substances cause an allergic response in the patient. The prick test introduces a tiny amount of a suspected allergen into the skin. An allergen will cause a small swelling at the spot of the prick. If the prick test is negative but the allergen is still suspected, an intradermal test—in which a small amount of allergen is injected under the skin—may be performed. This test is more sensitive than the prick test.

Food allergies Elimination diets are used to diagnose food allergies. If the symptoms disappear when the suspected food is eliminated from the diet and return when the food is reintroduced, the food is probably an allergen. A skin test may be used to confirm the diagnosis.

Sometimes a skin test for food allergies cannot be performed—for example, if a person is at risk for anaphylaxis. Blood tests called RASTs (radioallergosorbents) and ELISA (enzyme-linked immunosorbent assays) measure the level of food-specific IgE in the blood. A test called the CAP-RAST measures the amount of IgE in the blood that is specific for a given food. However, a positive skin test or CAP-RAST alone does not mean that the person is allergic to that particular food.

In a double-blind oral food challenge, the patient is given capsules that either may or may not contain the suspected food or the suspected food masked with other foods. If no symptoms appear, the patient is probably not allergic to the suspect food.

What Is the Treatment for Allergies?

Left untreated, allergies can lead to additional complications, including asthma. Allergic rhinitis is the leading cause of sinus infections, as along with nasal* polyps from the constant swelling of nasal passages.

Avoiding allergens The first line of defense against allergies is avoiding allergens. Pets, nickel-plated jewelry, or specific foods may be relatively easy to avoid. Allergens such as pollen, mold spores, and dust mites can be harder to avoid. Recommendations include the following:

- Staying indoors and closing windows during high-pollen periods
- Showering and changing clothes after outdoor activities
- Using a clothes dryer rather than drying laundry outside
- Removing rugs
- Vacuuming and scrubbing often
- Covering pillows and mattresses with protective material
- Washing bedding frequently in hot water
- Using special filters on heaters and air conditioners
- Keeping firewood and other sources of mold spores away from the house
- Keeping rain gutters clean to avoid mold
- Keeping grass short so that it will not flower
- Planting an allergen-free landscape

Recommendations for avoiding stinging insects include the following:

- Avoiding brightly colored clothes and perfumes that attract stinging insects
- Always wearing shoes outside
- Keeping all outside food covered

Medications There are many over-the-counter and prescription medications for treating allergies. Some people take them only when symptoms occur. Others use them daily to prevent or decrease the severity of symptoms. Antihistamines interfere with histamines that cause allergic symptoms by preventing the binding of histamines to their target cells. Decongestants to open nasal passages are used alone or in combination with an antihistamine to treat rhinitis. Corticosteroids may be used to treat severe allergies.

Both prescription and over-the-counter nasal sprays are available for treating rhinitis. These include antihistamines, decongestants, nasal steroids, anticholinergic medicines (those that block the physiological action of acetylcholine), and mast-cell inhibitors.

Immunotherapy Immunotherapy, commonly referred to as allergy shots, attempts to decrease the body's sensitivity to an allergen by developing an immunity or tolerance* to the allergen. Immunotherapy is used for allergies to substances such as pollen, dust mites, and animal

* **nasal** (NA-zal) of or relating to the nose.

* **tolerance** (TALL-uh-runce) a condition in which a person needs more of a drug to feel the original effects of the drug.

dander, but not foods. In the build-up phase of immunotherapy, increasing amounts of the allergen are injected once or twice per week for three to six months. Once an effective dose of the allergen has been determined, the treatment enters a maintenance phase and the effective dose is injected every two to four weeks. Immunotherapy may take as long as a year to be effective. Successful immunotherapy is usually continued for three to five years.

Immunotherapy can result in long-lasting relief from allergy symptoms after the treatment is completed. It can also prevent the development of new allergies. In children immunotherapy can prevent allergic rhinitis from progressing to asthma.

Living with Allergies

Although there is no way to prevent allergies, there are many ways to avoid allergic reactions. These include avoiding foods, plants, and other substances that cause allergies.

Identifying the sources of pollen that cause rhinitis can be very useful. Air-pollen counts are reported daily:

- A pollen count of 100 grains or less is considered low.
- Moderate counts of 100–500 may signal the need for an antihistamine before venturing outside.
- An allergic person should stay indoors if the count is over 500.
- Airborne pollen is at its lowest in the early morning.

Mold spores in the air are also tabulated. Wind and warm dry air increase the pollen and spore counts.

Altitude Sickness

Altitude sickness occurs at higher altitudes when it is harder for the blood to get an adequate supply of oxygen.

What Causes Altitude Sickness?

High altitudes have decreased atmospheric pressure, a condition under which humans inhale a decreased amount of oxygen*. Altitude sickness is caused by a lack of oxygen supply in the blood, a physiological state known as hypoxemia. The body attempts to compensate for this decrease in oxygen by hyperventilating, or breathing in rapid, shallow breaths. Hyperventilating, which is part of a physical acclimatization process, allows more oxygen to be delivered to body tissues. However, hyperventilation also causes abnormalities in body pH that take time to bring back to normal. The body increases the number of red blood cells to increase oxygen carrying capacity and alters red blood cells to increase their efficiency for dropping oxygen off to body tissues per unit of time. It generally takes a few days for this process to occur at altitudes up to 10,000 feet. The higher the altitude, the longer the acclimatization process.

What Are the Risk Factors for Altitude Sickness?

Altitude sickness can affect anyone ascending to a high altitude, especially if the ascent is done too quickly for the body to adapt accordingly. Rate of ascent to the higher altitude is a key factor. The geographical point above sea level at which an individual experiences altitude sickness varies from person to person. Altitude sickness usually starts to affect people at an elevation of 7,000 feet to 9,000 feet above sea level, especially when ascent occurs within one day. However, some people experience effects as

Did You Know?

During the 1968 Summer Olympics in Mexico City, athletes arrived up to two weeks early to help them become accustomed to the altitude. Mexico City is more than 7,000 feet above sea level, and many of the athletes live at much lower elevations. The athletes who had trained at a high altitude prior to the Olympics may have had an advantage over those who trained at lower altitudes.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

low as 5,000 feet. Physical condition and level of fitness are factors that affect the onset of altitude sickness, although being physically fit will not prevent an individual from developing altitude sickness. The amount of physical exertion placed on the body affects how much oxygen the body needs, making greater exertion a risk factor for altitude sickness when individuals are ascending. Altitude sickness is often seen in mountain climbers, trekkers, and skiers who travel to high-altitude areas. Previous episodes of altitude sickness and living at low altitudes predispose individuals for an episode. Young children are most susceptible to altitude sickness. Maintaining hydration, eating frequent high-carbohydrate meals, avoiding high salt intake, and alcohol avoidance help prevent the occurrence of altitude sickness.

What Are the Symptoms and Treatment of Altitude Sickness?

Altitude sickness may occur in varying degrees of severity. The general set of symptoms includes headache, as well as fatigue, nausea or vomiting, or dizziness. There may also be irritability, muscle aches and pains, and sleep disturbances. Symptoms are exacerbated by physical exertion and dehydration*. Upon reaching a high altitude, individuals usually take six to ten hours to develop symptoms. Given a halt in ascent and rest from physical exertion, symptoms usually either resolve in a day or so or become worse. If altitude sickness increases in severity, the individual may experience confusion, difficulty walking normally, and even development of a stupor or coma*. Difficulty breathing and other respiratory problems may develop.

Treatment of altitude sickness involves stopping the ascent and resting from physical exertion until symptoms resolve. Other treatments include increasing fluid intake and taking pain killers for aches and pain. If symptoms are severe or not resolving, a descent to lower altitude may be necessary. In some cases, patients may be given oxygen therapy. Acetazolamide is a drug sometimes used to prevent or treat occurrences of altitude sickness. Acetazolamide increases ventilation and thereby helps maintain the amount of oxygen present in the blood available to tissues.

Physiological Adaptation to Altitude Sickness

Acute Adaptations When first confronted with an increased altitude, the body automatically changes some of its normal processes to adapt in a process called acclimatization. The goal of adaptation to high altitude is to increase the availability of oxygen to the body tissues. One of the first adaptations is ventilatory acclimatization, which involves a change in breathing patterns. There is an increase in respiratory rate (the number of breaths taken per minute). This type of breathing, called hyperventilation, increases the amount of oxygen available to the tissues and increases the amount of carbon dioxide expired from the body. As the body releases more and more carbon dioxide in greater amounts than

with normal breathing, a change occurs in the blood pH. As the blood pH becomes higher than normal, the brain receives signals that tell it to keep the hyperventilation in check and not let it go on for too long. In the meantime, the kidneys excrete substances that help keep the body pH normal. This process may take up to four days and is improved by the use of acetazolamide.

Another form of adaptation involves the circulation. When individuals ascend to a high altitude, their heart rate increases in order to increase the amount of blood pumped out of the heart to the body tissues. Blood flow also increases to the brain in order to maintain proper brain function. Circulatory acclimatization takes place within minutes of ascent.

Chronic Adaptations In order to maximize the ability of the blood to carry oxygen to the tissues, the amount of hemoglobin present in the blood increases. This process requires weeks to accomplish. Red blood cells are made in the bone marrow and used to transport oxygen to the tissues. The more red blood cells present in the blood, the greater the oxygen-carrying capacity of the blood. In addition to an increase in the number of red blood cells, the change in pH of the blood also triggers an alteration in the red blood cell so that it has a greater than normal capacity to unload oxygen into the tissues.

How Can Altitude Sickness Be Prevented?

The best way to prevent altitude sickness is to ascend to high altitude gradually. For mountain climbers and hikers, a slow ascent allows the body time to acclimatize. When people drive or fly to a high-altitude location making a slow ascent impossible, they should minimize physical activity for the first few days during the acclimatization process. Maintaining hydration, eating frequent high-carbohydrate meals, avoiding high salt intake, and alcohol avoidance help prevent the occurrence of altitude sickness. Acetazolamide is sometimes used preventatively to avoid the occurrence of altitude sickness. The narrowing of blood vessels caused by lack of oxygen to tissue can be helped in part by endothelin and may potentially be prevented or greatly improved by endothelin antagonists*.

Alzheimer's Disease

Alzheimer's (ALTZ-hy-merz) disease is an incurable condition in which abnormal plaques and tangles form in the brain, accumulating over time and interfering with nerve cell connections. The disease leads to problems with memory and thinking and to changes in personality and behavior, generally called dementia (de-MEN-sha).

Joey's Story

Joey's grandmother does the strangest things. She tells the same stories over and over and often forgets words for common objects, such as *television* and *fork*. She puts her purse in the refrigerator and sometimes comes to dinner wearing her dress turned inside out. But what is most troublesome to Joey is that she often does not recognize him or his mom.

At first, the family simply thought his grandmother was getting old. She is in her 80s, and his mother told him that sometimes older people have trouble remembering things. But as his grandmother's forgetfulness and odd behavior became worse, the family realized it was more than just an occasional lapse in memory, which happens to everyone once in a while.

Joey's grandmother is one of the 4.5 million Americans who have Alzheimer's disease.

What Is Alzheimer's Disease?

Alzheimer's disease is a neurological* disorder in which structures called plaques and tangles form in the cerebral (se-REE-bral) cortex (KOR-teks), the outer surface of the brain, as well as in the brain matter just under the cortex. The cortex has several functional areas, including those involved with vision, hearing, speech, understanding, and bodily awareness. Plaques and tangles interfere with the normal functioning of the neurons (NOO-rahnz), or nerve cells, and the transmission of messages between the brain and other parts of the body. Although these structures occur to some extent with normal aging, they are much more prevalent in people who have Alzheimer's disease.

Alzheimer's disease is the most common form of dementia*. Autopsies* reveal the following abnormalities in the brains of people with Alzheimer's:

- Twisted nerve cell fibers, known as neurofibrillary tangles
- A mutated or changed protein called tau found in these tangles

- Outside the cells high concentrations of patches of plaque deposits composed of a sticky substance called beta amyloid, especially in the area of the cerebral cortex* and the hippocampus, the regions most responsible for memory and cognition
- Surrounding the plaques debris of dying neurons
- Decreases in a brain chemical called acetylcholine, a neurotransmitter* that helps signals move from one nerve cell to another

Alzheimer's disease is not a normal part of aging.

History of Alzheimer's Disease

As Alois Alzheimer (1864–1915), a German psychiatrist, peered into his microscope, he was puzzled by what he saw. The slides of the brain of his 51-year-old patient Auguste D. contained deposits and tangles that looked like a mass of threads. He had worked with Auguste D. at the asylum in Frankfurt-am-Main and was amazed by her bizarre behavior. In 1907, he wrote these words:

The woman showed as her first symptom a jealousy towards her husband. Soon she showed a rapidly increasing amnesia; she became lost in her own apartment, carried objects about aimlessly, hid them, sometimes believed she was to be murdered, and had spells of unrestrained screaming. ... The autopsy showed a diffusely atrophied brain ... remarkable changes of the neurofibrillae. In place of a normal cell, one or several fibrillae, which ran parallel to each other, were altered in a similar fashion.... Apparently we are dealing with an unidentified illness.

He did not know that his friend Emil Kraepelin (1856–1926) would refer to the condition as Alzheimer's disease in a journal article in 1911. The name stuck.

* **cerebral cortex** (suh-REE-brul KOR-teks) is the part of the brain that controls functions such as conscious thought, listening, and speaking.

* **neurotransmitter** (NUR-o-tranz-mit-er) is a chemical substance that transmits nerve impulses, or messages, throughout the brain and nervous system and is involved in the control of thought, movement, and other body functions.

These positron emission tomography (PET) scans show the dramatic difference in brain activity between a healthy person (*left*) and a person with Alzheimer's disease (*right*). Brain activity, indicated by red and yellow, has been greatly reduced in the brain at right. *Dr. Robert Friedland/Photo Researchers, Inc.*

* **neurologist** (new-RHAL-eh-jist) a physician who specializes in diagnosing and treating diseases of the nervous system.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

However, the disease received little attention until the late 1970s when several factors merged:

- **Science.** Advances in the electron microscope helped confirm that Alzheimer's disease was a neurological condition and thus dismissing the notion that memory loss and confusion are inevitable in aging.
- **Society.** In 1979 Robert Katzman (1925–2008), a neurologist*, became frustrated with doctors who would not accept that dementia is not a normal part of aging. Katzman believed that many doctors had little understanding of family members who struggled with Alzheimer's disease. Katzman and businessman Jerry Stone formed the support group the Alzheimer's Association to disseminate information about the condition.
- **Popular Media.** In October 1980, Abigail van Buren in her column "Dear Abby" referred interested readers to the Alzheimer's Association. The association was overwhelmed with requests.
- **Celebrities.** In May 1986, the famous movie star Rita Hayworth died from Alzheimer's disease. In order to bring attention to her terrible end, Yasmin Khan, her daughter, wrote President Reagan asking for funding for research. Congress passed the Alzheimer's Disease and Related Dementias Act in 1986, providing funds for research. Ironically, Ronald Reagan was to die from Alzheimer's disease in 2004.

What Causes Alzheimer's Disease?

In the early 2000s, scientists did not fully understand what causes Alzheimer's disease, and they suspected several factors may play a role. Age is the most important risk factor; the number of people with the disease doubles every five years beyond age 65.

Family history is another risk factor. Genes* seem to play a role in certain Alzheimer's cases. Studies in the early 2000s suggested that genes are associated with both the common form of Alzheimer's disease, which affects many people and generally begins at ages over 65, with increasing frequency as people age, and with a rare early onset form of the disease with onset between the ages of 30 and 60. At least five genes might be implicated in early-onset form, which runs in families and is inherited.

However, regarding the late onset form of the disease, researchers were as of 2009 unable to trace a clear link to heredity or to other factors, such as dietary habits, occupation, personality type, or environmental factors. Several risk factors were suspected of interacting with other predisposing factors. As of 2009, the only risk factor identified in late-onset Alzheimer's disease was a gene that makes one form of a protein called apolipoprotein E (ApoE). There are three forms of ApoE: ApoE2, ApoE3, and ApoE4. ApoE4 increases the risk but does not always cause Alzheimer's disease. Everyone has ApoE, which helps carry cholesterol in the blood,

but only about 15 percent of people have the form that increases the risk of Alzheimer's disease. Possibly other genes may increase the risk of the disease or protect against it, but in the early 2000s these had not been identified.

Several other factors may predispose one to develop Alzheimer's:

- Heart disease
- High blood pressure
- Stroke, especially small strokes called transischemic attacks or TIAs
- High cholesterol
- Infection from a virus
- Low levels of the vitamin folate
- Blows to the head from accidents or from repeated blows as in boxing or contact sports such as football
- Certain disorders such as Down syndrome associated with Trisomy 21
- Lifestyle factors, such as smoking, poor nutrition, drug use

How Is Alzheimer's Disease Diagnosed?

Alzheimer's is difficult to distinguish from other kinds of mental problems. Doctors usually begin by taking a medical history and doing a physical examination to make sure some other condition or other type of dementia is not causing the memory and behavior problems. Many diseases and conditions can cause symptoms similar to those of Alzheimer's. Some, such as vitamin deficiencies, can be corrected easily; others can be treated with prescription drugs.

Doctors also administer various verbal and written tests to assess how well the person's brain is functioning. They interview the person and his

RONALD REAGAN'S GOODBYE

In November 1994, former president Ronald Reagan, who was suffering from Alzheimer's disease, said farewell to the nation in a letter:

I have recently been told that I am one of the millions of Americans with Alzheimer's disease. Nancy and I had to decide whether we would keep this matter to ourselves as private citizens or would make it known. We had the feeling that it was important to announce this message publicly.

This letter had a great effect. Alzheimer's disease became widely recognized and research dollars funded studies into its cause and the search for a cure.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

* **spinal tap** also called a lumbar puncture, is a medical procedure in which a needle is used to withdraw a sample of the fluid surrounding the spinal cord and brain. The fluid is then tested, usually to detect signs of infection, such as meningitis, or other diseases.

family about recent events, looking for examples of the symptoms. If a person is younger than 60 years of age, a genetic test might be ordered because most cases of Alzheimer's disease in people who are between 40 and 59 years of age are linked to the presence of certain genes that can be identified. Sometimes doctors look for signs of a stroke or abnormal areas in the brain using x-rays or other high-technology equipment that allows them to see inside the body, such as magnetic resonance imaging* (MRI). With this sophisticated equipment and testing, accuracy of diagnosis is about 85 to 90 percent.

Once other possible causes of the symptoms have been ruled out, doctors begin to suspect that a person has Alzheimer's disease. If the symptoms worsen with time and no other explanation can be found, doctors say the person has Alzheimer's. However, diagnosis can only be absolutely confirmed by direct examination of brain tissue during an autopsy. Doctors look for plaques and fibers, which look like small, tangled spiral staircases.

In the early 2000s, some diagnostic methods were being investigated:

- OPTIMA Project from the United Kingdom measures thinning of the brain's medial temporal lobe and has made accurate diagnoses as many as five years before death; with refinement these brain scans may hold the key to early detection of the disease.
- Tau, a protein involved in cell death, can be detected from the spinal fluid of patients; however, most doctors do not want to perform a spinal tap* on frail elderly people.
- An eye drop test using certain chemicals may show greater pupil dilation in people who have Alzheimer's than in unaffected persons; the findings of this test must be replicated by other tests
- Positive emission tomography (PET) scans enable doctors to view brain activity to find affected areas in early cases

How Is Alzheimer's Disease Treated?

Several drugs help relieve some symptoms in some people. These drugs do not cure the disease but may slow its progression. The drugs donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne) may help symptoms for a limited time. Memantine (Namenda) is used sometimes for moderate to severe Alzheimer's cases. Also some medicines may help control behavioral symptoms such as sleeplessness, agitation, wandering, anxiety, and depression. The relief, however, is not permanent, and the drugs do not work for everyone.

Once Promising Treatments That Have Been Discredited

In the search for a cure, scientists looked at many possibilities. As of 2009 more than 75 drugs were being studied, most of them for alleviating symptoms. Sometimes after years of investigation researchers find that a

chosen treatment does not work. Substances that once were seen as promising but were later shown not to be include the following:

- **Estrogen.** Some studies suggested that estrogen, used by women to alleviate symptoms of menopause, also protects the brain; however, clinical trials indicated that estrogen does not slow the progression of the disease, and some studies even suggested that women who used estrogen with progestin were at greater risk of dementia.
- **Antioxidants.** A four-year study conducted at Columbia University on nearly 1,000 older people found that consuming certain antioxidants either through the diet or as supplements did not decrease the risk of Alzheimer's disease.
- **Ginkgo biloba.** Studies showed no evidence that the extracts from the leaves of the ginkgo biloba tree may cure or prevent the disease; studies ongoing in the early 2000s examined its possible potential to delay cognitive decline.
- **Tacrine or Cognex.** One of the first drugs approved, tacrine was withdrawn by its manufacturer because it caused serious side effects.

What Does the Future Hold?

In the early 2000s, scientists were working hard to develop effective therapies. Nine drugs were in their final stage before approval, and 23 were in the second phase of investigation. These drugs were designed to treat the symptoms and to target genetic pathways of the disease. Breakthroughs in drug research may revolutionize the way brain diseases are treated and prevented. Approaches under consideration included the following:

- **Personalized medicine or pharmacogenomics.** Researchers would study the genetic makeup of the patient and then give the right dose of the right drug; in a disease such as Alzheimer's in which tolerance of a drug influences its success, this procedure shows promise.
- **Vaccine.** A vaccine to dissolve beta amyloid plaque was under investigation; this approach worked in mice, but in human trials, several patients developed a type of brain infection. The company directed its research to the people who responded favorably to the vaccine.
- **Stem cell* research.** In animal models, stem cells were stimulated to become nerve cells, but scientists continued to explore if these neurons could replace the complex damage caused by Alzheimer's. As of 2009, there were no human trials with stem cells on Alzheimer's, although promoters of stem cell research mentioned the disease as a possible target.
- **Gene therapy.** This complex approach involves altering an individual's DNA. In 2005 a team of scientists used the first gene therapy procedure for a patient with Alzheimer's. After two years PET

Did You Know?

- Alzheimer's disease can occur in people in their 30s, but it is most common in people over age 65. Almost 90 percent of cases occur in the elderly, and as many as 50 percent of people over age 85 might have the disease.
- An estimated four and a half million people in the United States have Alzheimer's.
- Studies suggest that as many as 19 million adults and children have a relative with the disease. As many as 37 million Americans know someone with it.
- As more Americans live to advanced ages in the 21st century, the number of people with Alzheimer's could reach 14 million.
- The disease costs American businesses more than \$33 billion a year. Most of that, \$26 billion, comes from employees who must miss work to care for relatives with Alzheimer's disease. The rest is money spent on health insurance, research, and taxes for government programs such as Medicare.
- Patients with Alzheimer's disease can live as long as 20 years with the disease. The average person lives eight years after diagnosis of the condition.

* **stem cell** an unspecialized cell that gives rise to differentiated cells.

scans showed increased activity in the area of the gene transplant. Research was ongoing in the early 2000s.

- **Nanotechnology.** This futuristic procedure starts with atoms and rearranges them. Scientists correct misarranged atoms and then rebuild new structures one atom at a time. The hope was they might be able to rebuild the damage caused by the plaques and tangles of Alzheimer's using devices such as nanorobots and quantum devices.

Amebiasis

Amebiasis (am-e-BY-a-sis) is an infection of the large intestine by the single-cell parasite Entamoeba histolytica (ent-a-ME-ba his-to-LIT-i-ka). It frequently causes diarrhea or dysentery.

What is Amebiasis?

Amebiasis is a disease caused by an amoeba, or microscopic parasite*. At one stage in the amoeba's life cycle, it is enclosed in a protective wall called a cyst. Infection begins when a person swallows cysts in contaminated food or water. Amebiasis is found worldwide, including the United States, but it is most common in tropical areas where sanitation is poor.

When swallowed, the cysts resist destruction by stomach acids and travel to the intestine. In the intestine, the amoebae (plural) emerge from their cysts and multiply, usually without causing any symptoms. In some people, however, for unknown reasons, the amoebae invade the walls of the large intestine, where they cause abdominal pain, bloody diarrhea (dysentery), and sometimes fever. At this stage, there is a danger that the amoebae will invade other body organs.

During the infection, the amoebae produce cysts that pass out of the intestines in the stools (feces). Outside the body, the cysts can survive for

* **parasite** (PAIR-uh-site) is an organism such as a protozoan (one-celled animal), worm, or insect that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. Parasites live at the expense of the host and may cause illness.

Entamoeba histolytica, the parasite which causes amebiasis, seen under the microscope (left) and in the human intestine (right). *Custom Medical Stock Photo, Inc. Reproduced by permission.*

The U.S. and the World

- Nearly 500 million people worldwide may be carrying the *Entamoeba histolytica* parasite, but only about 50 million people develop symptoms of amebiasis.
- Although the *Entamoeba histolytica* parasite is found in the United States, the disease is a much larger problem in developing nations in the tropical areas of Africa, Latin America, and Asia. Poor sanitation, inadequate water treatment, and the use of human feces as fertilizer contribute to the problem.
- Worldwide, amebiasis causes up to 110,000 deaths each year, but only a few of those deaths occur in the United States.

* **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.

days or weeks. In areas with poor sanitation, drinking water contaminated with human feces can quickly spread amebiasis, and the cycle begins again.

What Are the Signs and Symptoms of Amebiasis?

Most ameba infections are asymptomatic, which means there are no symptoms. Even without symptoms, however, cysts are still produced, and the person is considered a carrier or cyst passer.

Amebic colitis Symptoms occur primarily when the amebae attack the wall of the large intestine. This is known as amebic colitis. The most common symptom is abdominal* pain that begins gradually. Additional symptoms may include diarrhea that contains blood or mucus, frequent bowel movements, and a constant nagging feeling of needing to move the bowels. In about one-third of cases, fever is present.

Amebic dysentery In rare cases, the symptoms of amebic colitis worsen with fever, chills, and severe diarrhea with blood and mucus. This condition is known as amebic dysentery (DIS-en-ter-y) and often leads to severe dehydration (excessive loss of body water).

Hepatic amebiasis If the amebae move through the bloodstream to other parts of the body, pockets of infection and pus can form in other organs. In about 1 percent of cases, the amebae infect the liver and cause a condition known as hepatic (he-PAT-ik) amebiasis. The symptoms of hepatic amebiasis include fever, a distended (swollen) abdomen, and pain and tenderness in the area of the liver just below the right ribs.

How Is Amebiasis Diagnosed and Treated?

The most common method for diagnosing amebiasis is examining stained stool smears under a microscope. *Entamoeba histolytica* also can be identified from samples of tissue obtained during visual examination of the colon with a flexible instrument called a colonoscope (ko-LON-os-cope) or during surgery.

If doctors find *Entamoeba histolytica*, they will prescribe medication for asymptomatic carriers (who can spread amebiasis if the amebae are not killed) and for people with active infections. Treatment usually lasts for about three weeks.

How Is Amebiasis Prevented?

There is no vaccine or prophylactic (disease-preventing) drug for amebiasis. Prevention of amebiasis depends on maintaining clean drinking water supplies, disposing of human waste properly, and using appropriate hygiene measures, such as thoroughly washing hands after going to the bathroom and before eating.

Municipal water supplies approved by local health departments in the United States are usually considered safe. When camping or traveling in other countries, however, it is important to use water only from safe sources and to avoid sources such as mountain streams.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a rare disease. It is hereditary in some cases, but in most cases, its cause is unknown. ALS is not an infectious disease, meaning people cannot catch it from someone who has it. ALS affects the body's neurons, or nerve cells, that control movement of the voluntary (skeletal) muscles.

How Common is Amyotrophic Lateral Sclerosis?

Amyotrophic lateral sclerosis (a-my-o-TROF-ik LAT-er-al skle-RO-sis) (ALS) is also called Lou Gehrig's disease for the famous baseball player who died after developing the condition. ALS is uncommon. In the United States, only one or two cases are diagnosed in every 100,000 people in a year. According to the Amyotrophic Lateral Sclerosis Association, up to 30,000 Americans have ALS at any given time. ALS is rarely diagnosed in people younger than age 40, and it occurs more often in men than in women. Fewer than 10 percent of cases run in families. The other cases occur seemingly at random, and researchers have as of 2009 discovered nothing that puts those with the disease at higher risk. A variant of

- * **neurons** are nerve cells. Most neurons have extensions called axons and dendrites through which they send and receive signals from other neurons.
- * **cerebral cortex** (suh-REE-brul KOR-teks) is the part of the brain that controls functions such as conscious thought, listening, and speaking.
- * **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.

LOU GEHRIG'S DISEASE

Lou Gehrig (1903–1941), who played first base for the New York Yankees from 1923 to 1939, was one of the greatest players in the history of baseball. His lifetime batting average was .340, and he hit .361 in six World Series. He twice led the American League in home runs, and he once tied for home runs with Babe Ruth. In 1934, he not only led the American League in home runs with 49, but also in batting average (363) and in runs batted in (165).

Gehrig, whose nickname was the Iron Horse, also set a major league record in 1939 for playing 2,130 consecutive games, a record that held for more than five decades. His career ended in that year, however, when he developed ALS. His fame drew attention to this condition, and in the United States, it had the common name of Lou Gehrig's disease after that.

Lou Gehrig was elected to the Baseball Hall of Fame in 1939. He showed his well-known winning spirit during the recognition day held in his honor at Yankee Stadium on July 4, 1939, shortly after he received the ALS diagnosis. He said: "Fans, for the past two weeks you have been reading about the bad break I got. Yet today I consider myself the luckiest man on the face of this earth. . . . I may have had a tough break, but I have an awful lot to live for."

Gehrig died of ALS just two years later at the age of 37. Several books as well as the 1942 film *Pride of the Yankees* chronicled his story.

ALS, known as Western Pacific ALS, had a particularly elevated incidence among people on the Pacific island Guam in the 1950s and 1960s. The rate later declined, but the prevalence of Western Pacific ALS in Guam in the early 2000s is still high compared to the worldwide incidence of ALS.

What Happens to People with Amyotrophic Lateral Sclerosis?

ALS affects the upper and lower motor neurons* in the body. The upper motor neurons are located in the cerebral cortex* of the brain and send signals for muscle movement to the spinal cord, where the lower motor neurons then carry the signals to the muscles. Damage to the upper motor neurons results in such symptoms as heightened gag reflex or other reflexes, and stiff muscles. Damage to the lower motor neurons includes muscle weakness, cramps, and twitches. In ALS, both upper and lower motor neurons degenerate or die. In either case, they no longer function. For this reason, symptoms of both upper and lower motor neuron damage are part of the diagnosis of ALS.

Typically, the disease produces weakness and paralysis* in the muscles it affects, and it causes these muscles to waste away. About 40 percent of people with ALS first notice very minor symptoms, such as clumsiness in

their hands when they try to perform such routine tasks as buttoning a shirt. Others may feel weakness in their legs or notice that their speech has become slower.

As time goes on, the person's arms and legs become weaker. They may experience muscle spasms, weight loss, and difficulty in breathing, eating, and swallowing. ALS does not affect the mind, however, and people with ALS are able to think as clearly as before. People with ALS have no loss of sensation or sense of touch.

People usually die within a few years after they develop ALS. In a very few cases, symptoms may stabilize at some point, remaining the same for years without getting any worse.

How Is Amyotrophic Lateral Sclerosis Diagnosed and Treated?

Physicians can distinguish ALS from other diseases of the nervous system by its usually late onset in life and by the progressive nature (worsening of symptoms) of the illness. The fact that the sense of touch is not affected also helps in diagnosis. Multiple sclerosis (MS), a more common disease, like ALS, affects the nervous system. Unlike ALS, however, MS attacks the nervous system in a number of different ways rather than involving only the motor nerves.

Physicians perform different kinds of medical tests to diagnose ALS. Tests may include:

- electromyogram (EMG), which measures the electrical activity of the muscles
- computerized tomography (CT), which uses computers and x-rays to record internal body images
- magnetic resonance imaging (MRI), which uses magnetism to create internal body images
- muscle or nerve biopsy, in which a small sample of tissue is removed from the body and studied under a microscope
- blood and urine studies.

Is There a Cure for Amyotrophic Lateral Sclerosis?

ALS has no known cure, but a few medications can ease the muscle spasms and possibly even slow the rate at which symptoms get worse. People who have ALS maintain an independent lifestyle as much as possible by taking different measures. Physical therapy, such as massage and regulated exercises, can reduce disability somewhat by helping the muscles to work better. Such aids as canes, walkers, and wheelchairs can help people with ALS remain independent. Mechanical ventilation (machine-assisted breathing support) is often needed in the later stages of the disease.

▶ See also **Multiple Sclerosis • Paralysis**

British scientist Stephen Hawking has Amyotrophic Lateral Sclerosis. ALS causes the muscles to waste away but does not affect the mind. Hawking, whose specialty is theoretical physics, is known as a visionary thinker; he has given many lectures using a computerized speech synthesizer. *AP Images.*

How ALS Got Its Medical Name

French neurologist Jean-Martin Charcot (1825–1893) was the first to describe ALS and gave the disease its name. Charcot noted in detail the wasting of muscles (amyotrophy) and the hardening (sclerosis) of motor nerves along the sides (laterally) of the spinal cord. In France, ALS is known as “la maladie de Charcot” (meaning Charcot’s disease) and in Great Britain it is called “motor neurone disease.”

▲
A smear of human blood containing a variety of cells that can be distinguished by cell size, presence of a nucleus, and frequency compared to other elements in the smear. The most numerous are red blood cells, which do not have nuclei and have light centers surrounded by a darker thicker edge. White blood cells are larger than red blood cells and contain a nucleus. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

* **hemoglobin** (HE-muh-glo-bin) is the oxygen-carrying pigment of the red blood cells.

* **hemophilia** (hee-mo-FIL-e-a) is a hereditary disease that results in abnormal bleeding because the blood fails to clot. It occurs almost exclusively in males.

Anemia, Bleeding, and Clotting

Anemia is a condition that occurs when there are too few properly functioning red blood cells to carry oxygen throughout the body. There are many different causes of anemia. Sickle-cell anemia, also called sickle-cell disease, is a hereditary disorder in which abnormal hemoglobin within the red blood cells interferes with their functioning and survival. Hemorrhage (HEM-or-ij) is significant bleeding that can lead to anemia. Clotting is the process that changes blood into a thick, jellylike substance that stops bleeding. Hemophilia* is a hereditary disorder in which the blood does not clot normally, leading to excessive bleeding and possibly hemorrhage and anemia.*

Carrie's Story

When Carrie turned 13, she was determined to finally get rid of what she called her “baby fat.” She longed to look like the skinny models who graced the covers of fashion magazines. Carrie stopped eating the well-balanced meals her mother prepared. Instead she grabbed rice cakes or low-fat chips to stop the hunger pangs. At about the same time Carrie got her period for the first time.

It was not long before Carrie started to feel lightheaded whenever she stood up. In gym class she had to stop and rest every five minutes. Noticing Carrie's behavior and how pale she looked, the gym teacher suspected that Carrie had iron-deficiency anemia. This type of anemia is very common in teenage girls due to poor eating habits and iron loss

from menstruation*. At her coach's suggestion, Carrie visited her doctor. Together they came up with a healthy diet and exercise plan to help Carrie reach an appropriate weight and keep her iron level normal.

What Is Anemia?

Anemia is a condition in which the blood does not contain enough properly functioning red blood cells to carry oxygen to all the cells of the body. There are several dozen types of anemia that fall into three broad categories according to their underlying causes:

- The process for making red blood cells, called erythrocytes (e-RITH-ro-sites), is not functioning normally: Either the bone marrow—the tissue in the center of most bones—does not make enough erythrocytes, the erythrocytes do not contain enough hemoglobin, or the hemoglobin does not function correctly.
- Erythrocytes are destroyed faster than the bone marrow can replenish them. Sickle-cell anemia, caused by defective hemoglobin genes* inherited from one's parents, is an example of this type of anemia.
- The body's total blood volume is lost faster than it can be replaced, caused by hemorrhage or impaired clotting such as in cases of hemophilia.

The life of an erythrocyte Blood contains red and white blood cells, platelets, and plasma—the yellow-tinted portion made up of water and other substances. Erythrocytes are the most abundant cells in the blood and give blood its red color. They are produced from stem cells* in the bone marrow by a process called hematopoiesis (he-ma-tow-po-EE-sis).

As erythrocytes mature in the bone marrow, they fill up with hemoglobin. Hemoglobin consists of four protein chains, called globins, and four heme molecules. Heme contains iron that binds to and transports oxygen and carbon dioxide. This characteristic enables hemoglobin to absorb oxygen in the lungs, release oxygen to the cells of the body, and transport carbon dioxide from the cells back to the lungs.

As an erythrocyte matures, it rids itself of most of the normal cell components (including the nucleus) to make room for about 300 hemoglobin molecules, which take up most of the cell's volume. Without the usual components, erythrocytes cannot grow and divide, and each erythrocyte survives for only about 120 days. The spleen, an oval organ located between the stomach and the diaphragm on the left side of the body, contains cells called macrophages (MAK-ro-fayj-ez). The macrophages engulf and break down the old, dying erythrocytes and recycle the iron from the hemoglobin to be used to make more hemoglobin. More than 2 million erythrocytes die every second, and they must be replaced by hematopoiesis at exactly the same rate. If there are too few erythrocytes, the kidneys (and to a lesser extent, the liver) make a hormone called erythropoietin (ee-rith-ro-po-EE-tin). This protein is secreted into the blood and signals the bone marrow to make more red blood cells.

* **menstruation** (men-stroo-AY-shun) is the discharge of the blood-enriched lining of the uterus. Menstruation normally occurs in females who are physically mature enough to bear children. Most girls have their first period between the age of 9 and 16. Menstruation ceases during pregnancy and after menopause. Because it usually occurs at about four-week intervals, it is often called the monthly period.

* **genes** are chemicals inherited from both parents that help determine physical characteristics, such as whether a person has brown hair or blue eyes, or in this case, normal or abnormal hemoglobin.

* **stem cell** an unspecialized cell that gives rise to differentiated cells.

Blood production is a complex process that requires communication between many parts of the body, including the bone marrow, the kidneys, and the spleen. There are many places in the process where something can go wrong. Problems with stem cells, with the production and maturation of erythrocytes, with the manufacture of hemoglobin, and with spleen function, and problems caused by improper signaling between the kidney and bone marrow can all lead to anemia. A person can have anemia due to an inherited blood disorder, because of an acquired blood condition, or as a side effect of a disease or condition not directly related to the blood. Sometimes anemia can be related to the ingestion of certain medications.

Types of anemia Among the many different conditions and disorders that can cause low production of erythrocytes leading to anemia are the following:

- An iron-deficient diet, as in Carrie's story, is the most common cause of this type of anemia.
- Folate-deficiency anemia is caused by a lack of folate (folic acid) in the diet or poor absorption of the nutrient.
- Pernicious anemia is caused by vitamin B12 deficiency.
- Sideroblastic (sid-er-o-BLAS-tik) anemia is a disorder in which the heme portion of hemoglobin does not correctly bind iron.
- Thalassemia (thal-a-SEE-me-a) is a group of inherited disorders in which the rate of hemoglobin production in the bone marrow is low because of a defect in the globin portion of hemoglobin.
- Diamond blackfan anemia is a very rare blood disorder in which the bone marrow does not make enough red blood cells.
- Aplastic anemia refers to a group of disorders in which the hematopoietic cells of the bone marrow are defective or destroyed.

Hemolytic anemias are caused by the premature destruction of red blood cells. Sickle-cell anemia is the best-known hemolytic anemia. In this disorder abnormal hemoglobin—called hemoglobin S—causes the erythrocytes to be sickle- or crescent-shaped rather than rounded and flattish like a saucer. Because of their shape, sickle cells cannot flow easily, and they tend to bunch up and clog blood vessels and break apart. This action can cause inflammation, pain, and tissue damage. Sickle cells are also more easily destroyed than normal red blood cells, having a lifespan of only 10 to 20 days. Although people with sickle-cell disease make red blood cells faster than healthy people, their bodies cannot keep up with the destruction of their red blood cells, resulting in anemia.

Hemorrhage, which means losing a lot of blood very quickly, can result in anemia because the body cannot make new blood as fast as it is being lost. Hemorrhages can be caused by injury, a burst blood vessel, childbirth, or surgery.

What Are Bleeding and Clotting Disorders?

Almost as soon as blood starts to flow from a cut finger or scraped knee, tiny, clear disc-shaped platelets begin the process of clotting, which entails turning the blood from liquid to solid to stop the flow. Platelets stick together and form a small plug at the point of bleeding. They contain an enzyme (a protein) that causes fibrinogen (fy-BRIN-o-jen), a substance in the blood, to change to fibrin (FY-brin), a hard substance that does not dissolve. The fibrin piles up, helping the platelets to block the opening and stop the blood flow. Fibrin needs other proteins in the plasma, called clotting factors, to do its job. The clotting factors are numbered I through XIII.

Some people have blood that does not clot well. Blood clots also can form in the wrong places and at the wrong time.

Hemophilia and other bleeding disorders Hemophilia is an inherited deficiency in a blood-clotting factor that results in excessive bleeding. For hemophiliacs losing a tooth or falling off a bicycle can be life-threatening because the bleeding does not stop.

Hemophilia A is a deficiency in clotting factor VIII. Factors I through VII function properly, but then the clotting process is interrupted and blood from a wound continues to flow. Hemophilia B is caused by a deficiency in factor IX.

Hemophilia varies in severity:

- With mild hemophilia the levels of factors VIII or IX are 6 to 50 percent of normal. Excessive bleeding is usually associated only with major injuries, surgical procedures, or tooth extractions.
- With moderate hemophilia factors VIII or IX are 1 to 5 percent of normal. Excessive bleeding follows minor injury as well as dental extractions and surgeries.

◀ The gene for hemophilia is unintentionally passed from mothers (XX) to sons (XY) via the X chromosome. A son who inherits a defective X chromosome from his mother does not have a healthy X chromosome to rely on the way daughters (XX) do. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **blood clots** are thickenings of the blood into a jelly-like substance that helps stop bleeding. Clotting of the blood within a blood vessel can lead to blockage of blood flow.

* **pulmonary embolism** is a blockage of the pulmonary artery or one of its branches that is frequently caused by thrombosis, or formation of a blood clot, in the lower extremities.

- With the most severe forms of hemophilia, factors VIII or IX are less than 1 percent of normal. The blood cannot clot at all, and hemorrhaging or internal bleeding can occur even in the absence of injury.

Von Willebrand's disease is a common bleeding disorder caused by a deficiency or defect in von Willebrand factor, a protein that helps the blood to clot. Liver disorders can also prevent the blood from clotting well because the liver produces some of the most important clotting factors.

Thrombophilia Thrombophilia is the name for any of several inherited disorders in which the blood may clot excessively. Factor V Leiden is the most common form of thrombophilia. Some people with thrombophilia develop blood clots or thrombosis.

Thrombosis is a condition in which blood clots* form in the wrong places, such as in a leg vein. Clots in veins can break free and travel to the heart and lungs, where they can cause a pulmonary embolism*, or blockage, which can be fatal.

How Common Are Anemia and Bleeding and Clotting Disorders?

Anemia Anemia caused by nutritional deficiencies is very common in Africa and Southeast Asia. The World Health Organization estimates that between 1993 and 2005, 24.8 percent of the world's population, about 1.62 billion people, suffered from anemia, including 47.4 percent of all preschool-age children, that is approximately 293 million children.

Iron-deficient anemia is very common, especially in infants and teenagers who need a lot of iron to fuel their growing bodies. In addition 30 to 50 percent of American women are at risk for anemia because of blood loss during menstruation and inadequate amounts of iron in their diets to offset these monthly losses.

Thalassemia is most common in Asia, the Mediterranean basin, and the Middle East. It is also fairly common in Africa. It affects about 1,000 Americans. Diamond blackfan anemia is so rare that there are only 25 to 35 new cases each year in the United States and Canada combined.

In contrast sickle-cell anemia affects millions of people around the world. In some parts of Africa up to 40 percent of the population has at least one *HbS* gene. In the United States more than 70,000 people have sickle-cell disease and 2 million carry the sickle-cell trait. It is particularly common in people whose ancestors came from sub-Saharan Africa, Spanish-speaking regions of the Western Hemisphere, Saudi Arabia, India, and Mediterranean countries such as Turkey, Greece, and Italy. One in every 500 African Americans is born with the disease and one in 12 has sickle-cell trait.

Bleeding and clotting disorders Hemophilia affects approximately 20,000 Americans and more than 400,000 people worldwide. Hemophilia A occurs in one out of every 5,000 live male births; hemophilia B in about

EUROPEAN ROYALTY AND HEMOPHILIA

History's most famous carrier of the gene for hemophilia was Queen Victoria (1819–1901), monarch of Great Britain and grandmother to most of the royalty in Europe. In 1853 Queen Victoria gave birth to her eighth child, Leopold, Duke of Albany, who had hemophilia and died at the age of 31 from internal bleeding after a fall.

Two of Queen Victoria's four daughters, Alice (1843–1878) and Beatrice (1857–1944), also carried the gene for hemophilia and subsequently transmitted the disorder to three of Victoria's grandsons and to six of her great-grandsons.

Alice's daughter Alexandra (1872–1918) was a carrier of hemophilia. She married Tzar Nicholas II (1868–1918) of Russia. Their son Alexei (1904–1918) was perhaps the most famous of the European royals with hemophilia. Alexei was the heir to his father's throne and his medical condition caused much anxiety in the royal household. Historians still discuss the role that Alexei's hemophilia played in the Russian revolution of 1918.

one in 10,000 live male births. About 60 percent of all cases of hemophilia are severe, and worldwide about 70 percent of people with hemophilia have no access to treatment.

Von Willebrand's disease is a common bleeding disorder that affects 1 to 2 percent of the U.S. population. Type I, the mildest form of the disease, accounts for 70 percent of cases. Although von Willebrand's disease occurs in both men and women, women are more likely to have symptoms because of heavy bleeding during menstruation and childbirth.

In the United States 5 to 8 percent of people have some form of thrombophilia, and more than 600,000 Americans are affected by abnormal blood clots. Deep-vein thrombosis affects 200,000 to 400,000 Americans. Almost one-third of them have post-thrombotic syndrome, a chronic disabling condition in the affected limb. In addition 100,000 to 200,000 Americans have pulmonary embolism and almost one-third of them die from it.

What Causes Anemia and Bleeding and Clotting Disorders?

Nutritional deficiencies Iron, folic acid, and vitamin B12 are all required for the bone marrow to make hemoglobin and erythrocytes. If these elements are missing from the diet or are not absorbed by the gastrointestinal tract, anemia can result.

Folate-deficiency anemia can be caused by a diet that is deficient in fresh fruits and vegetables that contain folic acid. It can also be caused by

What Do Babies and Teenage Girls Have in Common?

Infants and teenage girls are all at risk of developing iron-deficiency anemia. Teenage girls are at risk because they lose blood when they begin to menstruate, at a time when they are having growth spurts. In addition, many teenage girls are concerned about their weight and how they look: They may go on diets that do not provide enough iron. The combination of these factors often results in anemia.

Babies need lots of iron to fuel their rapid growth; their blood volume increases as fast as their bodies grow. Many doctors test 6- to 12-month-old babies for anemia, even if they seem happy and healthy because in the past so many babies developed iron-deficiency anemia. Typically iron is added to baby formula and baby cereals and only 2 to 3 percent of middle-class infants develop anemia. For breastfed babies, the iron in cereal or in supplements is especially important because breast milk alone cannot provide enough iron. Unfortunately, the rates of infant anemia are higher in lower-income communities because of poor nutrition.

* **bulimia** (bu-LEE-me-a) is an eating disorder in which a person has episodes of out-of-control overeating, or binges, and then tries to make up for them by making themselves vomit, by taking laxatives, or by exercising to excess to avoid gaining weight.

* **anorexia nervosa** (an-o-REK-se-a ner-VO-sa) is an emotional disorder characterized by dread of gaining weight, leading to self-starvation and dangerous loss of weight and malnutrition.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **autoimmune diseases** (aw-toh-ih-MYOON) are diseases in which the body's immune system attacks some of the body's own normal tissues and cells.

diseases, alcoholism, or some medications that interfere with the absorption of folate by the body.

Pernicious anemia occurs when individuals do not eat enough foods containing vitamin B12 or are unable to absorb the vitamin properly. To absorb vitamin B12, the lining of the stomach must produce hydrochloric acid and a chemical called “intrinsic factor.” If acid production is low or intrinsic factor is missing, the vitamin is not absorbed. People with a poor diet, bulimia*, anorexia nervosa*, diabetes, or thyroid disease, or who have had stomach surgery, stomach cancer, or a family history of pernicious anemia are all susceptible.

Other causes of low red blood cell production Sideroblastic anemia can be an inherited disorder, but it can also be caused by alcoholism, exposure to toxins such as lead, or acquired bone-marrow disorders. Thalassemia is an inherited disorder. Diamond blackfan anemia has an identifiable inherited genetic defect in about 25 percent of patients.

Aplastic anemia can result from destruction of blood-forming cells by cancer of the bone marrow or exposure to toxic chemicals, radiation, certain antibiotics*, or other medications. However, in many cases, the cause of aplastic anemia is unknown.

People with kidney diseases often develop anemia because the kidneys no longer produce enough erythropoietin in response to a decrease in red blood cells.

People who are frequently ill with infections are prone to anemia because infection slows the production of red blood cells. Anemia is very common in people with AIDS* because their immune systems* do not function properly, leaving these individuals prone to infections.

Hemolytic anemia In addition to inherited disorders such as sickle-cell disease, there are a variety of other causes of hemolytic anemia. Erythrocytes can be destroyed too soon or too fast for the following reasons:

- Defects in the membranes surrounding red blood cells cause them to be destroyed by macrophages
- Abnormal spleen function
- Exposure to certain drugs or toxic chemicals
- Infection
- Problems with the immune system

People with autoimmune diseases*, such as rheumatoid arthritis, can develop hemolytic anemia. In autoimmune diseases the body's immune system does not work correctly. In addition to destroying foreign cells, such as bacteria that cause infection, the immune system attacks and destroys its own cells, including erythrocytes.

Hemorrhage and hemophilia Hemorrhage is any profuse internal or external bleeding from the blood vessels. The most obvious cause of hemorrhage is trauma (injury) to a blood vessel. Hemorrhage can also be

WHY ARE HEMOPHILIACS ALMOST ALWAYS MALE?

Chromosomes are paired thread-like structures found in the nucleus or controlling region of the body's cells. They determine the development of individual characteristics. One obvious characteristic is sex, whether a person is male or female. A female has two X chromosomes and a male has one X and one Y chromosome.

Chromosomes are composed of genes, the individual units that determine everything from eye color to how the body functions. The X chromosome carries genes that control the production of clotting factors VIII and IX. In hemophiliacs, these genes cause the body to produce too little factor VIII or factor IX. Even if a girl (XX) has one X chromosome with a hemophilia gene, the other X chromosome is probably normal, and her body will produce enough factor VIII or IX to ensure that the blood will clot. The Y chromosome, however, has no part in the production of blood-clotting factors. Boys (XY) who inherit an X chromosome with a hemophilia gene from their mothers have no other X chromosome to compensate for the hemophilia gene.

* **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

caused by aneurysms, weak spots in artery walls that are often present at birth. Over time the blood vessel wall at the site of an aneurysm balloons out and becomes thinner, making it more likely to leak and rupture.

Hypertension, or high blood pressure, is often a contributing factor in brain hemorrhage, which can cause strokes*. Uncontrolled diabetes can weaken blood vessels, especially in the eyes, resulting in a condition called retinopathy (ret-i-NOP-a-thee). Blood vessels also simply wear out with age. Some medications that affect blood clotting, including aspirin, can increase the likelihood of hemorrhage.

Bleeding disorders such as hemophilia can lead to hemorrhage. Hemophilia is caused by a defective gene that can be passed from mothers to sons via the X chromosome. Female carriers of the hemophilia gene have normal levels of clotting factors. Although a man with hemophilia and a woman carrier can produce a daughter with hemophilia, this is very rare. Up to one-third of hemophiliacs have no family history of the disorder. In these cases, a mutation (a change in a gene) has produced a new hemophilia gene, which may be passed on to subsequent generations.

What Are the Symptoms of Anemia and Bleeding and Clotting Disorders?

Anemia Mild anemia often has no symptoms. Symptoms of more severe anemia depend on various factors, including a person's age, how quickly the anemia developed, and other concurrent illnesses. Symptoms may be more obvious with a rapidly developing anemia. Moderate anemia,

such as pernicious anemia that usually develops slowly over a long period of time, may have few noticeable symptoms.

Like Carrie, people with moderate-to-severe anemia may feel tired, weak, dizzy, and short of breath, symptoms caused when the cells of the body are not getting enough oxygen. This lack of oxygen can also cause irritability and apathy. Sometimes people with moderate-to-severe anemia appear pale and waxy. Other symptoms may include:

- Headaches
- Loss of appetite
- Indigestion
- Sore tongue
- Bleeding gums
- Insomnia (difficulty sleeping)
- Rapid heartbeat
- Fatigue
- Poor concentration
- Menstrual irregularities in women

Babies born with thalassemia major have severe anemia during the first year of life that results in slow growth, abnormal bone development, and an enlarged liver and spleen. People with thalassemia minor may not have any symptoms.

People with sickle-cell trait usually have no symptoms of anemia, and they grow and develop normally. However, people with sickle-cell disease often have severe anemia, as well as delayed growth, episodes of pain, and frequent infections. Their skin may become yellowish (jaundiced) from the excessive destruction of red blood cells.

Hemorrhage and hemophilia Visible blood is the most obvious sign of hemorrhage. However, internal hemorrhaging may have no symptoms until complications develop. Symptoms of a brain hemorrhage depend on where the bleeding is occurring and can include the following:

- Headache
- Stiff neck
- Decreased alertness
- Balance problems
- Vomiting
- Drowsiness
- Changes in vision
- Numbness or weakness
- Difficulty swallowing, speaking, reading, or writing
- Confusion

- Loss of function on one side of the body
- Coma

Although hemophilia is present at birth, babies who are not circumcised (a surgical procedure to remove the foreskin of the penis) seldom experience problems until they begin to crawl. Once they start to bump into hard surfaces or fall, they begin to bleed into muscles or joints. This internal bleeding can cause joints to bruise and swell painfully.

Symptoms of von Willebrand's disease include frequent nosebleeds, a tendency to bruise easily, and prolonged bleeding during menstruation, childbirth, or following surgery.

How Is Anemia Diagnosed and Treated?

Diagnosis A complete blood count (CBC) is used to test for anemia. A small sample of blood is drawn and the numbers and volume of the different types of blood cells and the hemoglobin content of the red blood cells are measured. Some of the blood is smeared onto a slide and the color, size, and shape of the red blood cells are observed under a microscope. Iron-deficiency anemia is characterized by small red blood cells. Folate-deficiency and pernicious anemias are characterized by large red blood cells.

Sickle-cell disease and sickle-cell trait can be diagnosed by a test called hemoglobin electrophoresis (e-lek-tro-fo-REE-sis), which detects the presence of hemoglobin S and other abnormal hemoglobins.

Anemia is often caused by problems in the bone marrow where blood cells are made. Sometimes it is necessary to take a bone-marrow sample to determine the cause of the anemia. A needle is inserted into the hip bone and a sample of marrow withdrawn and analyzed.

Whereas it is easy to determine if a patient is anemic, finding the underlying cause can be more difficult. Anemia can be a symptom of many different diseases and disorders, and treatment depends entirely on the cause. Individual and family medical histories, symptoms, diet, illnesses, and drugs and medications are all important elements in diagnosing the cause of anemia. Treatment is specific for each type of anemia and is based on treating the underlying deficiency or disease.

Treatments If the anemia has a nutritional cause, changing to a diet rich in the deficient nutrient or taking supplements such as iron or vitamins often cures the problem. Food containing vitamin C, such as oranges, cantaloupe, and broccoli, can help the body to absorb iron. Treatment for most other types of anemia is much more complex and in some cases impossible.

Erythropoietin is sometimes administered to increase the production of red blood cells in anemia caused by cancer, AIDS, kidney disease, or rheumatoid arthritis. Other drugs are used to stimulate red blood cell production in people with some types of thalassemia or sickle-cell disease. Sometimes drugs that reduce the activity of the immune system (immunosuppressives) are used to treat hemolytic anemia caused by autoimmune

Granny Heath and Liver Therapy

In *My Second Life* (1944) author and physician Thomas Hall Shastid (1866–1947) recalls how his schoolteacher, “Granny Heath,” proclaimed that the raw or cooked liver of just about any farm animal was the perfect remedy for what she called the “littleness of blood.”

Doctors George R. Minot (1885–1950), William Parry Murphy (1892–1987), and George Hoyt Whipple (1878–1976) used liver to effectively treat pernicious anemia. They were awarded the Nobel Prize in 1934 for their research on blood chemistry and histology, which established the scientific basis for liver therapy.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **blood transfusion** is the process of giving blood (or certain cells or chemicals found in the blood) to a person who needs it due to illness or blood loss.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

* **convulsions** (kon-VUL-shuns), also called seizures, are involuntary muscle contractions caused by electrical discharges within the brain and are usually accompanied by changes in consciousness.

disease. Occasionally the spleen must be removed to stop the premature destruction of erythrocytes.

Aplastic anemia is sometimes treated with a bone-marrow transplant from a relative with compatible cell types. However, it is often difficult to find a transplant donor with the right cell type.

There is no cure for sickle-cell anemia. Treatment is preventative and directed at symptoms:

- Antibiotics to prevent infections
- Pain-relieving medications
- Intravenous fluids to offset dehydration*
- Oxygen therapy
- blood transfusion*

Complications of sickle-cell anemia In addition to the symptoms and complications of anemia, people with sickle-cell disease periodically experience bouts of critical illness, called crises. Sickle-shaped red blood cells clump more easily than normal red blood cells. Sickle-cell crises begin suddenly when clumping of sickled red blood cells in the blood vessels obstructs the normal flow of blood, depriving tissues and organs of oxygen. The first crises usually appear in early childhood.

Crisis can be brought on by respiratory infection, loss of body fluids from vomiting or diarrhea, or situations in which the body’s need for oxygen is increased. They may occur for no obvious reason. A crisis can last for several days and cause fever and sharp intense pain in the back, abdomen*, chest, arms, and legs. In infants the hands and feet may become swollen and painful.

Crisis can damage almost any part of the body, but especially the bones, kidneys, intestines, lungs, liver, spleen, and the central nervous system*, including the brain. Crises can also damage the eyes and cause stroke, convulsions*, or paralysis.

People with sickle-cell disease are more susceptible to all kinds of bacterial and fungal infections. They are more likely to experience kidney failure and liver problems. By age 30, about 70 percent of people with sickle-cell disease have developed gallstones.

How Are Bleeding and Clotting Disorders Diagnosed and Treated?

Sometimes anemia is caused by chronic bleeding, such as from a wound in the skin or mucous membranes inside the body (ulcer). The source of bleeding must first be found and treated. Iron supplements are often needed to help boost hemoglobin production. In severe cases, a blood transfusion is used to replenish the volume of blood in the body.

Hemorrhage When bleeding is visible the causes of most hemorrhages are obvious. Blood tests and spinal-fluid tests can reveal evidence of brain hemorrhage. Computed tomography (CT or CAT) scanning is

an important imaging technique for detecting bleeding in the brain and other tissues.

The first goal in treating a hemorrhage is to stop the bleeding. Hemorrhage caused by trauma or the tearing of blood vessels can be treated by clamping or surgically repairing the tears. Hemorrhage resulting from vessel leakage due to high blood pressure can be treated with medicines to reduce blood pressure, prevent vessel spasm, and reduce pain. Surgery may be needed to reduce the pressure of blood that has collected in the brain. Blood factors to help the blood clot may be administered to those with bleeding disorders.

If the blood loss is life-threatening, a blood transfusion is necessary. In less severe cases, the body itself can slowly bring the blood volume and hemoglobin content back to normal. In fact, people can survive the loss of two-thirds of their blood volume over a 24-hour period.

Hemophilia Hemophilia can be diagnosed by measuring the levels of clotting factors in the blood. DNA testing (direct analysis of the genes) can determine whether a woman carries a gene for hemophilia. Tests can also be performed on fetuses to determine if they have inherited hemophilia. However, mild cases of hemophilia may not be diagnosed until adulthood, when unexplained and excessive bleeding accompanies surgery or a visit to the dentist. Likewise von Willebrand's disease often goes undiagnosed or is misdiagnosed.

Hemophiliacs are often supplied with the missing blood-clotting factor. These factors are collected, purified, and combined from the blood donations of many people. Since the mid-1990s they have also been produced by genetic engineering, which does not require blood donations. The clotting factors are transfused through a person's vein at a hospital, doctor's office, or by a properly trained individual at home.

People with mild cases of hemophilia may never or only rarely need transfusions. With a major injury or surgery, a hemophiliac may need transfusions two or three times per day for days or weeks. Some people with severe hemophilia may get transfusions on a regular basis as a preventative measure.

The medication desmopressin (DDAVP) can sometimes help release any extra stores of factor VIII in people with mild or moderate hemophilia A or von Willebrand's disease. This is a temporary treatment that may help avoid a transfusion after a minor injury.

Complications of hemophilia People with hemophilia bruise very easily, but skin bruises are rarely serious. Bleeding from small cuts and scrapes can usually be stopped by applying firm pressure to the area for several minutes. Deep cuts, however, can bleed profusely and require treatment.

Joint bleeding is a serious complication of hemophilia. Prompt treatment is necessary to prevent severe pain and swelling, and joint bleeding can lead to arthritis (inflammation of the joints), deformity, and disability. Boys with hemophilia often learn to recognize joint bleeding as a tingling sensation before the pain or swelling occurs.

HIV and Hemophilia

Between 1979 and 1985 an estimated 55 percent of people with hemophilia were infected with HIV—the virus that causes AIDS—through transfusions of clotting factors obtained from contaminated blood. Almost 90 percent of those with severe hemophilia became infected. Not only did hemophiliacs often get many transfusions, but each transfusion contained pooled clotting factors drawn from the blood of a large number of donors. This situation greatly increased the risk that the transfusion was infected with HIV.

The blood supply was later considered safe. Today, potential blood donors are screened to eliminate those who might have been exposed to HIV, and all blood is tested for the virus. In addition, clotting factors drawn from blood are treated by heat and other virus-killing techniques.

Did You Know?

Cooking acidic foods such as tomatoes in cast-iron skillets or pans can add significant amounts of iron to the diet.

* **remission** is an easing of a disease or its symptoms for a prolonged period.

Bleeding into a muscle, most often the calf, thigh, or forearm, commonly occurs simultaneous with or following an injury. The resulting swelling, which can develop over several days, may create pressure inside the muscles and damage nerves and blood vessels. Symptoms include muscle tightness, pain, a change in skin temperature, and tingling or numbness. Early treatment is needed to prevent permanent immobility or paralysis.

Any type of neck or head injury can be extremely dangerous for hemophiliacs. Neck and throat hemorrhages can obstruct breathing. Head injury, even a minor fall or bump on the head, can cause bleeding into the brain. Symptoms include irritability, headache, nausea, vomiting, double vision, and confusion.

Thrombophilia Some people with thrombophilia or thrombosis need treatment only during pregnancy, when recovering from surgery, or when sitting for long periods of time in a car or airplane. Other people need to take anti-clotting medication for their entire lives.

How Can Anemia and Hemorrhage Be Prevented?

The long-term effect of anemia is on the heart, which must work harder to pump more blood through the body. Over time the heart enlarges, increasing the risk of heart attack and heart failure.

Good nutrition plays a big part in preventing or treating many types of anemia. Maintaining a healthy diet requires eating daily foods that include the following:

- Iron from beef, liver, oysters, sardines, egg yolks, spinach, collards, kale, turnip greens, dried peas and beans, potatoes in their skins, pumpkin, dried fruit, whole grains, wheat germ, soy flour, iron-fortified cereals, molasses, carob
- Folic acid found in dark-green leafy vegetables, meat, eggs, orange juice, and wholegrain cereals
- Vitamin B12, which is only found in animal products, such as meat, fish, and dairy

A healthy diet, regular exercise, cutting down on excess sodium intake, maintaining a normal weight, and taking prescribed medications properly can often control high blood pressure that can lead to a hemorrhage. The use of cocaine, amphetamines, and alcohol are associated with brain hemorrhages, particularly in young people. Wearing helmets when bicycling, skateboarding, and rollerblading, and always wearing seatbelts in motor vehicles can help prevent serious head injuries. Retinopathy can be prevented or lessened by controlling diabetes by keeping blood sugar at a near-normal level.

Living with Sickle-cell Anemia

Many people with sickle-cell disease go through long periods of remission* during which they may feel relatively well, engage in most normal activities, and are free of crises. Other people experience pain on a daily basis, and some are hospitalized with crises several times per year.

In the United States, babies, regardless of ethnic background, are tested for hemoglobin S as part of routine newborn screening. Before this screening became commonplace, many babies with sickle-cell disease died from infections in infancy. The use of preventative antibiotics significantly reduced this infant mortality. Children with sickle-cell anemia receive a complete set of immunizations.

Daily folic acid may stimulate new red blood cell production. Fluid intake is important to prevent the dehydration of cells that increases their sickling. Lifestyle habits that can help sickle-cell patients stay healthy and have fewer crises include:

- Avoidance of extremes of heat and cold
- Avoidance of stress and overexertion
- Receiving adequate sleep
- Having regular medical check-ups.

Prospective parents who might be carrying the *HbS* gene may choose to be tested and receive genetic counseling before having children.

Living with Hemophilia

As soon as a child is diagnosed with hemophilia, parents try to prevent or reduce occurrences of bleeding. The children should have soft toys without sharp corners and padded clothing, particularly at the elbows and knees, while learning to walk. Children should be immunized, but the injections should be given under the skin, rather than into the muscle, to prevent hemorrhage. Children should clean their teeth regularly and visit the dentist to prevent tooth decay and gum disease* that can lead to bleeding episodes.

Hemophilia is usually not fatal, and people often live long and active lives with the disorder. Activities such as swimming, walking, and bicycling can help build up muscles that support the joints. Contact sports such as football or wrestling, however, are prohibited because of the high risk of head or neck injury. People with hemophilia should never take aspirin because it increases the tendency to bleed and interferes with clotting.

Anencephaly

Anencephaly is a serious and fatal medical condition in which there is defective formation of the brain and skull during fetal development.

What Is Anencephaly?

Anencephaly is a serious and fatal medical condition in which there is defective formation of the brain and skull during fetal development. The brain is minimally developed and almost entirely absent. There may be rudimentary portions of the hindbrain* present, responsible for basic functions such as breathing. The skull is only partially formed. A fetus*

Diagram of Anencephaly

The brain of a normal infant (left); the brain of an infant with anencephaly (right). *Illustration by Argosy. Reproduced by permission of Gale, a part of Cengage Learning.*

with anencephaly may die in the womb or may survive birth and die shortly thereafter. Fetuses with anencephaly are often spontaneously aborted by the body of the mother, or they are stillborn (born dead). Those who are born temporarily breathing are usually blind and deaf, as well as unconscious due to a lack of the portion of the brain that makes consciousness possible.

During fetal development, a structure known as the neural tube is formed as a precursor to what later becomes the central nervous system in the baby. The proper formation of a neural tube, including closure of the tube, is critical to brain formation and function in later life. Anencephaly is caused by a defect in the neural tube structure during formation. Defects in neural tubes during pregnancy usually occur around 24 to 28 days after fertilization or approximately three to four weeks into the pregnancy. Anencephaly is one of many different types of neural tube defects, in which the neural tube fails to close properly.

What Causes Anencephaly?

Many different environmental factors have been implicated as having a potential role in the development of neural tube defects, including anencephaly. Maternal type 1 diabetes*, maternal obesity*, folic acid deficiency or drugs that impact folic acid levels in the body, specific toxins sometimes found in cornmeal, some poisons such as arsenic, and excessively high maternal body temperature may contribute to neural tube defects during pregnancy. Hyperthermia*, a term used to describe excessively high body temperature, may be caused by fever or recreational activities such as using a hot tub.

Folic Acid and Anencephaly Prevention

Folate is a form of folic acid, a type of B vitamin necessary for human health. Folate is found in some food groups and can also be taken as a vitamin supplement. It is a critical component of neural tube formation, which takes place in the third to fourth week of pregnancy. Many pregnant women are not aware of their pregnancy until after this time, and so they may engage in activities that harm neural tube formation without realizing it. In order to reduce the potential incidence of neural tube defects, sexually active women of child-bearing age are encouraged by healthcare providers to take folic acid supplements.

Among women who have a pregnancy affected by anencephaly or some other type of neural tube defect, the recurrence risk is approximately 2 to 4 percent for subsequent pregnancies. If there are multiple occurrences of neural tube defects in a family history, the risk is higher. Women who have had a child with anencephaly are recommended to take 4 mg of folic acid daily, whereas other women of child-bearing age are recommended to take only 0.4 mg daily. Folic acid supplementation is responsible for preventing two-thirds of all neural tube defects. It is a critical component of the campaign against the occurrence of neural tube defects such as anencephaly.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

* **hyperthermia** (HY-per-ther-ME-ah) a state in which the body either produces or absorbs more heat than it can dissipate resulting in a significantly raised body temperature.

* **alpha-fetoprotein** (AL-fah-FEE-toe-PRO-teen) is a substance produced by a fetus and present in maternal blood and amniotic fluid, measured to determine likelihood of neural tube defects.

Frequency of Anencephaly

In the United States approximately 1.2 cases of anencephaly occur per 10,000 births. Because many fetuses with anencephaly never make it to birth, the frequency during pregnancy is higher, approximately one in 1,000 pregnancies. Female fetuses tend to be more frequently affected than male. The United States has geographical regions with higher levels of known neural tube defects such as anencephaly than other regions. An increase in the frequency of neural tube defects has been tracked from the West to the East Coast, with South Carolina having the highest prevalence of neural tube defects of all the states. Hispanic populations also experience a higher rate of these defects for reasons that were unknown as of 2009. Outside the United States, regions with high numbers of neural tube defects include Guatemala, northern China, Mexico, and some areas of the United Kingdom.

Physical Appearance of Anencephaly

At birth, babies with anencephaly are missing a large portion of their brain and part of their skull. The area of missing skull may or may not be covered by skin. Facial features are present and may appear relatively normal. Breathing and reflexes are present, but the child is missing the portion of the brain responsible for consciousness and is also deaf and blind.

Alpha-fetoprotein Measurement

Alpha-fetoprotein (AFP)* is a substance made in the liver of an unborn fetus. AFP can be measured in the blood and amniotic fluid of a pregnant woman. The level of AFP present is used to determine the likelihood that the fetus has a neural tube defect, such as anencephaly. In this manner, AFP measurement can generally be used as a screen for problems such as anencephaly. However, if the region of missing skull on the fetus is covered with skin, the AFP level may not be altered from normal. If the mother has type 1 diabetes, the production of AFP during pregnancy is delayed and altered, and so it may be difficult to use this method as a screen.

Aneurysm

An aneurysm (AN-you-rizm) is an abnormal localized dilation, or swelling, of a blood vessel (a balloon-like bulge), that may cause massive bleeding, shock, or death if it ruptures (breaks open).

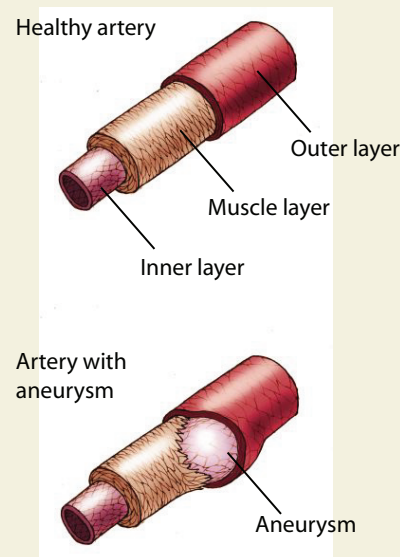

Why Are Aneurysms Called “Silent Killers”?

Aneurysms are sometimes called “silent killers” because they may go undetected for years until they break open. A segment of an artery*, or vein* (although venous aneurysms are not common), or other blood vessel may weaken and begin to bulge, like an underinflated balloon whose air is squeezed from the ends to the middle. The bulge may grow slowly for years until one day the blood vessel wall gives way (ruptures). This rupture is a medical emergency that may lead to death. There are two major classes of aneurysms: aortic aneurysms, which occur in the major artery that carries blood away from the heart, and cerebral aneurysms, which occur in an artery in the brain. Aneurysms of the aorta are virtually always caused by atherosclerosis (the build-up of plaque in arteries, which causes the arteries to lose elasticity and to harden). In the case of aortic aneurysms, a tiny tear develops within the inner layer of the aorta (the largest artery that carries blood away from the heart). Blood leaks through this tear into the middle layer of aortic tissue, causing the inner and middle layers to separate (dissect). Over time, this so-called dissecting aneurysm results in an elongated, blood-filled channel running up and down the aorta, which can break open, causing fatal bleeding.

Aortic aneurysms may arise in the abdominal portion of the aorta (abdominal aortic aneurysms) or the thoracic portion of the aorta (thoracic aortic aneurysms). In the United States more than 15,000 people die annually due to abdominal aortic aneurysm rupture. The most common aneurysm is the cerebral aneurysm, which is a stroke*.

How Do Aneurysms Happen?

Aneurysms result when the normal structure of a blood vessel becomes weak in an area. Such deterioration can be a result of atherosclerosis, where fatty deposits of lipoproteins, including cholesterol, accumulate on the walls of the blood vessels, but this kind of weakness in a blood vessel may also come about as a result of infection or trauma, or the aneurysm

▲ People with aneurysms develop bulges in the walls of an artery, vein, or other blood vessel. Top: A healthy artery. Bottom: Artery with an aneurysm. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **artery** An artery is a vessel that carries blood from the heart to tissues in the body.

* **vein** A vein is a vessel that carries blood to the heart. Veins have greater capacity and thinner walls than arteries and contain valves that prevent blood from flowing backward and away from the heart.

* **stroke** is a brain-damaging event usually caused by interference with blood flow to a region of the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

Colored magnetic resonance angiography scan of the abdominal arteries (red) of a patient with high blood pressure. At center, just below the renal arteries, the aorta is bulging, a condition known as an aneurysm. If left untreated, the blood vessel can rupture. *Zephyr/Photo Researchers, Inc.*

Monster of a Headache

R.E.M. was rocking its way through Europe during its 1995 “Monster” Tour when drummer Bill Berry got a sudden, terrible headache and could not see. It turned out that Berry had a brain aneurysm, which was operated on immediately. The surgery was a complete success, and the band was able to finish touring with their excellent drummer.

* **congenital** (kon-JEH-nih-tul) means present at birth.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

may be congenital*. An increased incidence of aneurysm may be seen with certain conditions, such as syphilis or Marfan syndrome. Many times, however, an aneurysm develops without any known cause.

Abdominal aortic aneurysm affects many more men than women. It also occurs more often in people who are older than age 55, who are smokers, or who have high blood pressure. People with other family members who have had these types of aneurysms are more likely to develop the aneurysms themselves.

There usually are no signs of a growing aneurysm. In the case of abdominal aortic aneurysms, the affected person will sometimes feel pain in his or her abdomen*. A large aneurysm in the abdomen may press against the spine and cause back pain. The rupture of an aneurysm in an artery can kill a person quickly. The rupture of a brain aneurysm constitutes a kind of hemorrhagic stroke. It is a medical emergency. Symptoms may include numbness, paralysis, stiff neck, vision loss, confusion, and loss of consciousness.

What Are the Signs and Symptoms of Aneurysms?

The signs and symptoms of an aneurysm depend on the location of the aneurysm and how large it is. Initially, for example, there may be no symptoms at all. As the aneurysm grows, however, symptoms may develop. For example, an expanding abdominal aortic aneurysm may cause severe, deep pain in the individual’s back and/or abdomen. The feet and legs may become cold and numb, due to interference with blood flow to the lower limbs. The physician may feel a pulsing mass in the individual’s abdomen and may hear a characteristic sound as he or she listens to the area with a stethoscope. If the abdominal aortic aneurysm should rupture, severe, life-threatening symptoms will occur, including dizziness, fainting, rapid heart rate, nausea and vomiting, intensely severe abdominal and back pain, and eventually shock from blood loss. If the expanding aneurysm is located in the chest (thoracic aortic aneurysm), the individual may develop pain in the jaw, neck, upper back, or chest, as well as coughing, hoarse voice, and difficulty breathing and shortness of breath. The symptoms of an expanding brain aneurysm depend on where it is located. Possible symptoms of a growing brain aneurysm include the drooping of an eyelid, double vision, other vision impairment, pain in or behind the eye, an abnormally dilated pupil, a numb or weak feeling on one side of the body or the face. If the brain aneurysm ruptures, then the signs and symptoms may include an intensely unbearable headache, nausea and vomiting, stiff neck, unconsciousness, and other signs of stroke (difficulty swallowing, difficulty talking and understanding speech, confusion, dizziness, loss of balance, difficulty walking, weakness, or paralysis of limbs). If the patient has a peripheral aneurysm, then the person might notice a pulsing bump in his or her neck, arm, or leg, as well as limb pain or muscle cramping with exercise, unhealing sores on the toes or fingers, or even gangrene due to loss of blood flow.

How Do Doctors Diagnose and Treat Aneurysms?

Fortunately, many aneurysms can be detected before they rupture. Doctors often are able to feel the pulsating sensation of abdominal aneurysms through the skin. Also, aneurysms often cause subtle changes in how the heart sounds, and doctors might notice these changes when listening to the heart. The most reliable methods of checking for aneurysms are x-rays, ultrasound* exams, and other imaging techniques that can provide more detailed images of the body.

Wait and see If an aneurysm is discovered, sometimes a doctor may adopt a wait-and-see strategy, but often this approach depends on the aneurysm's location, size, and the person's overall health. Small aneurysms might be checked every six months or so to confirm that they are not growing. Aneurysms usually grow slowly.

Surgery Sometimes surgery is required. One method involves removing the section that is bulging and replacing it with an artificial blood vessel. Another technique for repairing aortic aneurysms involves snaking a thin, flexible wire up from an artery in the leg to the aneurysm, where a tube or coils are attached to the artery's walls on either side of the aneurysm.

How Are Aneurysm Prevented?

It is most important to detect aneurysms before they break open. More than 60 percent of people whose aneurysms rupture die before they reach the hospital, and a large percentage may die during or after emergency surgery. However, regular medical care and surgery allows the vast majority of people whose aneurysms are discovered before they rupture to recover.

Animal Bites and Stings

Animal bites are wounds caused by the teeth of a wild or domestic animal or human. In addition to mammals, many insects, spiders, and reptiles can bite or sting humans. A person's reaction to a bite or sting depends on the type of wound, whether venom is injected during the bite, whether the person is allergic to the venom, and whether the biting animal is carrying a disease-causing agent.

Are Animal Bites Dangerous?

Animal bites can range from mild to serious. When the skin is not broken, bites usually are not dangerous. Animal bites can be very serious if skin, muscles, or tendons are torn; bones are crushed; a deep hole (puncture) is made; or the animal injects venom into the wound or the wound becomes infected by germs in the saliva.

Who Bites and Why?

Between 80 and 90 percent of all bite wounds that receive emergency room medical treatment in the United States are caused by dogs. Of these, about 1 percent are serious enough to require hospitalization. Cats are responsible for 5 to 15 percent of all bites. About 6 percent of cat bites require hospitalization. Other reported bites are caused by animals such as rats, mice, rabbits, ferrets, snakes, farm animals, and zoo animals and vary in severity. Children between the ages of 5 and 14 are most likely to be bitten, and very young children are most likely to die from a bite. Between 10 and 20 people die of bites each year in the United States. In developing countries where rabies* is poorly controlled, the death rate from dog bites can be quite high.

Dogs Dog bites usually occur on the hands, face, or legs. About one million people per year seek medical care for dog bites in the United States, and many more bites are unreported. Sixty percent of those bitten are children, so dog bites are a major health problem of children. Dog bites rarely become infected, and rabies in dogs is rare in the developed world. On average, 12 people, mostly young children, die each year from dog bites in the United States.

Most dogs do not bite unless provoked or teased, so most dog bites can be prevented by following simple guidelines that include the following:

- Ask permission from a dog's owner before petting the dog.
- Do not pet unfamiliar dogs.
- Do not tease dogs or pull their ears or tails.
- Avoid bothering dogs when they are eating or sleeping.
- Do not approach a dog that is protecting puppies.
- Back away very slowly from a growling dog or wait calmly for the dog to leave. Do not run away, as running stimulates the dog to chase.
- Learn the warning signs that a dog may attack: flattened ears, tail held low, lips lifted to expose teeth, growling.

Cats Cat bites and scratches are also very common, and they are more likely than dog bites to become infected and require hospitalization. Cat bites most often involve the hands, followed by the legs, face, and torso. Rabies is rare in cats, but it is more common in cats than in dogs in the United States. One infection caused by cat bites or cat scratches is cat scratch disease, which causes enlargement of the lymph nodes* but usually goes away by itself after about three weeks.

Humans Human bites are dangerous because the human mouth contains bacteria* that can cause serious infection. The most common human bite wound occurs during fights when one person punches another person and cuts his knuckles on his opponent's teeth. Children sometimes bite other children or adults, and these wounds result from skin being caught between the teeth. The condition can be made worse when people are embarrassed about the bite and do not see a doctor right away, because delay in treatment can cause an infection to develop.

Snakes

Twenty-five species of poisonous snake live in the United States, and at least one type can be found in every state except Maine, Alaska, and Hawaii. Pit vipers, which include rattlesnakes, copperheads, and cottonmouths, cause 99 percent of poisonous snakebites in the United States. Coral snakes cause the other 1 percent. Worldwide, about 15 percent of all snake species are poisonous to humans.

Venoms of different snake species range in toxicity, and a poisonous snake does not always release venom when it bites. The poisons in some species are mild, whereas others are neurotoxins (noor-o-TOK-sins;

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **tetanus** (TET-nus) is a serious bacterial infection that affects the body's central nervous system.

* **tourniquet** (tour-nih-KETZ) is a device, often a bandage twisted tight around an arm or a leg, used to stop blood flow or hemorrhage.

poisons for neurons) that may cause damage to the brain or spinal cord or cause people to stop breathing.

Any snake bite should receive emergency medical care because many people do not know what species of snake bit them, and even nonpoisonous snakes can cause infection or an allergic reaction. Each year, between 4,000 and 7,000 people are treated for snakebite in emergency rooms in the United States, with the most bites being reported in North Carolina. Men are bitten about nine times more often than women. Between 1988 and 2008, only 97 deaths in the United States were caused by snakebites.

Other Animals Mice, rats, guinea pigs, and hamsters sometimes bite, as do exotic pets such as ferrets, monkeys, snakes, snapping turtles, and birds. Horses, mules, sheep, pigs, and goats can also bite. Wild animals such as skunks, raccoons, bats, sharks, and Gila monsters cause bite injuries each year. Bites from wild animals are especially dangerous because the animals sometimes have rabies.

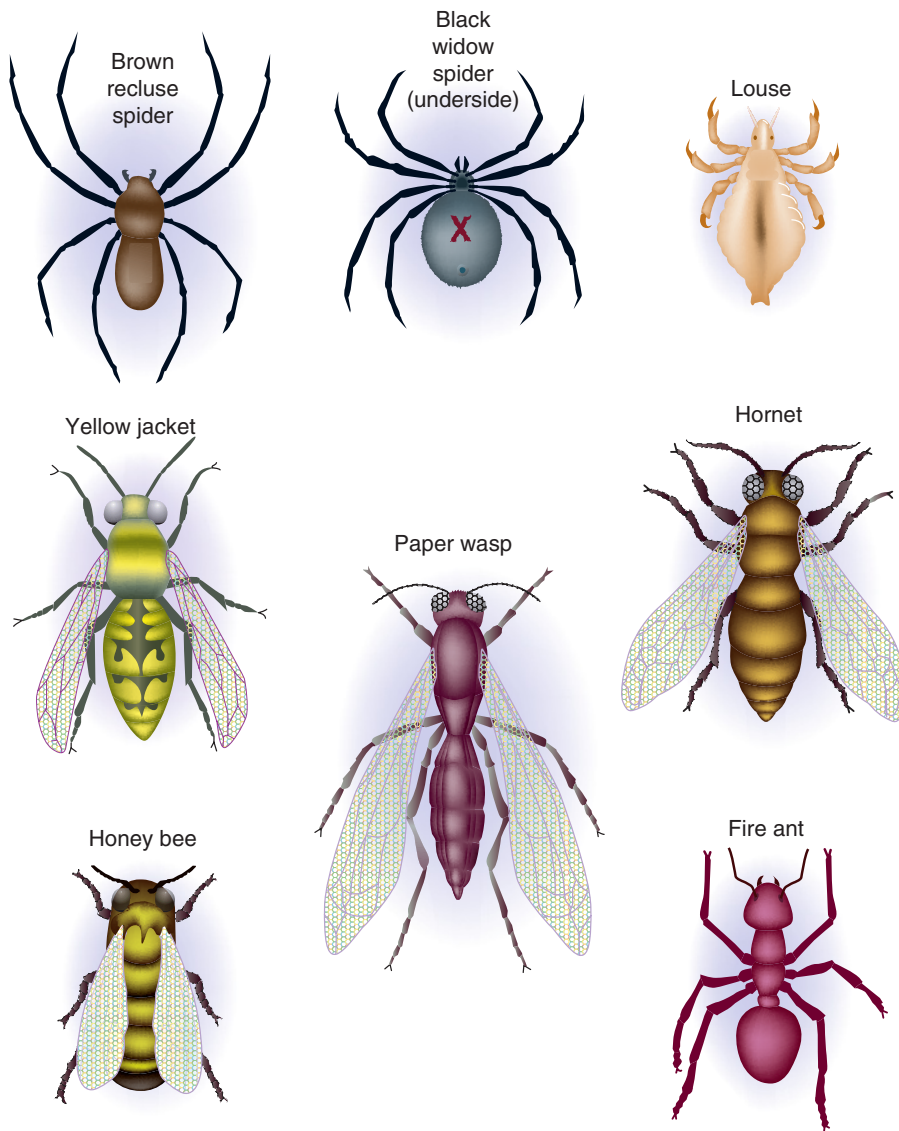

Wild or wounded animals should never be approached. If a wild animal that usually avoids people starts to approach instead or to seem friendly, it may be sick. Skunks and raccoons are nocturnal, and if they are seen walking around in midday, they should be considered to be ill, perhaps rabid. A law officer, park ranger, or animal control officer with training in handling sick or injured animals should be notified promptly about any sick animal or animal that is acting abnormally.

How Are Animal Bites Treated?

All bites should be cleaned as soon as possible. If the skin is broken but not torn or bleeding, the wound should be washed with soap and water and treated with antibiotic cream to prevent infection. When any of the following situations occur, the person who has been bitten should get medical care promptly.

- Any cat bite (but not necessarily a cat scratch wound)
- Any dog bite on the hand, foot, or head
- Any bite that causes substantial tissue or bone damage or that does not stop bleeding after applying pressure for 15 minutes
- Any bite that is wide enough to potentially need stitches or that is especially deep
- Any bite to a person who has diabetes*, cancer, lung disease, AIDS*, or any medical condition that might weaken the immune system*
- Any wild animal bite
- Any bite to a person who has not had a tetanus* shot within the past five years
- Any bite wound that shows signs of infection: redness, warmth, swelling, and tenderness at the bite site and/or discharge of pus

Many doctors agree that ice packs, tourniquets*, and incisions should *not* be used. Bites should be washed with soap and water, and the bitten

Biting and stinging insects.
Illustration by Argosy. Reproduced by permission of Gale, a part of Cengage Learning.

area should be kept still and lower than the heart. Walking and other movement should be limited to what is only absolutely necessary, and a doctor should be seen as soon as possible. Suction devices from snakebite kits if used immediately or tourniquet wrapped snugly two to four inches above the bite might slow the spread of venom until a hospital can be reached. Bites of poisonous snakes are treated with antivenin to neutralize the toxin (poison). Although death is rare, poisonous snakebites usually require 12 to 24 hours of observation in the emergency room. Pain and swelling can last for several weeks.

Rabies Rabies is a viral disease that affects the nervous system and is fatal if left untreated. In humans, symptoms can develop between five days and several years after a person has been bitten by a rabid animal, although the average incubation time is 20 to 90 days. A rabid animal,

- * **mammals** are warm-blooded animals with backbones, who usually have fur or hair. Female mammals secrete milk from mammary glands to feed their young. Humans are mammals.
- * **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.
- * **vectors** (VEK-tors) are animals or insects that carry diseases and transfer them from one host to another.
- * **malaria** (mah-LAIR-e-uh) is a disease spread to humans by the bite of an infected mosquito.
- * **elephantiasis** (eh-luh-fan-TIE-uh-sis) is the significant enlargement and thickening of body tissues caused by an infestation of parasites known as filaria.

whose saliva contains the rabies virus, usually infects other animals or individuals by biting them. All mammals* can get rabies, but the disease is extremely rare among pets or domestic animals in the United States because they are vaccinated against it. More than nine out of ten cases of rabies occur in wild animals, particularly skunks, raccoons, bats, and foxes. Small rodents such as rats and mice are almost never rabid. In the developing world, rabies is common in dogs. The World Health Organization estimates that at least 35,000 people worldwide die from being bitten by a rabid dog each year, almost all of them in developing countries where routine veterinary vaccinations rarely occur.

In the United States, rabies rarely is transmitted to people. Between 1980 and 2003 only 40 cases of human rabies were reported. Nevertheless, a person who has been bitten or scratched by a suspected rabid animal needs immediate medical treatment. Once developed, rabies almost always results in death. A safe, effective rabies vaccination* is available. The vaccine is given in multiple doses beginning as soon as possible after exposure. It is no more painful to receive than any other routine vaccination. Early treatment with the rabies vaccine is essential if the person is to survive.

What Are Animal Stings?

Animal stings occur when an animal, often an insect, breaks the skin and injects saliva into the body. The saliva may contain venom or a substance that causes an allergic reaction. Depending on the type of venom, a person can experience pain, itching, red bumps, nerve damage, or, in rare cases, death. Bites from mosquitoes and ticks can be dangerous in places where those biters are vectors* (carriers) for diseases caused by bacteria, viruses, or parasites.

Which Insects Sting and How Are Stings Treated?

Various insects and spiders sting or bite. The best way to prevent being bitten or stung is to avoid areas where these insects or spiders live or to wear protective clothing when there is the possibility of encountering them.

Mosquitoes In many parts of the United States, mosquitoes are a summertime annoyance. Only female mosquitoes bite. When they bite, they inject saliva into the skin in the process of having a blood meal. The red itchy bump that appears at the site of the bite is an allergic reaction to the saliva. Mosquito bites go away on their own after several days. Mosquito repellent sprays help deter mosquitoes from biting, and calamine lotion or hydrocortisone cream may help ease the itching caused by bites.

In some parts of the world, certain types of mosquito can transmit diseases. For example, parasites carried by mosquitoes cause malaria* and elephantiasis*.

Chiggers Chiggers, also called redbugs, are the larvae (immature stage) of red mites. They live in woods, pastures, and areas with high grass and weeds. Chiggers attach to a person's clothing and then move to bare skin

around the tops of socks, in armpits, or at waistbands. There they bite the skin, inject a fluid that dissolves cells, and suck up the liquefied tissue. Chiggers cause extremely itchy bumps that can keep itching for days after the larvae are removed. Bathing and scrubbing after exposure to chiggers will kill or dislodge them, and rubbing alcohol followed by calamine lotion is said to help relieve the itching.

Fire Ants In the United States, fire ants come in a variety of types: imported (from South America) or native, red or black. Different types live in different geographic regions, but they are most common in the southeastern states. Fire ants usually build mounds in soft soil, but sometimes they nest in the walls of buildings.

Fire ants are very aggressive and territorial. When a person or animal disturbs their nest, they swarm. Thus, many ants can sting people at once. The venom causes a painful burning sensation, hence the name “fire” ant,

ANAPHYLACTIC SHOCK

For most people, insect bites cause pain or itching. For some people, however, insect bites can cause potentially fatal anaphylactic (an-a-fa-LAK-tik) shock. This severe whole-body allergic reaction can be triggered by insect bites and certain foods or drugs in allergic individuals. The severity of the reaction varies from person to person. In severe cases, death can occur within a few minutes.

In general, what happens during an anaphylactic reaction is as follows:

- The reaction usually begins within minutes of being bitten or stung. In response to the substance to which a person is severely allergic, mast cells (a type of immune system cell) release huge amounts of histamines and several other chemicals. Histamines cause the blood vessels to “leak” and allow fluid to escape into the surrounding tissue. Small amounts of histamines help to heal damaged tissue but when too much fluid leaves the blood vessels, blood pressure can drop suddenly.
- At first, a person might begin sneezing, itching, and feeling weak, nauseated, and panicky. The fluid that leaves the blood vessels causes tissues to swell rapidly. Often one can see swelling of the face and ears. Other tissue inside the body also swells, especially those lining the throat, which makes breathing difficult and the person

begins to wheeze and gasp for breath. The chest and stomach muscles then begin to tighten. Fluid begins to leak into the lungs, so that they no longer function properly.

- When blood pressure is very low, the heart has difficulty pumping enough blood through the body. When the airways are blocked and the lungs are filled with fluid, not enough oxygen enters the blood. These two factors cause a condition called circulatory collapse. If left untreated, lack of oxygen in the brain renders the person unconscious, and death soon follows.

Anaphylactic shock is a serious medical emergency and must be treated quickly. A shot of a chemical epinephrine can be given to help reverse the symptoms of shock. Epinephrine (also called adrenaline) stimulates the heart and improves airflow through the lungs. Antihistamines and other drugs are given to counteract the allergic reaction, raise blood pressure, and increase the flow of blood.

People who know they are allergic to insect venom or certain foods often learn how to use an anaphylaxis kit such as an Epi-Pen, which allows them to inject themselves with epinephrine. The kit is carried with them at all times so that an immediate injection of epinephrine can keep them alive until emergency medical personnel arrive.

* **Lyme disease** (LIME) is a bacterial infection that is spread to humans by the bite of an infected tick. It begins with a distinctive rash and/or flu-like symptoms and, in some cases, can progress to a more serious disease with complications affecting other body organs.

* **convulsions** (kon-VUL-shuns), also called seizures, are involuntary muscle contractions caused by electrical discharges within the brain and are usually accompanied by changes in consciousness.

followed by tiny itchy white blisters. Fire ant stings can be fatal, but only to the small number of people who are allergic to their venom.

Ticks Ticks live in woods and fields all over the United States. Their flat dark bodies are about the size of a match head. Ticks bite humans and other animals because they need blood to survive. Usually, a tick bite causes only minor itching or irritation, but ticks also spread a number of diseases with their bites, including Rocky Mountain spotted fever and Lyme disease*, both of which can be very serious illnesses. If a tick is seen on the skin, tweezers should be used to pull the tick up and out of the skin. The bite should be washed with soap and water and watched for signs of infection.

Spiders Almost all spiders have glands that contain venom, but only 20 to 30 of the 30,000 species of spider in the world are potentially dangerous to humans. Spider bites can cause pain, nausea, fever, and cramps, but the majority of bites are minor and cause only swelling, a blister, and temporary pain. The brown recluse spider and the black widow spiders are the most dangerous spiders found in the United States. Tarantulas also bite, but the bite usually is no worse than a bee sting.

The brown recluse spider is mostly found in the south central United States, in dark places such as woodpiles, sheds, and barns. With legs extended, this spider can be as large as a half-dollar. Males and females look alike and vary in color from orange to brown. They are covered with short hairs and have a violin-shaped marking on their back. Brown recluse bites usually are not fatal, but the spider's venom can cause serious illness, especially for children and the elderly.

Following a bite by a brown recluse spider, the skin around the bite may quickly become warm and swollen. Within about 15 minutes the bitten person may become dizzy and sick to the stomach. Other symptoms include fever, chills, weakness, convulsions*, and joint pain. After about four days, the bite area gets hard to the touch, and it takes about six to eight weeks for the body to recover. There is no known antidote for brown recluse venom, so treatment involves several medications, usually antibiotics, antihistamines, and steroids. Rarely the bite of a brown recluse can result in necrotizing fasciitis, sometimes called the flesh-eating bacteria disease. This bacterial infection begins under the skin and spreads throughout the body. The death rate for necrotizing fasciitis is about 40 percent.

Black widow spiders live in all parts of the United States but are most common in the warmer regions. They live in the same types of places as brown recluse spiders. Black widows are about one-half inch long (not including the legs), and they can be identified by the reddish-orange hourglass shape on the belly of their black bodies.

Black widow spiders do not bite unless they are disturbed. Among black widows, only adult females bite. The juveniles and adult males are harmless. Most people who are bitten by black widows experience some

swelling and redness at the bite site, followed by increasing pain for up to 48 hours. Black widow venom affects the nervous system, and it may cause cramps in the legs, arms, and chest. Other symptoms include sweating, chills, convulsions, fever, nausea, headache, and difficulty breathing. Treatment involves cleaning the bite and receiving antivenin* medicine and antibiotics. In 99 percent of the cases, complete recovery takes place within a few hours. Complications do occur occasionally in children, the elderly, or people with allergies, and in the most serious cases they may result in death.

Scorpions Scorpions are about as long as an index finger. They have eight legs and a curled tail with a stinger on the end. There are 30 different kinds of scorpions in the United States, and they can be found all over the country. The stings of two species, both of which live in the southwestern states, can be fatal.

Scorpion venom causes a burning feeling in the skin, followed by swelling and discoloration. About a day later, the face, mouth, and jaw muscles become hard to control. Other symptoms include nausea, vomiting, drooling, convulsions, and difficulty breathing. Scorpion bites are treated with antivenins and other medications to control muscle spasms and convulsions. In 99 percent of cases, complete recovery occurs after three days. However, if a person is particularly sensitive to the venom, and if muscle spasms begin immediately after the sting, then the person may die.

Bees, Wasps, and Yellow Jackets Honeybees and bumblebees are fat and round, and when they sting they leave their stinger in the skin. Wasps and yellow jackets are long and thin, and when they sting they keep their stinger and they can sting again. All of these insects inject venom into the skin, which causes pain, itching, swelling, and redness. For most people, bee stings are painful but not dangerous. However, some people are severely allergic to bee venom; for these people, bee stings can be fatal unless they are given medication right away. Africanized bees, also often called killer bees, are dangerous because they swarm, and many bees can sting a person at once. Even nonallergic people can be killed by killer bees, but this occurrence is very rare.

After a sting, the stinger should be scraped off the skin, as pulling it out may squeeze more venom into the bite. Ice or cold compresses may help reduce pain and swelling.

Jellyfish

The oceans are home to many types of animal that bite or sting. The most familiar culprit is the jellyfish. All types of jellyfish have stinging tentacles that can cause a burning welt on a person's skin. In Australia, the sting of the box jellyfish can be fatal, but most jellyfish stings are just painful. Jellyfish such as the Portuguese man-of-war and sea nettles are common in warm coastal waters in the United States near the Atlantic Ocean. Avoiding contact with jellyfish while swimming can sometimes

* **antivenin** is an antibody (protein) capable of neutralizing a specific venom.

* **eating disorder** is a condition in which a person's eating behaviors and food habits are so unbalanced that they cause physical and emotional problems.

* **body image** is a person's impressions, thoughts, feelings, and opinions about his or her body.

be difficult, especially when there are many of them in the water. Vinegar, calamine lotion, and antihistamines are said to help relieve the pain of stings.

Anorexia Nervosa

Anorexia nervosa (an-o-REK-see-a ner-VO-sa—commonly referred to as anorexia) is an eating disorder involving excessive dieting; preoccupation with food; distorted body image*; fear of getting fat; and rapid, significant weight loss. The disorder primarily affects young women.*

Wendy's Story

Wendy took ballet since she was five. For as long as she could remember, her dream was to dance professionally after she graduated from high school. When Wendy was 13, her ballet company planned a performance of *Swan Lake*, and Wendy hoped to be chosen for the lead part.

But at that time Wendy was also going through puberty*. She noticed that her hips and thighs got rounder. Constantly in front of the mirror in the dance studio, Wendy could not help seeing every new curve of her body, and she felt self-conscious about how her developing breasts looked in her leotard. She became very worried about gaining weight. What if she got too heavy for her dance partner to lift? With try-outs for the spring ballet fast approaching, Wendy feared a tinier dancer would be chosen for the lead instead of her. She began longing for the body she had at age 11: tiny and light, like the “perfect” ballerina she dreamt of being.

For a month, Wendy was on a crash diet, keeping a strict record of everything she ate. She weighed herself morning and night. When there was time, she jogged after dance class. She was relieved to have lost some weight and wanted to lose more. She allowed herself only the tiniest portions of food and started to skip lunch altogether. Pleased with her weight loss, Wendy decided to cut back to just a small salad for dinner and maybe just a yogurt for breakfast.

Fear of Fat

No one sets out to have anorexia. It takes hold slowly and might start with a simple desire to lose a few pounds. However, in fully developed cases, people with anorexia are malnourished, often depressed, obsessed with food and/or exercise, and are still convinced that they are fat.

People with anorexia refuse to eat enough food to maintain normal healthy body weight. Because they fear getting fat, people with anorexia use extreme dieting to lose a lot of weight rapidly. They also may exercise excessively to burn off calories. People with anorexia lose at least 15 to 20 percent of their normal body weight. For example, a girl who starts out at 130 pounds might drop to 100 pounds. Anorexia involves a distorted awareness of the body. People with this condition become preoccupied with thinness and may continue to believe that they are fat even though others see them as unnaturally thin. Over time, the weight that people with anorexia want so desperately to control becomes frighteningly out of control for them.

Anorexia is much more common among girls and women (90–95% of cases), but boys can have it too. It has been estimated that 1 or 2 out of 100 young women in the United States have anorexia nervosa and that a considerably higher number have less severe eating disorder symptoms. The disorder usually begins during adolescence. Girls who participate in activities that value thinness, such as dancing, gymnastics, or figure skating, are at higher risk than others for developing anorexia.

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

* **menstruation** (men-stroo-AY-shun) is the discharge of the blood-enriched lining of the uterus. Menstruation normally occurs in females who are physically mature enough to bear children. Most girls have their first period between the age of 9 and 16. Menstruation ceases during pregnancy and after menopause. Because it usually occurs at about four-week intervals, it is often called the monthly period.

ATHLETES AND ANOREXIA

Girls and young women involved in sports that place a high value on thinness are three times more likely than others to develop anorexia or bulimia (bu-LEE-me-a; binge eating followed by vomiting or other methods of emptying the stomach). A 1992 study conducted by the American College of Sports Medicine estimated that as many as 62 percent of females involved in sports such as gymnastics and figure skating struggled with eating disorders.

Many well-known athletes have spoken out about their battles with eating disorders, including gymnasts and Olympic gold medal winners Nadia Comaneci and Cathy Rigby. Christy Henrich, who in 1989 was ranked the number two gymnast in the United States, died from complications of anorexia in 1994 at the age of 22. The pressure to be thin does not appear to be easing up. The average gymnast in 1976 was 5 feet 3 inches tall and weighed 105 pounds; the average gymnast in 1992 was 4 feet 9 inches tall and weighed 88 pounds. The American Academy of Sports Medicine has expressed concern about insufficient recognition of the problem and lack of treatment for what is called the female athlete triad of disorders, which is defined as the combination of disordered eating, lack of periods (amenorrhea), and osteoporosis (the loss of material from the bone, which makes them weak and brittle).

What Causes Anorexia?

No single factor causes anorexia. Emotional problems, family difficulties, social pressure, and biological variability all play a role. Widespread glamorization of thinness in fashion magazines and among Hollywood stars influences many girls to diet excessively. Once started, some extreme dieting practices can be hard to stop. Girls who have a high need for perfection and control may see dieting as a way to be the prettiest, thinnest, and most perfect person among their peers; to live up to their parents' expectations for perfection; or to look like fashion models or movie stars whom they admire. A girl who feels controlled by others and longs for independence may use control of eating as a way to assert herself. In other cases, anorexia may develop because of pressure to be extra-thin when certain sports or activities demand it.

What Can Happen When Someone Has Anorexia?

Anorexia can cause a number of serious medical problems, such as disturbed heart rhythms and vitamin and mineral deficiencies that can harm vital organs. With anorexia, the body is literally starving. Bone and muscle begin to waste away. Blood pressure and body temperature drop because the body cannot maintain proper levels. Hair, nails, and skin become dry and brittle. Girls with anorexia often stop menstruating*, and overall

An anorexic person has a distorted perception of what her body actually looks like. She may lose a little weight from a normal diet, gain positive attention from people around her, and then become obsessed with losing more and more weight. But no matter how thin she gets, she still sees her body as unacceptable and unattractive.

Custom Medical Stock Photo, Inc.

Reproduced by permission.

body growth and development can begin to slow down. Without treatment, anorexia can cause irreversible damage to the body. It can lead to heart failure* and sometimes death. In the United States, about 1,000 young women die each year from complications of anorexia.

What Can Be Done About Anorexia?

Help is available for people with anorexia, but they need to be convinced they need it. Family members or friends may ask about the weight loss. A girl with anorexia may be ashamed or self-conscious and may say she does not have a problem. Many girls with anorexia resist getting help because they do not want to gain weight. Seeking help sooner, rather than later, can be life-saving, but the distorted body image that is part of anorexia can make it hard for people with the condition to realize how dangerously thin they are.

Treatment for anorexia typically includes several parts and a few different health professionals. Treatment may begin with a medical visit to evaluate nutritional status and overall health. The doctor may ask about weight loss, order blood tests, and ask about the patient's eating habits and beliefs about her body. Nutritional counseling helps with planning and following a healthy diet. Individual psychotherapy allows the person to talk about feelings and problems that led up to the anorexia, come up with new solutions, and work on body image. Group therapy brings together people with similar concerns to share their experiences and receive support. Medications are sometimes used to reduce anxiety* and depression*. Individuals with anorexia who are in a severe health crisis may have to be hospitalized in order for their condition to be stabilized. They may need to become better nourished before other aspects of treatment can begin.

* **heart failure** is a medical term used to describe a condition in which a damaged heart cannot pump enough blood to meet the oxygen and nutrient demands of the body. People with heart failure may find it hard to exercise due to the insufficient blood flow, but many people live a long time with heart failure.

* **anxiety** (ang-ZY-e-tee) can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person's physical or mental well-being.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

* **congenital** (kon-JEH-nih-tul)
means present at birth.

Anosmia

Anosmia is the complete inability to detect odors.

Kayla's Story

Kayla was born with a condition called congenital* anosmia that left her unable to smell any odors. At first Kayla did not realize that she was different from other people. Later when she did, she pretended that she could smell the same way others people did because she did not want to be different. Kayla was eight before her parents realized she had no sense of smell.

Once Kayla's parents discovered that she could not smell, they became concerned about her safety. They knew that she would not smell smoke if a fire started in the house and that she would not be able to smell a gas leak, either. Kayla's parents added extra smoke detectors in their house and switched from a gas stove and hot water heater to an electric one.

Sometimes food was a problem for Kayla. One mean girl played a trick on her and gave her spoiled milk to drink. Kayla could not smell that the milk was sour, so she drank it, but when she tasted it, she spit it out all over herself. As Kayla got older, she became anxious about her personal hygiene because she could not smell her own body odor. Some days she was depressed about her hidden disability, but she tried to remind herself that having no sense of smell was not a life-threatening problem and not nearly as limiting as being blind or deaf.

What Is Anosmia?

People with anosmia cannot smell odors. This condition can be temporary or permanent. Some people are born without the ability to smell, whereas others develop this condition later in life. Although through normal aging, many people's ability to smell gradually weakens, aging rarely causes a total loss of this sense. It is difficult to tell how many people have anosmia. Estimates are that about 2 percent of Americans have a noticeably reduced sense of smell, although not all have completely lost their ability to smell.

What Causes Anosmia?

In order to have a sense of smell, three factors must occur.

1. Air-carrying scent molecules must enter the nose and flow past odor receptor cells.
2. Odor (olfactory) receptors, which are more than 100,000 million separate nerve cells, must be stimulated by the odor molecules.
3. The information from the odor receptors must be transmitted to the brain and processed.

Any time one of these three factors is interrupted, individuals may have a decreased ability to smell or in certain cases may lose their sense of smell completely.

Almost everyone at one time or another has had a stuffy nose from a cold or an allergy*. A bad cold or allergic reaction can block airflow into the nose and prevent a person from smelling odors. This situation illustrates a temporary form of anosmia. The condition clears up when the cold or allergy symptoms go away. Sometimes medicines such as antihistamines* or nasal sprays*, if used in moderation, can help relieve a stuffy nose and restore the ability to smell.

Certain conditions can also lead to a permanent blockage of the nasal* cavity so that air cannot reach the odor receptors. This situation can occur

Smell Disorders

Disorders of the sense of smell are called "osmias." Total inability to detect any odors is called anosmia. Other smell disorders include the following:

- **Hyponosmia:** a decreased sense of smell
- **Dysosmia:** a false identification of a smell
- **Phantosmia:** perceiving a smell when none exists; an odor hallucination
- **Agnosia:** the inability to identify or classify odors

* **allergy** (AL-uhr-jee) is an immune system-related sensitivity to certain substances, for example, cat dander or the pollen of certain plants, that cause various reactions, such as sneezing, runny nose, wheezing, or swollen, itchy patches on the skin, called hives.

* **antihistamines** (an-tie-HIS-tuh-meens) are drugs used to combat allergic reactions and relieve itching.

* **nasal spray** (NA-zal) spray is a mist that is sprayed into the nose.

* **nasal** (NA-zal) of or relating to the nose.

* **polyps** (PAH-lips) are bumps or growths usually on the lining or surface of a body part (such as the nose or intestine). Their size can range from tiny to large enough to cause pain or obstruction. They may be harmless, but they also may be cancerous.

* **endocrine** (EN-do-krin) refers to a group of glands, such as the thyroid, adrenal, and pituitary glands, and the hormones they produce. The endocrine glands secrete their hormones into the bloodstream, and the hormones travel to the cells that have receptors for them. Certain hormones have effects on mood and sometimes cause emotional swings.

* **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.

when a person has nasal polyps*. A birth defect or an injury to the nose can also block the nasal cavity.

Damage to the odor receptors can occur from infection with certain viruses. These receptors also can be permanently damaged by inhaling chemicals, either accidentally or intentionally (e.g., snorting cocaine or inhaling paint thinner). Endocrine* (hormonal) disorders can also damage odor receptors. In addition, some people, through an error in prenatal development, are born without odor receptors and never have the ability to smell. Often these people have other congenital defects as well.

Damage to nerves that carry information from the odor receptors to the brain and that process odor information in the brain can occur in many ways. These include:

- Injury from a blow to the head or face
- Accidental nerve damage during surgery or dental work
- A severe, long-term sinus infection
- Spinal meningitis* during infancy
- Long-term use of certain medications
- Diseases in which the central nervous system becomes damaged such as Parkinson's disease and Alzheimer's disease

Even though there are many known explanations for why individuals develop anosmia, in about one-fourth of cases doctors cannot find a specific reason why the sense of smell has been lost.

SMELL AND TASTE ARE RELATED

S mell and taste are closely linked, although in humans the sense of smell is about 10,000 times more powerful than the sense of taste. Odors are detected by nerve cell receptors in the nasal cavity. These receptors allow people to distinguish among hundreds of different odors. Taste is detected by receptors in the tongue. These receptors can detect only five different tastes: sweet, sour, salty, bitter, and *umami* (a Japanese word meaning savory).

The flavor of food is determined by a combination of taste, smell, texture (the way the food feels in the mouth), and appearance. People with anosmia can still taste the five basic tastes, but without being able to smell food, they miss much of the food's flavor. For them, all sweet foods tend to taste very much alike, as do all sour foods or all bitter foods. Because their food lacks a variety of flavors, people with anosmia may lose interest in eating and develop nutrition problems. About 80 percent of people who go to the doctor complaining of a problem with taste actually have a problem with their sense of smell.

How Is Anosmia Diagnosed?

Diagnosis begins with a complete medical history, physical examination, and review of all medications being taken. Many tests may be done to look for conditions that could be causing the anosmia. Some of these tests are a complete blood count, an analysis of the function of various endocrine (hormone-producing) glands, and x-rays or a CT scans* of the head. In some cases a biopsy (tissue sample) may be taken from the nose and examined under the microscope.

Two tests are commonly used to measure the amount and type of smell loss. The Connecticut Chemosensory Clinical Research Center (CCCRC) test has two parts. In part one, the patient is asked to sniff a bottle with plain water and one with the chemical butyl alcohol and ask to identify the sample with an odor. Each nostril is tested separately. In the second part, the patient is given ten samples of common smells such as cinnamon, coffee, peanut butter, and chocolate and asked to identify them. In the other test, called the University of Pennsylvania Smell Identification Test (UPSIT), the patient is given 40 scratch and sniff samples and four possible answers for each sample. The patient is then asked to match the scratch and sniff smell to one of the four suggested answers. These tests help determine the degree of smell loss and whether the patient has anosmia or another type of odor disorder.

How Is Anosmia Treated?

If another disease or disorder is causing anosmia, the doctor treats that medical problem, and in some cases the sense of smell returns. For example, if polyps are blocking airflow into the nose, they can be removed surgically. Sometimes, however, damage to the nerves is permanent or there is no cure for the underlying condition causing loss of smell (e.g., Parkinson's disease* or Alzheimer's (ALTS-hy-merz) disease*). In general, treatment of complete anosmia is difficult and often not very successful.

Anthrax

Anthrax (AN-thraks) is a rare infectious disease caused by the bacterium Bacillus anthracis.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **Parkinson's disease** is a disorder of the nervous system that causes shaking, rigid muscles, slow movements, and poor balance.

* **Alzheimer's (ALTS-hy-merz) disease** is a condition that leads to gradually worsening loss of mental abilities, including memory, judgment, and abstract thinking, as well as changes in personality.

Over the course of a few days, cutaneous anthrax develops into a sore with a coal-black center. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

* **gastrointestinal** (gas-tro-in-TES-tih-nuhl) means having to do with the organs of the digestive system, the system that processes food. It includes the mouth, esophagus, stomach, intestines, colon, and rectum and other organs involved in digestion, including the liver and pancreas.

What Is Anthrax?

Anthrax is primarily a disease of livestock, such as sheep, cattle, or goats. It is rarely seen in humans, and most cases occur in developing countries. Anthrax is most likely to occur in people whose work regularly brings them into contact with animal hides, such as those who cut sheep's wool, livestock handlers, laboratory workers, and veterinarians. The bacterium *Bacillus anthracis* (buh-SIH-lus an-THRAY-kus) is found naturally in the soil of farming regions all over the world, including parts of the United States. It can exist undisturbed for many years as spores, a temporarily inactive form of the organism with a protective, shell-like coating. Grazing animals typically become infected with anthrax if they eat vegetation or feed (food) contaminated with spores. Livestock in the United States rarely get anthrax.

There are three forms of anthrax in humans, each resulting from a distinct route of infection. Cutaneous (kyoo-TAY-nee-us), or skin, anthrax, the least serious form of the disease, occurs when the bacteria enter a break in the skin. Gastrointestinal* anthrax is caused by eating food contaminated with anthrax bacteria; this form is very rare. The third and deadliest form of the disease, inhalation (in-huh-LAY-shun) anthrax, also called pulmonary anthrax or "wool sorter's disease," is also very uncommon and results from breathing in anthrax spores.

How Common Is Anthrax?

Historians believe that anthrax has existed for thousands of years, at least since the fifth and sixth plagues described in the Bible's Book of Exodus. (In Egypt, the fourth plague was of insects and the fifth plague was a contagious disease among animals. These events may have occurred in the thirteenth century B.C.E.) Cutaneous anthrax, the most common form of the disease (about 95 percent of anthrax cases), occurs most often in agricultural regions in Asia, Africa, South and Central America, southern and eastern Europe, the Middle East, and the Caribbean. Anthrax is rare in the United States: According to the Centers for Disease Control and Prevention, between 1955 and 1999 only 236 cases of anthrax were reported in the United States, nearly all the cutaneous form. Before 2001 the last case of inhalation anthrax in the United States was reported in 1978.

How Does a Person Get Anthrax?

Scientists do not believe that anthrax can be passed from person to person. Cutaneous anthrax occurs when someone with a cut, sore, or other break in the skin touches an infected animal or the by-product of an infected animal, such as contaminated hide, wool, or goat hair. Gastrointestinal anthrax usually is traced to contaminated foods, especially undercooked meat. Inhalation anthrax comes from breathing anthrax spores into the lungs. Although spores are inactive forms of the bacteria, they germinate, or become activated, in the moist, warm environment of the lungs. Someone has to inhale thousands of spores to contract the disease,

ANTHRAX IN THE NEWS

In 2001, just after the terrorist attacks on the World Trade Center in New York and the Pentagon in Washington, D.C., the threat of biological terrorism arose when anthrax spores were discovered in Florida, New York City, and the offices of the U.S. Congress. More than 20 people showed signs of either inhalation anthrax (in the lungs) or cutaneous* anthrax (on the skin). Several of those with the inhalation form of the disease died. In most of those cases, authorities were able to trace the exposure to letters intentionally contaminated with a highly concentrated, aerosolized (designed to spray into the air as an aerosol) form of anthrax spores.

Initially, the anthrax threat was assumed to be part of the same terrorist plot that targeted the World Trade Center. Government investigators later suspected that a single person without ties to a specific terrorist organization could have mailed the anthrax-laced letters. Regardless of their origin, the letters proved that anthrax can be used as a weapon. The production and release of highly potent forms of anthrax bacteria—to cause illness deliberately in large groups of people—is a type of biological warfare, or bioterrorism, that cannot be ignored. As a result, national, state, and local governments and public health officials planned responses to possible future attacks with biological weapons.

- * **cutaneous** (kyoo-TAY-nee-us) related to or affecting the skin.
- * **ulcer** is an open sore on the skin or the lining of a hollow body organ, such as the stomach or intestine. It may or may not be painful.
- * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.
- * **shock** is a serious condition in which blood pressure is very low and not enough blood flows to the body's organs and tissues. Untreated, shock may result in death.
- * **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.

and spores found in soil rarely are concentrated enough to cause inhalation anthrax.

What Are the Signs and Symptoms?

Symptoms of the disease usually appear within one to seven days after infection with *Bacillus anthracis* and differ according to the way in which a person became infected with the bacterium. An anthrax skin infection typically begins as a raised, itchy bump, and within a few days it develops into a small sore or ulcer* with a black, coal-like center. This visible sign of cutaneous anthrax explains how the disease got its name, which is derived from the Greek word *anthracis*, meaning “coal.” Gastrointestinal anthrax can cause nausea, loss of appetite, fever, and severe bloody vomiting and diarrhea. The first symptoms of inhalation anthrax often resemble those of a common cold or influenza and include cough, difficulty in swallowing, headache, swollen lymph nodes* in the neck, and tiredness. Within days the symptoms rapidly progress to severe breathing problems and shock*, often leading to heart failure and death.

How Do Doctors Make the Diagnosis?

Bacillus anthracis bacteria sometimes can be seen in a bit of skin from the sore of a person who has cutaneous anthrax or in the coughed-up mucus* of someone with inhalation anthrax when those samples are

* **cultured** (KUL-churd) means subjected to a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

* **vaccine** (vak-SEEN) is a preparation of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.

viewed under a microscope. To help confirm the diagnosis, samples of blood or fluid taken from the nose or sores are cultured* to identify the anthrax bacteria. Blood tests also are used to detect anthrax antibodies*, which indicate that someone has come into contact with anthrax-causing bacteria and may have the disease. Chest X-rays can help diagnose inhalation anthrax.

What Is the Treatment for Anthrax?

Doctors prescribe antibiotics to fight anthrax infections. Patients with gastrointestinal and inhalation anthrax typically need intensive, round-the-clock care with intravenous* medications and fluids in a hospital. Inhalation anthrax can cause severe breathing problems that may require the use of a respirator, a machine that can assist a person's breathing until he or she recovers.

What to Expect

Untreated, all three forms of anthrax can lead to widespread infection and death. If it is treated, cutaneous anthrax generally is not fatal. Gastrointestinal anthrax results in death in about half of all cases. Even with medical treatment, inhalation anthrax is often fatal.

How Is Anthrax Prevented?

Agricultural and textile workers in developed countries such as the United States are instructed to wash their hands after working in the soil or handling animals and animal by-products. People who live in high-risk areas of the world are advised to avoid contact with livestock and not to eat improperly prepared or undercooked meat. An anthrax vaccine* exists, but this vaccine is not given routinely in the United States, except to people in the military or to scientists who may come into contact with the bacteria through their research. Veterinarians and people whose jobs involve handling livestock typically are vaccinated against the disease if they work in high-risk areas of the world. In the fall of 2001, when anthrax spores contaminated several U.S. post offices and office buildings, public health experts recommended antibiotics for people who had been exposed to anthrax—even if they had no symptoms of the disease. Officials stressed, however, that it was not necessary or advisable for the general public to take antibiotics to prevent anthrax.

Antibiotic Resistance

Antibiotic resistance is the ability of microorganisms, specifically bacteria, to adapt to and to withstand the effects of antibiotics*. Such microorganisms are often called “superbugs.” As a result of antibiotic resistance, antibiotics for superbug infections may become far less effective or may not work at all, leaving doctors with few, if any, choices with which to treat them. In the early 2000s, antibiotic resistance is a growing, worldwide medical and health problem.*

What Is Antibiotic Resistance?

Normally, doctors use antibiotics to fight infections caused by bacteria. Usually this treatment kills the bacteria, and the patient soon recovers. Sometimes, however, a few unusually hardy bacteria do not die. These bacteria not only survive the antibiotic treatment, but they pass on their hardiness to their offspring so that the next generation is also resistant to antibiotics. According to the World Health Organization, some of the antibiotic-resistant bacteria living in the early 21st century are resistant to as many as 10 different drugs. Because antibiotics are a common treatment for infections, doctors have to try to find another drug that will work against the antibiotic-resistant infection. Unfortunately, options are limited, and in some cases, other treatments are not available.

Ironically, one of the factors that helps bacteria to become antibiotic-resistant is the antibiotic itself. How does this happen? Just as one person has slightly different characteristics from another person, individual bacteria are not all the same. A small percentage of them have characteristics that allow them to resist antibiotics. Some of these bacteria can defuse the antibiotic before it can take effect, others are able to pump out the antibiotic before it can harm them, and still others are able to change their structure so that the antibiotics cannot attack them. Normally, the number of antibiotic-resistant bacteria remains small, because antibiotic resistance does not give a bacterium any advantages over a non-resistant one. The problem arises when people overuse antibiotics, which creates the right environment for resistant bacteria to flourish. The repeated use

* **microorganisms** are tiny organisms that can only be seen using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

* **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

of antibiotics kills the non-resistant bacteria but leaves the antibiotic-resistant bacteria alone. In a short time, the antibiotic-resistant bacteria multiply, passing on their resistance to the following generation, which then has its own resistant offspring. Sometimes, the bacteria can even pass on its resistance to other bacteria that are not offspring, and it does this by exchanging the genetic material, or DNA*, that makes them resistant to antibiotics. Soon, the number of antibiotic-resistant bacteria can become very large.

Antibiotic resistance can lead to bacterial infections that are extremely difficult to fight and may cause serious illnesses in people and even death.

What Causes Antibiotic Resistance?

Antibiotics are often very helpful for a wide range of illnesses. This pattern of effectiveness causes some doctors to quickly prescribe antibiotics even when they are uncertain about a diagnosis and whether antibiotics will help. In addition, doctors often prescribe so-called broad-spectrum antibiotics that kill many different types of microbes, rather than selecting a more targeted antibiotic that works against the specific microbes that are causing the illness. Both the improper prescribing of antibiotics and the use of broad-spectrum antibiotics can promote antibiotic-resistant bacteria.

As a result, during the second half of the 20th century, dangerous antibiotic-resistant bacteria became prevalent in hospitals. An example is methicillin-resistant *Staphylococcus aureus*, or MRSA, which is a type of bacteria that is resistant to antibiotics such as methicillin, penicillin, amoxicillin, and others. MRSA infections have also become increasingly common in other health centers and nursing homes, and among people who already have weakened immune systems*. Other antibiotic-resistant microbes include vancomycin-resistant enterococci, or VRE; extended-spectrum *Streptococcus pneumoniae*, or ESBL; and penicillin-resistant *Streptococcus pneumoniae*, or PRSP. As of 2009, new strains of resistant bacteria were continually being identified, a pattern causing great concern in the healthcare community.

Patients also contribute to the development of antibiotic resistance. Some individuals have developed much trust in the effectiveness of antibiotics and want prescriptions for them. For instance, a patient with a bad cold may request an antibiotic, even though healthcare professionals know antibiotics have no effect on viruses, and because colds are caused by viruses, antibiotics do nothing for a cold. In some cases, perhaps a doctor gives the prescription to appease the patient. Taking unneeded antibiotics kills some bacteria and leaves behind antibiotic-resistant bacteria that can then multiply.

Some researchers have wondered if the daily use of antimicrobial products, such as hand soaps and household cleaners, may promote antibiotic resistance. A study conducted in 2005 tried to determine if the use of antibacterial cleaning and hygiene products caused an increased antibiotic resistance after one year's time. The results showed that it did not. The conclusion stated that findings might be different if the products

were used more extensively or over a longer period of time and additional studies were suggested.

Some scientists and healthcare professionals believe that antibiotic resistance may also arise, and perhaps primarily arises, from the use of antibiotics to improve the health and the growth of cows and other agricultural livestock. According to the Union of Concerned Scientists, 70 percent of all antibiotics produced in the United States are used on livestock. The overuse of these antibiotics encourages antibiotic-resistant strains of bacteria, which then arrive in the human diet in beef and other food products. Scientists still are not sure exactly how much effect livestock antibiotics have, but several organizations mounted campaigns to curtail the use of antibiotics to promote growth in livestock, so that people can purchase and eat antibiotic-free meats.

What Is the Effect of Antibiotic Resistance?

According to an October 2007 study reported in the *Journal of the American Medical Association*, 94,360 patients in the United States developed an invasive MRSA infection in 2005, and 18,650 of them, or nearly 20 percent, died. In addition, the World Health Organization has stated that antibiotic-resistant bacteria are responsible for up to 60 percent of the infections that occur among hospital patients in the United States, and the Centers for Disease Control reported that 27,000 nursing-home patients in the United States had antibiotic-resistant infections as of 2005. People with such infections are typically ill for a longer period and have a greater risk of dying.

Medical professionals are particularly alarmed because MRSA and similar infections have reached beyond the medical setting and in the early 2000s were occurring in the general population, and among people who were perfectly healthy before the infection. Public outbreaks of infection with antibiotic-resistant bacteria have occurred among people who were evacuated from Hurricane Katrina in 2005, among members of some small religious groups, and even among players on the St. Louis Rams football team in 2000. Medical professionals believe the football players picked up the infection from equipment they shared, and the bacteria probably entered their bodies from cuts they got from the artificial turf on the playing field. Outbreaks have also occurred in schools, and in 2007 a high school student in Virginia died from infection with an antibiotic-resistant strain of bacteria.

How Are Antibiotic-Resistant Infections Treated?

When a patient has an infection that resists a certain antibiotic, medical professionals may try another antibiotic, perhaps several, before finding one that is effective. Doctors sometimes have limited choices, because some of the drug options have dangerous side effects. In addition, doctors are increasingly finding that bacteria are resistant to more than one antibiotic, a particular problem in hospitals where bacteria may be resistant

* **vaccines** (vak-SEENS) are preparations of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.

to all of the available antibiotics. When this happens, patients can become very ill or die. Doctors are alarmed about antibiotic resistance, because they fear that surgeries and other hospital procedures that are quite safe in the early 2000s may become much, much more dangerous in subsequent years because of the mounting risk of antibiotic-resistant infection.

Will New Treatments Become Available?

In response to the problem of antibiotic resistance, researchers in the early 2000s were working to develop new drugs that attack the bacteria in a slightly different way than antibiotics typically do. For instance, researchers in 2007 found a way to target an enzyme that helps bacteria exchange its DNA. By curbing the enzyme's function, they could stop the bacteria from passing on its resistance to other bacteria. Other scientists were using different methods to curtail resistant bacteria. This work presented a constant struggle, however, because even the new drugs might only be effective for a short time if the bacteria are able to develop resistance to them, too.

In addition to developing new antibiotics, researchers were working on new vaccines* that improve the body's ability to defend itself against the bacteria, and they were also working on bacteria-attacking viruses, called bacteriophages. Despite these efforts, many medical professionals were concerned that the new drugs were not coming quickly enough to restrain the growing problem of antibiotic resistance, and the number of deaths due to antibiotic resistant infections might continue to rise. Because of concerns like these, antibiotic resistance is often described as a worldwide, public health emergency.

Can an Antibiotic-Resistant Infection Be Avoided?

The Centers for Disease Control launched the Campaign to Prevent Antimicrobial Resistance, which is designed to prevent antibiotic resistance in hospitals and other healthcare facilities. The campaign has four main strategies:

- Prevent infections in the first place, so that antibiotics are not necessary
- Diagnose and treat infection effectively with the appropriate antimicrobial therapy
- Use antimicrobials wisely
- Prevent transmission, or the spread of the infection from one patient to another

Beyond the steps that medical professionals can take, everyone can help reduce antibiotic resistance. Individuals can take several measures to reduce the chance of becoming infected:

- Wash hands often with soap and water. If soap and water are not available, an alcohol-based hand sanitizer is a good replacement.
- Try to keep hands from becoming dry and cracked, because bacteria can infect an individual through even very small openings in the skin.

- Clean and cover cuts and other wounds.
- Keep counters and other frequently touched household surfaces clean.
- Avoid sharing razors, hand towels, and washcloths to prevent the spread of bacteria from one person to another.
- Before touching public surfaces, such as gym equipment or grocery carts, clean them with disinfecting wipes.
- Shower after participating in contact sports.

In addition, medical professionals recommend that patients who have prescriptions for antibiotics follow their doctors' directions exactly. For instance, a patient should take all of the prescribed antibiotic as recommended by the doctor. Even if the patient starts to feel better, the person should take the remaining pills. Patients should not save antibiotics to use for a later illness and should never give them to someone else to take.

* **personality disorders** are a group of mental disorders characterized by long-term patterns of behavior that differ from those expected by society. People with personality disorders have patterns of emotional response, impulse control, and perception that differ from those of most people.

* **impulsive** means acting quickly before thinking about the effect of a certain action or behavior.

* **conduct disorder** is diagnosed in children and adolescents who have had serious problems with lying, stealing, and aggressive behavior for at least 6 months.

* **antisocial behavior** is behavior that differs significantly from the norms of society and is considered harmful to society.

Antisocial Personality Disorder

Antisocial personality disorder (APD) is an ongoing pattern of behavior in an adult that involves disregard for social rules and serious violation of the rights of others through aggressive, dishonest, reckless, and irresponsible acts.

What Is Antisocial Personality Disorder?

Antisocial personality disorder (APD) is one of the ten different types of personality disorders* that are classified as of the early 2000s by mental health experts. Like other personality disorders, APD refers to a personality style that consists of troubled ways of thinking, feeling, and behaving, and it is diagnosed only in adults (but the personality style and the problematic behavior it causes must have been present since adolescence). As of 2009, of all the personality disorders, APD had been the focus of the most research and attention, perhaps because people with APD often cause harm to others and have a negative effect on society.

Adults with APD engage in aggressiveness or physical assaults, cheating, lying, or other behaviors for which they can get arrested. They are often impulsive* and reckless and disregard their own safety or the safety of others. People with APD tend to be poor planners, and they may ignore financial responsibilities such as paying rent or other bills. They often have poor work records, and many engage in impulsive criminal behavior or spousal abuse. To be diagnosed with APD, a person must have had symptoms of conduct disorder* since the age of 15, thus demonstrating a long-standing pattern of antisocial behavior*.

APD was first described in the 1800s as a “defect of moral character” and as “moral insanity.” The terms psychopath and sociopath have also been used to describe what was later called antisocial personality disorder. Those people with APD seem to lack a conscience and fail to learn from consequences or punishment alone. They may fail to show remorse and may lack sympathy for those they have hurt. People with APD may experience most emotions at a shallow level.

What Causes Antisocial Personality Disorder?

Antisocial behavior tends to run in families. Researchers have tried to determine how much of this tendency is due to genetics and biology and how much is learned behavior. Some studies have identified certain brain problems and learning defects in people with APD. For example, researchers have found that areas of the brain that are involved in thinking ahead and in considering the consequences of one’s actions may be different in people with APD. This finding lends evidence to the theory that an inherited brain problem may contribute to the poor planning and impulsivity that are characteristic of people with APD.

Other studies have found differences in the brains of people with APD that may contribute to disordered learning and attention. One series of

experiments demonstrated that people with antisocial personalities did not experience normal anxiety before being given a shock and that they did not learn to avoid the shock like other subjects in the experiment did. This may explain why people with APD do not seem to learn from negative consequences or punishment.

Research that separates genetic from environmental factors (for example, studies of identical twins* raised in different homes) has shown that genetic factors explain about half of antisocial behavior. Family environment or upbringing plays an important role as well. Experts have speculated that a combination of genetic inheritance and environmental factors lead to most cases of APD. In other words, some people seem to have a biological tendency to develop APD and the family environment will determine whether that tendency is fulfilled. People without the biological tendency for APD, regardless of the family environment in which they are raised, are not likely to develop APD as an adult (although they may have conduct disorder as a youth).

How Is Antisocial Personality Disorder Treated?

Treatment of APD presents a challenge because those with APD are unlikely to consider themselves as having a problem and are, therefore, unlikely to seek help. If individuals lack motivation to change their own behavior, it is unlikely that any meaningful change will take place. Because people with APD tend to violate the rights of others, they often encounter the criminal justice system. Although they may be imprisoned, punishment alone usually fails to teach individuals with APD to behave differently. Still, APD is a serious social problem. Some early interventions may help prevent APD from developing in those at risk, such as youth with severe conduct disorders and those who are juvenile offenders.

Anxiety and Anxiety Disorders

Anxiety (ang-ZY-e-tee) is a feeling of fear, worry, or nervousness that a person experiences for no apparent reason. Anxiety disorders are conditions in which the patient's anxiety becomes so intense and long-lasting that it causes serious distress and may lead to problems at home, school, or work.

Michelle Has a Panic Attack

On the first day of ninth grade, when Michelle started high school, she suddenly felt dizzy, sweaty, and short of breath as she walked down the hall toward her locker. For a few minutes, everything around her seemed strangely unreal. At first, Michelle thought it was just a mild case of nerves. When the scary feelings returned the next day and the next, however, Michelle began to fear that she was losing control of her mind or that she had some terrible physical illness. In fact, Michelle was suffering from an anxiety disorder, namely panic disorder.

What Are Anxiety Disorders?

Everybody feels a little nervous now and then. People's palms may get sweaty when they take an important test, their heart may pound as they wait for the opening kickoff of a big game, or they may have butterflies in their stomach as they get ready for a first date. These common feelings are normal. People with anxiety disorders, however, feel afraid, worried, or nervous even when there is no clear reason for concern. The feelings associated with anxiety disorders are intense and long-lasting, and they may get worse over time. These emotions are very distressing to a person experiencing them, and they can be so overwhelming that they can cause serious problems at home, school, or work.

Anxiety disorders are the most common of all mental disorders. In fact, some type of anxiety disorder affects more than 40 million people in the United States 18 years of age and over, or 18 percent of the adult population. There are several different types of anxiety disorders, and some individuals suffer from more than one at the same time.

Generalized anxiety disorder Generalized anxiety disorder (GAD) is the term for constant, intense worry and stress over a variety of everyday events and situations. People who experience generalized anxiety typically

Self-injury and other behaviors that seem impossible to control are signs of an anxiety disorder. Cognitive-behavioral therapy and medication can help people learn how to change unwanted behaviors like cutting (intentionally cutting one's own skin with a blade or other sharp object), shown here, and how to create new ways of thinking about themselves and the stresses they encounter in their daily lives. *Dr. P. Marazzi/Photo Researchers, Inc.*

expect something bad to happen, even when there is no real reason for thinking this way. For example, they may worry all the time about their grades or sports performance even when they are successful students or athletes. They may worry about the wellbeing of loved ones, about school, their own health and safety, or upsetting experiences they imagine could happen in the future. These feelings may be accompanied by such physical symptoms as tiredness, chest pain, trembling, tense muscles, headache, or upset stomach. When individuals have experienced these symptoms for six months or longer, a mental health professional may diagnose them as having generalized anxiety disorder. GAD affects about 7 million Americans, with women twice as likely to have it as men.

Separation anxiety disorder Separation anxiety is the normal fear that babies and young children feel when they are separated from their parents or approached by strangers. It is not unusual for children to have mild separation anxiety on the first day of school in kindergarten or first grade or the first day of overnight camp. In most cases, this anxious feeling goes away after a few days as a child gets used to a new situation, new friends, and new adults in charge. For most children, separation anxiety lessens with age and experience.

In some children, however, this normal fear is exaggerated. These children experience extreme fearfulness whenever they are away from their parents or their home. Children with separation anxiety disorder may call their parents at work for reassurance, may be afraid to sleep over at a friend's house, or may suffer intense homesickness at camp. Separation anxiety disorder can cause these children to be frequently absent from school and avoid participating in normal childhood social activities that do not involve their parents. Children with separation anxiety disorder tend to worry a great deal; in particular, they may be afraid that their

Nothing to Fear

Not every fear is a phobia or a symptom of another anxiety disorder. Fears are not considered phobias unless they cause long-lasting and serious problems in a person's life. Many fears are common at certain points in a child's development.

Common normal fears include:

- Birth to 6 months: loss of physical support (fear of falling), loud noises, large fast-approaching objects, or sudden movement
- 7 to 12 months: strangers
- 1 to 5 years: loud noises, storms, animals, darkness, separation from parents
- 3 to 5 years: monsters, ghosts
- 6 to 12 years: injury, burglars, being sent to the principal, punishment, failure
- 12 to 18 years: tests in school, athletic competition, social embarrassment

parents will get sick or be injured. They may also have frequent nightmares about getting lost.

Separation anxiety can carry over into the teenage years. Teenagers with separation anxiety may be uneasy about leaving home, and they sometimes start refusing to go to school. Separation anxiety may be triggered by a change in schools or by a stressful event at home, such as a divorce, illness, or death in the family.

Panic disorder Panic disorder involves repeated attacks of intense fear that strike often and without warning. People having a panic attack may feel as if their surroundings are unreal, or they may fear that they are going to die. In addition to the fear, they may have such physical symptoms as chest pain, a pounding heart, shortness of breath, dizziness, or an upset stomach. Many people with panic disorder go to a hospital emergency room thinking they are having a heart attack. Panic disorder affects about 6 million adults in the United States, two-thirds of them women.

Obsessive-compulsive disorder Obsessive-compulsive (ub-SES-iv-kum-PUL-siv) disorder (OCD) is an anxiety disorder in which people become trapped in a pattern of repeated, unwanted, upsetting thoughts called obsessions (ob-SESH-unz) and behaviors intended to control the upsetting thoughts that are called compulsions (kom-PUL-shunz). The thoughts and behaviors seem impossible to control or stop. Common obsessions include fears of dirt or germs, whether the house is locked, and whether a loved one is safe. Common compulsions include washing the hands repeatedly, checking the door repeatedly to make sure it is locked, and saying something over and over to assure someone's stays safe. About 2.2 million adults in the United States are diagnosed with OCD. It is equally common in men and women.

Phobias Phobias (FO-bee-uhz) are unrealistic long-lasting fears of some object or situation. The fear can be so intense that people go to great lengths to avoid the object of their dread. There are three types of phobia problems that mental health professionals may diagnose: specific phobias; social phobia (also called social anxiety disorder); and agoraphobia (AG-or-uh-FO-bee-uh).

People with specific phobias have an intense fear of specific objects or situations that pose little real threat, such as dogs, spiders, storms, water, heights, and flying in planes. Specific phobias are common in the U.S. population, affecting about 19 million adults.

People with social phobia have an extreme fear of being judged harshly, embarrassed, or criticized by others, which leads them to avoid social situations. Social phobia is diagnosed in 7 percent of the adult U.S. population, or about 15 million persons. It is equally common in men and women.

People with agoraphobia are terrified of having a panic attack in a public situation from which it would be hard to escape, such as being in

a crowded store or stadium or in a form of public transportation such as a bus or train. If left untreated, the anxiety can become so severe that the affected person may refuse to leave the house.

Post-traumatic stress disorder Post-traumatic stress disorder (PTSD) is marked by long-lasting symptoms that occur after people have been through an extremely stressful, life-threatening event, such as a rape or mugging, tornado, aviation disaster, car crash, or after engaging in combat during military service. People with the disorder may relive the traumatic event repeatedly in painful memories or nightmares. They may have such other symptoms as depression*, anger, crankiness, and a lack of normal emotions, and they may be easily startled, unusually fearful, and have trouble paying attention. A person with PTSD may also have such symptoms as depersonalization* and derealization*. About 8 million Americans suffer from PTSD.

What Causes Anxiety Disorders?

Genetic factors Many doctors think that anxiety disorders are caused by various factors. Genetics may play a role in some cases. For example, research has shown that a twin is more likely to have obsessive-compulsive disorder if the other twin has it and if they are identical twins* (twins that have identical genes*), rather than if they are fraternal twins (twins that do not have identical genes). Other twin studies have found a genetic component to panic disorder and social anxiety disorder.

Brain circuits Some research has focused on pinpointing the exact brain areas and circuits involved in the emotions of anxiety and fear, which lie at the root of anxiety disorders. Scientists have shown that when faced with danger, the body sends two sets of signals to different parts of the brain. One group of signals goes straight to the amygdala (uh-MIG-duh-luh), a small almond-shaped structure deep inside the brain that sets the body's automatic fear response in motion. This response readies the body to react to the threat. The heart starts to pound and send more blood to the muscles for quick action, while stress hormones and extra blood sugar are released into the bloodstream to provide extra energy. The other set of signals takes a roundabout route to the cerebral cortex (suh-REE-brul KOR-teks), the thinking part of the brain. Thus, the physical response to danger or stress is set in motion before the brain understands just what is wrong. As a built-in safety measure, this learned response is stored in the amygdala so the response will be quickly available for the next dangerous situation.

In people with anxiety disorders, an experience that feels scary, even one involving a normally safe object or situation, can create a deeply etched memory of fear. This memory can lead to the automatic physical symptoms of anxiety when the object or situation is experienced again. These symptoms in turn can make it hard for the individual to focus on

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

* **depersonalization** (de-person-al-i-ZAY-shun) is a mental condition in which people feel that they are living in a dream or are removed from their body and are watching themselves live.

* **derealization** (de-reel-i-ZAY-shun) is a mental condition in which people feel that the external world is strange or unreal.

* **identical twins** are twins produced when a single egg from the mother is fertilized and divides to form two separate embryos of the same sex with nearly identical DNA.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

- * **psychotherapy** (sy-ko-THER-a-pea) is the treatment of mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth.
- * **temperament** (TEM-per-uh-ment) is the genetically or biologically based part of an individual's personality.
- * **self-esteem** is the value that people put on the mental image that they have of themselves.

anything else. Over time, people may start to feel anxiety in many situations that do not resemble the original fear-producing event. Studies have shown that memories stored in the amygdala may be hard to erase. People can, however, gain control over their responses with experience and sometimes with psychotherapy*.

Temperament Another factor to take into account is a personality quality called temperament*. Temperament refers to a person's inborn nature that includes certain behavioral traits. To some extent, people's tendency to be shy or nervous may be inborn, simply part of their nature. Some research suggests that babies who are easily upset never fully learn early in life how to soothe themselves the way other children with calmer temperaments do. Those with a high-strung temperament may react more strongly to stressful or anxiety-provoking situations than people whose temperament makes them more adaptable. Some experts believe that people with an inhibited or cautious temperament may be more likely to have problems with anxiety.

Life experiences Yet another factor that plays a role in some anxiety disorders is stressful or negative life experiences, especially when they occur early in life. Scientists have found that when rat pups are separated from their mothers at an early age they have a much more intense startle response to later stressful situations than rat pups that were not separated. In addition to separation from a parent, human children may be affected by such stressful situations as child abuse, family violence, the untimely death of a parent or sibling, or growing up in an unsafe neighborhood. Unsafe conditions or frightening experiences may teach children to be overcautious, to expect bad events, or to worry excessively about possible dangers. People with low self-esteem* may also be prone to developing anxiety disorders.

What Are the Symptoms of Anxiety Disorders?

The fear response associated with all of the anxiety disorders can involve a number of physical symptoms, including the following:

- Pounding or racing heartbeat
- Heavy sweating
- Trembling or loss of coordination
- Shortness of breath
- Choking sensations or feeling a lump in the throat
- Chest pain
- Nausea and vomiting
- Diarrhea
- Dizziness or faintness
- Numbness
- Tingling sensations in the hands or feet
- Chills

Anxiety disorders also can lead to changes in the way a person feels, thinks, or behaves. For example, people with anxiety disorders might experience the following:

- Feel afraid and nervous
- Fear they are losing their self-control or going crazy
- Fear they will die or be seriously injured
- Worry about a parent's possible future injury or illness
- Worry about being away from home
- Worry about future and what may happen, expecting the worst
- Refuse to go to school
- Be afraid to meet or talk to new people
- Avoid new situations at school or work
- Have trouble sleeping due to worry or fear

Without treatment, people may be driven to take extreme measures to avoid situations that trigger these unpleasant symptoms. They may refuse to join in many activities. Relationships with family and friends may suffer as a result. In addition, people who are always thinking about fears and worries are unable to concentrate on school, work, or sports. They may fail in the present to do as well as they can in these areas.

How Are Anxiety Disorders Diagnosed and Treated?

Anxiety disorders often occur along with other mental disorders, such as depression, eating disorders*, or substance abuse*. Anxiety disorders may also accompany physical illnesses. In such cases, these other problems must also be treated. People with the symptoms of an anxiety disorder need a complete medical checkup to rule out other illnesses. They also need a thorough psychological evaluation. The mental health professional will ask about symptoms and the problems that they cause. With children and teenagers, the professional generally talks to parents and involved teachers.

Medications Medications cannot cure anxiety disorders, but they can help to relieve symptoms. Several kinds of medications are used to treat anxiety. Although these medications work well, they can be dangerous if mixed with alcohol, and some can be habit-forming. Antidepressant medications*, originally developed to treat depression, have increasingly been prescribed to treat anxiety. Finding the right medication and dose for a given person can take some time. Fortunately, if one medication does not work well for a given patient, several other medications can be tried.

Psychotherapy Medications often are combined with psychotherapy, a treatment in which people talk about their feelings, experiences, and beliefs with a mental health professional. In therapy, a person can learn how to change the thoughts, actions, or relationships that play a

* **eating disorders** are conditions in which a person's eating behaviors and food habits are so unbalanced that they cause physical and emotional problems.

* **substance abuse** is the misuse of alcohol, tobacco, illegal drugs, prescription drugs, and other substances such as paint thinners or aerosol gases that change how the mind and body work.

* **antidepressant medications** are used for the treatment and prevention of depression.

part in their problems. There are many kinds of psychotherapy; however, two kinds have been shown to work particularly well in treating anxiety disorders: cognitive (COG-nih-tiv) therapy and behavioral (be-HAY-vyor-ul) therapy. Often techniques from these two types of therapy are combined.

Cognitive-behavioral therapy helps people understand and change their thinking patterns so they can learn to react differently to situations that cause anxiety. This awareness of thinking patterns is combined with behavioral techniques. For example, someone who becomes dizzy during panic attacks and fears he is going to die may be asked to spin in a circle until he gets dizzy. When he becomes alarmed and starts thinking, “I’m going to die,” he learns to replace that thought with another one, such as “It’s just dizziness. I can handle it.” Although anxiety disorders can be extremely distressing to those experiencing them, the good news is that these disorders respond well to treatment.

Behavioral techniques help people replace specific, unwanted behaviors with healthier behaviors. Behavioral approaches that may be used to treat anxiety include relaxation training and deep breathing, for example. People are taught to take slow, deep breaths to relax, because people with anxiety often take fast, shallow breaths that can trigger such other physical symptoms as a racing heart and dizziness. Also, exposure (ek-SPO-zhur) therapy gradually brings people into contact with a feared object or situation, so they can learn to control their fear response to the object or situation that frightens them.

Appendicitis

Appendicitis (ap-pen-di-SY-tis) is the inflammation of the appendix (ap-PEN-dix), which is a small organ that branches off the large intestine. The inflammation usually begins abruptly, causes a characteristic right-sided abdominal pain, and may lead to rupture or bursting of the appendix, and to severe illness.

Appendicitis occurs when the appendix, attached to the first part of the large intestine, becomes infected with bacteria and inflamed. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

▲
Appendectomy scar one week after surgery. Dr. P. Marazzi/Photo Researchers, Inc.

* **acute** describes an infection or other illness that comes on suddenly and usually does not last very long.

* **peritonitis** (per-i-to-NI-tis) is inflammation of the peritoneum (per-i-to-NE-um), which is the membrane that lines the abdominal cavity.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

What Is Appendicitis?

Acute* appendicitis occurs when the appendix becomes inflamed. An inflamed appendix must be removed so that it does not rupture (break) and spread the infection to the rest of the abdomen, a condition known as peritonitis*. The appendix has no known function, and its removal has no adverse effect on the body.

In most cases, acute appendicitis begins with an obstruction of the appendix's interior cavity, known as the lumen. The appendix is a narrow, finger-shaped tube, usually three to six inches (7.6–15.2 cm) long, that branches off the large intestine into the lower right side of the abdomen*. It is also known as the vermiform appendix. Vermiform means worm-shaped. The appendix may become blocked for many reasons. Often, feces obstructs the appendix, but in some cases, a bacterial or viral infection may cause lymph nodes to swell—called lymphoid hyperplasia—and obstruct the appendix. The blockage leads to inflammation. Appendicitis is typically treated with an appendectomy (ap-pen-DEK-to-mee), which is the surgical removal of the appendix. If appendicitis is left untreated, it can be fatal, but it is rare for anyone not to receive treatment in time.

Some people experience off-and-on abdominal pain, a condition that may be identified as chronic appendicitis. Often, the cause of the intermittent pain is a prolonged, partial obstruction of the appendix. Some patients are able to live with the recurrent bouts, but most only experience full relief from symptoms following appendectomy.

Who Gets Appendicitis?

Appendicitis is not preventable. Each year in the United States, it affects about one in 500 people. Anyone can develop appendicitis, but it is most common in young people between the ages of 15 and 24, and it affects boys more often than girls. In all, about 7 percent of the population typically has appendicitis sometime during their lifetime.

What Happens to People with Appendicitis? David's Story

David's appendicitis happened suddenly, when he awoke at 1 a.m. with a terrible bellyache. He blamed it on the chips and ice cream he had eaten after dinner and tried to go back to sleep. By 7 a.m., his bellyache was worse, he was not hungry, and he felt very hot. He told his parents about the intense pain in his right side, and they took him to see the doctor immediately. A series of events followed rapidly.

March 2, 10 a.m. The doctor asked David numerous questions about the pain: Is it constant? Does the right side hurt the most? Is the pain worse when you move, cough, or take a deep breath? Are you nauseated? David said yes to all of them. His abdomen felt hard when the doctor touched it, and when the doctor pushed on the right lower part, David yelled. A nurse took David's temperature and a blood sample.

March 2, noon David's blood test showed more white blood cells than usual, which is one of the signs of inflammation. The boy's other symptoms of fever and abdominal pain led the doctor to diagnose appendicitis and to advise David's parents to check him into the hospital.

March 2, 8 p.m. David had been at the hospital for several hours, during which the nurses continued monitoring his condition. The pain did not go away and started to get worse. The doctor decided that David should be taken to the operating room right away to have an appendectomy. To prepare the patient for the surgery, the doctor explained anesthesia* and showed David where the surgeon would make a small cut in his abdomen to remove the diseased appendix. The doctor and nurses repeatedly reassured David and his parents that this was a common surgery.

March 2, 10 p.m. David awoke in the hospital recovery room, groggy, tired, and a little sore. His appendix, which had not yet ruptured, had been removed.

March 4, 8 a.m. David went home from the hospital, minus his appendix and with a slight soreness at the site of his appendectomy scar, but otherwise healthy.

Within several weeks, David was back to doing just about everything he had done before his bout with appendicitis. His appendectomy surgery had been a complete success.

Arthritis

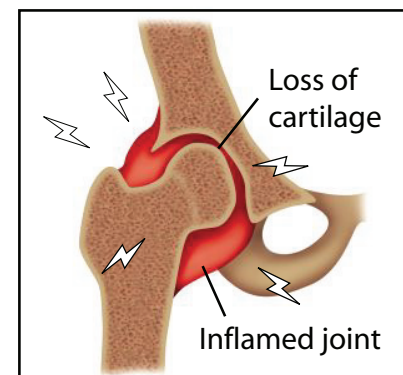

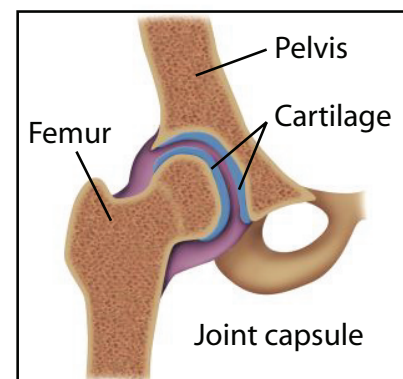

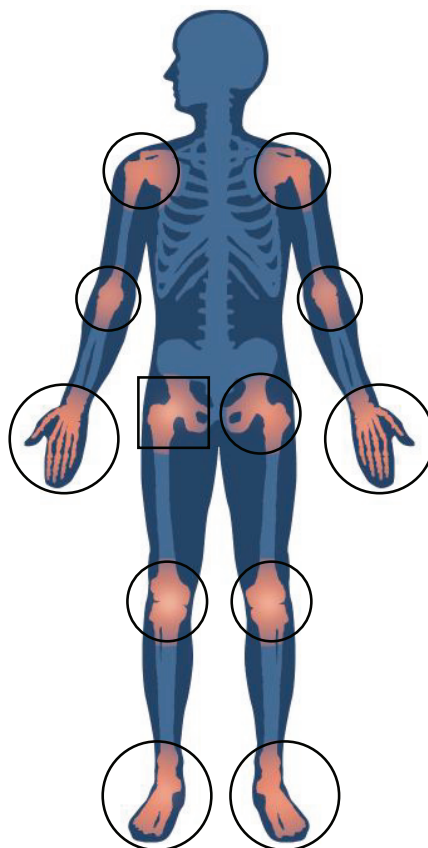

Arthritis refers to inflammation of the joints, often accompanied by pain, stiffness, or swelling. Arthritis may occur in many different diseases and medical conditions.

Jenny's Story

For many years, Jenny's father was a dedicated runner. He got up early each morning for a three-mile jog, and on weekends he sometimes ran as far as 10 miles or competed in road races. He even talked about training for a marathon, which would mean running more than 26 miles in one race. Gradually, however, Jenny began to hear her father mention that his knees were hurting when he ran and that they remained painful for a few hours after he stopped. Jenny noticed that his knees looked swollen and

Arthritis may affect many different parts of the body, including shoulders, elbows, hands, hips, and knees (left). In healthy joints (top right), a flexible cushion of cartilage allows bones to slide past each other smoothly. But in arthritis (bottom right), cartilage loss forces the bones to touch without their usual cushioning, which creates pain and inflammation.

Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.

that he sometimes had trouble sleeping because the pain annoyed him so much.

Jenny's father assumed the pain was simply a running injury that would get better with rest. But when the pain did not go away, Jenny's father visited a doctor. He was told he had a type of arthritis known as osteoarthritis (os-te-o-ar-THRY-tis). This surprised Jenny because her father was only in his 40s. She thought that arthritis was only a problem for older people like her grandparents.

What Is Arthritis?

Arthritis is a common problem for many older people, but it can affect anyone, from toddlers to centenarians*. Although people use the term as if it were only one disease, arthritis actually refers to a condition found in a large group of disorders. The major symptoms of arthritis occur in and around joints, making them stiff, swollen, and often painful. In addition to the joints, certain types of arthritic diseases may affect other parts of the body, including the heart and lungs.

As a group, the various forms of arthritis are among the most common medical conditions. As of 2006, the Arthritis Foundation estimated that about one in five people, or more than 46 million Americans, had it. Arthritis usually is chronic, which means the problem can last to some degree for months, years, or the rest of people's lives.

Arthritis affects millions of people. Although there are many types, the most common are:

- osteoarthritis*
- rheumatoid arthritis*
- juvenile rheumatoid arthritis*
- gout*
- fibromyalgia*
- lupus*
- Lyme disease*

These conditions develop for a variety of reasons, but they are not contagious*. Some forms of arthritis, however, can develop from contagious infections, such as sexually transmitted diseases or viruses that cause mumps and rubella (German measles). One form of arthritis, Lyme disease, develops from the bite of an infected tick. Sometimes arthritis occurs as one of the symptoms seen in conditions that primarily affect other organs. For example, inflammatory bowel disease may have arthritis as one of its symptoms.

What Is Osteoarthritis?

Jenny's father has osteoarthritis, the most common type of arthritis in adults. About 21 million Americans, almost half of those with arthritis, have this kind. Osteoarthritis is sometimes called "wear-and-tear" arthritis. That is because the pain, stiffness, and swelling often result from the wearing down of the protective tissues within and around joints.

* **centenarians** are people who are at least 100 years old.

* **osteoarthritis** (os-tee-o-ar-THRY-tis) is a common disease that involves inflammation and pain in the joints (places where bones meet), especially those in the knees, hips, and lower back of older people.

* **rheumatoid arthritis** (ROO-mah-toyd ar-THRY-tis) is a chronic disease characterized by painful swelling, stiffness, and deformity of the joints.

* **juvenile rheumatoid arthritis** a joint disease in children with symptoms of high fever, rash, swollen lymph glands, enlarged spleen and liver, and inflammation around the heart and of the lungs. Arthritis in the joints appears later. This disease is also known as systemic-onset chronic arthritis or Still's disease.

* **gout** occurs when deposits of uric acid in the joints cause inflammation and pain.

* **fibromyalgia** (fi-bro-my-AL-ja) is a group of disorders that are characterized by achy, tender, and stiff muscles.

* **lupus** (LOO-pus) is a chronic, or long-lasting, disease that causes inflammation of connective tissue, the material that holds together the various structures of the body.

* **Lyme disease** (LIME) is a bacterial infection that is spread to humans by the bite of an infected tick. It begins with a distinctive rash and/or flulike symptoms and, in some cases, can progress to a more serious disease with complications affecting other body organs.

* **contagious** (kon-TAY-jus) means transmittable from one person to another, usually referring to an infection.

▲ Colored X-ray of hands with severe rheumatoid arthritis. Swelling and bone deformation (yellow) is seen in finger and hand joints. Most joints are ragged due to bone erosion, with the thumbs also affected. People with rheumatoid arthritis may feel stiffness when they wake up in the morning, and their joints may feel warm to the touch. *SPL/Photo Researchers, Inc.*

More than 150 possible trouble spots The human body contains more than 150 joints that connect more than 200 bones. Toes and fingers have small joints; the spine, elbows, and knees have larger ones, and the hips and shoulders have even bigger ones. The bones do not touch directly. Instead, a tough, smooth, rubbery layer of tissue called cartilage covers the ends of the bones. When a knee, elbow, or other joint moves, the cartilage allows the bones to slide smoothly past each other. Cartilage also is flexible and absorbs some of the weight placed upon certain joints, such as the knee.

People with osteoarthritis, however, have lost some of the smooth cartilage in their joints. Eventually, the cartilage can wear away so much that the ends of the bones touch without any cushioning. The bones also can grow small spurs or bumps, which is why some people with osteoarthritis have lumps in their joints. These lumps often are most noticeable in the hands.

Those odd pains Osteoarthritis usually is felt first in the knees, hips, feet, spine, or fingers. These are joints that bear much of the body's weight or undergo frequent use for everyday activities. The pain increases as the cartilage between the bones wears down. People often start to avoid using the joint. For example, people might exercise less if they have pain in their knees, which only makes the problem worse. It leads to increased stiffness because muscles around the joints begin to weaken from disuse.

Stress No one is exactly sure why osteoarthritis happens, but often it results from stresses placed on the joint. In the example of Jenny's father, his years of running on hard surfaces caused damage to his knee cartilage. The pounding on pavement was too much stress for the cartilage to absorb.

Other types of stress or injury also can lead to osteoarthritis. People whose jobs involve hard physical labor (such as construction workers) or repetitive tasks (such as assembly-line workers) can develop osteoarthritis. In addition, an injury to a knee or elbow can increase the risk of osteoarthritis. Certain activities such as football or ballet can put a person at greater risk for developing osteoarthritis.

Even the stress of too much body weight contributes to the disease. People who are significantly overweight are more prone to osteoarthritis because their weight places extra stress on joints, especially knees and hips.

Age Many older people also develop osteoarthritis, even if they never put extra stress on their joints. That is because as people age, the rubbery cartilage tissue loses some of its ability to stretch and can become thinner. This change in the tissue places people at greater risk for osteoarthritis.

Heredity Not all older people develop osteoarthritis, just as not all runners or laborers do, which is one reason some doctors suspect heredity may play a role in determining who is at greatest risk for this type of arthritis.

Diagnosis It is important to understand what type of arthritis people have because treatments vary. Doctors diagnose osteoarthritis based on

the symptoms they see. They might look for loss of cartilage and bone spurs by performing x-rays. Doctors also look for other causes of the pain. For example, blood tests can show if the problem is rheumatoid arthritis rather than osteoarthritis.

If it hurts, why do doctors want patients to exercise? Once doctors have determined the problem is osteoarthritis, they typically tell patients something that might seem to make little sense. They want their patients to exercise the joint. This does not mean Jenny's father should return to running. It does mean he and others with the disease need to work with their doctors to find the best way to exercise.

Appropriate exercise can strengthen the muscles around the joint and help lessen the stiffness. Often the exercises are different from those done in the past. Some individuals give up running for swimming or water aerobics. Others walk or ride stationary bikes. If the pain is severe, a physical therapist who specializes in helping patients learn appropriate exercises might get involved. If people are overweight, doctors advise them to lose the extra pounds.

The pain of arthritis is often treated with aspirin or other over-the-counter drugs that reduce swelling. In addition, stronger prescription drugs can help if the pain is extreme. In some cases, doctors may recommend that corticosteroids* or artificial joint fluid, known as hyaluronic acid derivatives, be injected into the joints.

Often the pain of osteoarthritis decreases with treatment. For some people, however, surgery is performed to remove stray pieces of damaged cartilage, to smooth bone spurs, or in severe cases to replace damaged joints with mechanical ones. Hips and knees are the most likely candidates for replacement.

What Is Rheumatoid Arthritis?

The ancient Greeks believed the human body is filled with various substances they called "humors." Sometimes they said the humors got out of balance and caused illnesses, such as the aches and pains of swollen joints. The humors, they believed, could get back in balance, and the pain would subside. However, the problems also could return. One disease the Greeks observed is what was later called rheumatoid (ROO-ma-toid) arthritis. "Rheuma" derives from a Greek word that means "flux" or "discharge." The Greeks believed the humors were fluxing, or flowing, through the body to cause the bouts of pain.

When the body turns on itself In a way, rheumatoid arthritis is a disease in which substances in the body are out of balance. The body fights infections with chemicals known as antibodies. However in rheumatoid arthritis, the antibodies turn against healthy areas of the body and cause the thin covering around joints to become inflamed.

The pain usually starts in the hands or feet, but rheumatoid arthritis can affect many different joints as well as other parts of the body, such

* **corticosteroids** (kor-tih-ko-STIR-oyds) are chemical substances made by the adrenal glands that have several functions in the body, including maintaining blood pressure during stress and controlling inflammation. They can also be given to people as medication to treat certain illnesses.

* **Raynaud's disease** (ray-NOZE) is a condition in which discoloration of the skin typically on the fingers and/or toes occurs when individuals experience changes in temperature or emotional events. An abnormal spasm of blood vessels causes the reduced supply of blood to the affected areas of the body.

as the heart and lungs. The disease's cause is unknown. Some researchers believe that the immune system's attack on healthy tissues may be caused by the body's overreaction to viral infection. Rheumatoid arthritis is sometimes associated with Raynaud's disease*

More than 2 million Americans have rheumatoid arthritis, and most of them are women. Although it is primarily a disease that begins at middle age, its onset may be much earlier.

Known as the most disabling of the various diseases that cause arthritis, rheumatoid arthritis can lead to deformed joints, extreme pain, and loss of the ability to do common tasks such as walking.

Stiffness in the morning The symptoms of the disease can develop in a few days, or over months or years. For most people, a joint in the hands, feet, arms, or legs feels stiff, as it does in osteoarthritis and other forms of arthritis. Rheumatoid arthritis, however, has a few distinctive features. People tend to feel worse in the morning after awakening. They also can get a fever, and their joints can seem warm to the touch.

At first, the antibodies attack only the thin covering around joints. This covering contains cells that produce fluid to keep joints lubricated and working properly. As the covering is injured, it becomes thicker. Soon, damaging cells appear and eat away cartilage, bone, and other tissue. Swelling and pain result, and the joints become deformed. People with rheumatoid arthritis also can develop small bumps around joints, especially in their hands and elbows. Often, the disease flares up and then subsides on its own. Some people, however, receive no relief without treatment.

Diagnosis Doctors diagnose rheumatoid arthritis with special blood tests. They also look for other causes of the joint problems and use x-rays to look at the spaces between bones to see if they are narrowing.

Treatment Over-the-counter medications such as aspirin can ease the pain. Stronger prescription pain relievers and anti-inflammatory drugs are also available. Weight loss is urged for people who are too heavy. Some people need surgery to replace badly damaged joints in the arms, legs, or hips.

Many people, however, learn to live with the disease through a combination of rest and exercise. When the symptoms are at their worst, patients with rheumatoid arthritis try to avoid putting stress on their joints to help reduce damage. When the symptoms are less severe, however, doctors want the patients to exercise as a way of maintaining flexibility in the joints and strength in the muscles around them.

Patients with rheumatoid arthritis often learn relaxation techniques because the disease is known to flare up in times of emotional stress.

What Is Juvenile Rheumatoid Arthritis?

Juvenile rheumatoid arthritis is one of several common forms of juvenile arthritis that cause swelling and pain in the joints, and children with arthritis may experience a great variety of symptoms. The disease affects

THE UNITED STATES AND ELSEWHERE IN THE WORLD

- About 355 million people worldwide have arthritis.
- As of 2006, the Arthritis Foundation estimated that 46 million people in the United States (20 percent of the population) had arthritis. As baby boomers age, though, those numbers are expected to rise. In the decade from 2007–2017, the Centers for Disease Control predicted that 8 million new cases will be diagnosed.
- According to the Centers for Disease Control, the state with the highest percentage of residents with arthritis in 2005 was West Virginia with 35 percent. Hawaii, California, Washington, D.C., and Texas, each with about 22 percent of their population having arthritis, had the lowest percentages. The state median was 27 percent.
- A disease without age boundaries, arthritis affects nearly 300,000 American children. It is, however, especially prevalent among older people. As of 2005, half of all adults 65 years old and older had the disease.
- About three-fifths of Americans with arthritis are female.
- According to the Centers for Disease Control, the cost of arthritis and related diseases to the U.S. economy in the year 2003 was about \$128 billion, up more than \$40 billion since 1997. About 63 percent is due to medical costs, and the remainder is from lost earnings.
- People who have physically challenging jobs have a higher likelihood of developing arthritis. According to the Arthritis Foundation, 48 percent of all players in the National Football League retire with some form of the disease as a result of joint stress and injury-related complications suffered during their years on the playing field.

up to 50,000 American children. The causes are unknown, although heredity is believed to play a role.

Juvenile rheumatoid arthritis affects children under age 16. Although it is very similar to the adult form of rheumatoid arthritis, which is chronic, many young patients “outgrow” juvenile rheumatoid arthritis. Doctors use a similar approach to juvenile and adult rheumatoid arthritis: pain medication, exercise recommendations, and careful treatment to prevent joints from becoming deformed.

What Are the Other Forms of Arthritis?

Osteoarthritis is the most common form of arthritis, and rheumatoid arthritis is the most disabling, but more than 100 diseases are accompanied by the symptoms of arthritis. Listed below are a few of the other major ones, as well as several unusual types:

Gout Gout causes extreme pain that develops suddenly, often in the big toe. The pain, swelling, and redness develop because uric acid crystals build up in the joint. A natural substance found in the body, uric acid usually passes out of the system through the kidneys and urine*. When uric acid is not removed from the body, crystals form and settle in the joints. Many people associate gout with excessive eating and drinking. Although

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

Rheumatism

Rheumatism is a non-medical word that many people use to refer to many different forms of arthritis, including rheumatoid arthritis. Older men and women sometimes talk about “having a touch of rheumatism” when their joints ache, especially on cold, rainy days.

* **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

those activities, as well as obesity*, increase the risk for gout, it can develop for no apparent reason. According to the Arthritis Foundation, about 2.1 million Americans have gout, and about 75 percent of them are men.

Fibromyalgia Fibromyalgia causes pain in the muscles and in the ligaments and tendons that are attached to bones around joints. Often people with fibromyalgia are excessively tired and have trouble sleeping. The causes are unknown, although people with the disease often experience psychological stress, which does not mean the disease or its pain are not real. Unlike other forms of arthritis, fibromyalgia affects muscles and tissues around joints, not the joints themselves. It also does not lead to permanent damage. About 3.7 million Americans have fibromyalgia, and most of them are women.

Lupus Lupus is a disease that affects joints as well as other body parts, such as the kidneys, nervous system, heart, and skin. Lupus has many symptoms, including fatigue, rashes, chest pain, fever, and sensitivity to sunlight. Like rheumatoid arthritis, lupus is an autoimmune disease with no known cause. In autoimmune diseases, the cells in the body that usually fight infections instead attack healthy cells and tissue. According to the Lupus Foundation of America, this disease affects 1.5 million Americans, and 90 percent of them are women. The disease mainly strikes women in their childbearing years. People of color, including African Americans, Asians, Hispanics, and Native Americans, are two to three times more likely to develop lupus than are women of European ancestry.

Lyme disease Lyme disease is a bacterial infection spread by the bite of an infected insect known as a deer tick. The first signs are usually fever and a red rash on the skin where the bite occurred, although early symptoms are sometimes overlooked. Joint problems may follow but may not appear until months to years later. If caught early, the disease usually can be overcome with antibiotics. Lyme disease is a special concern for people who spend time outdoors in certain regions of the United States.

Living with Arthritis

Severe arthritis can limit a person’s ability to walk, dress, or bathe easily. A growing number of devices are designed to help people with varying forms of arthritis to perform simple tasks more easily and to continue living independently. These range from easy-to-open bottles and gripping clamps on poles for reaching high objects to electric scooters.

Although doctors do not yet know how to prevent arthritis, they typically recommend many ways people can reduce its impact. These include:

- maintaining a healthy weight
- exercising to maintain joint flexibility and muscle strength

- exercising carefully, especially in contact sports such as football
- wearing well-cushioned sneakers when walking or running on hard surfaces
- getting adequate rest
- following the doctor's instructions about pain medications
- learning relaxation techniques to reduce flare-ups in times of stress

With a fuller understanding of arthritis, its limitations, and its treatments, people with arthritis can lead full and happy lives.

* **joint** is the structure where two or more bones come together, allowing flexibility and motion of the skeleton.

Arthritis, Infectious

Infectious arthritis (in-FEK-shus ar-THRY-tis) is a bacterial, fungal, or viral infection of the tissue and fluid within a joint. The infection causes inflammation and can result in pain, swelling, and limited motion of the joint.*

- * **cervix** (SIR-viks) is the lower, narrow end of the uterus that opens into the vagina.
- * **rectum** is the final portion of the large intestine, connecting the colon to the outside opening of the anus.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.
- * **sickle-cell anemia** also called sickle-cell disease, is a hereditary condition in which the red blood cells, which are usually round, take on an abnormal crescent shape and have a decreased ability to carry oxygen throughout the body.
- * **lupus** (LOO-pus) is a chronic, or long-lasting, disease that causes inflammation of connective tissue, the material that holds together the various structures of the body.
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).
- * **rheumatoid arthritis** (ROO-mah-toyd ar-THRY-tis) is a chronic disease characterized by painful swelling, stiffness, and deformity of the joints.

What Is Infectious Arthritis?

Most of the time, bacteria cause infectious arthritis. Infectious arthritis is also called septic arthritis, and the infected joint is referred to as a “septic joint.” *Staphylococcus* (stah-fih-lo-KAH-kus) or *Streptococcus* (strep-tuh-KAH-kus) bacteria are the culprits in most cases of septic arthritis. Infectious arthritis also can occur in other diseases, for example, in Lyme disease and tuberculosis. Bacteria can be introduced directly into the joint by injury or surgery, but more often the bacteria are carried to the joint through the bloodstream from an infection somewhere else in the body. The most common cause of septic arthritis in young adults is *Neisseria gonorrhoeae* (nye-SEER-e-uh gah-no-REE-eye), the bacterium that causes gonorrhea. These bacteria may spread from infected areas, such as the cervix*, rectum*, and the male urethra, and infect joints at the hands, wrists, elbows, and knees. Certain viruses, including those that produce measles, rubella (roo-BEH-luh, a rash-causing viral infection that is also called German measles), and hepatitis B or C, also can cause infectious arthritis. Fungi found in soil, bird droppings, and some plants are uncommon causes of infectious arthritis.

People whose immune systems are weak because they have a disease such as diabetes*, sickle-cell anemia*, certain cancers, lupus*, or AIDS* are more likely to get infectious arthritis. Alcoholism and intravenous drug use also put people at higher risk. Because a joint that is damaged is more vulnerable to germs, people with existing disease involving the joints (for example, rheumatoid arthritis*) are more likely to develop infectious arthritis. Anyone who has had joint-replacement surgery is at increased risk for infection of that joint in the future.

How Common Is Infectious Arthritis?

Cases of infectious arthritis are more common in some places than in others. Rates are highest in Africa, Latin America, and Asia. In the United States, about 20,000 cases of infectious arthritis occur each year. Men, women, and children of all ages can get infectious arthritis, but almost half of patients in whom the illness is diagnosed are 65 years or older.

Is Infectious Arthritis Contagious?

Infectious arthritis is not contagious, but certain viruses and the bacterium that causes gonorrhea can be transmitted from one person to another. However, contracting a particular infection caused by these organisms does not necessarily mean individuals will also get infectious arthritis.

What Are the Signs and Symptoms of Infectious Arthritis?

The symptoms of infectious arthritis vary by type of infection and the particular joint that is affected. With infectious arthritis, symptoms usually appear within a few hours or days and include redness, warmth, swelling, pain, and sometimes fever and chills. It is difficult to move the affected

joint because of the pain and swelling. Arthritis from a viral infection tends to come on more slowly, often with absence of fever and with less swelling, limitation of movement, and pain at the affected joint. Viruses may infect the joint directly, or sometimes the response of the body's immune system to a virus may cause joint inflammation (called "postinfectious arthritis"). Inflammation stemming from a fungal infection or tuberculosis usually develops very slowly, sometimes over weeks or months. The bacteria that cause Lyme disease can settle in a joint and may lead to recurrent bouts of infectious arthritis. Usually, swelling and limitation of movement of the joint are the main symptoms of this form of arthritis.

How Do Doctors Make the Diagnosis?

A doctor who suspects infectious arthritis based on a patient's symptoms and the findings of a physical examination will want to know the details of the person's medical history. Taking a medical history might include asking questions about whether the patient is sexually active; injects drugs; has been bitten by a tick (which can cause Lyme disease); has had arthritis in the past; or has recently been injured, hospitalized, or exposed to an illness. Laboratory tests can help confirm the diagnosis. A common diagnostic test is aspiration* of some of the synovial fluid* within the affected joint. The doctor inserts a thin, sterile needle through the skin directly into the joint and removes a sample of fluid. The fluid is then examined under a microscope to look for evidence of microorganisms (such as bacteria) and infection-fighting white blood cells. Some of the sample is put in a jelly-like medium containing nutrients that support the growth of bacteria, and this is placed in an incubator for a few days. If bacteria grow, bacterial infectious arthritis is diagnosed. This synovial fluid can also be tested for evidence of viral or fungal infections. In addition, blood tests can help diagnose arthritis caused by a virus or bacterium. If the suspected cause of inflammation is a fungus or tuberculosis, a tissue sample from the infected joint may need to be removed and analyzed. X-rays, computerized tomography*, or magnetic resonance imaging* studies can detect excess fluid and sometimes destruction of the tissues within or surrounding an affected joint.

What Is the Treatment for Infectious Arthritis?

The type of organism causing infectious arthritis determines which medicines are needed to treat the infection. Antibiotics are prescribed to treat joint infections caused by bacteria, and anti-fungal medications are given for infection due to a fungus. Doctors also may recommend that individuals with infectious arthritis keep the affected joint elevated (raised up) and avoid moving it. Over-the-counter anti-inflammatory medications, such as ibuprofen*, can relieve swelling and pain. Sometimes, to help healing and decrease discomfort, some of the excess synovial fluid is removed from a joint. This procedure may have to be repeated several times. In certain cases, a septic joint might be drained by a surgical procedure to help cure the infection.

* **aspiration** (as-puh-RAY-shun) is the sucking of fluid or other material out of the body, such as the removal of a sample of joint fluid through a needle inserted into the joint.

* **synovial (sih-NO-vee-ul) fluid** is the fluid produced in the synovium, the inner lining of the flexible capsule that encloses the joint space between two bones. This fluid lubricates and nourishes the joint.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

* **ibuprofen** (eye-bew-PRO-fin) is a nonsteroidal anti-inflammatory drug (NISAD) used to reduce fever and relieve pain or inflammation.

How Long Does the Infection Last?

Eliminating the infection can take time. Antibiotics may need to be given intravenously for three weeks or more. It may take even longer for someone to be able to use an affected joint without feeling pain. In cases of severe infectious arthritis, physical therapy may be recommended after other treatment has been completed to help patients recover full movement and function of the joint. Infectious arthritis can be cured with prompt and proper treatment. In cases that are severe or when treatment is delayed, the infection may cause permanent damage to the joint and the bone, sometimes resulting in persistent pain and disability.

Can Infectious Arthritis Be Prevented?

Doctors may recommend that people who have a high risk of the disease, such as those with artificial joints, take antibiotics prior to having certain procedures, such as dental procedures. Administration of antibiotics as a pre-emptive measure (prophylaxis) prior to circumstances in which bacteria may be expected to enter the blood stream may prevent an infection in the joint, even when the person has no symptoms of disease. Abstinence (not having sex) will prevent arthritis caused by sexually transmitted diseases such as gonorrhea. For sexually active people, the use of latex condoms can lessen the risk of exposure to bacteria that can cause infectious arthritis.

Ascariasis

Ascariasis (as-kah-RI-ah-sis) is an infection of the intestines by parasitic roundworms that usually causes no symptoms but is sometimes serious.

What Is Ascariasis?

The world is full of roundworms*. Hundreds of thousands of different kinds inhabit the Earth, and a few types inhabit the bodies of humans as well. The most common of these is a worm called *Ascaris* (full name *Ascaris lumbricoides*), which is estimated to infect 1 billion people worldwide.

Ascariasis, which is what the infection or infestation is called, usually occurs in tropical and subtropical areas where sanitation is poor and where raw or improperly treated human sewage is used to irrigate or fertilize crops. Most cases occur in Africa and Asia, but it has been estimated that 4 million people in the United States carry *Ascaris* (AS-ka-ris), most of them in rural southeastern areas.

Ascaris is a parasite*. Like many other parasites, it usually leads a live-and-let-live existence, doing little damage to its host. Unlike many parasites, however, it infects only humans. Although *Ascaris* worms are found in people of all ages, children are most likely to be heavily infected.

What Is the Life Cycle of the Ascaris Worm?

Adult *Ascaris* worms live in the upper portion of the small intestine. They are 8 to 15 inches (20 to 40 cm) long, one-eighth to one-fourth inch (3 to 6 mm) in diameter, and live for about one year. Fertilized females produce up to 240,000 microscopic eggs per day, which pass out of an infected person's body in the stool (feces). Fertilized eggs must remain in the soil for two to three weeks before they can infect another person. The eggs, however, can remain alive and viable*.

Infection usually begins when soil containing eggs gets on people's hands. If they eat or touch their mouths before washing their hands, the eggs can get into their mouths and be swallowed. The eggs may also get into the body in food that has been contaminated with human waste.

The eggs hatch in the small intestine and release free-swimming larvae*. The larvae penetrate the wall of the small intestine and enter the bloodstream. Next comes the pulmonary* stage of the infection, when the larvae enter the lungs and move up the bronchial tubes, which are the passages that carry air to and from the lungs. They finally reach the pharynx (FAR-inks), the back of the throat, where they are swallowed. Then

▲ The roundworm *Ascaris lumbricoides* is the largest of the human intestinal parasites. Sinclair Stammers/Photo Researchers, Inc.

Did You Know?

- About 1 billion people worldwide are infected with *Ascaris* worms.
- An adult *Ascaris* worm is 8 to 15 inches (20 to 40 cm) long.
- A female *Ascaris* worm can produce 240,000 eggs a day.

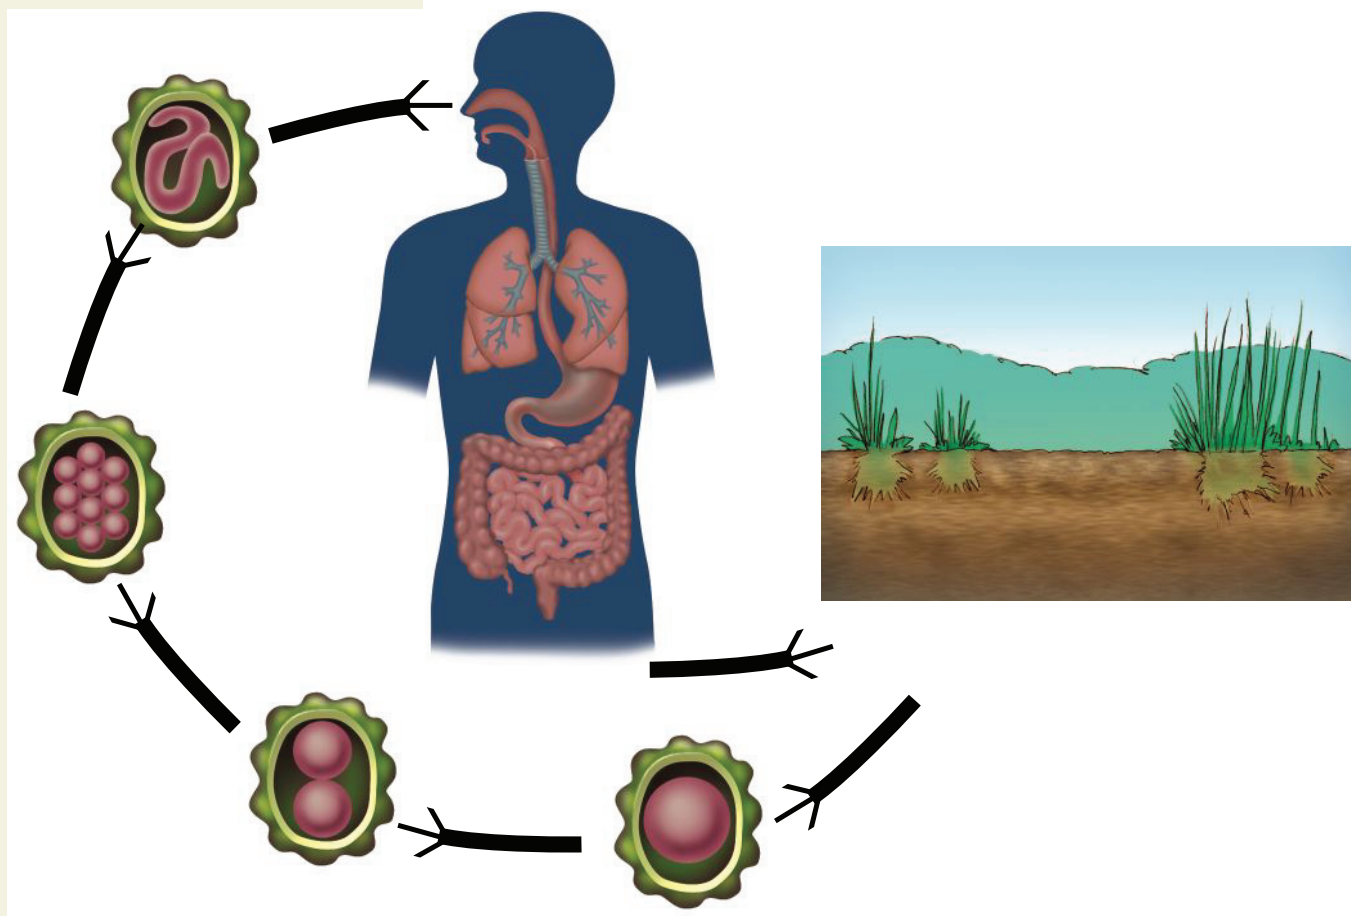

* **roundworm** is one of several types of cylinder-shaped worms that live in people. Roundworms are also known as nematodes (NEE-muh-to-des).

* **parasite** (PAIR-uh-site) is an organism such as a protozoan (one-celled animal), worm, or insect that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. Parasites live at the expense of the host and may cause illness.

* **viable** means an organism can survive, grow, develop, and function.

* **larvae** (LAR-vee) are the immature forms of an insect or worm that hatches from an egg.

* **pulmonary** refers to the lungs.

▲ Ascariasis infections begin when people swallow worm eggs that they have picked up from infected food or from soil. The eggs hatch in the small intestine, become larvae, and swim through the bloodstream to the lungs and then on to the throat, where they are swallowed. Back in the stomach and small intestine, the larvae become adults, mate, and produce new eggs. The entire cycle takes 2 to 3 months. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **asthma** (AZ-mah) is a condition in which the airways of the lungs repeatedly become narrowed and inflamed, causing breathing difficulty.

they move through the stomach and back to the small intestine where they were hatched. In the small intestine, they become adults and mate, and the females begin producing eggs. The entire cycle, from eggs being swallowed to new eggs being produced, takes two to three months.

What Are the Symptoms of Ascariasis?

Ascariasis usually causes no symptoms. In heavy infections, however, abdominal cramps occur, and occasionally a mass of worms can block the intestines, causing pain, vomiting, and bloating. Adult worms can also block other parts of the digestive tract, such as the appendix, bile duct, or pancreatic duct, causing similar symptoms. When the larvae are migrating through the lungs, they may cause a fever, dry cough, wheezing, and sometimes asthma*.

How Is Ascariasis Diagnosed and Treated?

Because *Ascaris* produces such an abundance of eggs, they often can be seen when stool samples are examined under a microscope. Less commonly, an adult worm may be passed in the stool or may crawl up the throat and try to exit through the mouth or nose. *Ascaris* larvae may be identified in sputum* coughed up during the pulmonary stage.

Doctors may prescribe several different oral medications to treat ascariasis. If the intestine is blocked, surgery may be necessary. If the pulmonary stage is severe, corticosteroids* may be prescribed to lessen the symptoms.

How Can Ascariasis Be Prevented?

Thoroughly washing fruits and vegetables in clean water, washing hands before eating or preparing food, and washing hands after using the bathroom are advised. Improved sanitation and hygiene in developing countries would cut the risk of infection in those areas. Coupled with such improvements, routine or preventive treatment with deworming drugs, called anthelmintic (ant-hel-MIN-tik) medications, could reduce the prevalence of ascariasis worldwide.

Asperger's Syndrome

Asperger's syndrome is a developmental condition in which a child does not learn to communicate and interact with others in a typical way. The condition, also called Asperger disorder or Asperger's, is one of the pervasive developmental disorders, which is the group of conditions that includes autism (AW-tiz-um).*

Brian's Story

When Brian turned two years old, his parents were thrilled with his large vocabulary, which surpassed that of any other two-year-old they knew. Because Brian seemed so bright, they tried to ignore the fact that he spoke in a monotone, rarely made eye contact with them, and never wanted to play with the other children in his playgroup. When Brian became fixated on the weather channel on television, however, they had to admit that something might be wrong. When Brian's parents mentioned these

* **sputum** (SPYOO-tum) is a substance that contains mucus and other matter coughed out from the lungs, bronchi, and trachea.

* **corticosteroids** (kor-tih-ko-STIR-oyds) are chemical substances made by the adrenal glands that have several functions in the body, including maintaining blood pressure during stress and controlling inflammation. They can also be given to people as medication to treat certain illnesses.

* **autism** (AW-tih-zum) is a developmental disorder in which a person has difficulty interacting and communicating with others and usually has severely limited interest in social activities.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

behaviors to their pediatrician, she suspected that Brian had a form of autism called Asperger's syndrome.

What Is Asperger's Syndrome?

Asperger's syndrome is in the same group of developmental disorders as autism. Both autism and Asperger's syndrome are brain conditions that affect a person's ability to relate to others and to use language normally in order to communicate. The main difference between children with Asperger's syndrome and children with autism is that intelligence and development of language is not delayed in children with Asperger's syndrome. In fact, children with Asperger's syndrome are often so clever with words that Hans Asperger (1906–1980), the Austrian doctor who first described the condition, called them “little professors.” However, children with Asperger's syndrome often talk in a monotone, do not look people in the eye when they are talking, and may seem obsessed with odd or narrow interests. For example, they may memorize and recite train timetables or weather statistics but may have little idea of their usefulness.

Despite their intelligence and verbal abilities, children with Asperger's syndrome are socially atypical and unaware of what other people are thinking and feeling. They rarely if ever try to share their interests or enjoyment with people around them. Thus, they have difficulty making friends, and they may be teased and become socially isolated. People with Asperger's syndrome may also be hyperactive, irritable, anxious, or depressed.

What Causes Asperger's Syndrome?

Asperger's syndrome, like autism in general, results from some abnormality in the brain. However, as of the early 2000s, no one knew exactly what the abnormality is or what causes it. Parents of a child with any form of pervasive development disorder, including Asperger's syndrome, are more likely to have another child with the same disorder, suggesting that genes* are involved. Some experts believe that the hereditary link is stronger in Asperger's syndrome than it is in classical autism.

The prevalence of Asperger's syndrome is not known. In some children, it is hard to distinguish Asperger's syndrome from milder forms of classical autism. However, the disorder is diagnosed at least five times more frequently in males than females.

How Is Asperger's Syndrome Treated?

Parents, teachers, and mental health professionals may all become involved in helping children with Asperger's syndrome. Behavioral training to assist in the learning of social skills is important. Children with Asperger's syndrome may attend special education classes and practice behaviors such as looking people in the eye while talking and trying to understand another's point of view. They may also learn to read emotions such as anger or fear from the expressions on other people's faces, something that most children can do easily. Sometimes children with Asperger's syndrome are

helped by special medications to treat associated problems such as hyperactivity, anxiety*, and depression*.

There is no cure for Asperger's syndrome. However, children with this condition, because they have greater verbal skills, often do better as they grow to adulthood than do children with autism. Although they may always be socially awkward, many children with Asperger's syndrome become well educated and live and work independently.

* **anxiety** (ang-ZY-e-tee) can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person's physical or mental well-being.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

Asthma

Asthma is a condition that causes episodic breathing difficulties. These episodes are caused by narrowed and inflamed airways of the lungs. Asthma "flares" or "attacks" can be triggered by dust, pollutants, smoke, allergies, cold air, or infections.

* **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.

A Breathless Story

When Stacy was young, her parents noticed that she seemed to get tired more quickly than her friends while playing. She also had repeated coughing spells, and her breathing was sometimes noisy. After examining Stacy, asking lots of questions, and having her use a little machine to measure her breathing, the doctor diagnosed her problem as asthma. As part of the way Stacy took care of herself, she sometimes had to take asthma medicine at school. This made her teachers and friends interested in learning more about asthma. When Stacy was 12, she began a school-wide project with the help of her teacher and the nurse. The goal was to make her school more comfortable for those who have asthma. No smoking was allowed, even during after-school events. Extra measures were taken to keep the school as free as possible of substances that can trigger asthma flares, such as dust, mold, cockroaches, and strong fumes from paint and chemicals. A plan was set up that allowed students with asthma to take their own medicines at school. Special lessons were offered to all students and teachers about what asthma is and how to help a classmate who has it. The result was a school that was a healthier place not just for Stacy but for everyone.

What Is Asthma?

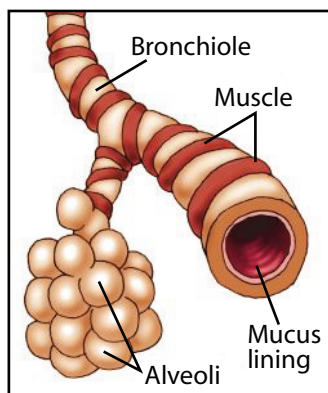

Several changes happen inside the airways in the lungs of people who have asthma. First, there is inflammation, or swelling, of the lining of the airways. Second, the swollen tissues make a thick, slippery substance called mucus*. Third, the muscles around the airways may squeeze tight, causing the airways to narrow. These three processes—inflammation, mucus production, and muscle constriction—combine to reduce the size (the diameter) of the airways. That makes it harder to breathe, like trying to blow air through a narrow straw.

During an asthma attack, these changes get worse. The airways swell on the inside while they are being squeezed on the outside. At the same

time, thick mucus plugs the smaller airways. The person may start to make whistling or hissing sounds with each breath. The person's chest may also feel tight. In addition, the person may cough to try to clear the lungs.

What Are the Severities of Asthma?

Cases of asthma vary in severity. Some people may have only mild symptoms a few times per month, whereas others may have severe symptoms every day. Asthma has four levels, depending on how severe each case is.

Mild intermittent A person with this type of asthma has daytime symptoms less than twice per week and nighttime symptoms less than twice per month. Attacks are brief and usually do not affect activities. Intermittent means the symptoms come and go.

Mild persistent A person with this type of asthma has mild symptoms more than twice per week, never more than once per day. Nighttime symptoms occur more than two times a month.

Moderate persistent A person with this type of asthma has symptoms every day and flare-ups more than twice per week. Nighttime symptoms occur more than once per week. When symptoms do occur, they can last for days and can make it hard for the sufferer to participate in certain activities.

Severe persistent A person with this type of severe asthma has symptoms throughout the day and night. The asthma makes it hard or impossible for a person to participate in many physical activities.

What Triggers Asthma?

People with asthma have what are sometimes called “sensitized” airways. Everyday factors that cause little or no trouble for most people can sometimes cause people with asthma to have a flare-up or attack. These factors are known as asthma triggers. There are two main kinds of triggers: allergic and non-allergic triggers. An allergic trigger results from substances called allergens*, which trigger an allergy. Examples of allergens that may trigger asthma are pollens, molds, animal dander (small scales from fur or feathers), dust mites*, cockroaches, and certain foods and medicines. Most of these allergy-causing substances enter the body through the air people breathe, but some are swallowed.

The second kind of asthma trigger is called an environmental or non-allergic trigger. It has nothing to do with an allergy but causes the same kind of reaction in the airways. Irritating substances in the air, such as tobacco smoke, wood smoke, fresh paint, cleaning products, perfumes, workplace chemicals, and air pollution can trigger or make asthma worse. Other non-allergic triggers include cold air, sudden changes in air temperature, exercise, heartburn, and infections of the airways, such as a cold

* **allergens** are substances that provoke a response by the body's immune system or cause a hypersensitive reaction.

* **dust mites** are tiny insects that live in dust and in materials such as carpets, pillows, mattresses and furniture.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

or the flu. Exactly which of these might trigger a reaction varies from person to person.

Who Gets Asthma?

Asthma is one of the most common health problems in the United States. The number of people with the condition grew rapidly in the late 1990s and early 2000s. The reason for this increase is not yet known. Asthma can affect both children and adults. It is the most common chronic* health problem seen among children and teenagers. Childhood asthma is slightly more common in boys than girls. The condition is also more common among African American children than white children, although the reason for this difference is not clear. It may have to do with environmental conditions.

What Are the Symptoms?

Following are the most common symptoms of asthma. A person may have all, some, or just one of these symptoms:

- Shortness of breath
- Coughing, particularly if it lasts longer than a week
- Wheezing (whistling or hissing sounds made primarily when breathing out)
- A feeling of tightness or discomfort in the chest

The degree to which asthma interferes with a person's daily life varies significantly. Some people have ongoing problems. The frequency of their attacks may range from several times per week to almost constantly. Their ability to take part in physical activities may be limited until, with treatment, they are able to get their asthma under control. Those with milder problems are usually able to do whatever they want to do, so long as they reduce their environmental triggers, take their medicine as directed, and follow any other advice from their doctors.

Childhood asthma Babies often wheeze when they have a cold or other infection of the airways, blockage of the airways, or other problems. This symptom may go away on its own with no ill effects. However, if the problem is severe, lasts a long time, or comes back, treatment may be needed. In older children, normal breathing should be quiet. Wheezing may be a sign of asthma, but it can also signal an infection, lung disease, heartburn, heart disease, a blood vessel blocking the airways, or even a piece of food or other object (such as part of a toy) lodged in the airway. In addition to noisy breathing, asthma in children can cause rapid breathing and frequent coughing spells. Parents may also notice that the child tires quickly during active play.

Nighttime asthma Asthma tends to get worse at night. Nocturnal (or nighttime) asthma occurs while a person is sleeping. For some people, nocturnal asthma is one of many symptoms; other people seem to have coughing or wheezing only at night.

FOUR CENTURIES OF MEDICAL RESEARCH

The word “asthma” comes from the Greek word for “panting,” which is a symptom that occurs in several different pulmonary (lung) disorders.

Asthma was first described as a disease rather than a symptom by the English chemist Thomas Willis (1621–1675).

In 1698, Sir John Floyer (1649–1734) gave the first formal account of an asthma attack or “fit.” However, an accurate diagnosis of asthma was not possible until the early nineteenth century when the celebrated French physician René Laënnec (1781–1826) invented the stethoscope*.

During the early nineteenth century, asthma was treated in a variety of ways, including by taking whiffs of chloroform and even by the smoking of ordinary tobacco.

* **stethoscope** (STETH-o-scope) is a medical instrument used for listening for sounds produced in the chest, abdomen, and other areas of the body.

Exercise-related asthma Many people with asthma have trouble with noisy breathing during or after exercise, a condition known as exercise-induced asthma. Other symptoms include coughing, a rapid heartbeat, and a feeling of tightness in the chest five to ten minutes after exercise. For some people, exercise is the only asthma trigger. That means they only have asthma symptoms after exercise-like activities and do not have symptoms at any other time. Cold or dry air, high pollen counts, air pollution, a stuffed-up nose, and an infection of the airways are all factors that tend to make the problem worse. Types of exercise that may lead to wheezing include running, using a treadmill, and playing basketball—in short, exercises that are aerobic (designed to increase oxygen consumption).

Job-related asthma Occupational asthma is caused by breathing in fumes, gases, or dust while on the job. Asthma can start for the first time in a worker who was previously healthy, or it can get worse in a worker who already had the condition. Symptoms include wheezing, chest tightness, and coughing. Other symptoms that may go along with the asthma include a runny or stuffed-up nose and red, sore, itchy eyes. The asthma may last for a long time, even after the worker is no longer around the substance that caused it.

Severe attacks Status asthmaticus (STA-tus az-MAT-i-kus) is a severe asthma attack that does not get better when individuals take their medicine as usual. This kind of attack is an emergency that must be treated right away in a hospital or doctor’s office, where other medicines may be used.

An asthma patient uses a metered dose inhaler to deliver medication to his lungs. © by Leitha Etheridge-Sims.

How Is Asthma Diagnosed?

The doctor performs a physical checkup and ask questions about symptoms and when they occur. In addition, the doctor may do various tests to help identify asthma and its causes. Some of the tests are described below.

Allergy tests Allergy tests help identify those substances to which a person is allergic. Skin tests are most common. Tiny amounts of possible allergens are put on the skin, and the skin is checked to see which substances, if any, cause a reaction. In another type of allergy test, a blood sample is checked for certain antibodies, which are substances made in the blood that fight foreign or harmful substances. People with allergies may have high levels of immunoglobulin E (IgE) antibodies. However, the blood test is generally not considered as precise as the skin test, and it cannot check for as many allergens.

Chest x-ray An x-ray is an invisible wave that goes through most solid matter depending on its density and produces an image on film. After the film is developed, a special picture can be viewed that shows how the lungs and other structures look. An x-ray can help rule out other causes of wheezing.

Lung-function tests These tests show how well the lungs are working. In one test, the person blows into a device called a spirometer (spi-ROM-i-ter), which measures the amount of air going in and out of the lungs. Another test uses a peak flow meter to measure how fast the person can breathe air out of the lungs. A peak flow meter is a simple, hand-held device that can be used at home. Many people with asthma use peak flow meters regularly to check for early warning signs of an upcoming asthma attack. Doing so gives them time to take certain medicines that can often stop the attack.

Why Is Treatment Needed?

Asthma that is not under control can cause many problems. People miss school or work, must go to the hospital, and can even die (rarely) because of asthma. With a doctor's help, though, most people can control their asthma. People with well-controlled asthma have few, if any, symptoms during the day and can sleep well at night. They can also take part in their usual activities, including sports and exercise. However, asthma does not go away just because its symptoms do. Individuals need to continue taking care of their condition: avoiding triggers, not smoking, and living in a healthy, clean environment. Ongoing attention is required even in mild asthma cases.

How Is Asthma Treated?

Besides avoiding exposure to asthma triggers, asthma is mostly treated with medicines. There are two characteristics of asthma: inflammation and spasms (or constriction) of the muscles in the airways. Asthma

treatment focuses on both. Asthma medicines fall into two groups: those used to prevent symptoms and control the disease for a long time, and those that give short-term relief during an asthma attack. Taking the right medicine at the right time is important.

Long-term control medicines Long-term control medicines are taken every day to help prevent symptoms from starting. It may take several weeks for these medicines to produce their best results, though. The most effective ones work by reducing swelling in the airways. Many are inhaled (breathed into the lungs). Not everyone needs such medicines. However, they may be very helpful for people who have daytime asthma symptoms three or more times per week or nighttime symptoms three or more times per month. Medicines for long-term control of asthma include the following:

- **Inhaled corticosteroids*** (kor-ti-ko-STER-oids). These strong drugs prevent and reduce swelling in the airways. They also make the airways less sensitive to triggers. However, they work only if they are used regularly. These drugs are taken every day by people with long-lasting asthma. They are not the same as the unsafe steroids some athletes use to build muscles.
- **Other inhaled drugs.** These medications also help prevent and reduce swelling in the airways and make the airways less sensitive. However, it can take four to six weeks of regular use before they start to work. These drugs are taken every day by people with long-term asthma, but they can also be used before exercise or contact with a trigger.
- **Oral corticosteroids.** These drugs are taken by mouth in pill or liquid form. Unlike inhaled corticosteroids, they sometimes cause serious side effects when used for a long time. However, they can often be used safely for a short time to treat severe asthma attacks and to quickly bring asthma under control. They are sometimes taken every day or every other day by people with the most severe asthma.
- **Long-acting bronchodilators** (brong-ko-DY-lay-tors). These drugs relax the muscles around the airways, making breathing easier. They can prevent or reduce narrowing of the airways. However, they keep working only if they are used regularly. These drugs are inhaled or taken by mouth in a pill. Some are especially useful for preventing nighttime or exercise-related asthma.
- **Inhaled anticholinergics** (AN-tih-ko-lin-ER-jek). This medicine is a type of bronchodilator. It relaxes the muscles around the airways, making breathing easier. The medicine takes about an hour to work, so it should not when quick relief is needed. The drug can be breathed in using an inhaler or nebulizer. It works best when taken with a short-acting bronchodilator; however, it is not commonly used to treat asthma.
- **Leukotriene modifiers** (loo-ko-TRY-een). These drugs prevent and reduce swelling in the airways and make the airways less sensitive

* **corticosteroids** (kor-ti-ko-STER-oids) a group of adrenal-cortex steroids, such as cortisone, that are distinguished by their main biological activity.

Breathtaking Facts

- About 20 million people in the United States have asthma. Of these, about 9 million are children and teenagers.
- More than one in every ten children in the United States have asthma-like symptoms.
- About one in four children with serious asthma continue to have symptoms as adults.
- Asthma results in about 24.5 million lost days of work each year among adults.
- Children miss about 12.8 million school days each year because of asthma.
- According to the Centers for Disease Control and Prevention (CDC), between 1980 and 2004, the number of Americans who reported having asthma rose from 3 percent to 7 percent.
- During that same time, asthma rates among children increased from 4 percent to 12 percent.

to triggers. They also prevent squeezing of the muscles around the airways. These drugs are taken regularly by mouth in a pill.

- **Anti-IgE therapy.** This is a newer type of medicine that blocks the substances in the blood that cause allergy-related asthma symptoms. The drug is for people who have moderate to severe asthma symptoms that continue despite other treatments. In the early 2000s, anti-IgE therapy was only approved for persons age 12 and older. It is given by injection.
- **Allergy vaccines.** In some cases, a person's asthma symptoms can be prevented or lessened if the individual takes a course of special allergy injections over months or years. These shots contain small amounts of the allergens that trigger the person's asthma. The course of injections causes the person to become less sensitive to the allergen when exposed to it.

Short-term relief medicines Short-term relief medicines are taken only when needed to relax and open the airways quickly. They can be used to relieve symptoms or to prevent them if a person's peak flow meter readings begin to drop, signaling an upcoming asthma attack. However, the effects last for only a few hours. They cannot keep the symptoms from coming back the way long-term control medicines can. These drugs are inhaled and are taken at the first sign of trouble or before contact with a trigger.

Medicines that provide short-term relief of asthma are called short-acting bronchodilators. These drugs relax the muscles around the airways, making breathing easier. They begin to work within five minutes, and their effects last for four to six hours. Such drugs are taken right after symptoms start or just before exercise.

How Are Inhaled Medicines Taken?

Many asthma medicines are made to be breathed into the lungs. Such inhaled drugs go straight to the place where they are needed. The most popular device for taking inhaled medicines is a metered dose inhaler, which gets the drug to the lungs in exact amounts. The inhaler is a small, hand-held canister with a button that the person pushes to make the medicine spray out. Often a tube, called a spacer, is attached to the canister to make it easier to use.

Another type of device that is sometimes used to take inhaled medicines is a nebulizer (NEB-you-lyz-er), which turns liquid medicine into a very fine mist. These devices are helpful for babies, young children, and elderly or very sick adults who would have trouble handling a metered dose inhaler.

Breathing Easier

People with asthma should try to figure out what makes their symptoms worse and take steps to avoid or control those substances or situations. Here are a few ways that many people control some common asthma triggers. Not all of them will work for everyone.

Pollens and outdoor molds To control pollens and outdoor molds, people with asthma often do the following:

- keep windows and doors closed when pollen or mold spore counts are high
- avoid walking in gardens and fields when they are in bloom and when pollen and mold spore counts are highest
- ride with the car windows shut and the air conditioner on during pollen season
- ask their doctors about starting or increasing a long-term control medicine before peak pollen season begins

Indoor molds To control indoor molds, people with asthma often do the following:

- fix leaky faucets, pipes, and other sources of water
- clean moldy surfaces with a product that contains bleach
- remove wallpaper, which can have mold growing on it
- get rid of houseplants, which can gather mold and dust

Animal dander Dander is small scales from the hair of animals, such as cats, and from bird feathers. Some people are allergic to it, and people with asthma often take the following steps:

- keep pets with fur or feathers out of their homes, if possible
- have pets stay out of bedrooms, in particular, and keep bedroom doors closed
- remove carpets and cloth-covered furniture or keep pets away from these materials
- use polyester-fill rather than feather pillows and avoid down comforters

Dust mites People with asthma often find that they are allergic to dust because of the tiny animals that live in the dust, called mites. Many people with asthma find that it helps to keep their homes especially free of dust. For example, they take the following steps:

- wash their bedding each week in hot water (it must be hotter than 130 degrees F to kill mites)
- enclose mattresses and pillows in special dust-proof covers or wash pillows each week in hot water
- try not to sleep or lie on cloth-covered furniture or cushions
- remove carpets in bedrooms and those laid on concrete
- keep stuffed toys out of beds and wash the toys each week in hot water
- wear a dust mask while vacuuming or have someone else do the vacuuming

Winning Ways

Jackie Joyner-Kersey (b. 1962) has often been called the world's greatest female athlete. What many fans never suspect is that she is also an asthma patient. Joyner-Kersey became active in sports at age 9. As a teenager, she was an all-state player in basketball and a Junior Olympics champion in pentathlon, an athletic contest in which each person takes part in five different events. While still in high school, Joyner-Kersey began having trouble breathing. When she first found out that she had asthma, she did not take it seriously. She often skipped her medicine. After a serious asthma attack, though, she realized that she had to work to control the condition just as she worked to win at sports. After college, Joyner-Kersey went on to win six Olympic medals as well as to break the world and Olympic records in the heptathlon, an athletic contest with seven different events: 100-meter hurdles, high jump, shot put, 200-meter dash, long jump, javelin, and 800-meter race. In the early 2000s she served as a spokesperson for groups that educate the public about asthma.

Cockroaches Many people with asthma are sensitive to cockroach droppings and make a special effort to get rid of these stubborn creatures by taking the following steps:

- keeping all food out of bedrooms
- storing food and garbage in closed containers and never leaving food or crumbs sitting around
- using poison bait, powder, gel, paste, or traps (following label instructions) to kill cockroaches
- staying out of the room until the odor goes away if a spray is used to kill roaches

Certain foods and medicines It is important to do the following:

- avoid foods that have caused problems in the past
- tell the doctor about any past reactions to medicines

Smoke and strong odors Smoking is not good for people, not good for the person smoking or people who are in the same room with tobacco smoke. People with asthma are especially endangered by tobacco smoke and find it is best not to smoke, to ask other family members to quit smoking, and to ask visitors not to smoke.

People with asthma also do the following:

- avoid using a wood-burning stove, kerosene heater, or fireplace, if possible
- try to stay away from strong odors and fumes, such as perfume, hairspray, and fresh paint

Exercise It is healthy for just about everyone to exercise, and people with asthma are no exception. To make their exercise and sports activities more enjoyable, people with asthma usually do the following:

- warm up for six to ten minutes before exercising
- avoid exercising outside when air pollution or pollen counts are high or when the air is cold
- pick activities that do not cause symptoms (sports that involve running are the most likely to trigger problems)
- ask a doctor about taking medicine before exercise to prevent symptoms

Astigmatism

Astigmatism (a-STIG-ma-tiz-um) is an eye condition that causes objects to appear blurry because the front part of the eye is misshapen.

What Is Astigmatism?

The eyeball usually is round and nearly the same size as a ping-pong ball. The front part contains a clear layer of tissue called the cornea and the lens that help to focus the light that enters the eye. When people have astigmatism, the cornea and/or the lens is misshapen, and their curved

* **retina** (RET-i-na) is the tissue that forms the inner surface of the back of the eyeballs; it receives the light that enters the eye and transmits it through the optic nerves to the brain to produce visual images.

surfaces are unequal. If the curve is just slightly off-shape, only objects at a distance may appear blurry. People with more serious astigmatism, however, may experience a distortion of all images.

Who Gets Astigmatism?

Astigmatism is a common problem that affects the shape of the cornea or lens and distorts vision. Often the degree of astigmatism is different in one eye than in the other. As of 2009, the cause of astigmatism was unknown. It usually is present at birth and often is found in several members of the same family, which means that in some cases the trait is probably inherited.

What Happens to Vision When People Have Astigmatism?

Variations in the shape of the cornea or lens cause a person with astigmatism to see images that are out of focus when they reach the eye's retina*. The retina is made of layers of light-sensitive cells at the back of the eyeball that act like the film in a camera. The distorted image is projected onto the retina and transmitted to the brain for processing through the optic nerve.

The first signs of astigmatism are determined by how severely the cornea or lens is misshapen. In mild problems, people with astigmatism may find that they have headaches or tired eyes at times or distorted vision at certain distances. In severe problems, people with astigmatism may find they have blurry vision that makes reading, playing sports, and other activities difficult. Often the problem is discovered during an eye exam in school, at the doctor's office during a check-up, or when a parent notices that a child is having trouble seeing clearly. Usually astigmatism does not worsen as a person gets older.

In many people, astigmatism is accompanied by nearsightedness (myopia) or farsightedness (hyperopia). In myopia and hyperopia, the eye is also shaped incorrectly. In the former, the eye is long and egg-shaped rather than round, or has a steep cornea, causing images to focus in front of, rather than on the retina. In hyperopia, the cornea is too flat or the eye is too short, causing images to focus behind the retina. Like astigmatism, these conditions disrupt proper vision.

What Is the Treatment for Astigmatism?

Astigmatism may be managed with prescription eyeglasses or so-called "toric" contact lenses. The latter are available in soft lenses and rigid gas-permeable (RGP) lenses, although some patients find that RGP lenses offer better visual acuity (sharpness). Both glasses and toric contact lenses help change the way that images are focused as they pass through the cornea and the lens, and both allow clear images to arrive at the retina.

Besides eyeglasses and contact lenses, astigmatism can be treated with refractive surgeries. One of the most common is the laser eye surgery called laser assisted in situ keratomileusis (LASIK), which reshapes the cornea and can correct both astigmatism and either nearsightedness or farsightedness. Other surgical options are conductive keratoplasty (CK),

which uses heat rather than a laser to correct vision and is sometimes recommended for patients over 40 years of age, and astigmatic keratotomy (AK), which involves incisions to help reshape the cornea.

Some people with astigmatism report some improvement after doing various eye exercises, but exercise alone cannot eliminate the need for other means of vision correction.

Atherosclerosis See *Heart Disease*.

Athlete's Foot

Athlete's foot is a skin infection caused by a fungus. It affects the soles of the feet and the spaces between the toes.

What Is Athlete's Foot?

The human body is home to many different kinds of fungi*. Most never cause a problem. Athlete's foot is caused by one group of fungi called dermatophytes (der-MA-to-fites), which are microorganisms* that live on the skin, hair, and nails. Dermatophytes need a warm, moist environment to survive and to reproduce, such as the feet of athletes, for example. But in fact, anyone with wet or sweaty feet may be prone to getting athlete's foot. Athlete's foot is also called tinea pedis (TIN-e-a PED-is), or ring-worm of the foot.

* **fungi** (FUNG-eye) are microorganisms that can grow in or on the body, causing infections of internal organs or of the skin, hair, and nails.

* **microorganisms** are tiny organisms that can only be seen using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

* **contagious** (kon-TAY-jus) means transmittable from one person to another, usually referring to an infection.

How Do People Get Athlete's Foot?

Athlete's foot is somewhat contagious*, and the most common places where people catch it are also the dampest ones: public showers, pool areas, wet towels, and bath mats. People who wear the same shoes or sneakers all the time are more likely to develop athlete's foot, as are people who wear shoes or socks made from certain synthetic* materials such as rubber, vinyl, or nylon. Anything that keeps the feet warm, wet, and sweaty gives the fungus an opportunity to grow and survive.

What Are the Signs and Symptoms of Athlete's Foot?

Athlete's foot is a condition with very specific symptoms, and these symptoms can be mild or intense, depending on the case and the person. A person with athlete's foot may feel burning and stinging on the soles of the feet and in between the toes. The skin can feel very itchy as well. The fungus causes the skin to become red, flaky, or soggy. Sometimes the skin can become cracked.

How Do Doctors Diagnose and Treat Athlete's Foot?

Diagnosis When examining a patient with athlete's foot, a doctor usually has an easy time making a diagnosis because the fungi that cause skin problems are usually easy to recognize. Just to be sure, the doctor may take a small scraping of skin to gather some of the fungus. The fungus can then be cultured, or grown, in a small dish in a laboratory, which gives the doctor an opportunity to identify the fungus, if present.

Treatment Most cases of athlete's foot can be cured with antifungal creams or sprays, which are put directly on the skin to kill the fungus. Many of these creams and sprays are available without a prescription at drugstores. If athlete's foot persists, doctors may prescribe stronger antifungal creams than those available over the counter or possibly an antifungal medication to be taken orally. If a bacterial infection has developed along with the fungal infection, then the doctor may also prescribe an antibiotic to kill the bacteria.

How Do People Prevent Athlete's Foot?

People who tend to get athlete's foot can take some simple measures to help prevent it. The most important one is to keep their feet as dry as possible because the fungi that cause athlete's foot do not grow well in dry places. Taking a few extra minutes to dry feet thoroughly after showering, bathing, and swimming can help a lot. Other methods of prevention are:

- Wearing sandals and not going barefoot around a pool area or a public shower
- Wearing shoes that are well ventilated, such as sneakers with small holes on their tops or sides to let air in and out

- Wearing shoes and sneakers made of leather rather than of synthetic materials such as vinyl and nylon
- Wearing cotton or wool socks rather than polyester socks
- If possible, not wearing the same pair of shoes or sneakers every day, as switching between pairs gives shoes a chance to dry out after being worn.

Those people who are particularly prone to athlete's foot may find they can keep the fungi away by using antifungal powders on their feet every day.

Attention Deficit Hyperactivity Disorder (ADHD)

Attention is the mental process in which a person concentrates awareness on a specific object, issue, or activity and excludes other potential stimuli from the environment. Attention Deficit Hyperactivity Disorder (ADHD) is a common developmental disorder that affects both children and adults, although it is usually diagnosed in childhood. ADHD affects a person's ability to study, learn, work, play, and even socialize with others. People with ADHD are less able to sit still, plan ahead, organize and finish tasks, and tune in fully to what is going on around them than are people without the disorder.*

A Tale of Two Students

Justin and Katie are both seventh-grade students with ADHD. However, they act quite differently at school. Justin has a very hard time sitting still and staying in his seat. His classmates and teachers think of him as "hyper." Justin gets bored easily, so he tends to talk too much and get

* **stimuli** (STIM-yoo-lie) are things in the environment that excite a person to function, become active, or respond. The singular form is stimulus.

* **hyperactivity** (hy-per-ak-TI-vi-tee) is overly active behavior, which makes it hard for a person to sit still.

into trouble. He also bothers the other students, which leads them to get angry at him.

Katie does not wiggle and fidget the way Justin does. But she has similar difficulty keeping her mind on her work and paying attention to the teacher. Katie also forgets which assignments she is supposed to do. She finds it tougher than most to keep track of her backpack, books, and school supplies. Sometimes she loses her homework, and sometimes she just forgets to turn it in.

Just about every classroom in the United States has students like these. Experts believe that about 5 percent of students, or one in 20, have a form of ADHD. Boys are three to four times more likely than girls to be affected by ADHD. Of course, everyone has a hard time paying attention and staying focused now and then, but students with ADHD have this problem more often and to a greater degree.

What Is Attention Deficit Hyperactivity Disorder?

Attention Deficit Hyperactivity Disorder (ADHD, also called ADD) is a condition that causes poor attention span, easy distractibility, hyperactivity*, and impulsiveness. People with ADHD may have only one or two of these problems, or they may have all of them. Those with an attention problem have a hard time keeping their mind on any one subject for long. They may get bored with a task after only a few minutes. People who are hyperactive seem to be in constant motion. They may feel restless and squirm or fidget a lot. People who are overly impulsive seem not to think before they speak or act. They may blurt out embarrassing comments without thinking or take dangerous risks. The symptoms usually begin before seven years of age, although they may not be recognized as signs of ADHD until later. The behaviors associated with ADHD can lead to trouble with school; work; or relationships with family, friends, and teachers.

Difficulties caused by ADHD often improve during the late teen years and adulthood. Many adults are left with only a few signs of ADHD, but a few still have the full disorder. People with ADHD do not outgrow the condition. While they often become less hyperactive when they get older, people with ADHD may still have problems with restlessness and short attention span. By using certain coping strategies, many people with ADHD learn to deal with the condition successfully and can achieve in school and thrive in rewarding careers. Many people are able to find the right kind of job for their strengths and abilities. For example, a person might be better suited for a position that offers variety and constant change rather than one that requires long periods at a desk.

What Causes Attention Deficit Hyperactivity Disorder?

Doctors and researchers are not sure why certain people have ADHD. Theories have focused on various possible causes, such as diet, head injuries, exposure to drugs before birth, and even family and home environment.

However, none of these theories offers a satisfactory explanation for most cases of ADHD.

Researchers interested in learning about possible biological causes of ADHD have looked at how the brains of people with ADHD may function differently than other people's brains. Neuroscientists, or scientists who study the brain and nervous system, believe that attention is largely a function of the brain's reticular activating (re-TIK-yoo-lur AK-ti-vay-ting) system, or RAS. This system includes a group of nerve fibers located in several parts of the brain, including the thalamus*. Within the RAS, the thalamus appears to play a key role in the moment-to-moment changes in the focus of attention. The thalamus and cerebral cortex cooperate to register any incoming sensory signals, evaluate their contents, and mobilize brain resources in response to the demands made. Put simply, the thalamus receives the messages that comes through a person's senses and then relays the information to the proper receiving areas in the brain.

Using a special scanning test called a positron emission tomography, or PET scan, researchers can watch the brain as it works. The test lets them see how much glucose, a type of sugar, is used by the areas of the brain that inhibit impulses and control attention (glucose is the brain's main source of energy). Some studies have found that the areas of the brain that control attention use less glucose in people with ADHD, which means that these areas of the brain appear to be working less hard. Other researchers speculate that ADHD has something to do with differences in the neurotransmitters* that deliver signals to the brain areas that control attention. Some research also suggests that use of alcohol or drugs by the mother during pregnancy can harm development of the baby's brain cells. Such maternal choices may be one cause of ADHD, although it is

* **thalamus** (THAL-uh-mus) refers to a pair of large egg-shaped areas located in the middle of the brain just under the cerebral cortex. The plural form is thalami.

* **neurotransmitters** (nur-o-trans-MIH-terz) are chemical substances that transmit nerve impulses, or messages, throughout the brain and nervous system and are involved in the control of thought, movement, and other body functions.

A boy with Attention Deficit Hyperactivity Disorder receives one-on-one instruction with his teacher. The method of teaching a child according to his or her own special way of learning is an effective way of managing ADHD.
Ellen B. Senisi/Photo Researchers, Inc.

* **identical twins** are twins produced when a single egg from the mother is fertilized and divides to form two separate embryos of the same sex with nearly identical DNA.

* **psychiatrist** (sy-KY-uh-trist) is a medical doctor who has completed specialized training in the diagnosis and treatment of mental illness. Psychiatrists can diagnose mental illnesses, provide mental health counseling, and prescribe medications.

likely there are many causes. A person's genetic makeup may be involved. ADHD seems to run in families. Children with ADHD usually have at least one parent, sibling, or other close relative with the disorder. Scientific studies have also found that if one identical twin* has ADHD, the other twin is likely to have it as well.

What Does *Not* Cause Attention Deficit Hyperactivity Disorder?

Experts used to think that attention problems were caused by slight brain damage or minor head injuries. However, most people with ADHD have no sign of brain damage or history of head injury. Another theory was that overactive behavior was caused by refined sugar and food additives. However, scientists found that eating a special diet seemed to help only about 5 percent of children with ADHD, mostly very young children or those with food allergies. It is true, however, that too much caffeine (found in coffee, tea, and some sodas) or some red/yellow dyes can intensify hyperactive behaviors.

How Is Attention Deficit Hyperactivity Disorder Diagnosed?

Many factors besides ADHD can cause similar kinds of problems. For example, depression can lead to trouble paying attention, and anxiety can make it hard to sit still. A learning disability can lead to poor school performance, and small seizures can cause mental lapses. Even an ear infection that leads to on-again-off-again hearing loss can cause behaviors that look like ADHD symptoms. In addition, everyone has trouble staying focused and getting organized at times. For these reasons, ADHD needs to be diagnosed by a trained medical or mental health professional.

Diagnosing ADHD is difficult because symptoms vary, and no single test can determine whether someone has ADHD. In most cases, parents notice early on that their child is much less attentive or has less control over his behavior than other children. However, the disorder usually is not diagnosed until the child enters school and is expected to follow directions, cooperate with others, and be quiet at certain times.

To make the diagnosis, a psychologist or psychiatrist* looks for patterns of certain behaviors that have lasted for more than six months and interfere with two or more areas of a person's life (such as school and play, school and home, or home and work). In addition to interviewing the child and family members, the specialist may need to speak with others who know the child well, such as teachers and coaches. Former teachers may be asked to fill out an evaluation. Special tests may also be administered to clarify the diagnosis.

The behaviors that experts look for fall into three categories: inattention, hyperactivity, and impulsivity. Signs of inattention in a child include:

- Failure to pay close attention to details
- Difficulty in sustaining attention in work and play

- Seeming not to listen when spoken to directly
- Failure to follow through on instructions and finish tasks
- Difficulty organizing tasks and activities
- Avoidance, dislike, or seeming reluctance to engage in tasks that require concentration
- Likelihood to be distracted by peripheral sights and sounds
- Tendency to lose things
- Tendency to forget things

Hyperactivity refers to overly active behavior. Children experiencing hyperactivity might engage in the following:

- Fidgeting with their hands or feet
- Squirming while seated
- Leaving their seat in the classroom and elsewhere
- Running about or climbing excessively
- Having difficulty playing or engaging in leisure activities quietly
- Seeming constantly on the go or acting as if driven by a motor
- Talking excessively

An impulsive child might engage in the following:

- Blurting out answers before questions have been completed
- Interrupting or intruding on others
- Having difficulty waiting his or her turn

Not everyone with ADHD has all of the above symptoms. There are three kinds of ADHD that are commonly recognized. People who have significant problems with attention but are not really hyperactive or impulsive are diagnosed with ADHD-Inattentive Type. Those who have problems mainly with hyperactivity and impulsivity are diagnosed as having ADHD-Impulsive Hyperactive Type. Individuals with significant problems with impulsivity, hyperactivity, and attention are diagnosed with ADHD-Combined Type.

Children with ADHD may have other behavioral disorders as well. These may include oppositional defiant disorder*, depression*, anxiety*, and delays in learning speech and language.

How Is Attention Deficit Hyperactivity Disorder Treated?

Usually, ADHD is first treated with behavioral (be-HAY-vyor-ul) therapy, which involves working with a psychologist or psychotherapist* to learn ways of coping with the condition. The therapist can help people become more aware of their behavior, develop strategies for controlling it, and even help them practice how to deal with situations that caused problems in the past. A person also might find it helpful to participate in a support group with others who have similar difficulties.

* **oppositional defiant disorder** (op-uh-ZIH-shun-ul de-FY-unt dis-OR-der) is a disruptive behavior disorder that can be diagnosed in children as young as preschoolers who demonstrate hostile or aggressive behavior and who refuse to follow rules.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

* **anxiety** (ang-ZY-e-tee) can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person's physical or mental well-being.

* **psychotherapist** (sy-ko-THER-a-pist) is any mental health professional who works with people to help them change thoughts, actions, or relationships that play a part in their emotional or behavioral problems.

Can Food Cause Hyperactivity?

Anyone who drinks too much cola or coffee is likely to have a hard time concentrating, because caffeine can overstimulate the brain. At one time, mental health specialists believed that sugar and other food additives actually contributed to ADHD. As a result, parents were encouraged to stop serving children foods containing artificial flavorings, preservatives, and sugars. It was thought that this restricted diet could actually prevent or cure the symptoms of the condition. Later, researchers abandoned this theory.

* **stimulant** (STIM-yoo-lunt) a drug that produces a temporary feeling of alertness, energy, and euphoria.

* **side effects** are unwanted symptoms that may be caused by vaccines or medications.

Parents and teachers are involved in the treatment plan as well. Parents can learn how to establish more structure for the child, define limits more clearly, and be consistent with discipline, all of which are especially important for a child with ADHD. Teachers can provide predictable routines and structure in the classroom and try to keep the student away from distractions. Both parents and teachers can establish certain penalties and rewards to help the child make progress with behavior.

If these strategies are not effective enough in controlling the condition on their own, then a psychostimulant (SY-ko-STIM-yoo-lint) medication such as methylphenidate (meth-il-PHEN-uh-date; Ritalin, Concerta, Methylin, Metadate), dextroamphetamine (dex-tro-am-PHET-uh-meen; Dexedrine, Dextrastat), or mixed amphetamine salts (Adderall) might be prescribed. It may seem strange that an inattentive, overly active person would be treated with a stimulant*. However, these medications work by stimulating certain areas of the brain that make it possible for many people with ADHD to concentrate, behave more consistently, and take part in activities that were impossible before. These drugs may work to control ADHD by increasing the amount and activity of some of the brain chemicals known as neurotransmitters. The behavior and general functioning of nine out of ten typical children with ADHD improve when the individuals take one of these drugs. If one stimulant medicine does not help, another can be tried.

When taken as directed by a doctor, stimulant medicines are considered safe. They usually do not make the patients “high” or jittery. However, they may cause other unwanted side effects*. Some patients may lose weight, feel less hungry, or grow more slowly. Others may have trouble falling asleep. If such side effects occur, they can often be handled by changing the dose or drug. A doctor needs to track closely the growth of any patient taking these medicines.

Why Is Attention Deficit Hyperactivity Disorder Diagnosed More and More Frequently?

More children than ever before are being diagnosed with ADHD-Predominantly Impulsive Hyperactive Type or ADHD-Predominantly Inattentive Type. In addition, the use of stimulant medications increased dramatically during the 1990s; according to one estimate, production of these medications increased by 700 percent between 1990 and 1997. There is some disagreement over why these patterns occurred. Some people think that greater awareness of the condition led more teachers to suspect problems among their students and more parents to seek help for their children. Others believe that some cases of bad behavior were misdiagnosed as ADHD. Some argue that parents may find it easier to accept that their child has a mental disorder rather than learn how to deal with unruly behavior or poor school performance due to other reasons. The debate continued, but as of 2009 experts agreed that ADHD is a real condition that can have serious consequences if it is not diagnosed and managed appropriately.

Strategies for Living with Attention Deficit Hyperactivity Disorder

The National Institute for Mental Health, the Federal agency for research on mental disorders, recommends the following strategies for living with ADHD:

- When necessary, ask the teacher or boss to repeat instructions instead of guessing about what was said.
- Break large assignments or job tasks into small, simple tasks. Set a deadline for each task and provide rewards for each completed task.
- Each day make a list of what needs to be done. Plan the best order for doing each task then make a schedule for doing them. Use a calendar or daily planner.
- Work in a quiet area. Perform one activity at a time. Take short breaks.
- Keep track by using a notebook with dividers. Write different kinds of information, such as assignments, appointments, and phone numbers, in different sections. Keep the book on hand.
- Post reminders of what needs to be done.
- Store similar objects together.
- Create a routine. Get ready for school or work at the same time, in the same way, every day.
- Exercise, eat a balanced diet, and get enough sleep.

Autism

Autism (AW-tiz-um) is a brain disorder that affects an individual's ability to develop normal communication skills and social responsiveness to other people. An infant with autism may seem to behave unusually from birth or may develop normally for a short time and then show autistic traits. To diagnose autism, symptoms must appear before the child is three years of age. Autism is part of a larger category of disorders called pervasive developmental disorders, all of which affect the brain's development.

A World of His Own

From a young age, Jamie was not very talkative and often looked down or away when someone talked to him. He also seemed to spend a lot of the time by himself. Although many people felt that he was just shy, Jamie was

diagnosed with autism. Children with autism may appear to be shy, but shyness and autism are very different. Shy children are quiet, but they do talk to people some of the time, especially to family members and friends with whom they feel comfortable, and they like to be around people some of the time. Autistic children prefer to be alone and isolated.

The symptoms of autism can range from mild to severe. Children with the most extreme forms of autism are almost totally isolated socially. Lacking the ability to relate normally to others, they always prefer to be alone. Even within their own family, they seldom make eye contact or try to share their interests in toys or other objects. Many children with autism never learn to talk. If they do, they use language in unusual ways, such as by constantly repeating rhymes or jingles. They may refer to themselves by their own name, or as “you,” instead of using “I” or “me.” Sometimes they repeat what someone has said to them rather than replying in a more typical way. Some children with autism may have above-average language skills, but often they do not use this ability to have conversations with others.

Like many children with autism, Jamie was concerned with order. Even as a young child, he kept his toys in the exact same spot on his shelves and would become angry if anything was moved. He might throw toys, break dishes, or even kick his mother. Most of the time, though, Jamie ignored other people. He seemed to live inside his own head. When his immediate environment became noisy or confusing, Jamie would bite himself until he bled. When Jamie started school, he was put in a special class where the atmosphere was calm and his activities were carefully planned. By the time he was 14, Jamie seemed more relaxed. He would talk to others if they talked to him first. He was also taking medicines that helped him control his anger. However, he still liked everything to be orderly.

What Is Autism?

Autism is a brain disorder that isolates individuals in worlds of their own. It can lead to a wide range of unusual behaviors. People with autism have trouble communicating with and relating to others. They are unable to understand other people’s thoughts, feelings, and needs. In many cases, language and intelligence are affected, and people with autism may have a limited number of interests and activities.

Many people with autism repeat the same actions, such as rocking or twirling their hair, for long periods. Some hurt themselves by banging their heads or biting their arms. Others seem painfully sensitive to touch, sound, taste, or smell. They may find any form of physical contact repugnant. Children with autism may refer to themselves by name instead of “I” or “me.” Some speak in a singsong voice.

What Are Some Other Signs of Autism?

Children with autism often behave in unusual ways. Their activities are limited, and they may become extremely upset if there is some change in their environment or daily routine. For example, some may have temper

Thinking in Pictures

Temple Grandin, the gifted animal scientist, invented equipment for handling livestock, wrote books, and gave lectures. Yet as a child, Grandin had many of the signs of autism. As a baby, she stiffened when picked up and struggled to be put down. By age 2, she was sometimes overpowered by her ultra-sharp senses. She screamed, flew into rages, and threw objects. At other times, she found that focusing intently on one object, such as an apple or her hand, made her feel calmer and safer. Her mother put Grandin in a special class with strict routines designed for children with speech problems. By age 4, Grandin had started to speak, and by age 5, she could go to regular school. As an adult, she recalled her experiences in a book called *Thinking in Pictures*. The book begins: “I think in pictures. Words are like a second language to me.” Grandin used the way her brain worked to imagine how the parts of complicated equipment she invented fit together.

* **mental retardation** is a condition in which people have below average intelligence that limits their ability to function normally.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **Asperger's syndrome** is a pervasive developmental disorder. Like autism, Asperger's syndrome is a developmental condition in which a child does not learn to communicate and interact socially with others in a typical way. Children with Asperger's syndrome have normal intelligence and generally good language development.

* **neurotransmitters** (nuro-trans-MIH-terz) are chemical substances that transmit nerve impulses, or messages, throughout the brain and nervous system and are involved in the control of thought, movement, and other body functions.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **identical twins** are twins produced when a single egg from the mother is fertilized and divides to form two separate embryos of the same sex with nearly identical DNA.

tantrums if a piece of furniture in their room is moved or if they are put at a different place at the dinner table.

Characteristic behaviors may include repetitive motor acts such as arm flapping, finger twisting, rocking, and walking on tiptoes. Some of these motions may be repeated for continuously for hours. Children with autism may also exhibit hyperactivity, fits of screaming, or self-injury, such as head banging. Often children with autism fear harmless objects, such as a vacuum cleaner, but fail to perceive real dangers, such as crossing a busy highway. They may also be oversensitive to noises, lights, and odors, and they may dislike being touched. Many children with autism also have mental retardation*. About one in four individuals with autism may develop seizures* by the time they reach their teens.

How Common Is Autism?

Autism occurs in people all over the world of every race and background. Estimates are that 2 to 10 out of every 10,000 people have autism. However, it may affect as many as 20 per 10,000 (or 1 in 500) if Asperger's syndrome* and other pervasive development disorders are included. Prevalence estimates have tended to increase along with increased public awareness of autism and Asperger's syndrome. Rates of autism are three to four times higher in boys than in girls. However, girls with autism tend to have more severe symptoms and lower intelligence.

What Causes Autism?

Autism is not transmitted from one person to another like a cold, so it is impossible to catch it from someone else. However, no one knows what causes autism. One incorrect explanation popular until the 1970s stated that autism resulted from a poor mother-child relationship in infancy. Later, researchers suspected that autism is caused by abnormal development of the brain before birth. However, as of the early 2000s, scientists had not discovered the exact cause of the abnormality.

Some studies suggested that autism may result from defects in the action of brain neurotransmitters*. Other studies indicated that brain cells and their connecting fibers may not grow properly in infants who develop autism. It is likely, however, that genes* have some role in causing autism. Parents who have one child with autism are more likely to have other children who have it (when compared to families who do not have children with autism). Identical twins* (who share the same genes) have a high rate of similarity regarding the problem. In other words, if one twin has the condition, the other is likely to have it too. If there is an autistic child in the family there is a higher rate of other developmental problems such as language and learning disabilities in siblings. Also, autism is more common among people with the chromosomal disorder known as fragile X syndrome*. Autism does not seem to be caused by one particular gene. Some scientists have speculated that autism may be due to a cluster of faulty genes. In most cases, these genes cause only mild symptoms, such as reading problems, but under certain conditions, autism may result.

What Other Disorders May Occur?

Other disorders often go along with autism:

- **Mental retardation.** Many people with autism are mentally retarded to some degree, which means that their intelligence is below average.
- **Seizures.** A seizure is a sudden burst of uncontrolled electrical activity in the brain that can range from brief blackouts to convulsions (intense, uncontrolled muscle spasms throughout the body). About one-third of children with autism have seizures, which can be controlled with medicine.
- **Fragile X syndrome.** This disorder is associated with a faulty X chromosome. About one out of 10 people with autism, mostly males, have fragile X syndrome, which causes mental retardation.
- **Asperger's syndrome.** Children with Asperger's syndrome, considered a mild form of autism, have a consuming interest in, or obsession with, one subject—often something unusual for their age. They generally have average or above-average intelligence and impressive verbal skills but lack nonverbal and social skills.

* **fragile X syndrome** is a disorder associated with a faulty X chromosome (a chromosome is a structure inside the body's cells that contains DNA, which is the genetic material that helps determine characteristics such as hair and eye color; females have two X chromosomes whereas males have only one). Fragile X syndrome is associated with mental retardation, especially in males.

What Are the Symptoms of Autism?

The symptoms of autism can range from mild to severe. In some children, hints of future problems are apparent at birth and become more noticeable as the child's development lags behind that of other children. In others, everything seems fine at first, but between 18 months and 3 years of age, the child starts to reject others and may seem to slip backward in development.

There are many tools like this picture exchange communication system which help the language skills of autistic children. *Adrian Sherratt/Alamy.*

Autism Is Not Schizophrenia

The term “autism” was introduced by the psychiatrist Eugen Bleuler (1857–1939) in 1911 to refer to a group of symptoms observed in people with schizophrenia. Bleuler described the symptoms as “detachment from reality,” with a “pre-dominance of inner life” withdrawn from the external world.

The Johns Hopkins psychiatrist Leo Kanner (1894–1981), founder of child psychiatry as a medical specialty, first identified autism as a disorder distinct from schizophrenia. Kanner believed that people with autism had not withdrawn from participation in the external world but that autism was a fundamental inability to relate from the beginning of life. In 1944 he designated the condition as “early infantile autism.”

Communication Healthy babies look at other people’s faces and react to sounds. Babies with autism avoid eye contact and seem unable to hear. They may start making speech sounds, then suddenly stop. About half of people with autism are never able to speak; others may start talking as late as age 5 to 8 years of age.

Those who do speak often use language in unusual ways. For example, they may repeat the same word or phrase or speak only in single words. Some children with autism have echolalia (ek-o-LA-lee-a), which means they repeat what they hear. Some speak in a singsong or robot-like voice.

People with autism also have trouble communicating with body language. Most people smile when talking about subjects they like or shrug when they cannot answer a question. People with autism often do not use their faces and bodies in these typical ways, and their tone of voice may not indicate their true feelings.

Relationships Usually, babies smile at familiar faces, and past the age of 7 to 9 months they show signs of fear around strangers. Babies with autism act as if they are unaware of the comings and goings of other people. They may seem impossible to reach. Some resist hugs and cuddling. Others accept physical contact but do not hug back. Older children with autism rarely seek love and comfort from others.

Children with autism also have trouble understanding what other people are thinking or feeling, and they are unable to imagine the point of view of someone else.

Interests Babies are fascinated by the world around them. They reach for objects and play with toys, constantly moving from one to another. Babies with autism often seem stuck on one activity. They may repeat one movement, such as rocking back and forth or flicking their fingers. Children with autism may also become obsessed with certain objects. For example, a child who is obsessed with watches might grab strangers’ arms to look at their wristwatches.

Senses Many people with autism seem painfully sensitive to touch, sound, taste, or smell. They might cover their ears and scream at the sound of a vacuum cleaner. Other senses may be extremely dull. Some children with autism do not seem to notice extreme cold or pain, to the point where they might break an arm and never cry.

Talents Some people with autism have remarkable talents. For example, at an early age, when other children are drawing lines and scribbles, some children with autism can draw detailed, realistic pictures. Other children learn to read before they even start to speak. Still others can play a song on the piano after hearing it once. A few people with autism can even memorize whole television programs or pages of the phone book. These people are sometimes called autistic savants (“savant” comes from the French word for “knowing”).

How Is Autism Diagnosed and Treated?

There is no specific test for autism. Parents may first suspect that something is wrong if the child does not respond to them and dislikes cuddling or being held. Physicians need to rule out other disorders that have similar symptoms, such as deafness or mental retardation. To diagnose autism, doctors and psychologists* ask parents about the child's early development and observe how the child behaves, communicates, and relates to others.

Treatment is most effective when it is begun at an early age. Educational treatment is often intense, time-consuming, and highly individualized in order to fit the varied skills and disabilities in individuals with autism. Behavioral treatments use rewards to establish new skills. Developing a communication system is important for successfully treating autistic behavior. Special education programs tailored to individual needs teach ways to better communicate and interact with others. For children with mild autism, educators reinforce existing skills and interests and build on them. Basic living skills, such as personal cleanliness and crossing the street safely, are also taught. Medications can decrease seizures, if present, and ease anxiety* and repetitive behaviors.

Behavioral treatments Some treatments focus on using rewards to teach new skills, then using the new skills to replace problem behaviors. Others build on the particular interests, skills, and needs of a child. Studies have shown that such treatments are more likely to work if they involve a regular routine and planned activities and teach tasks as a series of simple steps. It also helps if the parents are involved, and with training, parents can continue the treatment at home.

Medicines No medicine can fix the brain problems that seem to cause autism. However, doctors may prescribe medications to reduce symptoms such as head banging or violent outbursts. Some medications also decrease seizures and lessen problems related to paying attention. Most such drugs affect the amount of signaling chemicals, such as serotonin* in the brain.

Special education Special education classes can help a child with autism learn as much as possible. Some master simple skills such as dressing and handling money. Others learn to read, write, and do math. Many people with autism finish high school, and a few even earn college degrees. The sooner a child gets help, the greater the chance for learning to occur.

Living with Autism

Autism is not outgrown; children with the disorder usually are affected by it to some degree when they grow up. With special education and communication training, many people with autism can learn to lead a more nearly normal life. Some with milder autism may even finish high school and go on to college. Many, however, are unable to live and work independently and always need special care.

The Real “Rain Man”

In the movie *Rain Man*, actor Dustin Hoffman portrays an autistic savant, a person with mental deficiencies who is exceptionally gifted in one area. To prepare for the role, Hoffman studied real-life “rain man” Joe Sullivan. Like Sullivan, Hoffman's character insists on eating cheese puffs with toothpicks and repeatedly mutters the same comments to himself. Also like Sullivan, the character can do complicated math in his head and name the day of the week for any date past or future. When the movie came out in 1988, Sullivan was a high school graduate who held a job shelving books at a library.

* **psychologists** (sy-KOL-o-jists) are mental health professionals who treat mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth. Psychologists also study the brain, behavior, emotions, and learning.

* **anxiety** (ang-ZY-e-tee) can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person's physical or mental well-being.

* **serotonin** (ser-o-TO-nin) is a neurotransmitter, a substance that helps transmit information from one nerve cell to another in the brain. It is associated with feelings of well-being.

Avian Influenza

Avian influenza is found chiefly in birds, but can occur in humans.

Marti's Story

Marti had wanted a pet parrot for years, and she was delighted when her parents gave her one for her birthday. Excited, she called her friend Jen and asked her to come over to see the bird.

Jen refused. "I don't want to get sick," she said.

"What are you talking about?" Marti asked.

"Don't you watch the news? People in Asia are getting sick just from touching birds. Some are even dying. I'm not going to take that chance. And if you were smart, you'd get rid of that bird before you get sick, too." Jen had seen reports about avian influenza, but she didn't have all the facts. She didn't have anything to fear from Marti's new pet.

A model of the H5N1 virus that causes avian influenza. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

* **viruses** (VY-rus-sez) are tiny infectious agents that can cause infectious diseases. Viruses can only reproduce within the cells they infect.

* **feces** (FEE-seez) is the excreted waste from the gastrointestinal tract.

* **nasal** (NA-zal) of or relating to the nose.

What Is Avian Influenza?

Avian influenza, which was first isolated from a duck in Guangdong Province in China in 1996, is an infection caused by viruses* that occur naturally among birds. Wild birds carry these viruses in their intestines, and if domestic birds come into contact with wild bird feces*, saliva, or nasal* secretions, the virus can infect the domestic birds. As a result, the domestic birds can become ill and die. Avian influenza infection is very easily spread among birds if they come into contact with other infected birds or with surfaces or feed that has become contaminated with the virus. Bird handlers are at risk if they are exposed to sick or dead birds. During the 1990s and early 2000s, several outbreaks of avian influenza occurred in which the virus was passed from poultry to humans, resulting in more than 200 deaths.

Where Have Outbreaks Occurred?

The outbreaks occurred primarily in Asia. Between 2003 and 2008, Indonesia reported the most cases, 137, with 112 people dying from the virus. Vietnam was second, with 106 cases and 52 deaths. Egypt reported 50 cases of avian influenza in humans, and 22 people died there. In total, there were 387 confirmed cases of avian influenza in humans, with 245 people (about 63% mortality).

As of 2009, 48 nations had reported finding the highly pathogenic avian influenza virus H5N1 among domestic poultry, including Afghanistan, Benin, China, the Czech Republic, Denmark, Egypt, Germany, Hungary, India, Iraq, Israel, Japan, Korea, Poland, Russia, Saudi Arabia, and the United Kingdom. As of early 2009, it had not yet been found in the nations of the Western Hemisphere, including the United States.

How Are Humans Infected?

There are three types of influenza viruses: A and B (each of which is divided further into strains), and C. In general, the avian influenza virus is a type A virus, and it may be highly pathogenic type (HPAI) or low pathogenic (LPAI). HPAI and LPAI are differentiated through testing.

Most avian influenza viruses are LPAI and cause only mild illnesses in poultry. The opposite is true of most HPAI infections, which can lead to serious illness and a high death rate in an infected flock.

Humans can become infected with either HPAI or LPAI viruses by touching sick or dead birds, usually chickens, ducks, or turkeys, that are infected with the virus, or having contact with their feces or secretions either directly or on surfaces that remain contaminated even if the feces or secretions may no longer be present. There is no evidence that human beings can contract avian influenza by eating the cooked meat of poultry or cooked eggs; however, to be safe, meat and eggs should be thoroughly cooked, and meat should reach an internal temperature of at least 170 degrees F before being eaten.

Human beings have little natural resistance to H5N1, the strain of avian influenza that is of greatest concern. H5N1 can be deadly to birds.

People who have become infected with avian influenza may have inhaled the virus, or it may have entered their body through their mouth or eyes. Individuals who have handled a sick or dead bird or its feces and then touched their eyes is likely to transmit the virus from their hands into their eyes and thus into their body.

Why Is Avian Influenza Important?

Chickens, ducks, turkeys, and other domesticated poultry are important food sources for people around the world. Avian influenza can spread quickly among birds, killing them or making them sick so they must be killed to prevent further spread of the disease. The potential economic loss to the poultry industry and the loss of an important human food source is high. Another concern is the fact that the virus can infect humans as well as birds.

Pandemics, or worldwide outbreaks, of influenza in the past have killed millions of people. The great influenza pandemic of 1917 and 1918 claimed the lives of between 20 million and 40 million people around the world. Should an influenza pandemic of similar case-fatality ratio (the number of people reported to have the illness compared to the number of people who die from it) strike in the 21st century, more than 2 million Americans could die. Health officials think that the avian influenza strain H5NI has potential to become a pandemic; therefore, international organizations, such as the World Health Organization (WHO) and the World Organization for Animal Health work together to monitor, control, eradicate, and prevent further spread of the disease.

What Are Signs that a Bird Has Avian Influenza?

Although symptoms vary between different bird species and birds of different ages, the following signs may indicate an infection with the avian influenza virus:

- Coughing or sneezing
- Purplish discoloration of the legs, comb, or wattles
- Swelling of the head, eyelids, hocks, comb, or wattles
- Lack of energy
- Nasal discharge
- Misshapen or soft-shelled eggs or a decrease in the number of eggs laid
- Loss of coordination
- Sudden death

What Are the Human Symptoms of Avian Influenza?

In humans, symptoms of infection with the avian influenza virus include flu-like symptoms, such as cough, sore throat, muscle aches, and fever; conjunctivitis (pink eye); and respiratory ailments such as pneumonia and respiratory distress. These signs can be accompanied by vomiting, nausea, and diarrhea. In some cases, neurological* changes are also seen.

* **neurological** (nur-a-LAH-je-kal) refers to the nervous system, which includes the brain, spinal cord, and the nerves that control the senses, movement, and organ functions throughout the body.

* **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

WHAT IS A VIRUS?

A virus is an infectious agent that consists of a coil of DNA* inside a protective coat or shell. A virus attaches itself to a cell and injects its own genetic code, taking over the cell's machinery and beginning the production of more viruses. At the end, the cell explodes and dies, releasing new viruses to infect other cells.

While bacterial infections can be treated with antibiotics, they are ineffective against viruses. Special drugs called antivirals must be used to treat viral infections, although mild infections are often allowed to run their course until the patient recovers naturally.

Are Only Birds and Humans Susceptible to Avian Influenza?

Viruses are continually changing and adapting, and the H5N1 virus is no exception. Studies have shown that the virus can infect other mammals, including pigs (China), domestic dogs (Thailand), domestic cats (Thailand, Germany, Iraq, and Austria), martens (Germany), civets (Vietnam), and even zoo leopards and tigers (Thailand). H5N1 virus may continue to change as time passes and thus become able to infect additional mammals.

What Should People Do in Areas Affected by Avian Influenza?

The World Health Organization (WHO) prepared suggests people who live in areas affected by avian influenza take the following precautions:

- Avoid contact with poultry unless absolutely necessary
- Avoid touching feathers
- If contact cannot be avoided, wear protective clothing (such as a mask, rubber boots, and gloves), and wash thoroughly with soap and water afterwards
- Do not keep pet birds
- Do not sleep near poultry
- Keep children away from poultry

How Is Avian Influenza Treated?

The recommended treatment for avian influenza is the antiviral medication oseltamivir. This particular antiviral seems effective against most H5N1 viruses, which is not the case with the antivirals rimantadine or amantadine. However, because viral resistance is a serious concern, monitoring for resistance was ongoing in the early 2000s.

What Should a Poultry Farm or Processing Facility Do to Guard against an Outbreak?

Although as of 2009 there had not yet been an outbreak of avian influenza in the United States, poultry farms and processors were urged to take preventative measures to protect their workers and the general public. The viruses thrive in warm, moist conditions, especially when organic matter is present. However, the use of detergents and disinfectants, along with heating and drying, has been shown to kill the virus.

The Occupational Health and Safety Administration (OSHA) suggested that people who work with poultry wear protective equipment, including a respirator (worn by many poultry workers routinely). Safety glasses are not sufficient protection against aerosols or fine particles; OSHA suggested that a better choice is indirectly vented or nonvented safety goggles (such as eyecup goggles). Workers should remove their goggles and respirators carefully to avoid passing any viruses on the surface to the mucous membranes of the eye, nose, or mouth. Thorough washing of hands should be performed frequently. If workers notice flu-like symptoms or signs of conjunctivitis, they should consult a physician as soon as possible.

Any outbreaks should be reported to the animal health authorities in the area. Workers should take an antiviral under the supervision of a doctor.

Should Pet Birds Be Avoided?

In the United States, pet birds that are legally imported are held in quarantine* by the Department of Agriculture for 30 days to ensure that they do not have avian influenza or other potentially infectious diseases. These birds are tested for avian influenza and are not allowed to enter the country unless they test negative. Birds from U.S. sources should be healthy; however, people should request certification from the seller that the bird is of American stock and is healthy. In any case, a pet bird should be examined by a veterinarian soon after it arrives at its new home.

Good bird husbandry practices help keep pet birds healthy. The USDA suggests keeping pet birds away from other birds and away from people who own birds that live outdoors, such as chickens; cleaning cages daily; washing hands before and after handling birds, and cleaning and disinfecting clothing after visiting a bird fair or any site where there is live poultry, such as a county fair.

Bird owners should watch for the symptoms of avian influenza in their birds. If a bird shows symptoms or dies suddenly, the owner should contact an avian veterinarian immediately.

If a bird is healthy and has been determined to be free from avian influenza, owners and visitors should have no fear about enjoying these companion animals.

* **quarantine** is the enforced isolation (for a fixed period) of apparently well persons or animals who may have been exposed to infectious disease.

Is a Vaccine Available?

In 2007 the Food and Drug Administration approved a vaccine for humans that is effective against the H5N1 avian influenza virus. Clinical tests showed that the vaccine, which was derived from a human strain, was generally well tolerated by people who participated in the study. Reported side effects include muscle pain, headache, pain at the site of the injection, and a general feeling of being unwell. The vaccine was not available commercially, however; it was purchased by the federal government for the National Stockpile, and it was intended to be distributed if needed.

B

Babesiosis

Babesiosis is a rare disease carried by ticks infected with the Babesia parasite. The disease most often affects cows, horses, sheep, dogs, and cats, but it can be transmitted to people through tick bites.

What Are Babesia?

Ticks carry many different diseases, including babesiosis (ba-bee-ze-O-sis), Lyme disease, and Rocky Mountain spotted fever.

Babesia (ba-BEE-ze-a) are protozoa, or one-celled organisms, that often live as parasites*, infecting cows, horses, sheep, goats, dogs, cats, and other animals. Deer ticks pick up *Babesia* when they feed on infected animals. The protozoa then multiply in the tick, and when the tick bites a person or another animal, the protozoa travel from the tick into the new host, where they begin multiplying again.

What Happens When People Get Babesiosis?

The *Babesia* parasite invades the body's red blood cells and can destroy them. If left untreated, babesiosis may destroy red blood cells faster than the body can replace them.

Symptoms Many doctors believe that many cases of babesiosis do not cause any symptoms. However in some instances, symptoms may start one to four weeks after the tick bite occurs, and may last for several weeks or months. People with babesiosis may experience fever, chills, sweating, fatigue, and anemia. These symptoms are similar to those of malaria.

Diagnosis and treatment Doctors diagnose babesiosis by examining blood under a microscope. When they detect the parasite, they prescribe medications to fight the infection and to rid the body of the parasite. Babesiosis is usually curable, although repeated courses of treatment may be necessary.

Most patients recover with few, if any, lasting effects. The most serious and sometimes fatal cases are found in elderly people, in pregnant women, in people who have had their spleen* removed, or in people with immune deficiencies.

How to Remove a Tick

Using thin-tipped tweezers, grasp the tick as close to the person's skin as possible.

Pull straight upward firmly and steadily until the tick lets go (do not squeeze or twist the tick body).

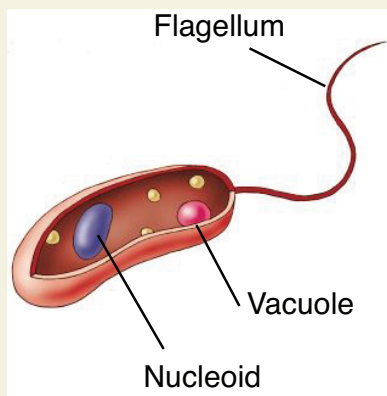

Clean the skin with soap and warm water, alcohol, or other antiseptic.

Save the tick for identification.

Petroleum jelly, lit matches, nail polish or other products do not help in tick removal and should not be used.

* **parasites** (PAIR-uh-sites) are organisms such as protozoa (one-celled animals), worms, or insects that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. Parasites live at the expense of the host and may cause illness.

* **spleen** is an organ in the upper left part of the abdomen that stores and filters blood. As part of the immune system, the spleen also plays a role in fighting infection.

▲ Anatomy of an individual bacterium. Its DNA (genetic material) is in the nucleoid area, but it is not enclosed within a membrane. This bacterium uses its flagellum (tail) to move around. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **DEET** (abbreviation for N,N-Diethyl-meta-toluamide) is the active ingredient in many insect repellants.

* **microorganisms** are tiny organisms that can only be seen using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

How Do People Prevent Babesiosis?

The best methods of prevention are using insect repellent containing DEET* and wearing protective clothing when people are outdoors. People in deer tick-infested areas should wear light colored, long-sleeve shirts and long pants tucked into socks or boots. Doing so can help to keep ticks from reaching the skin. People should look for ticks on the body, including the scalp, after returning from gardening, camping, hiking, or playing outdoors in wooded areas, grass or brush.

If ticks do attach themselves to the skin of people or pets, the ticks should be removed with tweezers as soon as they are discovered. Generally, infected ticks have to be attached to the body for at least 24 hours before they pass on the parasite.

Bacterial Infections

Bacterial infections occur when harmful forms of bacteria multiply inside the body. These infections range from mild to severe. Although they include such deadly diseases as plague, tuberculosis, and cholera, these and many other bacterial diseases can be prevented with good sanitation and/or cured by antibiotics.

What Are Bacteria?

Bacteria are microorganisms*, and they exist everywhere: in the air, in water, and in every animal and person. Bacteria are by far the most numerous organisms on Earth.

Most bacteria are harmless. Often bacteria are beneficial, even essential, to plant and animal life. Bacteria decompose (break down) dead plants and animals. This process allows a chemical element such as carbon to return to the soil to be used again. In addition, some bacteria enable plants to get nitrogen from the soil (and some enable plants to

use atmospheric nitrogen). Without bacteria, plants could not grow. In the human body, bacteria help keep the digestive tract working properly.

Bacteria can also cause disease. Like viruses*, bacteria can cause hundreds of illnesses. Some bacterial infections are common in childhood, such as strep throat (caused by streptococcus bacteria) and ear infections. Others cause major diseases, such as tuberculosis*, plague*, syphilis*, and cholera*. The infection may be localized (limited to a small area), as when a surgical wound gets infected with a staphylococcus (staf-i-lo-KOK-us) bacterium. It may involve an internal organ, as in bacterial pneumonia (infection of the lungs) or bacterial meningitis (infection of the membranes covering the brain and spinal cord).

Some bacteria, such as *Streptococcus pneumoniae*, also known as pneumococcus (noo-mo-KOK-us), almost always cause illness if they get into the body. Others, such as *Escherichia coli*, usually referred to by the short form *E. coli*, often are present in the body without doing harm. If the immune system* is weakened, however, these bacteria can grow out of control and start doing damage. Such illnesses are called “opportunistic infections.” In the 1990s and early 2000s, they became more common, in part because AIDS*, organ transplants, and other medical treatments have left more people living with weakened immune systems.

How Are Bacteria Different?

Unlike other living cells, a bacterium does not have a membrane that encloses its nucleus, the part of the cell containing DNA, the cell’s genetic material. Unlike viruses, most bacteria are complete cells that can reproduce on their own without having to invade a plant or animal cell. Some bacteria, however, do need to live inside another cell just as viruses do.

How do bacteria spread? Different bacteria spread in different ways. People get bacteria in the following ways:

- Through contact with contaminated water (cholera and typhoid fever)
- Through consumption of contaminated food (botulism, *E. coli* food poisoning, salmonella food poisoning)
- Through sexual contact (syphilis, gonorrhea, chlamydia)
- Through respiratory droplets expelled into the air, when infected people sneeze or cough (tuberculosis)
- Through contact with animals (anthrax, cat scratch disease)
- Through touching infected people (strep throat)
- Through skin via tick bites, lice, and cat bites
- Through open sores on the body
- Through infections such as Lyme disease, Rocky Mountain spotted fever, and typhus

Food Poisoning

Food poisoning is often the result of bacterial contamination. Important precautions for preventing food poisoning include the following:

- Avoiding raw or undercooked meat, poultry, seafood, and eggs
- Avoiding non-pasteurized dairy products
- Throwing out food items that are old or have an “off” smell
- Keeping foods cold until ready to serve
- Storing and cooking foods properly
- Washing knives, cutting boards, cooking utensils, and food preparation areas after every use
- Washing hands before preparing food, before eating, and after using the bathroom

* **viruses** (VY-rus-sez) are tiny infectious agents that can cause infectious diseases. Viruses can only reproduce within the cells they infect.

* **tuberculosis** (too-ber-kyoo-LO-sis) is a bacterial infection that primarily attacks the lungs but can spread to other parts of the body.

* **plague** (PLAYG) is a serious bacterial infection that is spread to humans by infected rodents and their fleas.

* **syphilis** (SIH-fih-lis) is a sexually transmitted disease that, if untreated, can lead to serious life-long problems throughout the body, including blindness and paralysis.

* **cholera** (KAH-luh-ruh) is an infection of the small intestine that can cause severe diarrhea.

Flesh-Eating Bacteria

A virulent strain of *Streptococcus A* bacteria caused illness in 117 people in Texas between December 1997 and March 1998. Of those 117 infections, 26 (17 adults and 9 children) resulted in death. Described in media coverage as “flesh-eating bacteria,” these pathogens induced hemolysis (he-MOL-y-sis), or the lysis (dissolution) of red blood cells. The Texas outbreak was short-lived, and experts remained uncertain about how it started.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **toxins** are substances that cause harm to the body.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

- From one part of the body, where they are harmless, to another part, where they cause illness (as when *E. coli* spread from the intestines to the urinary tract)
- Because of the after-effects of chronic debilitating conditions such as alcoholism. The alcoholic who has a diminished cough reflex inhales foreign material (usually food, liquids, or vomit) from the mouth into the lungs. Bacteria then enter into the lungs causing aspiration pneumonia.

How do bacteria cause illness? Bacteria can cause illness in several ways. Some destroy tissue directly. Some become so numerous that affected tissue cannot work normally. And some produce toxins* that kill cells. Exotoxins are toxins that are actively secreted by bacteria into the surrounding medium. Endotoxins are part of the bacterial architecture: They are usually part of the cell walls of bacteria and can be extremely toxic to people. Most bacterial toxins are exotoxins.

How Are Bacterial Infections Diagnosed and Treated?

The symptoms of bacterial infections vary widely but often include fever.

Diagnosis Doctors may test the patient's blood, sputum, or urine for evidence of harmful bacteria. If a lung infection is suspected, the doctor may take a chest x-ray or do a biopsy*, taking cells from an infected area to be examined. If meningitis is suspected, the doctor may do a spinal tap, using a needle to extract a sample of the spinal fluid that surrounds the spinal cord for testing so that the sample can then be studied.

Treatment Most bacterial infections can be cured by antibodies*, which were one of the great medical success stories of the twentieth century. These drugs either kill the bacteria or prevent them from reproducing. Penicillin, the first antibiotic, continued to be used in the 21st century to treat some infections. Other widely used antibiotics are amoxicillin, bacitracin, erythromycin, and tetracycline. Examples of antibiotic classes include cephalosporins and fluoroquinolones. Sometimes antitoxins are also given to patients to counter the effects of bacterial toxins, as in the case of tetanus or botulism toxins.

How Are Bacterial Infections Prevented?

Young children are vaccinated against diphtheria, whooping cough, tetanus, and *Hemophilus influenza B*, which are all bacterial infections. In addition, there are vaccines for cholera, meningococcal and pneumococcal infections, plague, and typhoid fever.

For many bacterial infections, good living conditions are the best prevention. That means clean water supplies, modern sewage systems, well-ventilated housing that is not overcrowded, and prompt medical treatment for people who do get sick.

Other precautions include the following:

- Washing hands (before handling food; after handling raw meat; after using the toilet; after touching animals; after having had contact with infected people)
- Washing fruits and vegetables before eating them
- Cooking meat thoroughly
- Abstaining from sexual contact or using condoms during sexual activity

How Do Bacteria Become Drug Resistant?

Virtually every kind of bacteria can be killed by specific antibiotics, and virtually every kind is naturally resistant to others. Some bacteria develop resistance to the antibiotics that are used to kill them. This is one of the big problems in controlling infectious diseases.

How does resistance occur? In some cases, resistance occurs by chance. As bacteria reproduce, mutations (variations) in their genes occur all the time. One of these chance mutations may happen to make a single bacterium in a person's body less vulnerable to a drug. This bacterium multiplies along with other bacteria. Whereas other bacteria are killed off by the drug, the mutated or resistant bacterium and its descendants, or daughter cells, thrive, and they may spread to other people.

Why does resistance occur more often? The use of antibiotics made the phenomenon of bacterial resistance far more prevalent than it would have been in their absence. The problem of resistance was made worse by people taking antibiotics that were not needed or by their taking antibiotics that were needed but then choosing to stop take them too soon.

Here is an example of how the use of an antibiotic can increase resistance: Let us say that a man has a bacterial infection. He takes an antibiotic, feels better, and stops taking the drug in five days, even though the doctor instructed him to take it for 10 days. Inside the man's body, the drug may have killed 80 percent of the bacteria. That was enough to make the man feel better. But the bacteria still alive are the 20 percent that were toughest, the ones best able to survive the drug. If the man had kept taking the antibiotic, the toughest bacteria might have been killed after he had been taking it for the remaining days. But now, having avoided the medication, they start to multiply. Soon the man feels sick again. But this time, all the bacteria in his body are the tougher kind. A scientist would say that the person's behavior had "selected" the most resistant bacteria for survival.

A similar process occurs when doctors prescribe antibiotics that are not needed. Let us say that a girl has a cough and fever. The doctor prescribes antibiotics on the chance that the girl has a bacterial infection. But

she actually has a virus, and viruses cannot be treated with antibiotics. The girl's immune system, her natural defense system, fights off the virus as it would have without the drug. Meanwhile, the antibiotic kills off some bacteria that usually live harmlessly in the girl's throat. The bacteria in her throat that survive are those that are better at resisting the antibiotic. Later, if those bacteria get into her ears, her lungs, or some other part of her body where they can cause illness, the antibiotic may not work as well against them.

If events like these happen repeatedly among many people, eventually strains of bacteria may arise that partially or completely resist a drug that is used to kill them.

Bedsores (Pressure Sores)

Bedsores, also called pressure sores or decubitus (de-KU-bi-tus) ulcers, are skin sores caused by prolonged pressure on the skin, usually in people who are paralyzed, bedridden, or too weak to move around much.

What Are Bedsores?

Bedsores develop when the skin is compressed for a long time between a protruding bone, such as a hipbone or elbow, and an external surface, such as a wheelchair or mattress. This compression limits the flow of blood in blood vessels that bring nutrients and oxygen to the skin and remove wastes. Without oxygen or nourishment, the underlying tissue may deteriorate, and a hole may open in the skin. If left untreated, bacteria* can infect the skin opening and lead to septicemia* or infection of muscle or bone.

Because protein and fluids help keep skin healthy and supple, elderly people with a poor diet often are at risk for skin-damaging bedsores. Other people at risk include those who cannot move much or shift their positions, perhaps because they are paralyzed or have a long-term illness, or are in a coma*. People who are confined to wheelchairs, particularly those who cannot sense pain clearly, are also vulnerable to skin sores because they may not feel the ulcer forming. Bedsores are not contagious*.

What Are the Symptoms of Bedsores?

A typical bedsore starts as a red area on the skin that may feel hard or warm to the touch. In people with darker skin, the sore may show as a shiny spot on the skin. If pressure is removed at this point, complications can be prevented. If the pressure is not removed, a blister, pimple, or scab may form over this area, which is a sign that the tissue beneath is dying. Eventually, a hole, or ulcer, will form in the skin. The dead tissue may appear small on the skin surface, but it may be larger in deeper tissues. The damage may extend all the way to the bones.

To diagnose bedsores, healthcare providers examine the skin for redness, blisters, openings, rashes, or warm spots, paying particular attention to bony areas. Any spots previously broken or healed over also are checked, as scar tissue can break open.

How Are Bedsores Treated and Prevented?

Bedsores can be prevented and treated in their early stages by relieving pressure on the body. Doing so requires changing a person's position in bed at least every two hours and in a wheelchair every 10 to 15 minutes. People at risk for bedsores should check themselves carefully at least twice daily or ask their caregivers to do so. Doctors recommend using long-handled mirrors to help with these exams because these tools help caregivers examine hard-to-see areas.

* **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.

* **septicemia** (sep-ti-SE-me-a) means a bacterial infection in the blood that spreads throughout the body, with potentially fatal results.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be woken up, and cannot move, see, speak, or hear.

* **contagious** (kon-TAY-jus) means transmittable from one person to another, usually referring to an infection.

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

Other helpful methods to prevent bedsores are:

- using soft pillows to cushion the legs, back, and arms from pressure
- using special mattresses or egg-crate foam mattresses to reduce pressure
- keeping bedclothes unwrinkled and free of crumbs
- keeping skin clean and dry, free of sweat, urine, and stool
- making sure the patient is eating a balanced diet and drinking lots of fluids to help skin stay healthy

If a bedsore does develop, treatment may include antibiotics to treat infections and special gels or dressings to promote healing. In more serious cases, doctors may need to surgically remove the dead tissue and close the sore. If the bedsore reaches the bone, then the affected bone tissue may have to be removed as well.

Bedwetting (Enuresis)

Bedwetting (also known as enuresis) is the involuntary release of urine past an age when control usually is expected.*

Bobby's Story

Bobby woke up and felt that, once again, his pajamas and sheets were wet and smelled of urine. Wetting the bed is why he had turned down Ramon's invitation to a sleepover birthday party planned for the following weekend. At ten years old, Bobby was ashamed that he still wet the bed. It was not as if he did it on purpose. It just happened. He knew most children his age did not urinate in their sleep, and he was tremendously afraid that his friends would make fun of him if they found out that he did. Better, he thought, to miss the party than to have everyone learn about his problem.

What Is Bedwetting?

Bedwetting is also called nocturnal enuresis (nok-TER-nal en-yu-REE-sis) Enuresis is the involuntary, unwanted release of urine either in the day or at night in people who are developmentally old enough (around ages 5 to 6) to have gained bladder* control. Bedwetting is a specific kind of enuresis that occurs at night during sleep

Most children are toilet trained by age three, although some continue to use diapers or training pants while sleeping. Past that age, it is normal for children to wet their beds occasionally, especially if they are sick or particularly tired. About 30 percent of four-year-olds wet the bed. This rate drops to about 10 percent of six- and seven-year-olds, while but only about 1 percent of adolescents and adults have problems with bedwetting. In young children, more boys than girls wet the bed. Some men and women develop incontinence* as they age, often because of medical conditions or medications they take. Bedwetting becomes a problem when it happens repeatedly in older children. In older children, bedwetting limits social activities and can be stressful and humiliating. It can contribute to psychological and emotional problems such as low self-esteem* and depression*.

What Causes Bedwetting?

Doctors are not exactly sure why some people experience problems with bladder control and others do not. They do know that bedwetting tends to run in families. Children who have a parent who wet the bed as a child are between 40 percent and 75 percent more likely to wet the bed themselves, depending on whether one or both their parents had problems with bedwetting. As of 2009, however, no specific genetic cause for bedwetting had been found.

Many children who wet the bed seem to sleep so deeply that they are not awakened by the urge to urinate. Other children have bladders that develop more slowly than most. Bedwetting is sometimes related to medical problems such as infections of the urinary tract, sickle-cell anemia*, diabetes*, or epilepsy*. However, most people who wet the bed do not have medical problems.

Bedwetting also is a common reaction to stress, especially if a person has previously stayed dry at night. For example, some younger children who are toilet trained resume wetting their beds after a new baby is born or parents separate. Starting a new school or moving to a new town can also trigger the condition or make it worse. Still, most bedwetting does not have an easily identifiable cause.

Research suggests that some people who wet the bed may produce less antidiuretic hormone (anti-di-u-RET-ik HOR-mone), or ADH, than do people who do not. ADH regulates how concentrated the urine is. People generally produce more ADH at night, allowing them to produce a smaller volume of more concentrated urine while they sleep. People who produce less ADH at night produce a greater volume of urine that is less concentrated (more diluted).

* **bladder** (BLAD-er) is the sac that stores urine produced by the kidneys prior to discharge from the body.

* **incontinence** (in-KON-ti-nens) is loss of control of urination or bowel movement.

* **self-esteem** is the value that people put on the mental image that they have of themselves.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

* **sickle-cell anemia** also called sickle-cell disease, is a hereditary condition in which the red blood cells, which are usually round, take on an abnormal crescent shape and have a decreased ability to carry oxygen throughout the body.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **epilepsy** (EP-i-lep-see) is a condition of the nervous system characterized by recurrent seizures that temporarily affect a person's awareness, movements, or sensations. Seizures occur when powerful, rapid bursts of electrical energy interrupt the normal electrical patterns of the brain.

What If My Child Gets Invited to a Sleepover?

Like Bobby, many children who wet the bed fear sleeping anywhere but at home. They worry that they will urinate during a sleepover or at camp and that they will be teased about it. These feelings can cause them to withdraw from certain social activities. Nevertheless, studies show that many children who wet the bed at home do not do it while sleeping elsewhere. Doctors theorize that this pattern might result because these children are not sleeping as soundly as they do at home. Deep sleep is a common reason children do not wake up when they need to urinate.

The parents of children who wet their bed sometimes can ease the situation by discussing the matter with the parents of the friend before the sleepover. Alerting the friend's parents might help the child overcome any uneasiness if bedwetting occurs.

Children can also be coached on not drinking liquids before bedtime and setting an alarm to get up at night for a bathroom break. In extreme cases, parents might want to consult their pediatrician about the temporary use of drugs that help eliminate bedwetting. Some medications are quite effective and work almost immediately.

How Is Bedwetting Treated?

Most children stop bedwetting without any treatment. Bedwetting in older children can be treated in different ways depending on what is causing it. First, a doctor does a complete physical examination to determine if bedwetting is caused by a medical condition. If it is, the underlying condition is treated medically with drugs or corrective surgery. However, only a very small number of adolescents who experience bedwetting have an underlying medical condition that is responsible for the problem.

If the bedwetting appears to be caused by emotional or psychological stress or depression, then consultation with a mental health professional is the first step to resolving the problem. Counseling to help deal with the source of stress, combined with behavior modification techniques to bring about nighttime bladder control, are often very effective.

Most people wet the bed for no identified reason. These people are usually helped by behavioral strategies aimed at staying dry during the night. Behavioral modifications such as holding urine for a short time when there is an urge to urinate, rewards for dry nights, and relaxation techniques aimed at reducing stress sometimes help. So do limiting drinking liquids after dinner and avoiding caffeinated beverages, such as colas. Sometimes parents wake their children after a few hours of sleep to encourage them to go to the bathroom and empty their bladder. The most effective behavioral technique, however, is the urine alarm. This pad with a bell or alarm attached to it is placed on the bed and individuals sleep on top of the pad. With this technique, an alarm rings at the first sign of wetness in their pajamas or the sheets. The alarm awakens sleepers and allows them to get up and finish emptying their bladder. In time, their brain comes to recognize the sensation of a full bladder and wakes them before urination occurs and the alarm goes off.

Nighttime dryness sometimes can be achieved by the use of medication. Some medications work to increase urine concentration. Others seem to work by making it easier for a person to wake up when the bladder is full. Some medications are quite effective and work almost immediately, whereas others may become effective over time. However, many people return to wetting the bed as soon as they stop taking the medication. As with all medicines, sometimes mild side effects occur.

Although bedwetting is not medically serious, it can have strong negative psychological effects on young people. It restricts their social lives and is embarrassing, upsetting, and frustrating. Fortunately most people can be helped to stay dry at night through a combination of the strategies mentioned above. It is important for parents to offer encouragement to children and help them understand that bedwetting is a common medical condition, not a personal weakness. Children should also be helped to realize they are not alone in their bedwetting. They probably know other people who secretly share their problem, but bedwetting is not something many children discuss with their friends or classmates.

Bell's Palsy

Bell's palsy is a sudden weakness or loss of function of certain facial muscles, usually on one side of the face, caused by swelling of a facial nerve.

Half a Face

Fifteen-year-old Shelly woke up one morning feeling like she had just received a shot of Novocain from the dentist. When she looked in the mirror, she saw that her face seemed limp on one side. She could not smile, and only one side of her face seemed to work. Shelly screamed for her parents and they came running. When they saw her face, they became worried that she had had a stroke* or had developed a brain tumor. They rushed her to the hospital emergency room.

At the hospital, the doctor examined Shelly and asked her and her parents about Shelly's medical history. Then the doctor performed several diagnostic tests to find out whether she had high blood pressure or Lyme disease. At that point, the doctor was able to explain that the symptoms indicated Bell's palsy, a fairly common and harmless condition.

It took three weeks for Shelly's condition to go away, and those three weeks felt more like three years to Shelly, but she was grateful that the condition was not something more serious.

▲ Bell's Palsy causes muscle weakness or loss of muscle function on one side of the face, which can result in a lopsided appearance. *Dr. P. Marazzi/Photo Researchers, Inc.*

* **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

What Is Bell's Palsy?

Bell's palsy is a condition that occurs when the facial nerve becomes irritated. The facial nerve runs from the brain through a small hole in the skull. Sometimes the facial nerve becomes irritated or swollen. The irritated nerve does not send normal signals to the muscles on one side of the face. The result is partial or complete loss of muscle function (called "palsy").

The symptoms of Bell's palsy begin suddenly and usually worsen over two to five days. The sudden numbness or weakness characteristic of Bell's palsy gets worse during the day, and the face feels stiff and pulls to one side. People with Bell's palsy typically have problems closing one eye and cannot wrinkle their forehead. They may feel pain behind the ear, they may experience involuntary facial movements called "tics," and hearing in the ear on the affected side may be very sensitive. They also may drool and have trouble eating and talking.

People with a stroke can look like they have Bell's palsy, so it is important to visit a doctor to find out what is causing facial paralysis. People with Bell's palsy often fear a brain tumor, but the symptoms of a brain tumor usually occur more gradually than the sudden start of Bell's palsy.

Ramsey Hunt syndrome is similar to Bell's palsy with symptoms that are so much alike, patients with Ramsey Hunt syndrome may be misdiagnosed as having Bell's palsy. There are, however, some key differences that differentiate it from Bell's palsy. These symptoms include severe pain inside the ear region (which may begin even before the onset of facial paralysis); a spinning sensation of dizziness; hearing loss; blisters (also known as shingles) in or around the ear, mouth, or throat; and sore lymph nodes.

Ramsey Hunt syndrome is caused by the varicella zoster virus (VZV). This virus, a strain of the herpes virus, also causes chicken pox. This virus may remain dormant in the body for decades, which explains why individuals over the age of 50 are most often afflicted.

BELL AND THE BRAIN

The Scottish scientist Sir Charles Bell (1774–1842) studied anatomy (the structure of organisms). His investigations of the brain have been called the "Magna Carta of Neurology." The Magna Carta or "great charter," is a famous document in English history that spelled out governmental law and people's rights, so this comparison is quite a compliment to Sir Charles Bell, who received the first medal awarded by the Royal Society of Great Britain for his book, *Idea of a New Anatomy of the Brain*.

Bell was the first to describe how sensory neurons (nerve cells) carry messages to the brain and how motor neurons carry messages to muscles and glands. Because of his work with nerve anatomy, Bell's palsy was named after him.

What Causes Bell's Palsy?

As of 2009, Bell's palsy was considered an idiopathic (id-e-o-PATH-ik) disease, which means that its cause is unknown or uncertain. One possible cause of Bell's palsy is irritation of the facial nerve after a viral infection, such as herpes zoster (which causes shingles) or herpes simplex (the cold sore virus). It also may be related to a blow to the face that damages the nerve or to conditions such as Lyme disease, diabetes, and high blood pressure.

Bell's palsy may happen to men and women of all ages but is most common between the ages of 30 and 60. Pregnant women and people who have diabetes, a cold, or the flu are more susceptible than others. One person in 60 to 70 develops Bell's palsy during his or her lifetime, which translates to about 40,000 people per year in the United States.

How Is Bell's Palsy Treated?

Eighty percent of people with Bell's palsy begin to recover several weeks after the onset of symptoms, and they recover completely within several months without treatment. A few people never recover completely and some of their symptoms continue permanently.

During recovery, the biggest concern is protecting the exposed eye from dryness and injury. Doctors sometimes prescribe antiviral medications during the first five to six days of the onset of Bell's palsy, and anti-inflammatory drugs sometimes help reduce swelling of the nerve.

* **caisson** (KAY-son) is a watertight container that divers or construction workers use under water.

Bends

The bends is a painful condition that can occur in scuba divers, in aviators flying at high altitudes, in people working in pressurized settings, and in some other situations. Also called decompression sickness, the bends results when rapidly decreasing pressure causes normally dissolved gases to bubble out from bodily fluids and tissues and enter the bloodstream. This effect may occur, for example, when divers return to the surface too quickly from the higher pressure of underwater depths.

What Are The Bends?

The bends is also called decompression sickness or caisson* sickness. Water pressure increases with depth. When a person is scuba diving, as the person goes deeper under water, the pressure of the air the person breathes also increases. This increase in pressure causes more air to dissolve in the bloodstream.

How Is the Body Affected?

The main components of air are oxygen and nitrogen gases. Oxygen is continuously used by the body, but nitrogen is not. In the case of a scuba diver, the ascent from depths results in a decrease in pressure. Consequently, the blood can no longer hold all the nitrogen dissolved in it. If a diver ascends slowly, the nitrogen escapes into the lungs and is breathed out harmlessly. If the diver ascends rapidly, however, the nitrogen bubbles into the blood—much as bubbles escape from a newly opened, and likewise rapidly depressurized, bottle of carbonated soda or a soft drink. These bubbles can lodge at joints, such as the elbow or knee, and cause pain. In severe cases, extreme pain may arise and cause the sufferer to double over. This symptom led people to give the sickness its common name of “the bends.” Similar scenarios apply to construction personnel in caissons, miners working deep underground, and others who are exposed to conditions of changing pressures. In fact, the first medical report on the condition came in 1754 from two physicians who were treating what they called “mal de caisson,” or caisson disease, in men toiling in a pressurized coal mine in France. Other reports soon followed from physicians attending caisson workers in the United States, and eventually the connection between the sudden changing of pressure and these symptoms became apparent.

Symptoms of the bends usually appear within 90 minutes of diving but may take as long as two days to appear. In minor cases, symptoms include itching, rash, joint pain, or skin discoloration. In severe cases, symptoms may include extreme pain at the joints, headache, seizures, hearing problems, nausea and vomiting, back or abdominal pain, vision disturbances, or chest pain.

How Do Doctors Treat the Bends?

Minor cases of the bends usually require no treatment, although the patient should still consult a doctor. Severe cases, by contrast, require treatment with a hyperbaric (hy-per-BARE-ik) chamber, a device that creates pressure to dissolve the gas bubbles. The patient is placed under high-pressure conditions, and the pressure is slowly and safely decreased. Prompt treatment increases the chances for a complete recovery. Unfortunately, these chambers are not available everywhere, and a person with the bends may have to be transported and possibly airlifted significant distances to receive proper treatment.

What Do Scuba Divers Need to Know?

About 5 million people scuba dive. Scuba divers must be certified by taking training classes in which they learn how to dive and resurface safely to avoid decompression sickness. The bends is a preventable condition when safety rules are followed carefully.

Binge Eating Disorder

Binge eating is excessive, out-of-control eating. A person with binge-eating disorder exhibits a repetitive pattern of eating significantly more food in a limited time (usually one to two hours) than most people typically would eat. Doing so often results in overweight or obesity.*

* **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

Binge-eating Disorder or Bulimia?

People with bulimia eat excessively, but afterward they induce vomiting, take laxatives, or exercise excessively to purge their body of extra calories. People with binge-eating disorder eat compulsively but do not try to get rid of the extra calories. This practice prevents some of the health problems associated with bulimia but results in other health problems related to being overweight.

* **anorexia nervosa** (an-o-REK-se-a ner-VO-sa) is an emotional disorder characterized by dread of gaining weight, leading to self-starvation and dangerous loss of weight and malnutrition.

* **bulimia** (bu-LEE-me-a) is an eating disorder in which a person has episodes of out-of-control overeating, or binges, and then tries to make up for them by making themselves vomit, by taking laxatives, or by exercising to excess to avoid gaining weight.

* **body image** is a person's impressions, thoughts, feelings, and opinions about his or her body.

What Is Binge Eating?

People who eat uncontrollably on a regular basis (at least twice a week for at least three months) are binge eaters. These people eat abnormally large quantities of food (sometimes thousands of calories) in one sitting. (Depending on body weight a person may require 1200 to 2000 calories per day.) Binge eating is sometimes referred to as compulsive overeating. The eating disorders anorexia nervosa* and bulimia* are officially considered psychiatric disorders. Binge eating was, as of 2009, acknowledged to be a psychological and physical problem, but it was not a separate psychiatric disorder as defined by the American Psychiatric Association.

Binge eaters eat abnormally large amounts of food at one sitting, often consuming as much as four times their daily calorie needs calorie needs (1200–2000 calories) in a short period. They tend to eat much faster than usual and continue eating even when they are no longer hungry. Often they eat until they feel uncomfortably full because during a binge they feel out of control and unable to stop eating even when they want to quit.

Binge eaters often develop the habit of eating alone so that others do not see them gorging themselves, hiding empty food containers to disguise how much they eat, and hoarding food in preparation for another binge. People who binge almost always feel embarrassed and ashamed of their eating. After bingeing, compulsive eaters often feel guilty, upset, disgusted, and/or depressed about how much they have eaten. They may vow to themselves never to binge again, but they are not able to keep this promise.

About 2 percent of Americans are binge eaters, and estimates are that between 30 and 50 percent of obese individuals binge. Women who binge outnumber men in a ratio of 3:2; however, binge eating is the most common male eating disorder. Unlike the anorexia nervosa or bulimia that usually starts in the teenage years, binge-eating disorder is more likely to develop in adults between the ages of 45 and 55.

What Causes Binge-eating Disorder?

Binge eating is thought to be caused by a combination of social, psychological, and genetic factors, and for many binge eaters, stress is the factor that triggers a binge. Social factors that encourage binge eating include the easy availability of inexpensive food in developed countries that makes it possible to binge eat and to hide this activity. Societies that value thinness can also promote depression and guilt among binge eaters, especially when the media send mixed messages that place food at the center of social events but also present thinness as necessary to be socially acceptable.

Psychologically, binge eaters share certain traits:

- Binge eaters tend to be obsessed with body image* and weight. People who diet continuously or who repeatedly gain and lose large amounts of weight (weight cycling) are more likely to become binge eaters.

- Binge eaters tend to have problems with impulse control and managing anger appropriately; some have difficulty appropriately expressing other emotions.
- Binge eaters almost universally have low self-worth and a negative self-image.
- Most binge eaters are depressed. It is not clear whether depression causes binge eating or if binge eating causes depression, but the two are likely to co-occur (be found together).
- People who are binge eaters report being sexually abused as children at a higher rate than the general population.

Research published in the early 2000s suggested that there is also a genetic component to binge eating. The appetite control system is complex and involves the interaction of multiple genes*, hormones*, and neurotransmitters*. The way appetite is controlled is not completely understood. However, researchers have found that some obese people have a mutation, or change, in a gene that suppresses the urge to eat once a person has eaten enough calories. Although researchers found that while only about 5 percent of obese people have mutations in this gene (meaning that this mutation is not the only cause of obesity), all the people with this mutated gene were binge eaters. The physiological basis for appetite and appetite control was under research in the early 2000s, and it was hoped that this work would lead to a breakthrough in treating obesity.

How Is Binge Eating Diagnosed and Treated?

Symptoms of binge eating may be difficult to detect because binge eaters tend to hide their behavior. Although many people are obese, not all obese people are binge eaters. Secretive eating, constant dieting without

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

* **neurotransmitter** (NUR-o-tranz-mit-er) is a brain chemical that lets brain cells communicate with each other and therefore allows the brain to function properly. In other words, a neurotransmitter transmits (carries) a chemical message from neuron to neuron.

Possible health consequences of binge-eating

- Anxiety
- Depression
- Obesity
- Obesity-related diseases
- Poor self-esteem
- Sleep problems
- Stress
- Substance abuse
- Suicidal thoughts
- Weight gain
- Weight obsession

* **antidepressant medications** are used for the treatment and prevention of depression.

* **psychotherapy** (sy-ko-THER-a-pea) is the treatment of mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth.

losing weight, obsessive concern about weight, and depression suggest that a person may be a binge eater, but none of these patterns proves binge eating. People who are obese and fail to lose weight may seek help from a healthcare professional due to concern about health problems related to obesity. An evaluation that involves questions about family and personal history, physical health, eating and dieting habits, psychological concerns, and personality issues may reveal binge eating behavior. However, people with binge-eating disorder often lie about their eating habits.

Medical professionals do not agree on how to treat binge eating, but they do agree that the earlier binge eating is detected and treated, the easier it is to break the pattern and control bingeing behaviors. As of 2009, no drugs were available specifically to treat binge eating, but antidepressant medications* often proved helpful, although they are not without potential side effects. The anti-obesity drug sibutramine (Meridia) may also be prescribed. This drug enhances the sensation of fullness and helps to suppress hunger. It does, however, have potentially serious side effects.

Psychotherapy* can be used either alone or in combination with medical treatment to treat binge eating. Cognitive behavior therapy, a type of psychotherapy that is designed to confront and then change the individual's thoughts and feelings about his or her body and behaviors toward food, is one of the more effective psychotherapeutic approaches. Psychotherapy may also address issues of self-control, emotional expression, and the triggers that set off binges. Nutritional counseling and support groups can be helpful supplements to other forms of treatment. Since stress is a common trigger for binge eating, finding ways to reduce or control stress helps give some individuals better control over binge eating.

Can Binge Eating Be Prevented?

Binge eating cannot always be prevented, but there are ways of reducing the likelihood that it will develop. These include the following:

- Making it clear that all family members are loved and appreciated the way they are. Parents should not obsess over their children's weight or appearance.
- Not using or offering food for comfort in times of stress
- Becoming aware of stresses that could lead to a binge
- Eating regularly and avoiding getting too hungry
- Eating meals together as a family
- Avoiding extreme or fad diets
- Seeking help promptly for social or emotional situations that lead to low self-worth, alcohol or substance abuse, or depression

Bioterrorism

Bioterrorism is the intentional use of harmful biological, or living, organisms (bacteria, viruses, or toxins) to cause injury or death in humans, animals, or plants.

The Weapons of Fort Detrick

As of 2009, on the grounds of the U.S. military base at Fort Detrick, in Frederick, Maryland, a massive biodefense laboratory housed a cluster of sealed chambers built to contain the world's deadliest bacteria and viruses. Work to develop bioweapons began at Fort Detrick in 1943. By 1969 the United States had several weaponized agents, such as anthrax, botulism, and Venezuelan equine encephalitis, and at that time President Nixon ordered a stop to U.S. programs in bioweapons. In the early 2000s, during the Bush administration, the U.S. work in biological weaponry was begun again under the auspices of the National Biodefense Analysis and Countermeasures Center (NBACC). The activity involved making and testing small amounts of weaponized microbes* and perhaps genetically engineered viruses* and bacteria* and also called for team exercises that simulated (faked) attacks by hostile groups. Although the United States

* **microbes** (MY-krobes) are microscopic living organisms, such as bacteria, viruses and fungi.

* **viruses** (VY-rus-sez) are tiny infectious agents that can cause infectious diseases. A virus can only reproduce within the cells it infects.

* **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.

* **microorganisms** are tiny organisms that can only be seen using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

* **epidemic** (eh-pih-DEH-mik) is an outbreak of disease, especially infectious disease, in which the number of cases suddenly becomes far greater than usual. Usually epidemics are outbreaks of diseases in specific regions, whereas widespread epidemics are called pandemics.

* **anthrax** (AN-thraks) is a rare infectious disease caused by the bacterium *Bacillus anthracis*.

signed the Biological and Toxin Weapons Convention (BWC) agreement in 1972 that prohibits the use of such agents in global warfare, federal authorities in the early 2000s justified this military activity as defensive against others who might engage in bioterrorism.

What Is Bioterrorism?

Also known as biological warfare, bioterrorism is a form of warfare that uses specific microorganisms* to deliberately cause illness or death in people, animals, or plant crops. When organisms are used in this way, they become weapons.

The History of Bioterrorism

Biological warfare was not new to the 21st century; it has a long and deadly history. Persian, Greek, and Roman writers tell of the use of animal cadavers to contaminate water supplies. In 1155 at the battle of Tortona, Barbarossa dumped the corpses of soldiers into wells to poison the water. In 1346, the Mongols catapulted the corpses of plague victims into the port city of Kaffa (later called Theodosia, also spelled Feodosia, in Ukraine) on the Black Sea in the Crimea causing an epidemic; the city surrendered. During the French and Indian Wars in the 18th century in North America, the British gave blankets contaminated with smallpox to Native Americans, leading to an epidemic* of the disease among the Indians.

The Mongols and the British troops did not know that certain microorganisms cause disease. They only knew that disease was rumored to have spread from dead bodies or, in the case of smallpox, even from the blankets that touched victims. People did not know that microorganisms caused infectious disease until 1876, when the German scientist Robert Koch (1843–1910) proved that anthrax (AN-thraks) bacteria causes the disease anthrax*. After World War II the United States and other nations experimented with harmful biological organisms and various methods of transmitting them. In 1972 more than 140 countries, including the United States and the Soviet Union, signed the Biological Weapons Convention treaty to stop research and production of biological organisms as weapons of war. Although the Soviets signed the treaty, they continued a high-intensity program through the early 1990s. At least 60,000 people were employed at BioPreparat in the USSR in the research and production of biological weapons, and hundreds of tons of anthrax spores, smallpox, and plague were stored. When the Soviet Union dissolved in 1991, many of its scientists went to work for other countries.

Many people believe that well funded terrorists can afford to purchase equipment to build biologic weapons or that it will be sold when ordered. Some countries—especially those harboring or supporting known terrorist groups—continue to manufacture and store stockpiles of dangerous microorganisms. The use of bioterrorism to wage warfare is favored among terrorists or fringe groups because it requires few resources compared with traditional warfare and can potentially harm large numbers of people.

How Can Biological Agents Be Spread?

Deadly microorganisms (also known as biological agents or bioweapons) can be spread purposely through air or food and water supplies or by intentionally infecting someone with a highly contagious agent and letting that person circulate in a community, starting a massive wave of disease. The agent could be disseminated in any busy public place with the intention to infect many people who then travel to various destinations unintentionally spreading the disease.

Some organisms can be aerosolized (AIR-o-suh-lized), meaning that they are processed into the tiniest of particles, in a wet or dry form, that can be sprayed or released into the air so that large numbers of people can inhale them. Aerosolized organisms can be dispersed by aerosol containers, small crop-dusting planes, ventilation systems, or contamination of an object that can carry disease throughout a region, such as the anthrax-tainted letters received by various government and media employees in the United States in late 2001.

The handling and release of many of these organisms are dangerous and could be deadly for potential terrorists trying to use them. Some harmful biological organisms become weakened, however, as they spread into water or food supplies, making them less likely to cause significant harm to anyone who comes into contact with them. For example, a person would have to inhale thousands of anthrax spores* to become sick. A terrorist group trying to use anthrax as a bioweapon would have to use a highly concentrated form to be able to harm large numbers of people via contaminated packages or envelopes. Some bioterrorism agents, such as the smallpox virus, can be spread from person to person.

What Are Potential Biological Agents?

The Centers for Disease Control and Prevention (CDC) separates biological organisms into categories according to their virulence (VEER-uh-lents), or ability to cause disease. Potential biologic agents used for terrorism are divided into three categories.

Category A agents Category A or high priority agents can be easily disseminated or transmitted from person to person, cause high death rates, cause public panic and social disruption, and require special action for public health preparedness. Category A agents include the following:

- Anthrax: Anthrax is caused by the bacterium *Bacillus anthracis*. The bacteria form spores, which are found in soil and have a hard coating that allows them to survive in harsh environments. The disease is not contagious from person to person, and natural human infection is rare. There are three types of anthrax: cutaneous (kyoo-TAY-nee-us) anthrax, which infects the skin; inhalation (in-huh-LAY-shun) anthrax, which results from breathing in large numbers of concentrated spores; and gastrointestinal* anthrax, which is

* **spores** are a temporarily inactive form of a germ enclosed in a protective shell.

* **gastrointestinal** (gas-tro-in-TES-tih-nuhl) means having to do with the organs of the digestive system, the system that processes food. It includes the mouth, esophagus, stomach, intestines, colon, and rectum and other organs involved in digestion, including the liver and pancreas.

- * **lesions** (LEE-zhuns) is a general term referring to a sore or a damaged or irregular area of tissue.
 - * **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.
 - * **vaccine** (vak-SEEN) is a preparation of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.
 - * **toxin** is a substance that causes harm to the body.
 - * **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.
 - * **respiratory failure** is a condition in which breathing and oxygen delivery to the body are dangerously altered. This may result from infection, nerve or muscle damage, poisoning, or other causes.
 - * **antitoxin** (an-tih-TOK-sin) counteracts the effects of toxins, or poisons, on the body. It is produced to act against specific toxins, like those made by the bacteria that cause botulism or diphtheria.
 - * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.
 - * **shock** is a serious condition in which blood pressure is very low and not enough blood flows to the body's organs and tissues. Untreated, shock may result in death.
- caused by ingesting (eating) spores. An anthrax vaccine does exist but requires many injections and has side effects. Antibiotics may be given for prevention.
- **Smallpox:** Smallpox, a deadly viral infection, is caused by the variola virus and is found only in humans. Smallpox is the most contagious disease known and is transmitted through direct contact with the lesions* of an infected person, by inhaling infected droplets of moisture released into the air by coughing patients, and even by handling contaminated clothing that contains fluid from smallpox sores. The symptoms of smallpox are high fever, headache, backache, vomiting, and a painful rash of lesions that covers the face, arms, and body and often leaves scars. The disease is fatal in up to 30 percent of cases. In the early 20th century smallpox claimed millions of lives, but in 1980 the World Health Organization (WHO) declared the disease was eradicated from the human population following an aggressive worldwide vaccination* program. Routine vaccination against smallpox in the United States ended in 1972. The Centers for Disease Control and Prevention (CDC) keeps an emergency supply of smallpox vaccine* in the event that bioterrorism attacks with smallpox occur in the United States. In 2002, some vaccine-making companies received approval from the CDC to make an additional supply of the vaccine should it be needed on a more widespread basis.
 - **Botulism toxin:** Botulism is caused by the toxin* produced by the bacterium *Clostridium botulinum*. The bacteria can be inhaled or swallowed, or they can enter the body through a wound, but the disease is not contagious from person to person. The toxin produced by the bacteria affects the nervous system, causing nerve damage and temporary paralysis*, including the muscles for speaking, swallowing, and breathing. Botulism can lead to respiratory failure* and even death. The bacterium and its toxin could be used to produce bioweapons. An antitoxin* against the *Clostridium botulinum* toxin was available from the CDC as of 2009, but at that time there was no vaccine available.
 - **Plague:** Plague, caused by the bacterium *Yersinia pestis* (yer-SIN-ee-uh PES-tis), can take three forms: bubonic (byoo-BAH-nik), septicemic (sep-tih-SEE-mik), and pneumonic (noo-MOH-nik). Bubonic plague, the most common form, involves the body's lymph nodes*; septicemic plague enters the bloodstream, causing internal bleeding and shock*; and pneumonic plague infects the respiratory tract*. The last form is potentially important in biological warfare because *Yersinia pestis* bacteria can remain alive in the air for up to an hour, making aerosolized transmission possible.
 - **Yersinia pestis** is found in rats and other rodents in all parts of the world, including the United States. Plague can spread from infected rats to humans by direct bites or from fleas. The pneumonic form of

plague is the only kind that is contagious among humans; transmission takes place when someone has close contact with an infected person who is coughing or sneezing. Symptoms of the plague include fever, chills, headache, abdominal pain, painful and swollen lymph nodes (called buboes, BYOO-boze), chest pain, coughing, bloody sputum*, and septic shock*. As of 2009 there was no vaccine available in the United States, but antibiotics could treat the disease successfully if it was diagnosed early.

- Tularemia: Tularemia, also known as rabbit fever, is caused by the bacterium *Francisella tularensis* and is highly infectious. The disease is not contagious among humans, and human infection is rare. Tularemia can be transmitted through contact with infected animals or contaminated water or soil. The disease is potentially dangerous as a biological weapon because even small numbers (fewer than 10 to 50) of the aerosolized bacteria can cause serious disease, such as life-threatening pneumonia*. Symptoms include fever, chills, headache, cough, and extreme tiredness. Patients also may have painful ulcers on the skin; swollen, painful eyes; and abdominal pain. Early treatment with antibiotics may prevent or limit the severity of the disease.
- Hemorrhagic viruses: Ebola, a hemorrhagic viral disease, which means that it causes bleeding from body openings, is a virulent viral disease. Fatality rates range from 50 to 90 percent. The United States and Soviet Union have investigated the use of ebola for biological warfare. Another viral hemorrhagic fever virus was first discovered in Marburg, Germany. The Marburg virus had fatality rates ranging from 25 to 100 percent, and although a vaccine was in development, no treatments as of 2009 existed aside from supportive care. Hantavirus is transmitted through the air from infected rodent dung. This hemorrhagic virus affects the kidneys. As of 2009, there was no vaccine for this disease.

Category B Category B agents are moderately easy to disseminate, can cause moderate morbidity (rates of disease) and low mortality (rates of death), and require specific action from the CDC. The following are Category B agents:

- Brucellosis: Bacteria of the genus *Brucella* cause disease in different vertebrates such as sheep, goats, cattle, deer, elk, pigs, and dogs. Contact can infect humans and cause a range of symptoms similar to the flu, although central nervous system (CNS) and heart infections are common. Brucellosis is only one example of a zoonotic disease, one that can be passed from animals to humans.
- Tetanus toxin: The epsilon toxin of *Clostridium perfringens*, the organism that causes tetanus*, is a Class B toxin.
- Food safety threats: Bacteria such as salmonella, shigella, and *E. coli* could be used to deliberately contaminate foods as a bioterrorist act.

* **respiratory tract** includes the nose, mouth, throat, and lungs. It is the pathway through which air and gases are transported down into the lungs and back out of the body.

* **sputum** (SPYOO-tum) is a substance that contains mucus and other matter coughed out from the lungs, bronchi, and trachea.

* **septic shock** is shock due to overwhelming infection and is characterized by decreased blood pressure, internal bleeding, heart failure, and, in some cases, death.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

* **tetanus** (TET-nus) is a serious bacterial infection that affects the body's central nervous system.

- **Q fever:** Q fever is a rickettsial zoonotic disease caused by *Coxiella burnetii*. Animals affected are sheep, goats, and cattle, but humans can inhale particles contaminated with the organism, which is resistant to heat and highly infectious by the aerosol route. A single inhaled organism can cause illness.
- **Venezuelan Equine Encephalitis (VEE):** Horses contract VEE through bites from infected mosquitoes. It is highly infectious but not particularly stable when spread by aerosol, and it does not persist for a long period of time.
- **Psittacosis:** Psittacosis, also called parrot fever, is a bacterial disease caused by *Chlamydia psittaci*, and it is transmitted from birds to people when people inhale dried bird feces. This disease could be easily aerosolized as a biowarfare agent.
- **Water supply threats:** Cholera is a well-known diarrheal disease caused by *Vibrio cholera*, acquired through drinking contaminated water. It could be spread by aerosols, but more likely it would be through contaminated food or water supplies.
- **Ricin toxin:** Ricin toxin is made from castor beans. It has high terrorist potential due to its ready availability, easy processing, and widespread reporting.

Category C Category C are third-priority agents that may be easily available and could be genetically engineered to have high potential for a public health impact. Examples are as follows:

- **Nipah virus:** Nipah virus infects pigs and humans, and in people it can cause a sometimes fatal form of viral encephalitis. The transmission is not understood, but it may be transmitted from pigs to humans by infected mosquitoes.
- **Hantavirus:** Hantavirus refers to a group of viruses transmitted to humans through the saliva or excrement of rodents, such as field mice, and which causes hemorrhagic fever and pneumonia.
- **Multi-drug resistant tuberculosis:** These forms of tuberculosis are resistant to one or more antibiotics and are highly contagious.

How Can People Protect Themselves?

Throughout the late 20th century, most biological defense strategies were geared to protecting soldiers on the battlefield rather than ordinary people in cities. In 1999 the University of Pittsburgh deployed the first automated bioterrorism detection system, called Real-Time Outbreak Disease Surveillance (RODS). RODS was designed to collect data from places such as hospital clinics, laboratories, 911 calling centers, veterinary clinics, ranching and feedlot operations, food processors, drinking water systems, school attendance records, and over-the-counter drug sales and use them to detect a terrorist event at the earliest possible moment. Following the terrorist incidents and anthrax scare of 2001, the Bush administration

proposed that billions of dollars be channeled into improving national and state resources with biosurveillance systems.

The Office of Homeland Security was formed in late 2001 to oversee the government's preparation for and defense against potential acts or threats of bioterrorism that might occur in the United States. The Bush administration authorized an increase in federal stockpiles of antibiotics to treat anthrax, plague, tularemia, and other potential bio-weapons, as well as the production of additional supplies of smallpox vaccine. Research continued in the development of better medical treatment and the creation of vaccines to protect people against biological agents. Medical professionals and emergency response teams were trained to diagnose diseases and respond quickly to epidemics that could result from bioterrorism. The following situations were believed to indicate the possibility of an outbreak:

- Notice of a disease or strain that is not normally within the population
- Patterns of resistance to antibiotics
- Evidence of symptoms among patients that is not typical of any disease or disorder
- Distribution that is inconsistent with the typical geographical location of a disease; for example, a tropical disease occurring in a northern city
- Other inconsistent elements such as a large number of cases, high illness or death rates, and changes from normal disease occurrences

Researchers experimented with high-tech devices such as tiny electronic boxes that contain living nerve cells to detect the presence of bacterial toxins and fiber-optic tubes lined with antibodies coupled to light-emitting molecules that can identify specific pathogens, such as anthrax. The technology of genetic engineering could produce a bacterial agent to target a particular genetic group or geographical population.

The Biological and Toxin Weapons Convention established in 1972 was signed by 162 nations as of 2009, and efforts were made to enforce the treaty. However, although diplomats might agree, some worried that so-called rogue nations (nations that in their international actions do not respect other nations) might resort to biological warfare in order to threaten and inflict harm, incite mass panic, and disrupt society.

Bipolar Disorder

Bipolar (by-POLE-ar) disorder is a condition in which periods of extreme euphoria, called mania (MAY-nee-uh), alternate with periods of severe depression*. Bipolar disorder is sometimes also called manic (MAN-ik) depression.*

What Is Bipolar Disorder?

Bipolar disorder is a type of mood disorder*. People with bipolar disorder experience two (thus the prefix “bi”) extremes in mood; they have periods of extremely elevated mood and boundless energy that are followed by periods of depression. Bipolar disorder can range from severe to mild. Different forms of bipolar disorder are distinguished from one another by the severity of the mood extremes and how quickly mood swings take place.

For example, full-blown bipolar disorder, or bipolar I, involves distinct manic episodes followed by depression. People with this form of bipolar disorder often experience trouble sleeping, changes in appetite, psychosis*, and thoughts of suicide.

In bipolar II, the mania is less severe and the person does not lose touch with reality but does have periods of depression that can be as severe as the depression in bipolar I disorder. Some people also experience mixed states in which symptoms of mania and depression exist at the same time; this form may be more common in younger individuals and children. Other people may experience a form of bipolar disorder in which there is a rapid cycling between “up” and “down” moods with few,

if any, normal moods in between. Cyclothymia is a condition in which there are mood swings but with milder highs and lows.

Who Has Bipolar Disorder?

Ernest Hemingway, winner of the Nobel Prize in literature, showed signs of having bipolar disorder. So did presidents Abraham Lincoln and Theodore Roosevelt and the composer Ludwig von Beethoven. All of these men were intelligent, creative, successful individuals, but they all fought the two faces of bipolar disorder. At one moment they would be on top of the world, full of ideas and creative and physical energy. Then a few days, weeks, or months later they would sink into the despair and lethargy of depression.

Bipolar disorder affects about 1 out of every 100 people, or at least 3 million Americans. It affects people of all races, cultures, professions, and income levels. Men and women are affected at equal rates. Bipolar disorder tends to run in families and is believed to have an inherited genetic component. Studies of twins show that if one member of a pair of identical twins* (twins who have identical genes*) has bipolar disorder, the other twin has about a 70 percent chance of also having the disorder. If one of a pair of fraternal twins (twins who do not have identical genes, but do have many of the same genes) has bipolar disorder, the risk of the other twin having it is only 15 to 25 percent.

What Are the Symptoms of Bipolar Disorder?

Bipolar disorder has two distinctive sets of symptoms.

Depression During the depression phase, a person may experience the following:

- persistent feelings of sadness and anxiety
- feelings of worthlessness or hopelessness
- loss of interest in activities that were formerly enjoyable
- fatigue and decreased energy
- sleeping too much or too little; difficulty getting up or going to sleep
- eating too little or too much
- unexplained periods of restlessness, irritability, or crying
- difficulty concentrating or remembering things
- difficulty making decisions
- thoughts of suicide or suicide attempts
- increased difficulties in relationships with friends, family, teachers, or parents
- alcohol or substance abuse

Mania During the manic or euphoric stage, a person may experience the following:

▲ Rock star Kurt Cobain (1967–1994), seen here at a December 13, 1993, concert, suffered from bipolar disorder. *AP Images.*

* **identical twins** are twins produced when a single egg from the mother is fertilized and divides to form two separate embryos of the same sex with nearly identical DNA.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **Attention Deficit Hyperactivity Disorder** or ADHD, is a condition that makes it hard for a person to pay attention, sit still, or think before acting.

* **anxiety** (ang-ZY-e-tee) can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person's physical or mental well-being.

* **separation anxiety** is the normal fear that babies and young children feel when they are separated from their parents or approached by strangers.

* **psychologists** (sy-KOL-o-jists) are mental health professionals who treat mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth. Psychologists also study the brain, behavior, emotions, and learning.

* **psychiatrists** (sy-KY-uh-trist) are medical doctors who have completed specialized training in the diagnosis and treatment of mental illness. Psychiatrists can diagnose mental illnesses, provide mental health counseling, and prescribe medications.

- high energy; ability to go with little sleep for days without feeling tired
- severe mood changes from extreme happiness or silliness to irritability or anger
- overinflated self-confidence; unrealistic belief in one's own abilities
- talking much more than usual; talking that is hard to stop
- increased activity, restlessness, distractibility, and the inability to stick to tasks
- racing, muddled thoughts that cannot be turned off
- decreased judgment of risk and increased reckless behavior
- substance abuse, especially cocaine, alcohol, and sleeping pills
- extremely aggressive behavior

How Is Bipolar Disorder Diagnosed?

Bipolar disorder usually begins in early adulthood, although many experts assert that younger children and teens may also have the disorder. Some children who are diagnosed with Attention Deficit Hyperactivity Disorder* (ADHD) may actually have bipolar disorder or may have both disorders. These children not only have symptoms of ADHD but often also have symptoms such as significant and sustained tantrums, periods of anxiety* (including separation anxiety*, periods of irritability, and mood changes. With many children, mood states change rapidly and without warning. Children with bipolar disorder are studied by psychologists* and psychiatrists* who previously did not believe that such disorders occurred in early childhood.

Doctors often ask family members about the person's symptoms, as people with bipolar disorder are often not aware of the changes they are experiencing. To be diagnosed with bipolar disorder, the person must have had at least one period of mania. However, because people with bipolar disorder spend more time in depression than mania, the diagnosis can easily be missed, and it often takes a long time before bipolar disorder is correctly diagnosed. Often after the first episode of mania or depression, five or more years may pass before another manic or a depressive period occurs. Despite the stretches of normal moods, bipolar disorder does not go away. Instead, the time between mania and depression gets shorter and shorter, and the symptoms may become more severe. Not infrequently, bipolar disorder can lead to psychosis or to suicide. About 19 percent of people who have required hospitalization for bipolar disorder commit suicide.

How Is Bipolar Disorder Treated?

Many people with severe mood swings can be helped by treatment. The drug lithium has been one of the medications of choice for treating bipolar disorder, and it is often very effective. Other medications are also helpful in controlling mood swings. These include various antiseizure medications (for example, valproate and carbamazepine) and antipsychotic medications (for example, aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone).

People with bipolar disorder need to continue to take their medications even when they feel normal to prevent the reoccurrence of mood swings.

Living with Bipolar Disorder

Living with a loved one who has bipolar disorder can be very hard on family members.

Perhaps the most effective step that family members can take is help the person with the disorder to get treatment and encourage him or her to stick with the treatment. Family members can also learn more about the warning signs that suggest a new mood episode may be coming and encourage the person to seek medical care to try to prevent a full-blown episode. Many family members find joining a support group or participating in family therapy is helpful in understanding and managing the impact of this difficult problem.

People who are taking about suicide need emergency help. Many telephone books list suicide and mental health crisis hotlines in their Community Service sections and help can be obtained by calling emergency services (911 in most communities).

Birth Control *See Pregnancy.*

- * **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.
- * **anencephaly** (AN-en-SEF-uh-lee) is a condition present at birth in which most of the brain is missing.
- * **congenital** (kon-JEH-nih-tul) means present at birth.
- * **genetics** (juh-NEH-tiks) is the branch of science that deals with heredity and the ways in which genes control the development and maintenance of organisms.
- * **nucleus** is the part of the cell that contains its genetic information.
- * **chromosomes** (KRO-mo-somz) are threadlike chemical structures inside cells on which the genes are located. There are 46 (23 pairs) of chromosomes in normal human cells. Genes on the X and Y chromosomes (known as the sex chromosomes) help determine whether a person is male or female. Females have two X chromosomes; males have one X and one Y chromosome.
- * **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

Birth Defects and Brain Development

Birth defects are abnormalities in the body structure or chemistry that occur while the fetus is developing in the mother's uterus. Hereditary or genetic causes, environmental influences, or a combination of factors may affect the embryo or fetus before it is born. Sometimes, the cause of a birth defect is unknown.*

What Are Birth Defects?

In 1994 and 1995, a number of infants along the Rio Grande in Texas and Mexico were born without a brain, a condition called anencephaly (an-en-SEF-a-lee). Some professionals suspected that the birth defects occurred when mothers were exposed to pollution in the environment. Although in the early 2000s there continued to be many unknowns about causes of birth defects, scientists knew that the human embryo is exceedingly vulnerable to drugs, viruses, and radiation during the first several months when critical systems are forming.

Some birth defects are inherited from parents, and others are acquired through the mother's contact with the environment or with disease. According to the March of Dimes, 3 to 5 percent of babies born in the United States have some type of birth defect. Some birth defects, such as anencephaly*, occur infrequently. Others, such as some congenital* heart defects, are more common. Some hereditary defects are more common in certain populations than in others.

Genetics, Embryology, and Birth Defects

The development of powerful electron microscopes has enabled the rapid increase in investigations in genetics* and embryology in the twenty-first century. Traditionally, geneticists have studied genes and chromosomes, and embryologists have studied the development of fetuses. However, in the early 2000s, areas of research combined genetics and embryology to understand why individuals develop birth defects. Study of the interplay between genetic and environmental factors of the uterus allowed scientists to understand these developmental abnormalities in humans.

Genetics In the nucleus* of most cells about six feet of deoxyribonucleic acid (DNA) are packaged into 23 pairs of chromosomes*, threadlike structures inside cells on which the genes* are located. Each gene is a segment of DNA that holds the recipe for making a specific molecule, usually a protein. These recipes are spelled out in varying sequences of the four chemical bases in DNA: adenine (A), thymine (T), guanine (G), and cytosine (C). A is always paired with T; G is always paired with C. The two are called base pairs. The DNA molecule looks like two ladders with

a side taken off and twisted together; the rungs of the ladders are the base pairs. Millions of these base pairs can make up a single gene. These genes direct the growth and characteristics of the organism through the production of chemical proteins. Proteins are made up of amino acids and are the essential components of all organs and chemical activities. Their functions depend on their shape and are determined by the 30,000 genes in the cell nucleus. The complete makeup of the genes of an individual is called the genome. Of course, with so many chemical reactions going on, various problems may develop.

Embryology The origin of the genetic material or DNA that a person inherits begins in the reproductive systems of parents. Sperm and egg (ova) or cells, called gametes carrying half of the parent's genes are created through a process called meiosis* or reduction division. In this complex process, the parent cells in the testes (sperm) of the male and the ovaries of the female (ovum) reduce their DNA by half so that they can join together and make a fertilized egg that contains one gene from the mother and one gene from the father. Human body cells or somatic cells have the full set of 46 chromosomes. However, each gamete has only half that number, or 23. In males, meiosis takes place in the testicles and occurs about every 74 hours, beginning at about 12 to 13 years of age and continuing through life. Millions of sperm are produced daily, but as many as 20 percent may be defective. A more complex process of meiosis occurs in females, beginning about the fifth month after conception when immature ova are formed. The ova remain in the premature form in the ovaries until hormones signal the release. The egg does not complete its development until conception when chemical changes occur as the main part of the sperm enters the ovum. Unlike the male, the female is born with all the ova she will ever have. At fertilization or conception, the 23 chromosomes of the father and 23 of the mother create a completely new individual with 46 chromosomes and a unique genetic makeup.

Scientists have come a long way in understanding the development of the embryo *in utero*, the Latin term for "in the uterus". This knowledge assists their understanding of genetic and birth defects. In the early stages of development, the fertilized egg (now called a zygote) divides to form a blastocyst; some of these cells become the three layers of the embryo:

- Ectoderm: the outer layer that gives rise to the hair, nails, skin, sense organs, brain, and spinal cord
- Mesoderm: the middle layer that gives rise to bones, muscles, circulatory and most of the reproductive organs
- Endoderm: the inner layer that eventually links the body cavity, the respiratory system, digestive tract, and many glands

During the first week the ovum that has been fertilized in the fallopian tube reaches the uterus and implants in the uterus. At about 12 days after conception, a band called the primitive streak appears along the back of the mass of cells; the neural tube, which develops into the spinal cord

▲ Butch Lumpkin uses an extra long driver to hit a tee shot at the BMW Charity Pro-Am on May 16, 2008. *Stan Badzi/PGA Tour/Getty Images.*

* **meiosis** (my-OH-sis) is the process of reduction division in which the number of chromosomes per cell is cut in half.

* **sickle-cell disease** is a hereditary condition in which the red blood cells, which are usually round, take on an abnormal crescent shape and have a decreased ability to carry oxygen throughout the body.

and brain, begins to develop at about this time and continues to develop throughout pregnancy. At about five weeks the general form of the human body becomes evident with traces of hands, feet, clavicle, and lower jaw. During the first 12 weeks of development, the cells of the embryo are rapidly dividing and becoming muscles, bones, and organs. Although during the first three months, the embryo is most vulnerable, at any time during the remaining six months, the fragile fetus is susceptible to many factors that affect development.

How Do Hereditary Factors Cause Birth Defects?

Hereditary birth defects are caused when a mistake is made as DNA divides and forms a template to transcribe copies. Then a process called translation enters in to create the final product. Many disorders of genetic origin occur in translation; the final product will be a mutation or change from the normal final product. One might relate the process to a group of workers on an assembly line making peanut butter and jelly sandwiches. Each person has a job to do: Unwrapping the loaf of bread, spreading the peanut butter, spreading the jelly, putting the top and bottom slices together. The process moves like clockwork, but if the jelly spreader drops his knife and misses out on his job, no jelly will be on the next sandwich. This simple illustration shows how one small slip can change the outcome of a product. Likewise, even small changes in the primary structure of a protein may affect the protein's properties. For example, in sickle-cell disease*, a single molecule of valine replaces the glutamic acid molecule that makes hemoglobin, the protein that carries oxygen in the red blood cells. The tiny error, one incorrect amino acid in a series of 287 amino acids, causes a change in the chemistry of the hemoglobin molecule that results in a deformity in the red blood cell and causes all of the problems of sickle-cell anemia. When chemist Linus Pauling (1901–1994) discovered this fact in the early 1950s, the science of molecular biology began.

Some diseases develop through random mutation to act as protection against prevalent conditions in certain areas. In the 1940s Anthony Allison from Kenya studied the blood of people living in malarial areas of Africa. He found that those individuals who had sickle cells, and even those with only one defective gene and therefore have the sickle-cell trait and not the disease, were less likely to contract malaria. Thus those individuals with a mutant gene have a survival advantage when they live in malarial areas. This correlation explains why the mutant gene is so prevalent in those areas. However, the gene was carried to the United States by slaves and persists in the U.S. population in the early 2000s even though malaria is extremely rare in the United States. Likewise, Tay-Sachs disease evolved among the Ashkenazi Jews from a single town in Poland. The mutations offered the carriers protection against tuberculosis but had a lethal effect on some of the population. Current incidences of sickle-cell disease and Tay-Sachs disease are a high price to pay for diseases of the past. Fortunately, because of genetic testing and counseling, Tay-Sachs disease is very rare in the early 2000s. Because of preimplantation genetic

diagnosis, fertilized ova that lack the mutated gene for sickle cell can be selected for implantation thus ensuring a normal child.

Genetic birth defects can be dominant or recessive single-gene traits, X-linked disorders, multigene traits, or aberrations in chromosomes.

- **Single-gene dominant or Mendelian inheritance.** The simplest patterns of birth defect inheritance are named for the Austrian monk Gregor Mendel (1822–1884), who observed them in the nineteenth century. In Mendelian inheritance, traits (both normal and defects) can be transmitted by way of dominant or recessive genes. A child inherits two copies of each gene, one from the mother and one from the father. If a defective gene is dominant, a child who inherits even one copy will have the defect. That is because the defective copy “dominates,” or overwhelms, the normal copy inherited from the other parent. Many of these defects may not show up until later life. Examples are Huntington’s disease and Lou Gehrig’s disease (nervous system disorders). Marfan syndrome is characterized by tallness and heart disorders, and certain kidney and cholesterol diseases.
- **Single-gene recessive traits.** According to Mendelian law, if a defective gene is recessive, the child must inherit two defective copies—one from the mother and one from the father—in order to have the defect. A person who inherits only one defective copy is healthy but can pass the defective copy on to his or her own children. Many of these disorders are rare but can be traced to specific mutations in the genes that produce enzymes. For example, thalassemia, a condition common in populations bordering the Mediterranean Sea, affects the hemoglobin. Cystic fibrosis affects the lungs and pancreas and is one of the most damaging of genetic disorders.
- **X-linked disorders.** Genes located on the X chromosome (the X and Y chromosomes determine the sex of an infant: two X chromosomes produce a female and an X and a Y chromosome produces a male) can cause birth defects. Such abnormalities are said to be X-linked. Hemophilia, a blood disorder; X-linked severe combined immunodeficiency (SCID), an immune disorder; Duchenne muscular dystrophy; and color blindness are examples of X-linked birth defects.
- **Multigene traits.** Interaction of several genes can cause certain defects. Many of these occur later in life and include Parkinson’s disease, epilepsy*, and Alzheimer’s disease.
- **Chromosome abnormalities.** Extra, missing, incomplete, or misshapen chromosomes cause some birth defects. Down syndrome, a condition caused by three copies of chromosome 21 or Trisomy 21, is one of the most common birth defects. Down syndrome produces mental retardation*, short stature, and distinctive facial features. Defects involving the sex chromosomes can produce problems in sexual development, including sterility, which is an inability to have children.

* **epilepsy** (EP-i-lep-see) is a condition of the nervous system characterized by recurrent seizures that temporarily affect a person’s awareness, movements, or sensations. Seizures occur when powerful, rapid bursts of electrical energy interrupt the normal electrical patterns of the brain.

* **mental retardation** is a condition in which people have below average intelligence that limits their ability to function normally.

- **Inborn errors of metabolism.** Metabolic disorders are related to faulty genes that control chemical reactions of the body, producing energy from food or supporting the growth of the body. The two most common metabolic disorders are phenylketonuria (PKU), a disorder in which the child cannot handle the chemical phenylalanine; the child must be placed on a special diet for life. The second metabolic disease is hypothyroidism in which the thyroid gland under produces hormones necessary for body functions.

How Do Environmental Factors Cause Birth Defects?

Starting at conception, the developing embryo is susceptible to many factors that affect development. Birth defects also can be caused by environmental factors, either alone or together with faulty genes. Environmental factors include the environment in the mother's uterus, or womb, and the possible influence of poisons in the earth's environment. Following are some common types of serious brain defects and their possible causes:

- **Anencephaly.** This fatal defect occurs when the neural tube fails to close during early development, and the child is born with a missing brain or only the parts that control processes such as breathing. Although the exact cause is not known, the condition has been linked to the nutrition of the mother and lower than normal levels of the B vitamin folic acid; pollution is also suspected.
- **Spina bifida.** In this disorder the failure of the neural tube to close properly causes an opening in the spinal cord and spinal column. This birth defect is one of the most common involving the nervous system and may be related to folic acid deficiency.
- **Cerebral palsy.** Cerebral palsy causes damage to the motor control centers of the young developing brain and can occur during pregnancy (about 75%), during childbirth (about 5%), or after birth (about 15%) up to about age three. However, about 80 percent of causes are unknown but may be traced to infection, malnutrition, and head trauma.

During the first weeks of embryonic development, exposure to toxins may disrupt the development of the offspring and cause serious birth defects. Certain agents may have a teratogenic effect on the embryo. The word "teratogen" literally means "giving rise to monsters." There are several known teratogens:

- **Alcohol.** Women who consume excessive amounts of alcohol during the early stages of pregnancy risk having babies with fetal alcohol syndrome (FAS). Children with this disorder may have various defects in growth, facial appearance, and mental ability.
- **Tobacco.** Nicotine from cigarette smoke in the mother's bloodstream is passed to the developing fetus and causes a variety of problems, including low birth weight, birth defects, and sudden

infant death syndrome (SIDS). Also, smoking causes the oxygen level of the mother to fall causing a condition called fetal hypoxia, which may damage the developing fetus.

- **Medications and street drugs.** Illegal drugs such as amphetamines, cocaine, and heroin may damage the developing central nervous system of the fetus and lead to birth defects. Even prescription and over-the-counter drugs can affect the fetus. Thalidomide was prescribed to pregnant women to combat morning sickness, and the drug caused babies to be born with defective limbs. Accutane, a medication given for severe acne, was linked to birth defects.

Environmental hazards may act as teratogens. Exposure to chemicals or other toxins in the environment may contribute to birth defects. Pregnant women should avoid weed killers, insecticides, and even certain household cleaning agents. An increase in birth defects has occurred after atomic bomb attacks, bomb tests, and use of certain munitions, such as the following:

- **Atomic bomb blasts.** Extensive lab tests have shown that human DNA exposed to radiation may break apart and rejoin in patterns differing from the original forms, causing mutations. Stages of embryonic development are sensitive to radiation. In Nagasaki and Hiroshima, where the United States dropped the atom bomb in World War II, the probability of severe mental retardation is strongly associated with the degree to which the mother was exposed to radiation. Women exposed during the third and fourth months had children with deformities such as facial clefts or too many fingers and toes; interestingly, embryos in other stages of development did not exhibit deformities. In the late 1950s studies of IQ tests showed survivors lost approximately five points and performed at a decreased level in school.
- **Dioxin or agent orange.** Agent orange was designed to defoliate the jungle, thus destroying coverage to Vietcong guerrilla soldiers in the Vietnam conflict. The virulent poison killed the rainforest and then got into the food chain, which led to a number of birth deformities. In Vietnam, some 150,000 children with birth defects can be traced to the parents' exposure to Agent Orange or to consuming dioxin in contaminated food and water.
- **U-238 or DU.** Depleted uranium (DU) or U-238 is a toxic, heavy metal byproduct that is used in munitions, ballasts for airplanes, tank armor, and other products. Since 1991 cancer rates in Iraq have risen tenfold, and the number of birth defects has multiplied fivefold. Internalized DU has been found to induce DNA damage and cancerous lesions in cells that make up bones in the body.
- **Bombing practice in Vieques.** Since 1941 Vieques in Puerto Rico has been used by the U.S. Navy for target practice. When a DU round is fired, 60 percent of its mass ends up as microscopic aerosol particles in the air, which can be carried to other areas. Breathing

Thalidomide and Phocomelia

In Europe in the late 1950s and early 1960s thalidomide, a sedative, was prescribed for pregnant women until it was linked to phocomelia (fo-ko-MEE-lee-ah), a birth defect in which the arms and legs had a flipper-like appearance and were very short and underdeveloped. If taken in the early months of pregnancy, thalidomide affects the developing middle stem cell layer when the limb buds are forming. Twelve thousand children with deformities in 46 countries were traced to thalidomide. Fortunately for Americans, thalidomide was never sold in the United States because Dr. Frances Kelsey of the Food and Drug Administration refused to approve it, insisting thalidomide's safety had not been proven.

the material can cause a host of problems, including possible birth defects. The United States is not the only country to use DU munitions; 18 countries including Israel, Saudi Arabia, Turkey, and Taiwan have bought them.

What Diseases Cause Birth Defects?

A number of infectious diseases may also affect the developing embryo and fetus. Some of the diseases may not affect the mother but can be passed on to the unborn fetus. Infections that can have major effects on the fetus include the following:

- **Cytomegalovirus (CMV).** This common virus may pass from mother to fetus and usually causes few symptoms in the mother. However, the developing fetus may develop microcephaly or an abnormally small brain and head size and have a number of central nervous system (CNS) problems.

THE UNITED STATES AND THE WORLD

- One of every 33 babies in the United States is born with a birth defect.
- Each year 7.9 million children (6% of total births) are born with serious birth defects of genetic or partial genetic origin.
- Each year hundreds of thousands additional children are born with non-genetic birth defects.
- An estimated 3.3 million children under the age of five years of age die of birth defects each year. Of those, about 95 percent live in countries with low or middle income.
- More than 28 million people worldwide live with birth defects, and about 94 percent live in countries with low or middle income.
- Birth defects are the leading cause of infant mortality in the United States. In 2003, 5,621 children died before their first birthdays because they had one or more birth defects. That number is 20 percent of all children who died under the age of one year.
- More than a million worldwide each year have heart defects, the most common birth defect.
- Neural tube defects, including spina bifida, total nearly 324,000 births worldwide yearly.
- The death rate from birth defects in the United States dropped 37.7 percent between 1979 and 1997. One reason for the decrease is improved medical care for infants with birth defects.
- Children with birth defects who survive their first year still may die of complications from the defects later in life. In 1997, 11,912 people of all ages died of birth defects, with only about half under the age of one year.

- **Syphilis.** This sexually transmitted bacterial disease can be passed to the fetus. The risk is 60 to 80 percent if the mother is infected and does not receive treatment that the bacteria will affect the CNS, causing meningitis or hydrocephalus*.
- **Rubella (German measles).** An expectant mother who has not been vaccinated for rubella may pass the virus to the developing fetus, in which the brain and CNS are affected. The child may have cerebral palsy or mental retardation, among other problems. Rubella can cause deafness, blindness, and heart defects in the newborn.
- **Toxoplasmosis.** This infection is caused by a parasite found in undercooked meat and in cat stools. While there are no symptoms in the mother, the fetus is affected. The child may develop learning disabilities, movement problems, and vision loss. Pregnant women should avoid changing cat litter boxes.

* **hydrocephalus** (HY-droe-SEF-uh-lus) is a condition, sometimes present at birth, in which there is an abnormal buildup of fluid within the skull, leading to enlargement of the skull and pressure on the brain.

How Do Doctors Diagnose Birth Defects?

Some birth defects can be diagnosed while the unborn child is still in its mother's womb. A procedure called ultrasound, which uses sound waves to produce an image of a fetus on a screen, can detect some malformations. For example, a defect called spina bifida, in which a part of the spinal cord is exposed, can be discovered by ultrasound.

In a procedure called amniocentesis (am-nee-o-sen-TEE-sis), a small sample of fluid surrounding the fetus is removed through a needle and examined. This test is useful in detecting inborn metabolic (body chemistry) defects and abnormalities in the chromosomes.

Many birth defects can be diagnosed by a doctor's physical examination of a newborn baby. Other tests, including x-rays, may be ordered if doctors suspect a birth defect; blood tests can detect certain disorders of the blood or body chemistry. Many infants with defects can develop normally if they receive prompt treatment.

Bladder Cancer

Bladder cancer occurs when cells in the bladder, the muscular sac that stores urine, divide without control or order. Bladder cancer sometimes spreads to other parts of the body.

What Is Bladder Cancer?

The bladder is the hollow muscular sac in the lower abdomen* that stores urine, the liquid waste produced when the kidneys filter the blood. Cancer usually begins when cells on the surface of the bladder wall begin dividing without control or order, forming a growth called a tumor. Over time, this tumor can grow through the bladder wall and spread to nearby organs.

Each year, about 53,000 Americans—38,000 men and 18,000 women—learn that they have bladder cancer. Among men, it is the fourth

The bladder is the hollow muscular sac in the lower abdomen that stores urine (the waste produced when the kidneys filter the blood) prior to discharge from the body. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

leading cause of cancer. In women, it ranks eighth. Bladder cancer usually strikes between the ages of 50 and 70. Early symptoms typically include blood in the urine and frequent or painful urination. Other conditions can also cause these symptoms, making a visit to a doctor necessary.

Is There an Association between Smoking and Bladder Cancer?

Cigarette smoking is most commonly associated with lung cancer, but smokers are also two to three times more likely than nonsmokers to develop bladder cancer. Cigarette smoke contains harmful cancer-causing chemicals called carcinogens* (kar-SIN-o-jenz). People can greatly reduce their risk for bladder cancer by quitting smoking or not starting in the first place.

Some factories and industrial plants release chemical carcinogens, which may explain why bladder cancer is more common in urban areas than rural. Exposure to certain kinds of chemicals in the workplace also appears to increase risk, according to the American Cancer Society. These chemicals can be found in the rubber, chemical, and leather industries, as well as hairdressers, machinists, metal workers, printers, painters, dry cleaners, textile workers, and truck drivers. That does not mean that most workers in these professions will develop cancer. In fact, most will not. They should, however, be aware of their risk and take precautions to decrease their exposure to chemical carcinogens.

In many cases, though, bladder cancer seems to develop without an apparent specific cause.

* **carcinogens** (kar-SIH-no-jenz) are substances or agents that can cause cancer.

* **urethra** (yoo-REE-thra) is the tube through which urine passes from the bladder to the outside of the body.

* **biopsy** (Bl-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **chemotherapy** (KEE-mo-THER-ah-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

How Is Bladder Cancer Diagnosed and Treated?

Diagnosis When medical professionals want to evaluate someone for bladder cancer, they usually perform a physical exam and test a urine sample to check for blood and cancer cells. They also can insert a thin, lighted tube called a cystoscope (SIS-to-skope) through the urethra* to examine the lining of the bladder. If cancer is a possibility, they perform a biopsy*, the typical procedure involved when any type of cancer is suspected. A biopsy is the removal of a tissue sample, which is then examined under a microscope. The presence of cancer cells indicates the disease is present.

If cancer is found, doctors typically want to know the depth of penetration, which is a measure of how far the cancer has moved beyond the surface of the bladder; they also want to know whether the cancer has spread to other locations in the body. Both findings have an impact on prognosis, as well as on treatment options. To determine depth of penetration and cancer spread, medical professionals may perform tests that create images of the inside of the body. These include the following:

- **Intravenous pyelogram (IVP):** This is a sequence of x-rays of the kidneys and bladder performed following the injection of dye into a vein.
- **CT scans:** Also called computerized tomography scans, these are series of detailed pictures of areas inside the body and are created by a computer connected to an x-ray machine.
- **MRIs:** Magnetic resonance images are generated through a procedure that uses a large magnet linked to a computer.
- **Ultrasound:** These images are created by bouncing sound waves off tissues inside the body and converting the resulting echoes into pictures.
- **Bone scans:** Radioactive material is injected, and it eventually collects mostly in abnormal bones, and then a scanner detects these areas and images of the bones are created on a computer screen.
- **Chest x-rays:** These x-rays show abnormalities in the lung, heart, aorta, and the bones in the area between the throat and abdomen..

Treatment The usual treatments for bladder cancer are surgery, radiation therapy, chemotherapy*, biological therapy, or a combination of these. The selected treatment usually depends upon how much of the bladder is involved and whether the cancer has spread to other parts of the body. In almost all cases, a surgeon removes tumors and surrounding tissue that is affected.

If the tumors are only on the surface of the bladder wall, the doctor can burn them away through a process called fulguration (ful-gu-RAY-shun), which involves inserting a tool with a small wire loop on the end through the urethra.

If the cancer has grown into or through the bladder's muscular wall, a surgeon will remove part or all of the organ in a procedure called

cystectomy (sis-TEK-to-mee). Sometimes, nearby reproductive organs need to be removed as well.

Radiation therapy is another common treatment for bladder cancer. Internal radiation involves placing a small container of radioactive material, called a radiation implant, directly into the bladder to destroy the cancer cells. Radiation also can come from a machine outside the body that focuses high-energy rays on the affected area to kill cancer cells. Sometimes a patient receives radiation before or after surgery or along with anti-cancer drugs called chemotherapy.

Biological therapy, also known as immunotherapy, is a form of treatment that attempts to trigger the body's own disease-fighting immune system against the cancer.

Living with Bladder Cancer

People who have part or all of their bladder removed often have to make some adjustments in their activities of daily living. When people lose just part of the bladder, they may find that they need to go to the bathroom more frequently. When the entire bladder is taken out, they must learn a new way of emptying the urine from their bodies.

Urostomy Upon removing the bladder, surgeons construct a new passageway to take over the bladder's function in a procedure called a urostomy. They might use a piece of the small intestine to create a tube that carries the urine to an opening, called a stoma, in the stomach area where the urine can drain into an attached bag. The patient must empty the bag periodically. A later method uses part of the small intestine to create a storage pouch inside the body, collecting the urine there. Patients learn to use a tube called a catheter to drain the urine through either a stoma or the urethra. In some cases, patients may receive a replacement bladder called a neobladder, which is a pouch made out of intestinal tissue that patients can empty through muscular control. The surgery for neobladders is complex and may result in side effects, including incontinence (the inability to control urination).

Special therapists work with bladder cancer patients to teach them to care for themselves and their stomas after surgery. These therapists can answer questions, address emotional and physical concerns, and suggest sources of additional information about urostomy. People who have a urostomy usually can resume all the activities they enjoyed before the operation.

Blindness

Blindness is the absence of all or most vision.

Corrine's Story

Corrine tried to imagine how she would describe a bird to her sister Amy, who might never be able to see one. She could say that it is small, that it has feathers, and that it sings. At least those are the characteristics her sister can feel and hear. But how could she describe the red of a male cardinal and distinguish it from the reddish-brown of a female cardinal, when Amy might never see anything at all? And what about all the other things Corrine's sister might not see: the television shows and the movies, the picture books Corrine saved to give her, the blue sky, the faces of their mom and dad?

Corrine's sister Amy was born prematurely*. The doctors told Amy's family that she had retinopathy (ret-i-NOP-a-thee) of prematurity. This condition, which results when the blood vessels in the eyes of a premature

Anatomy of the eye. The optic nerve (also referred to as the second cranial nerve) sends messages from the eye to the brain, making it possible to see.

Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.

baby grow abnormally and cause bleeding and scarring, may result in total or partial blindness.

What Is Blindness?

Blindness is complete loss of vision, as well as seriously compromised vision as described in the section on diagnosis below. A variety of diseases and injuries can cause blindness. Some people can take advantage of treatments to restore partial or complete eyesight, but many others who are blind must remain so for the rest of their lives.

Blindness can result from several breakdowns in the visual system, which includes the eyes, the brain, and the nerve pathway that connects them. The first steps in vision occur when light enters the eye's pupil and passes through a transparent lens, which focuses it on the retina*. The retina contains millions of receptors called rods and cones. Rods help individuals see light and are especially useful in low-light conditions. Cones help people see light and colors and provide detail to the images they see. When light strikes the rods and cones, it activates chemicals that create electrical impulses. An optic nerve* tract transmits the impulses to a portion of the brain, known as the visual cortex*. The visual cortex translates the information from the nerves into the image that individuals ultimately see.

How Is Blindness Diagnosed?

Blindness is diagnosed through a standard eye test, called the Snellen test, that requires a patient to read from a test chart containing lines of increasingly smaller type. The notation for normal eyesight is 20/20 (or 6/6 in countries where metric measurements are used). Expressed as a fraction, this notation includes a numerator (the first number) that refers to the distance between the patient and the test chart, which is usually 20 feet (6 meters). The denominator (the second number) denotes the distance

* **retina** (RET-i-na) is the tissue that forms the inner surface of the back of the eyeballs; it receives the light that enters the eye and transmits it through the optic nerves to the brain to produce visual images.

* **optic nerve** is the nerve that sends messages, or conducts impulses, from the eyes to the brain, making it possible to see. The optic nerve is also referred to as the second cranial nerve.

* **visual cortex** is a portion of the brain's cerebrum that processes visual information transmitted from the eyes.

Helen Keller

Helen Keller (1880–1968) became a writer and activist despite losing her sight and her hearing before she was two years old. She was able to communicate using the manual alphabet after she learned to associate the movements of another person's hands with letters, words, and the objects around her.

During the 1930s Helen Keller lobbied the U.S. Congress to provide federally funded reading services for people who are blind. Her efforts resulted in the inclusion of Title X in the 1935 Social Security Act, establishing federal grant assistance for the blind.

The story of Helen Keller's life, and the role of her teacher, Anne Sullivan, was made into the movie *The Miracle Worker* (1962), which won Academy Awards for actors Patty Duke and Anne Bancroft. It is available on video and DVD and is often broadcast on television.

* **strabismus** is a condition that causes the eyes to cross or not work together correctly, which may lead to permanent loss of vision in one eye.

* **glaucoma** is a group of disorders that cause pressure to build in the eye, which may result in vision loss.

* **cataracts** (KAH-tuh-rakts) are areas of cloudiness of the lens of the eye that can interfere with vision.

at which a normal-sighted person could read the line with the smallest letters that the patient is able to decipher. For example, if the patient's visual acuity is 20/100, the patient can correctly read at 20 feet a line that a person with normal vision can read at 100 feet. People are considered to have visual impairment if their vision cannot be corrected with eyeglasses or contact lenses to better than 20/40.

Besides using the Snellen test to determine the acuity or sharpness of central vision, medical professionals also check for loss in patients' field of view, including their side or peripheral vision. In a typical peripheral-vision test, a doctor asks a patient to look straight ahead and to announce when an object that is moving along one side or the other disappears from view. A person is defined as blind if individual has a visual field of less than 20 degrees.

In all, about 130,000 people in the United States are totally blind, about 1.2 million are legally blind but have some vision capability, and more than 8 million Americans have a visual impairment, according to the American Federation for the Blind.

What Treatments Are Available?

Corrine's sister Amy might not lose her vision. As of the early 2000s doctors could use a probe to "freeze" parts of the eye or a laser to burn areas of the retina and prevent permanent damage from retinopathy of prematurity. Thousands of other people with potentially vision-threatening conditions, such as strabismus*, glaucoma*, and cataracts*, can also benefit from treatments, especially if the disorders are detected early. As of 2009 many patients and medical professionals were hopeful about ongoing attempts to use computerized sensing devices and various implants at the visual cortex, the retina, or other sites to replace damaged portions of the normal visual system. These attempts, some of which also included cameras, were believed to have the potential to restore sight, at least partially.

Other individuals whose conditions may not be reversed or improved through available treatment options may benefit from special devices such as voice-recognition software for computers and from programs that train guide dogs to assist with daily tasks such as walking, going to school, and working. A large percentage of people who are legally blind or visually impaired, however, still have sufficient visual capabilities to do many of the same activities that people with normal sight perform, including reading books and newspapers, participating in some sports, and navigating independently through their daily routines.

What Causes Blindness?

Many conditions may cause blindness. The most common cause of vision loss in infants and young children is amblyopia (am-ble-O-pe-a).

Amblyopia Amblyopia, sometimes called lazy eye, is reduced vision in one eye. Although it can result from several conditions, it most frequently

TRACHOMA

Trachoma is a chronic infection of the eye by *Chlamydia trachomatis* bacteria. The bacteria infect the linings of the eyelid, causing them to become thick and rough. If the condition is untreated or if the infection returns, the eyelashes can turn inward and cause small scars on the eyes' surfaces. Eventually, blindness results. Trachoma is the leading cause of preventable blindness in the world.

Trachoma is spread through contact with the discharge from the eyes of infected persons. For example, if infected individuals rub their eyes and then shake another person's hands, the bacteria that cause trachoma can be transmitted to the other person. The bacteria may also transfer to an uninfected person if that individual uses the handkerchief or towel of an infected person.

Trachoma is especially common in developing countries where people live in overcrowded conditions and have inadequate access to clean water and effective health care. According to the World Health Organization (WHO), 6 million people worldwide have become blind from the disease, and more than 2 percent of the global population—150 million individuals—need treatment, although it is often unavailable.

Treatment, including the use of antibiotic ointments and oral antibiotics, can stop trachoma before it causes blindness. Some individuals may also benefit from surgery on the eyelids. WHO has established a Global Alliance for the Elimination of Trachoma that hopes to stop trachoma by the year 2020 through treatment and prevention.

arises as a consequence of constant strabismus (stra-BIZ-mus), in which one eye consistently turns away from an object under view and may give a person a cross-eyed appearance. About 3 to 5 percent of children have either constant strabismus or intermittent strabismus (in which the eye's deviation only occurs occasionally). Of these, an estimated 30 to 50 percent develop amblyopia. In most cases, strabismus has no known cause. Early detection of amblyopia can often lead to successful treatment. Treatment may include an eye patch placed over the stronger eye to help strengthen the affected eye, or in some cases, surgery is performed to align the affected eye correctly.

Cataracts Some children are born with cataracts, which cloud the lens in the eye and prevent images from being seen clearly or at all. People also develop cataracts as they age, which makes it one of the most common causes of reduced vision. More than 400,000 new cases of cataracts develop each year in the United States. Surgery to remove cataracts is common for adults and for those few children with them. This procedure restores vision in more than 95 percent of cases.

▲ Guide dogs wear a special harness when they work, but may switch to a regular leash during their off-duty hours. It is important not to approach or play with a guide dog when it is working. *Peter Skinner/Photo Researchers, Inc.*

Diabetes Diabetes may lead to vision loss if diabetic retinopathy develops. Diabetic retinopathy, one of the leading causes of blindness in adults, results in vision loss if blood vessels supplying the eye's retina are damaged by the disease. The blood vessels sometimes leak or break open to damage the retina. More vessels may also grow and start to cover the retina or grow into the fluid that fills the eyeball, further reducing vision.

According to the National Diabetes Information Clearinghouse, doctors have diagnosed diabetes in 14.6 million people in the United States. In addition, 6.2 million likely have the disease, although it is still undiagnosed. Of this 20.8 million total, the clearinghouse reports that diabetic retinopathy is quite common and leads to an estimated 12,000 to 24,000 new cases of blindness annually. Almost all people with diabetes can show signs of damage to their retina after two or three decades of living with the disease. Diabetic retinopathy has no symptoms at first, but as the damage increases, vision becomes blurred. Doctors typically recommend that people with diabetes undergo annual vision exams, which include the use of a device that can spot damage to the retina.

The best treatment for diabetic retinopathy is prevention, which means managing diabetes (and high blood pressure, if present) with proper nutrition, exercise, and medications. In some cases, laser treatment may avert worsening of diabetic retinopathy. Besides this potentially blinding condition, people with diabetes also are at higher risk for cataracts and glaucoma.

Glaucoma Glaucoma is a disorder that causes fluid pressure to build up inside the eye and may cause optic nerve damage. The disorder may go undetected for many years before its effects on vision are noticed. Glaucoma is one of the leading causes of blindness in the United States, with elderly people and people of African ancestry at increased risk.

Macular degeneration Macular degeneration is similar to diabetic retinopathy. Changes in the blood vessels supplying the central portion of the retina, known as the macula, cause the vessels to leak and to damage cells that are needed for the central part of the field of vision. Peripheral or side vision usually remains, but without treatment, the damaged field of vision may expand. Doctors sometimes recommend laser surgery to treat the leaking blood vessels when people are in the early stages of macular degeneration in order to prevent or slow progressive vision loss. Others compensate for vision loss by using magnifying devices. According to the American Macular Degeneration Foundation, the disease affects more than 10 million Americans.

Infections Ocular (OK-yoo-lar) herpes may cause vision loss as a result of herpes virus infections, usually the herpes simplex virus that causes cold sores or the herpes zoster virus that causes chickenpox and shingles. The National Eye Institute estimates that ocular herpes affects approximately 400,000 people in the United States.

A BEST FRIEND

Dorothy Harrison Eustis (1886–1946) was an American living in Europe when she first saw German shepherd dogs used as guides for people with blindness. The dogs were part of a program to help former soldiers who had been blinded in World War I.

She was impressed. The dogs allowed the retired soldiers to live more independently. With the dogs as their guides, the blind men could walk through and across crowded streets. Eustis wrote in 1927 about one such man: “No longer a care and a responsibility to his family and friends, he can take up his life where he left it off; no longer dependent on a member of the family, he can come and go as he pleases. . . .”

Eustis returned to the United States in 1929 and founded the first school to train guide dogs in Nashville, Tennessee. Called the Seeing Eye, the school moved to Morristown, New Jersey, in 1931, where it remains.

Guide dogs are often German shepherds, although Labrador and golden retrievers, boxers, and even mixed breeds may also serve well. The dogs begin their training at about 18 months of age with a sighted trainer. After a careful match is made between the dog and a person who is blind, the person spends three or four weeks working with the trainer and the dog.

During this continued training, the dogs learn when to stop and when to proceed at street corners based on commands from their owners. The dogs do not read traffic signs or lights because dogs are color blind. Rather, the owner listens for traffic and, when the road sounds clear, tells the dog to cross. If danger is present, however, the dog’s training will override the order. Dogs also steer owners away from people and from objects in their path.

Infection of the eyes by the *Chlamydia trachomatis* organism is a leading cause of blindness in developing nations. The eyes of newborn babies may become infected during childbirth if the mother has chlamydia.

Accidents About 15 percent of cases of blindness in adults and 8 percent in children result from accidents, according to a 2004 report from the National Center for Policy Research for Women and Families.

How Do People with Vision Loss and Blindness Adapt?

Millions of people who have visual impairments, including more than 1 million people who are legally or totally blind, can engage in many of the same activities that people with normal vision perform. People with partial sight can use powerful eyeglasses and magnifying devices to improve their ability to read and to see objects. People with blindness can also do the following:

- listen to books, newspapers, and magazines on tape
- use computers that read text aloud and respond to spoken commands

The United States and the World

- According to the American Foundation for the Blind, 1.3 million people in the United States are legally blind, which means that even with correction, the better of their two eyes has central visual acuity less than 20/200.
- At least 37 million people are blind worldwide, and another 124 million have visual impairment, according to the World Health Organization.
- Approximately 100 million people in the United States need eyeglasses to see clearly, and 14 million have visual impairments that cannot be corrected with glasses.
- Blindness and eye disabilities are expected to increase substantially because the large number of people who were born shortly after World War II (1945–1964), and are called post-war baby boomers, are in the early 2000s reaching the age when many eye disorders are more likely to occur. A 2004 report in the Archives of Ophthalmology estimated that by 2020, 5.5 million Americans aged 40 years old and above would experience blindness or low vision. This represents a 66 percent increase from 2004 numbers.

- read Braille, a system that translates letters into patterns of raised dots that are read by touching them
- use guide dogs to increase their safe mobility
- take many of the same classes, jobs, and roles as people with sight
- become parents and teachers
- become famous entertainers (if they are talented), such as singers Stevie Wonder, Ronnie Milsap, Heather Hutchison, and the late Ray Charles.

Body Image

Body image is a person's impressions, thoughts, feelings, and opinions about his or her body. A person's perception of body image may be influenced by his or her mood, self-esteem, and relationships with other peers.

Questions Teens Ask Themselves

"I'm fat." "I wish I had curly hair." "Why haven't I had a growth spurt yet?" "No one else in my class has diabetes." "Will I ever be strong enough to play on the football team?"

Most teenagers have similar questions and concerns about their bodies. They think a lot about their appearance, which seems in a constant state of change during adolescence. All individuals have an "image" of their body and appearance and how well it fits in with what they consider normal, acceptable, or attractive. For adolescents, body image is a big part of their total self-image.

Am I Fat?

Too much focus on physical appearance can create body image problems, especially for females. Even those of normal healthy body weight can feel fat when comparing themselves to super-thin models and movie stars. Studies have found that 80 percent of adolescent girls feel fat, and up to 70 percent of adolescent girls are on a diet at any given time. Four out of five American women are dissatisfied with their appearance, and half of American women are on a diet. These attitudes and behaviors are showing up at younger ages. One study found that half of the girls in grades three through six want to be thinner, and 33 percent of them have already tried to lose weight. Dissatisfaction with body image and the quest for perfection can lead to feelings of failure, unhealthy dieting, and serious eating disorders.

Why Is Body Image So Important to Adolescents?

Teenagers' bodies undergo so many changes that it is easy to understand why they may be preoccupied with their appearance and their body image. Both boys and girls experience growth spurts and sexual development. Girls' breasts and hips enlarge, body hair grows, and menstruation* is beginning. Boys' muscles grow, their voices get deeper, and their testicles and penises get larger. Their facial features may change, and hormones may cause skin problems. It takes a while to get used to their new "image" or appearance.

Teenagers are very susceptible to criticism, teasing, or negative comments. Some teenagers lose confidence in their appearance if they receive

* **menstruation** (men-stroo-AY-shun) is the discharge of the blood-enriched lining of the uterus. Menstruation normally occurs in females who are physically mature enough to bear children. Most girls have their first period between the age of 9 and 16. Menstruation ceases during pregnancy and after menopause. Because it usually occurs at about four-week intervals, it is often called the monthly period.

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

* **acne** (AK-nee) is a condition in which pimples, blackheads, whiteheads, and sometimes deeper lumps occur on the skin.

negative or insulting comments about their looks, racial or ethnic features, physical abilities, or body changes associated with puberty*. With all of the focus on the body's appearance, teenagers may need to be reminded to give equal value to other important aspects of themselves, such as personality, inner strengths, mental aptitudes, and artistic and musical talents, which, along with body image, contribute to overall self-image.

What Are Normal Concerns about Appearance?

Most people pay attention to their appearance. They may check themselves in the mirror, think about which clothes look nice on them, and try to look their best. Adolescents, whose bodies are changing dramatically, are notorious for paying special attention to their appearance. It is typical for adolescents to feel self-conscious about their looks at times, especially the appearance changes triggered by puberty.

Jack feels self-conscious about his lack of body hair, while his friend Ben thinks that he has too much. Both boys feel a bit uncomfortable when they first get on the court for basketball practice because their uniforms reveal their legs, upper chest, and armpits. Terry feels self-conscious about having some acne* and did not want his girlfriend to take his picture at the class picnic. Anna finds that her legs seem to be growing faster than the rest of her body, and her feelings were hurt when someone teased her by calling her a beanpole. Nick is sure he has not grown at all this year and does not like being shorter than most of the girls in his seventh grade class. Luckily, the awkward body changes of adolescence almost always even out eventually.

Some self-criticism involves aspects of appearance that have nothing to do with puberty. Megan dislikes the freckled skin on her arms. Darlene wishes her hair were straight instead of curly, while Angela wishes she had Darlene's waves. Andrea does not like her nose, and Paula wishes her lips were different. Jeanne thinks her complexion is too fair, and Derek thinks he is too dark-skinned.

Learning to like one's own body, coming to accept its imperfections, and growing to appreciate its unique beauty means having a healthy body image. Developing a healthy body image is an important task of adolescence.

What Are Extreme Concerns about Appearance?

Some people continue to have problems with body image long after adolescence is over. Body dysmorphic disorder (BDD) is a condition that involves extremely negative body image. BDD goes beyond self-criticism of one's features, concern with one's appearance, or poor body image. People who have BDD become overly preoccupied with what they see as flaws in their physical appearance, and they are often the only ones to perceive their features or characteristics as flaws. They may pick out tiny imperfections that others may not even notice and worry over these imperfections in a way that is out of proportion to their importance. Their self-criticism can leave them very distressed and too self-conscious to fully

enjoy life. People with BDD are plagued by critical thoughts about their appearance and have a distorted body image that causes them to believe that they are ugly.

Marianne spent hours each day worrying about whether the skin on her hands was too wrinkly. She looked at them over and over, checking to see if the wrinkles were deeper than they had been the day before. She used all types of lotions and creams but still felt that her hands were ugly. She never left the house without gloves, even in summer. She often called her sister to talk about the wrinkles, and her sister always said the same thing, “To me, your hands look the same as mine do, just like normal hands. I don’t know why you let this bother you so much. I wish I knew what to say to make you stop getting so worked up over your hands.”

Some experts estimate that BDD affects 1 to 2 percent of adults in the United States. Both males and females can have BDD. People with BDD, or “imagined ugliness”, often stay at home and often become depressed* or isolated, and many experience anxiety*. Some have unnecessary plastic surgery* or go to great lengths to change or hide aspects of their appearance. Preoccupation with their appearance can leave them distracted and unable to enjoy activities with family and friends. Experts say that people with BDD often engage in the following behaviors:

- complain about their appearance, focusing on particular traits
- look in the mirror frequently
- constantly try to fix, adjust, or hide their perceived flaws
- talk constantly about their perceived flaws
- ask others over and over for confirmation or reassurance about their appearance
- avoid situations where their flaws might be seen

What Leads to Body Image Problems?

Teenagers’ body images are strongly affected by what they see on television and in the movies. Magazines are filled with pictures of beautiful young women and lean and muscular young men. Teenagers are influenced by these images and may wish to look like their favorite models or stars. However, the degree of physical perfection that media images convey is largely an illusion created by professional makeup and styling, special lighting, and computerized alterations in photographs. When people compare themselves to these perfect-looking images, they are likely to be disappointed with their own appearance. Feeling the need to look perfect, or to have a perfect body, can lead to body image problems.

Body image problems affect both boys and girls, but they tend to bother girls more deeply than boys. One reason is that in American culture, girls’ and women’s value traditionally is linked closely to physical appearance. Boys’ appearance, while important, is not generally seen as their most important feature. Boys, however, often feel pressure to be tall, muscular, and strong.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

* **anxiety** (ang-ZY-e-tee) can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person’s physical or mental well-being.

* **plastic surgery** is the surgical repair, restoration, or improvement in the shape and appearance of body parts.

WHAT DOES PERFECT MEAN?

Some girls are more influenced than others by the thinness craze. How much value a girl places on thinness may depend on how much value her cultural group gives it.

One study of about 300 American eighth and ninth grade girls suggested that certain cultural differences might affect girls' body image ideals. The study compared the body image of girls of European ancestry with the body image of girls of African ancestry.

Ninety percent of the girls of European ancestry in the study felt dissatisfied with their body weight and shape, whereas only 30 percent of the girls of African ancestry felt dissatisfied with their bodies. When asked to describe the "perfect girl," the descriptions by girls of European ancestry often focused on thinness as the key to popularity and happiness: For example, they described the perfect girl as someone who is 5 feet 7 inches tall and 100 to 110 pounds (a trim, healthy body weight for someone 5 feet 7 inches tall is about 125 pounds).

Girls of African ancestry were more likely to emphasize the importance of personality and to downplay the importance of physical traits and thinness when they described the perfect girl. They described the perfect girl as someone who is smart, enjoyable, easy to talk to, funny, and not conceited. They were more likely to describe beauty as an inner quality; in fact, two-thirds of them described beauty as the "right attitude." Their descriptions of the body weight and dimensions that they would like to have were more in line with healthy weights. Not surprisingly, studies have shown that there is lower incidence of anorexia and bulimia among girls of African ancestry than among girls of European ancestry.

Some teenagers have illnesses or disabilities that they cannot change. These conditions may challenge their body image at first. Teenagers who focus on what the body can do, rather than on what it cannot, learn that even with physical limitations, it is possible to develop a strong positive body image. Sometimes overcoming limitations caused by a disability can create an unexpected boost to body image. For example, Tyrie, who has used a wheelchair since age nine, began to race competitively as an adolescent. The upper body strength and physical endurance he has developed by training for races has given him new confidence in his body's capabilities. He is proud of his muscular arms and chest, not to mention his medals. Even though he does not walk, his friends see him as one of the strongest guys in the tenth grade.

When Are Body Image Problems a Sign of Other Problems?

Some teenagers are satisfied with how they look and feel confident about their appearance. Others are more self-critical and always come

up lacking when comparing themselves to others. Extreme dissatisfaction with body image can lead to depression, social isolation, or eating disorders*.

Sometimes body image can become distorted, and people may mistakenly believe themselves to be fat or ugly. These distorted or mistaken ideas can cause a person to feel extremely distressed, self-critical, and overly preoccupied with their physical imperfections. Someone who has a constant and distressing preoccupation with minor bodily imperfections may have BDD, an extremely distressing, obsessive preoccupation with perceived flaws in one's appearance.

What Causes Body Dysmorphic Disorder?

Although it may not be recognized and diagnosed until later, BDD usually begins before age 18. BDD usually starts during adolescence when the body undergoes many changes and when teenagers are forming ideas about what is acceptable or desirable in physical appearance. Media images that emphasize perfection, as well as a person's own extremely high expectations or perfectionism about appearance, can be factors in the development of BDD. Harsh critical comments or ridicule about appearance by family or friends can be destructive to a person's body image and may make a person more likely to develop BDD.

In addition to social influences that may cause body image to be negative or distorted, biological factors may make certain people more likely to develop BDD. Many experts believe that BDD is linked to obsessive-compulsive disorder* (OCD), which causes people to become extremely preoccupied with certain distressing thoughts. OCD also causes people to feel compelled to perform certain repetitive actions. BDD involves extreme preoccupation with appearance, harsh self-critical thoughts, and repeated checking or attempts to fix appearance.

How Is BDD Treated?

Because people with BDD are plagued by insecurity and self-consciousness and tend to isolate themselves, sometimes they alone know that they have this problem. Seeking treatment by a mental health professional can help relieve their distress. Treatment of BDD often involves psychotherapy that focuses on understanding the person's negative thoughts and opinions about his or her appearance, making needed adjustments in distorted thinking patterns about body image, and decreasing avoidance and repetitive thoughts and behaviors. Medications are sometimes used to relieve distress and to reduce anxiety or depression that can accompany BDD.

In some cases, a person's preoccupation with his or her appearance may actually be a symptom of another underlying disorder, such as an anxiety disorders*, an eating disorder, or OCD. Evaluation by a mental health professional can determine whether someone's BDD symptoms are connected to another problem. When that is the case, the person is treated for the other problem as well.

* **eating disorders** are conditions in which a person's eating behaviors and food habits are so unbalanced that they cause physical and emotional problems.

* **obsessive-compulsive disorder** is a condition that causes people to become trapped in a pattern of repeated, unwanted thoughts, called obsessions (ob-SESH-unz), and a pattern of repetitive behaviors, called compulsions (kom-PUL-shunz).

* **anxiety disorders** (ang-ZY-e-tee dis-OR-derz) are a group of conditions that cause people to feel extreme fear or worry that sometimes is accompanied by symptoms such as dizziness, chest pain, or difficulty sleeping or concentrating.

* **anorexia nervosa** (an-o-REK-se-a ner-VO-sa) is an emotional disorder characterized by dread of gaining weight, leading to self-starvation and dangerous loss of weight and malnutrition.

* **bulimia** (bu-LEE-me-a) is an eating disorder in which a person has episodes of out-of-control overeating, or binges, and then tries to make up for them by making themselves vomit, by taking laxatives, or by exercising to excess to avoid gaining weight.

* **psychotherapist** (sy-ko-THER-a-pist) is any mental health professional who works with people to help them change thoughts, actions, or relationships that play a part in their emotional or behavioral problems.

Can BDD Be Prevented?

Experts say that teenagers can help prevent BDD by getting help with body image concerns early. While it is normal for adolescents to feel self-conscious about their changing looks, it is also important that they learn to like and accept their body and appearance. In time, many adolescents find that the very features they once wished were different are actually the ones that make their looks uniquely attractive. Concerns about appearance that get in the way of enjoying activities, being with friends, or that cause distress, anxiety, or depression may be a sign of body image problems. By paying the right kind of attention to such concerns early, mental health professionals can help prevent body image problems from becoming more serious.

Some people develop an intense fear of gaining weight even though they do not have BDD. They may begin to diet or exercise excessively, lose weight rapidly, and refuse to eat enough food to maintain a healthy weight. A person with this pattern may have an eating disorder called anorexia nervosa*. People with anorexia develop a distorted body image and see themselves as fat when they are not. Even though they may get dangerously underweight and malnourished, they continue to feel fat and refuse to eat.

Bulimia* is another eating disorder that involves body image problems. People with bulimia have a distorted body image that causes them to be self-critical and to feel fat, and they place too much importance on weight and body shape. People with bulimia have episodes of out-of-control overeating, or binges, and then try to make up for them by making themselves vomit, by taking laxatives, or by exercising to excess to avoid gaining weight. People with excessive body image problems may need assistance from several mental health professionals, including a physician, a psychotherapist*, and a nutritionist.

What Leads to a Good Body Image?

There are certain changes people can make in their appearance or physical capabilities, but having a good body image does not require a perfect body. People develop a healthy body image by taking care of their body, appreciating its capabilities, and accepting its imperfections. Positive body image is linked to an awareness that appearance is only one part of a person's identity or character and to a mature sense of what really matters and what does not in evaluating an individual.

Most teenagers can control their appearance to some extent; for example, they may choose haircuts or clothing that reflect how they see themselves. By doing so, they can create an outer image that pleases them. Eating healthy foods and getting plenty of exercise can help teenagers develop strong, fit bodies of which they can be proud. Cutting down on junk foods helps them stay trim, and physical activities help them develop strength, coordination, and new capabilities. Healthy behaviors contribute to attractive appearance on the outside and add to positive inner feelings about body image.

* **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.

Body Odor

Body odor occurs when a person's sweat comes into contact with the bacteria that are growing on his or her skin. All people sweat and have the potential to produce body odor. There are several factors that contribute to body odor. Some people may suffer from conditions that create excessive sweating, and some people's body odor may be more offensive than others.

What Is Body Odor?

Body odor is the smell of bacteria* reproducing in the sweat that is present on a person's body. The scent and strength of body odor is influenced by many things including diet, hygiene, gender, health, and certain medications. Body odor is typically associated with the underarms, groin,

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

* **physiologic** (fiz-ee-o-LOJ-ik) refers to an organism's healthy and normal functioning.

* **menstrual cycle** (MEN-stroo-al SYkul) culminates in menstruation (men-stroo-AY-shun), the discharging through the vagina of blood, secretions, and tissue debris from the uterus that recurs at approximately monthly intervals in females of reproductive age.

feet, genitals, pubic hair, and anus. These parts of the body contain apocrine sweat glands. Generally, human beings find most body odor to be an offensive smell, whereas other species, like dogs, simply use body odor as a means to identify other animals.

What Causes Body Odor?

The human body has millions of sweat glands that secrete fluid to cool the body when its temperature rises. Perspiration, or sweating, is one of the human body's most natural and healthy responses. People perspire when they are hot, when they are exercising, and when they are nervous or uncomfortable. Adolescents, especially boys, tend to sweat quite a bit more during puberty*. Perspiration is the body's built-in cooling system. In fact, two drops of sweat has the ability to cool up to a quart of blood by one degree Fahrenheit. Still, sweat encourages the bacteria that is present on the skin to multiply. The more bacteria that are present on the skin, the greater the degree of body odor.

There are two types of sweat glands. Eccrine glands are present all over the body, and apocrine glands are present in areas where there are hair follicles, such as the groin, armpit, and scalp. Eccrine glands secrete fluid directly onto the skin that is made up of water and salt. The fluid that apocrine glands secrete, however, is made up of fats and proteins. These fats and proteins are broken down by bacteria on the skin. During puberty, apocrine glands become much more active, causing even more body odor.

Hygiene While perspiration does not have a smell, the presence of sweat causes the bacteria that is normally present on the skin to multiply at a rapid rate. More numerous bacteria cause a person to have body odor. After activities that cause excessive sweating, such as working outside in

PHEROMONES AT WORK

Pheromones are chemicals that are released by the body that trigger a physiologic* response in another animal of the same species. These responses can be positive or negative and may produce responses that are sexual, aggressive, or territorial in nature.

While pheromone stimulation is most noticeably present in other species, studies have shown that human beings also subconsciously respond to pheromones released by other humans. For instance, some studies suggest that the menstrual cycles* of women who are close to one another often synchronize. This may be mediated by pheromones. Other studies have shown that human beings tend to choose their mates based on the pheromones that he or she emits. While many scientists dispute this claim, some perfume and cologne companies even add pheromones to their products in the hopes of convincing people that it will help them attract a mate.

the sun or engaging in strenuous exercise, people need to bathe with soap and water to remove the odor-producing bacteria. The use of deodorant and an antiperspirant is a helpful preventative measure.

Diet Certain diets can affect the type of bacteria that is present on a person's body, thereby affecting the amount or offensiveness of his or her body odor. For instance, a person who eats a lot of garlic will probably notice that his or her body odor has a pungent, garlicky smell. The spices cumin and curry also tend to have these pungent odor-producing properties.

Health and Medication Hyperhidrosis, or excessive sweating, is a medical condition that has effects that may amplify a person's body odor. It can be caused by multiple conditions, including heredity, menopause*, which causes hot flashes; hypoglycemia*, or low blood sugar; low levels of male hormones; and hypothyroidism*, or an overactive thyroid gland. Certain medications may also be the cause of excess sweating that leads to body odor. These include medications used to treat mental conditions, morphine, thyroxine, and analgesics such as aspirin.

In some cases, trauma may cause conditions that contribute to body odor. Rectovaginal fistulas are abnormal passageways between the rectum* and the vagina*. These fistulas can occur during childbirth or develop from conditions such as inflammatory bowel disease and infections. When this occurs, gas or stool may exit the body through the vagina, and sometimes fecal incontinence* may occur. This condition must be repaired surgically.

Social Issues and Treatment

People who have hyperhidrosis and body odor may suffer serious social consequences. These people often suffer with embarrassing body odor, wet marks or stains on clothes, and discomfort. Furthermore, they may have difficulty in school, work, social, business, and romantic situations. While proper hygiene is essential in preventing body odor, it sometimes cannot be controlled through bathing and the use of over-the-counter deodorants and antiperspirants. People who suffer from severe hyperhidrosis may need to talk to their doctor and pursue another treatment plan, which may include prescription antiperspirants, the use of nerve blockers that can prevent perspiration, medications, and in some cases, surgery.

Botulism

Botulism (BOH-chu-lib-zum) is an uncommon, nerve-paralyzing illness caused by toxins produced by Clostridium botulinum (klos-TRIH-de-um boh-chu-LIE-num) bacteria.*

What Is Botulism?

There are seven types of botulinum toxin, each designated by a letter from A through G. Only four types (A, B, E, and F) make people sick. There are three forms of naturally occurring human botulism: infant botulism, food-borne botulism, and wound botulism. Inhalation (in-huh-LAY-shun) botulism is an additional form of the illness that could possibly be intentionally spread through the air by someone intent on harming others. *Clostridium botulinum* is commonly found in soil and grows best in low-oxygen environments. The bacteria form spores* that remain dormant, or inactive, waiting for conditions that allow them to grow. The spores can exist anywhere, and people might eat food containing these spores without becoming sick. When conditions are right, however, the spores can activate and produce toxin.

Food contaminated with the toxin is the culprit in cases of food-borne botulism; most outbreaks stem from food that is improperly cooked or incorrectly canned or preserved. In food-borne botulism, the toxin itself is swallowed, but in cases of infant botulism an infant swallows the spores and they then activate in the intestine and produce toxin. It is believed that the infant intestine lacks enough protective intestinal bacteria, stomach acid, and immune globulin* to prevent the spores from activating.

Wound botulism is rare and develops when bacteria infect a wound and multiply, producing the toxin. Bioterrorists have attempted without success to aerosolize* botulinum toxin, but the threat of inhalation botulism as a biological weapon has raised concerns.

How Common Is Botulism?

More than 100 cases of botulism are reported in the United States each year. Infant botulism accounts for about 72 percent of reported cases and food-borne botulism for about 25 percent. Wound botulism is the rarest form, but health officials have noted an increase in this type in California, a rise they attribute to the intravenous* use of illegal drugs from Mexico.

How Can a Person Contract Botulism?

Botulism is not contagious. Outbreaks of food-borne botulism usually can be traced to improperly home-canned foods, especially those with low amounts of acid, such as asparagus, green beans, beets, and corn, which allow the *Clostridium botulinum* bacteria to grow. Various frozen foods have also been implicated in outbreaks of the disease. Many infants contract botulism by inhaling or swallowing spores; honey is one source of these spores. Wound botulism sometimes is linked to crush injuries.

What Are the Signs and Symptoms of Botulism?

The two or more of the following symptoms indicate botulism: sudden blood in the urine*, difficulty swallowing, blurred or double vision*, droopy eyelids, slurred speech, dry mouth, and muscle weakness. These symptoms appear when the toxin interrupts nerve impulses to the muscles, which paralyzes the muscles. If untreated, paralysis may progress to involve the arms, legs, trunk, and muscles of the respiratory tract*.

In food-borne botulism, symptoms generally begin 18 to 36 hours after eating the contaminated food, but they can occur after as little as 6 hours or as much as 10 days. Infants with botulism may appear drowsy or sluggish, not eat well, be constipated, and have a weak cry and muscle weakness. In infants, it can take 3 to 30 days for the symptoms to appear and progress.

How Do Doctors Make the Diagnosis?

Laboratory tests can detect the toxin in blood, stool (feces), or wound samples. Because the symptoms of botulism are similar to those of stroke* and several other nerve diseases, doctors also may order a brain scan, spinal tap*, or other nerve- and muscle-function tests to check for other possible causes. The doctor may ask whether the patient has eaten any home-canned foods and, if so, order tests on the suspect food.

How Is Botulism Treated?

The Centers for Disease Control and Prevention (CDC) has a supply of antitoxin* against botulism. The antitoxin can slow or halt the damage caused by botulinum toxin. The sooner it is given, the more effective it is

* **aerosolize** (AIR-o-suh-lize) is to put something, such as a medication, in the form of small particles or droplets that can be sprayed or released into the air.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

* **double vision** is a vision problem in which a person sees two images of a single object.

* **respiratory tract** includes the nose, mouth, throat, and lungs. It is the pathway through which air and gases are transported down into the lungs and back out of the body.

* **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

* **spinal tap** also called a lumbar puncture, is a medical procedure in which a needle is used to withdraw a sample of the fluid surrounding the spinal cord and brain. The fluid is then tested, usually to detect signs of infection, such as meningitis, or other diseases.

* **antitoxin** (an-tih-TOK-sin) counteracts the effects of toxins, or poisons, on the body. It is produced to act against specific toxins, like those made by the bacteria that cause botulism or diphtheria.

* **enemas** (EH-nuh-muhz) are procedures in which liquid is injected through the anus into the intestine, usually to flush out the intestines.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

in easing the symptoms. To help rid the body of the toxin, doctors sometimes cause vomiting or prescribe enemas*. In severe cases, patients who are unable to breathe well enough on their own might need a ventilator (VEN-tuh-lay-ter), a machine that can help a person breathe for several weeks. Wound botulism might require surgery to remove the source of the toxin-producing bacteria.

What Are the Complications and Duration of the Disease?

Most people with botulism require hospitalization, but they typically recover after weeks or perhaps months of care. Paralysis of the respiratory muscles can lead to pneumonia*. Even after recovery, some patients may be tired and feel short of breath.

How Can Botulism Be Prevented?

Although botulinum toxin is extremely potent, it can be destroyed easily. Heating food and drinks to an internal temperature of 185 degrees Fahrenheit for at least 5 minutes will detoxify them. Boiling home-canned foods before eating them also lessens risk. Health officials advise when

FOR GOOD AND EVIL

Botulinum toxin is the first biological toxin licensed for treatment of human diseases. The U.S. Food and Drug Administration (FDA) approves its use to relax painfully cramped or tight muscles and as an ingredient in medications for the treatment of migraine headache, chronic lower back pain, stroke, brain injury, and cerebral palsy. Botulinum toxin injections (called Botox) can paralyze muscles that cause the skin to wrinkle. Their use is popular among some people looking to maintain a youthful appearance.

Ironically, the same substance has the potential to cause mass destruction if it is dispersed into the air or introduced into the food supply. The U.S. government developed botulinum toxin for potential use as a weapon during World War II. Japan, Iraq, and the Soviet Union have also experimented with botulinum toxin as a biological weapon, and Iran, North Korea, and Syria were suspected of having done so as well.

However, scientists have been perplexed and terrorists thwarted by how difficult it is to prepare botulism toxin for use as a weapon. Terrorists in Japan attempted to unleash it on at least three occasions between 1990 and 1995, but their plan for wide-spread destruction failed each time. In addition to tracking the efforts of bioterrorists, the U.S. government developed elaborate methods to detect and respond to an attack with botulinum toxin. A national surveillance system involving doctors and hospitals was designed to alert the Centers for Disease Control and Prevention to botulism outbreaks, and stores of antitoxin were stockpiled to treat victims.

people can or preserve foods at home that they use a pressure cooker and high temperatures—about 250 degrees Fahrenheit—to kill the spores. It is also best to avoid eating commercially prepared foods from cans that are swollen, punctured, or leaking. Because honey can contain spores of *Clostridium botulinum*, doctors advise that infants younger than one year not be given this sweetener. Breast-feeding can help protect against infant botulism. Receiving prompt medical care for infected wounds and not injecting street drugs can help prevent wound botulism.

Brain Cancer

Brain cancer is a malignant tumor that originates in the brain.

Billy's Story

Billy was 16, a high-school junior, when he first began experiencing headaches and blurry vision. Over a period of several months his symptoms worsened. Billy lost interest in sports and most everything

▲
Magnetic resonance image (MRI) of a brain showing a glioma tumor (colored green). *Scott Camazine/Alamy.*

* **MRI**, which is short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

* **radiation therapy** is a treatment that uses high-energy radiation from x-rays and other sources to kill cancer cells and shrink cancerous growths.

* **malignant** (ma-LIG-nant) refers to a condition that is severe and progressively worsening.

* **tumors** (TOO-morz) usually refer to abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.

* **benign** (be-NINE) refers to a condition that is not cancerous or serious and will probably improve, go away, or not get worse.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

else. All he wanted to do was sleep. Billy’s parents took him to the local hospital where he was rushed in for an emergency MRI*. It showed a tumor growing in Billy’s brain, causing a buildup of fluid that created pressure in his skull. That explained why Billy was having terrible headaches.

Billy was admitted to the hospital’s pediatric cancer ward. Surgeons inserted a temporary shunt to drain the excess fluid from his brain. Two weeks later a team of neurosurgeons removed the tumor. For the next year and a half Billy underwent radiation therapy* to kill the cancer cells that remained after surgery. Two years later Billy was back in school, doing well and playing sports again.

What Is Brain Cancer?

Brain cancers are primary malignant* tumors* that originate in brain cells. Often the term “brain tumor” is used instead of “brain cancer” because all brain tumors—whether malignant or benign*—destroy normal brain tissue as they grow and most continue to grow unless they are completely removed or destroyed. Given that the brain is enclosed within the skull, which allows no room to expand, any growth produces pressure that can destroy normal tissue. Most brain tumors in adults are secondary tumors rather than brain cancers, having spread to the brain from other parts of the body. In contrast, most brain tumors in children are primary tumors originating in the brain. Unlike most other cancers, brain cancer can spread through the brain but rarely metastasizes or spreads to other parts of the body.

There are approximately 130 different forms of brain cancer. They are broadly categorized according to the type of brain cell in which they develop. No matter what the cell type, however, the two most important issues to determine about any brain tumor are where it is located and how fast it is growing. Both of these determinations can be made with the help of computerized axial tomography* (CAT) and magnetic resonance imaging (MRI).

Glial-cell cancers Eight out of 10 brain cancers are gliomas that originate in glial cells of the central nervous system* (CNS). There are three types of glial cells:

- Astrocytes support and nourish neurons*.
- Oligodendrocytes produce the myelin sheaths that surround the axons of neurons.
- Ependymal cells line the ventricles—cavities in the brain that contain cerebrospinal fluid* (CSF).

Astrocytomas Most primary brain tumors, including about one-half of those in children, are astrocytomas originating in astrocytes. Whereas adult astrocytomas occur most often in the cerebrum*, childhood astrocytomas also arise in the cerebellum* or brain stem* and metastasize

throughout the brain, intermingling with normal brain tissue and making these tumors difficult to remove surgically.

Astrocytomas are classified according to how fast they grow:

- Low-grade or grade I astrocytomas are the slowest-growing and most common type in children.
- Intermediate or grades II or III are called anaplastic astrocytomas and are moderately fast-growing.
- Glioblastomas or glioblastoma multiforme (GBM) are grade IV astrocytomas. They are the fastest-growing and account for two-thirds of adult astrocytomas. GBM is the most common brain cancer and among the deadliest of all cancers.

Some types of childhood astrocytomas tend to have good prognoses:

- Juvenile pilocytic astrocytomas, which most often occur in the cerebellum
- Subependymal giant cell astrocytomas, which occur in the ventricles and are almost always linked to an inherited condition called tuberous sclerosis
- Optic gliomas, which are low-grade astrocytomas originating in the optic nerve* and are often associated with an inherited condition called neurofibromatosis type 1.

Oligodendrogliomas and ependymomas Tumors originating in oligodendrocytes are called oligodendrogliomas. They usually occur in the cerebrum, grow slowly, and do not spread to surrounding tissue. They account for only about 4 percent of brain tumors and are most common in middle-aged adults.

Tumors arising in ependymal cells are called ependymomas. They account for almost 10 percent of brain tumors in children and can cause the ventricles to swell, leading to hydrocephalus*.

Other brain cancers Many less-common brain tumors arise from cells other than glial cells:

- Meningiomas arise in the meninges*. Although they account for one out of three primary brain and spinal-cord tumors, primarily in adults, about 80 percent are benign.
- Schwannomas are tumors that arise from Schwann cells that line the inner-ear nerve.
- Brain lymphoma* is a highly malignant cancer originating in lymphocytes*. Brain lymphomas are common in people with AIDS* and other immune system* disorders.

Other types of brain tumors are much more common in children than in adults:

- Primitive neuroectodermal tumors (PNETs) begin in immature cells of the CNS. They account for about one-fourth of childhood brain tumors.

* **neurons** are nerve cells. Most neurons have extensions called axons and dendrites through which they send and receive signals from other neurons.

* **cerebrospinal fluid** (seh-ree-bro-SPY-nuhl) is the fluid that surrounds the brain and spinal cord.

* **cerebrum** (se-RE-brum) is the largest, front and upper part of the brain that is responsible for mental processes.

* **cerebellum** (se-re-BEL-um) is the back portion of the brain that is responsible for muscle coordination and balance.

* **brain stem** is the part of the brain that connects to the spinal cord. The brain stem controls the basic functions of life, such as breathing and blood pressure.

* **optic nerve** is the nerve that sends messages, or conducts impulses, from the eyes to the brain, making it possible to see. The optic nerve is also referred to as the second cranial nerve.

* **hydrocephalus** (HY-droe-SEF-uh-lus) is a condition, sometimes present at birth, in which there is an abnormal buildup of fluid within the skull, leading to enlargement of the skull and pressure on the brain.

* **meninges** (meh-NIN-jeez) are the membranes that enclose and protect the brain and the spinal cord.

* **lymphoma** (lim-FO-muh) refers to a cancerous tumor of lymphocytes, cells that normally help the body fight infection.

* **lymphocytes** (LIM-fo-sites) are white blood cells, which play a part in the body's immune system, particularly the production of antibodies and other substances to fight infection.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **leukemia** (loo-KEE-me-uh) is a form of cancer characterized by the body's uncontrolled production of abnormal white blood cells.

* **edema** (e-DEE-ma) means swelling in the body's tissues caused by excess fluids.

* **nausea** (NAW-zha) refers to a feeling of being sick to one's stomach or needing to vomit.

* **double vision** is a vision problem in which a person sees two images of a single object.

- Medulloblastomas are fast-growing PNETs in the cerebellum that account for about 15 percent of childhood brain tumors. They are more likely than other types to spread beyond the CNS.
- Gangliogliomas are tumors containing both neurons and glial cells. They can usually be cured by surgery, alone or combined with radiation therapy.
- Pleomorphic xanthoastrocytomas and dysembryoplastic neuroepithelial tumors are mixed-cell tumors that are usually curable by surgery alone.
- Craniopharyngiomas are slow-growing tumors at the base of the brain.
- Germinomas are the most common type of germ-cell tumor in the brain.

How Common Is Brain Cancer?

Brain and spinal-cord tumors account for about 1.5 percent of all cancers and 2.3 percent of cancer-related deaths. There were an estimated 21,810 malignant brain and spinal-cord tumors diagnosed in the United States in 2008, and CNS tumors caused an estimated 13,070 deaths.

Brain and spinal-cord tumors are the second most common cancer in children after leukemia*, accounting for 21 percent of all childhood cancers. In the United States, about 3,400 CNS tumors are diagnosed each year in children under 20, about one-fourth of which are considered benign. About 75 percent of children with brain tumors of all types survive at least five years.

How Do People Know They Have Brain Cancer?

Symptoms of brain tumors depend on the size, type, and location of the tumor. Symptoms can be caused by a tumor pressing on a nerve or damaging an area of the brain. Symptoms may appear suddenly or gradually worsen over time. Tumors often cause edema*—fluid buildup in brain tissue—leading to brain swelling and pressure. Headaches are one of the most common symptoms of a brain tumor, occurring in about 50 percent of patients.

In very young children, parents may notice an increase in head size and possibly bulging of the soft spots in the skull. Increased pressure in the brain can also cause the following:

- Nausea* and vomiting
- Blurred vision, crossed eyes, or double vision*
- Drowsiness
- Irritability
- Loss of appetite
- Developmental delay
- Decreased intellectual and motor skills

Other common symptoms of brain tumors include the following:

- Changes in hearing or speech
- Numbness or tingling in the arms or legs
- Muscle twitching or jerking
- Difficulty with balance or walking
- Weakness or paralysis* in a part of the body
- Difficulties with facial movements or swallowing
- Mood or personality changes
- Problems with concentration or memory
- Lethargy
- seizures* or convulsions*

About one-half of people with brain tumors have seizures at some point, and seizures are sometimes the first symptom of a brain tumor in children.

How Do Doctors Diagnose Brain Cancer?

Diagnostic procedures for brain cancer include the following:

- A complete physical exam and medical history
- A neurologic exam* to evaluate brain function, including alertness, muscle strength, coordination, reflexes, and responses to pain
- An eye examination to check for optic-nerve swelling, indicating increased intracranial pressure
- MRIs, which almost always reveal brain tumors and may pinpoint the location
- Magnetic resonance spectroscopy (MRS) to help determine the type of tumor
- Positron emission tomography* to help determine whether an abnormality seen on an MRI is cancerous
- Chest x-rays to look for cancer elsewhere in the body that has spread to the brain

Although MRIs have generally replaced CT scans for diagnosing brain tumors, CT scans are sometimes used with children because they are much faster and less confining.

A biopsy* is required to determine if a brain tumor is cancerous. If diagnostic imaging indicates that the tumor can be treated surgically, an operation called a craniotomy is performed to remove all or as much as possible of the tumor. A pathologist examines the tumor tissue during the operation, in what is called a surgical or open biopsy. If the risk of surgery is too great—for example, if the tumor is near a vital area or deep within the brain—a stereotactic or needle biopsy is performed. With certain types of brain cancers, a spinal tap* is performed to check for the spread of cancerous cells in the CSF.

* **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **convulsions** (kon-VUL-shuns), also called seizures, are involuntary muscle contractions caused by electrical discharges within the brain and are usually accompanied by changes in consciousness.

* **neurologic exam** refers to systematic tests of how well various parts of the nervous system are functioning.

* **positron emission tomography** (POZ-i-tron i-MISH-en toe-MAH-gruh-fee) also called PET imaging or PET scanning, uses a radiotracer that accumulates in an area of the body and emits gamma rays that are detected as diagnostic images.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **spinal tap** also called a lumbar puncture, is a medical procedure in which a needle is used to withdraw a sample of the fluid surrounding the spinal cord and brain. The fluid is then tested, usually to detect signs of infection, such as meningitis, or other diseases.

* **chemotherapy** (KEE-mo-THER-ah-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

How Do Doctors Treat Brain Cancer?

The treatment and prognosis for brain cancer depend on the following factors:

- The tumor type, grade, size, and location
- Whether surgery is possible and, if so, how much of the tumor can be removed
- The patient's age
- Whether the tumor interferes with brain function
- Whether cancer has spread through the CSF to other parts of the brain or spinal cord

Survival rates for brain cancer vary greatly. The prognosis is generally better for younger people than for older patients.

Surgery In the early 2000s, surgical removal of as much of the tumor as possible was the frontline treatment for brain cancer. Tumors that have spread widely cannot be cured surgically; however, surgery can reduce the amount of tumor that has to be treated with radiation or chemotherapy* and can prolong life. Surgery can also alleviate some symptoms of brain cancer or make them amenable to treatment with medications such as anti-seizure drugs.

Surgery alone or in combination with radiation therapy can cure many low-grade brain cancers, including non-infiltrating astrocytomas. When possible, surgery is also the primary treatment for infiltrating or diffuse astrocytomas. However, most astrocytomas and oligodendrogliomas spread through the brain, mixing with normal cells and are, therefore, very difficult to remove surgically. Intermediate- or high-grade astrocytomas, including GBM, cannot be cured by surgery alone. Ependymomas and meningiomas can sometimes be cured with surgery.

PNETs tend to grow fast and have a poorer prognosis. They are generally treated with surgery, followed by radiation and possibly chemotherapy. Medulloblastomas and gangliogliomas can often be cured with surgery alone or surgery plus radiation.

Radiation therapy External-beam radiation therapy is often used to destroy those cancer cells remaining after surgery. Sometimes tumors remaining after surgery for astrocytomas, oligodendrogliomas, and ependymomas can be controlled with radiation therapy. Brain stem gliomas are usually astrocytomas that grow throughout the organ, so surgery is not an option. They are usually treated with radiation; however, the prognosis is generally poor. Up to one-half of all medulloblastomas and most all germinomas are curable with radiation therapy alone.

Other types of radiation therapy for brain cancer include the following:

- Three-dimensional conformal radiation therapy (3D-CRT), in which several relatively weak x-ray beams are focused on the tumor from different directions

- Intensity modulated radiation, which uses a computer to move the patient around the x-ray beam
- Conformal proton beam radiation therapy, which is similar to 3D-CRT but uses a proton beam rather than x-rays
- Stereotactic radiosurgery for inoperable tumors, which delivers a high dose of radiation in a single treatment
- Brachytherapy, in which radioactive material is inserted directly in or near the tumor
- Whole brain and spinal cord radiation therapy for tumors that have spread through the CNS

Children younger than three years of age are not usually treated with radiation because of potential long-term effects on development. Chemotherapy may be used instead, radiation treatment may be postponed until the child is older, or surgery may be repeated if the tumor returns.

Chemotherapy Chemotherapy is less often used to treat brain cancer, because most chemotherapy drugs do not cross the blood-brain barrier*. However, chemotherapy is used to treat high-grade tumors in conjunction with surgery and/or radiation therapy. Sometimes chemotherapy drugs are placed directly on or near a tumor during surgery. For some brain tumors chemotherapy is administered directly into the CSF in the brain or spinal canal. Lymphomas, medullablastomas, and some oligodendrogliomas tend to respond better to chemotherapy than most other brain cancers.

Can Brain Cancer Be Prevented?

Brain cancer usually has no apparent cause; however, there are a few known risk factors*:

- Radiation treatment for previous cancers, particularly radiation to the head for childhood leukemia
- Certain types of brain cancers that occasionally run in families
- Immune system impairments that increase the risk of brain lymphoma
- Embalmers and pathologists who work with formaldehyde
- Plastic and textile workers exposed to vinyl chloride or acrylonitrile

Brain Chemistry (Neurochemistry)

The brain communicates with itself by sending chemical information from one neuron, or nerve cell, to another. Brain chemistry is the sum of all the chemical messaging that takes place in the brain, which allows it to carry out its daily functions, such as generating movement, speaking, thinking, listening, regulating the systems of the body, and countless others.

Out of Balance: Hector's Story

Now a tenth-grader, Hector had been experiencing severe depression* since he was in seventh grade. Everyone feels down or depressed every now and then, but Hector felt this way most of the time. He had a hard time making friends, he was not interested in his schoolwork, and he spent most of his time hanging out in his room alone. He had even thought about suicide. At first, his parents believed that this was just a phase, but as it persisted they became really concerned. What was happening to their son, who had been generally upbeat and friendly until a few years earlier?

At the insistence of his parents and teachers, Hector started seeing a psychiatrist*, who tried to help Hector talk about what he was feeling. Based on her meetings with Hector, the psychiatrist decided to prescribe a type of medication known as an antidepressant. This medication increases the amount of the brain neurotransmitter* called serotonin (ser-ah-TO-nin), which is associated with feelings of well-being and control.

Diagram of a neuron. *Diagram by Hans & Cassidy. Reproduced by permission of Gale, a part of Cengage Learning.*

The medicine, a selective serotonin reuptake inhibitor (SSRI), works by inhibiting (preventing) neurons from reuptaking (reabsorbing) the chemical messenger serotonin once it is released into the brain. As a result, there is more serotonin available, and this change sometimes helps alleviate the symptoms of depression. If Hector's depression were being caused by too little serotonin, the medication likely would help him.

Sure enough, it did. Hector continued to see his psychiatrist while taking the medication. After about six months, his doctor decided to try taking Hector off the SSRI. Hector was afraid that his terrible feelings would return, but they did not. He found that talking through any problems with his doctor was enough to keep him on track.

A Cascade of Chemicals

From their laboratory studies researchers learn about the chemicals that the neurons (NUR-ons) in the human brain use to communicate with each other. They know that all the feelings and emotions that people experience are produced through chemical changes in the brain. The "rush" of happiness that a person feels at getting a good grade on a test, winning the lottery, or reuniting with a loved one occurs through complex chemical processes. So are emotions, such as sadness, anxiety, and stress. When the brain tells the body to do something, such as to sit down

* **enzymes** (EN-zimes) are proteins that help speed up a chemical reaction in a cell or organism.

* **neurological** (nur-a-LAH-je-kal) refers to the nervous system, which includes the brain, spinal cord, and the nerves that control the senses, movement, and organ functions throughout the body.

* **Parkinson's disease** is a disorder of the nervous system that causes shaking, rigid muscles, slow movements, and poor balance.

or run, a chemical process is set in motion. These chemical communicators, or neurotransmitters, are the “words” that make up the language of the brain and the entire nervous system.

The billions of tiny neurons in the brain communicate with each other across small spaces called synapses (SIN-ap-siz). When one neuron is charged into action, it releases its chemical messenger, which then moves across the synapse to the next neuron where it is accepted by a special receiving area, called a receptor, on the surface of the neuron. The chemical is accepted only by receptors that recognize it, in a kind of “lock and key” system; that is, certain keys work only in certain locks. Once attached to a receptor site on another neuron, different neurotransmitters either trigger “go” signals that prompt the neuron to pass certain messages on to other cells or produce “stop” signals that prevent certain messages from being forwarded.

Any one neuron may be receiving many chemical messages, both positive and negative (go and stop), from the other neurons surrounding it. These neurotransmitters may be competing to get the neuron to respond in different ways, or they may work together to produce a certain effect. Because all of this happens within a split second, the neurotransmitter must be cleared away quickly so that the same receptors can be activated again and again. This clearing away can happen in one of three ways. The chemical may be pumped back into the nerve ending it comes from, a process known as “reuptake,” it may be destroyed by enzymes* near the receptor sites, or it may simply spread out into the surrounding area of the brain and be destroyed there.

Modifying Neurotransmission with Drugs

Many neurological* conditions, ranging from emotional disorders, such as depression, to movement disorders, such as Parkinson's disease*, are associated with imbalances of certain neurotransmitters in the brain. Researchers have been able to develop many medications that work to correct these imbalances, improving people's symptoms and helping them lead more fulfilling lives. At the same time, many legal and illegal drugs, such as nicotine in cigarettes and the street drugs heroin and cocaine, work by changing neurotransmitter levels. People report feeling good or up when they start taking these drugs, but soon the neurons in their brains become accustomed to the change in chemical balance so that it takes more of a drug to get that same elevated feeling. Next, the brain starts to crave the substance. The result is chemical dependency or addiction. What happens when brain chemicals are modified is described in the three examples of neurotransmitters (serotonin, dopamine, and gamma-aminobutyric acid) below.

Serotonin Many studies have linked low levels of the neurotransmitter serotonin to depression, impulsive and aggressive forms of behavior, violence, and even suicide. The medications categorized as SSRIs, such as the one that was given to Hector, prevents the neurons that release this chemical from taking it back in once it is in the synapse. As a result, the

UP FOR DEBATE: MEDICATING MENTAL AND BEHAVIORAL DISORDERS

Depression, social anxiety, excessive shyness, and hyperactivity are examples of the conditions that might be treated successfully with medications that alter neurotransmitter levels in the brain. Before these medications became available, people with these and other problems either had to live with them or work with a psychiatrist or psychologist to deal with their feelings. Subsequent research in brain chemistry disorders led to the development of medications that can be used, allowing more people to overcome much of their social difficulty.

Some experts fear that people may be relying too heavily on these medications as a quick fix. While many experts do not deny that there are some people who need drug treatment, they also argue that there are people who think that feeling down or socially awkward occasionally is the same as having a disorder. These people then ask their doctors for medications that should be reserved for others who more severe conditions. When symptoms interfere with a person's life to a large extent, medication is considered. In many cases, whereas medications can help to decrease symptoms, more complete and long-lasting relief is achieved through therapy that helps with behavior change. Normal variations in feelings in response to various life changes and challenges are to be expected. Other forms of intervention, such as behavioral therapy and exercise, should be considered as alternatives to medication or in addition to medication when symptoms create suffering and present undue difficulties.

One debate surrounds treatment for a condition known as attention deficit hyperactivity disorder (ADHD), which usually is diagnosed in childhood. Children with this condition have a hard time paying attention and sitting still, and they tend to be impulsive and overactive. Often this diagnosis is given to children who misbehave in school. The exact cause of ADHD

is still unknown, but it may involve the interplay of neurotransmitters in brain function. From the 1980s into the early 2000s, increasing numbers of children were diagnosed with ADHD, and many of them took medications that enhance the activity of the neurotransmitters dopamine and norepinephrine. Both of these neurotransmitters are excitatory and help the individual be more alert, more focused, and therefore better able to stay on task. Studies have shown that children with ADHD have lower levels of these types of neurotransmitters in the brain. However, no one knows exactly how these drugs work to control ADHD symptoms.

The area of the brain thought to be altered in ADHD is the reticular activating system (RAS), which impacts attention. This system includes a group of nerve fibers located in several parts of the brain, including the thalamus. Within the RAS, the thalamus appears to play a key role in the moment-to-moment changes in the focus of attention. The thalami and cerebral cortex cooperate to register incoming sensory signals, evaluate their contents, and mobilize brain resources in response to the demands made. In this manner, the thalami receive messages that come through the senses and then relay the information to the proper receiving areas in the brain.

Although most children (possibly from 70 to 90%) diagnosed with ADHD are helped by medication, some experts believe that some parents and doctors may be too hasty in labeling children with a diagnosis of ADHD to justify what is simply bad behavior and then medicating children who do not really need to be given drugs. Others feel that children with ADHD were underdiagnosed for many years and only later were appropriately diagnosed and treated. There is no easy solution to this debate. However, many experts agree that ADHD is a real condition that can have serious consequences if it is not diagnosed and managed appropriately.

person has more serotonin available to attach to receptors in the brain, which can ease the symptoms of depression, as it did for Hector.

The illegal drug called Ecstasy, or MDMA, also changes the level of serotonin in the brain, but much more radically. It causes the serotonin-releasing neurons to dump their contents all at once, which floods the brain with the chemical and produces feelings of extreme happiness and

* **schizophrenia** (skit-so-FREE-nee-ah) is a serious mental disorder that causes people to experience hallucinations, delusions, and other confusing thoughts and behaviors, which distort their view of reality.

* **stimulant** (STIM-yoo-lunt) a drug that produces a temporary feeling of alertness, energy, and euphoria.

* **sympathetic nervous system** is the system of nerves that prepares the body for action by speeding up the heart and breathing rates and raising the blood pressure.

hyperactivity (excessive activity). This feeling comes with a price. Because Ecstasy uses up the brain's supply of serotonin, the person is likely to feel depressed when the immediate rush caused by the drug wears off after a few hours. This down period lasts until the brain can restore its supply of serotonin to normal levels. Repeated use of Ecstasy may lead to depression or other problems over time, because the neurons can bounce back only so often.

Dopamine Neurons in the core of the brain release dopamine (DO-pa-meen), a neurotransmitter that affects processes that control movement, emotional response, and the ability to experience pleasure and pain. In people who have Parkinson's disease, dopamine-transmitting neurons in this area of the brain die, which causes progressive loss of movement control. A medication called L-DOPA, which the brain can convert into dopamine, often helps control these symptoms. Some researchers have theorized that people with the mental disorder schizophrenia* are, in fact, overly sensitive to the dopamine in their brains. Some of these people seem to have been helped by medications that block dopamine receptors in the brain, thereby limiting the neurotransmitter's effect.

Another class of drugs known as amphetamines (am-FET-a-meenz) works by increasing the level of dopamine that neurons release and then preventing them from taking it back in through the reuptake process. These drugs have medical uses, such as the treatment of attention deficit hyperactivity disorder, but some people misuse amphetamines as stimulants* to increase energy levels or to lose weight.

Gamma-aminobutyric acid Gamma-aminobutyric acid, or GABA, is the main neurotransmitter that works to inhibit the brain's neurons from acting. Research suggests that certain types of epilepsy, disorder characterized by recurring seizures that affect a person's awareness and movements, may be the result of having too little GABA in the brain. The neuronal messaging system goes into overdrive, with tens of thousands of neurons sending messages intensely and simultaneously, which produces a seizure. Researchers believe that enzymes may be responsible for breaking down too much GABA, and they have developed medications that appear to help combat this process.

Hormones: Another Piece of the Brain Chemistry Puzzle

Norepinephrine (nor-e-pi-NE-frin) is a neurotransmitter that is involved in various arousal systems in the brain (systems that bring about alertness and attention) and in the sympathetic nervous system*. In the sympathetic nervous system, it is norepinephrine that causes the blood vessels to narrow, raising blood pressure, and speeds breathing and heart rates. Norepinephrine also functions as a hormone when it is released by the adrenal glands located just above the kidneys, with similar results. Norepinephrine, epinephrine, and other hormones produced by the

adrenal gland are involved in the fight-or-flight response of the body to stress.

Hormones are chemical substances that are sent into the bloodstream by the endocrine* (EN-do-krin) glands found throughout the body. They carry messages that produce certain effects in the body, much as the nervous system neurotransmitters do. In fact, there are many substances such as norepinephrine that function both as neurotransmitters and hormones. This connection illustrates the close relationship between these two body regulation systems. The brain plays an important role in regulating the release of hormones, and if hormone levels get out of balance (as neurotransmitter levels sometimes do), it can have an impact on how the brain functions and therefore on how a person feels.

The neurotransmitters, hormones, and other chemicals that function within the brain are kept under tight regulation that is very sensitive to even slight changes. The brain is able to maintain this level of control and is given protection by a physical guardrail known as the blood-brain barrier* (BBB). The BBB is made up of tightly fitted cells lining the blood vessels that lie up against the brain tissue, as well as their supporting brain cells. The supporting brain cells are known as astrocytes, called so because of their characteristic star-shaped appearance. The BBB keeps out bacteria and carefully restricts the passage of chemicals such as neurotransmitters between the brain and the rest of the body. Hormones produced by parts of the brain are able to act on other areas of the body outside the central nervous system and are transported to the bloodstream and specific endocrine organs to provide their function.

Learning and Memory

The processes of learning and memory are performed by specific parts of the brain using neurotransmitter signaling. The thalamus is greatly involved in learning and memory, as is another part of the brain known as the hippocampus*. In all parts of the brain (including the thalamus and hippocampus), a property of neurons known as neuronal plasticity (or neuroplasticity) contributes to the functioning of each physical area. Neuronal plasticity is the ability of neuronal pathways, the functional connections between specific sets of neurons, to change and form new connections with other neurons. Forming new pathways allows the brain to adapt and change with respect to the environment. In other words, neuronal plasticity is the ability of the brain to remap its pathways as a result of new experiences, including the input of new information. Neuronal plasticity plays a large role in the process of drug addiction, in which the brain forms new pathways that cause cravings and the need for the abused substance. Neuronal plasticity is also critical to the process of learning and memory. In fact, even as individuals read new information their brain is changing to accommodate the new information.

Learning and memory are among the most complex functions of the brain. Within a fraction of a second individuals may learn something that

* **endocrine** (EN-do-krin) refers to a group of glands, such as the thyroid, adrenal, and pituitary glands, and the hormones they produce. The endocrine glands secrete their hormones into the bloodstream, and the hormones travel to the cells that have receptors for them. Certain hormones have effects on mood and sometimes cause emotional swings.

* **blood-brain barrier** is a biological shield in the body that helps prevent germs or other potentially harmful materials in the blood from entering the brain and spinal cord.

* **hippocampus** a part of the brain that is involved in learning and memory

they may remember for the rest of their life. Their brain was somehow changed within that fraction of a second. In order to study the processes of learning and memory neuroscientist Eric Kandel (b. 1929) took the simple animal, the marine mollusk *Aplysia*, and framed it to withdraw from painful stimuli. Then he studied the biochemical changes that took place in the animal's primitive brain as a result of the training. These were the first studies of the molecular biology of learning and memory and initiated later attempts to understand the neurochemical aspects of these most complex brain functions.

Brain Injuries

Brain injuries usually result from impact or trauma to the brain that can lead to a variety of medical problems, depending on the nature of the injury.

Call a Doctor Right Away

Any significant impact or trauma to the head should be checked out by a doctor. Brain injuries may result from penetrating wounds or damage associated with impact. Penetrating wounds may be caused by foreign objects (for example, a bullet) or skull fragments that cause damage to brain tissue. Impact injuries might be the result of hitting the head with force against a hard object, such as the windshield of a car, or of being hit by a hard object, such as a baseball. Skull fractures may allow bacteria* access to the brain, leading to dangerous infections. The most common type of brain injury results from minor trauma. Such injuries usually do not involve loss of consciousness (being “knocked out”). More serious brain injuries may occur with or without a skull fracture as a result of impact trauma.

The brain is surrounded by a liquid called cerebrospinal (se-REE-bro-spy-nal) fluid (CSF). The CSF acts as a cushion to absorb some of the force of impact. Unfortunately, in the course of an impact injury to the head, the brain can shift, and tissue damage can occur, especially from rapidly speeding up or slowing down—much like what happens to Jell-O in a container that is dropped or suddenly yanked. The brain damage may be at the point of impact, opposite the point of impact, or spread across any area of the brain. The delicate nerve tissues, the blood vessels, or the membranes surrounding the brain, called the meninges (men-NIN-jeez) may be torn or injured. The damage may result in abnormal brain activity, cerebral hemorrhage* or cerebral edema*. Because the skull is rigid and

Impact to the head may cause leakage of fluid and blood from blood vessels in the scalp, forming a painful lump. A stronger blow can tear the meninges, the protective membrane surrounding the brain, or injure the brain tissue itself. The bleeding and brain swelling this type of injury can produce may lead to increased pressure within the skull, resulting in a variety of problems including concussion and permanent brain damage. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.

* **hemorrhage** (HEH-muh-rij) is uncontrolled or abnormal bleeding.

* **edema** (e-DEE-ma) means swelling in the body's tissues caused by excess fluids.

there is only limited room inside it, the swelling brain causes increasing pressure inside the skull, which can force brain tissue to press directly against the inside of the skull, resulting in more damage.

What Are the Causes of Brain Injury?

There are many causes of brain injury. One of the most common causes is motor vehicle accidents. Impact to the skull may be caused by the head striking the windshield or dashboard as well as being struck by loose objects in the car. Whiplash, a sudden, quick movement of the head back and forth (like cracking a whip), also can produce the kind of forces associated with impact. Head injuries also may result from falls from bicycles, skateboards, roller skates, or roller blades or during sporting events, particularly when a helmet is not worn, or other slips, trips, or falls. Anytime there is trauma to the head, the possibility of brain injury is present, and a doctor should be consulted immediately if there is any change in level of consciousness, balance, ability to move, memory, or vision.

Not all brain injuries are the result of trauma. The brain can be damaged by lack of oxygen, as with drowning or near-drowning, or a particularly difficult birth. The brain can also be damaged through starvation, vitamin deficiencies, or certain other types of malnutrition. Toxins, such as heavy metals (e.g., lead), can irreversibly damage the brain. Additionally, a wide variety of medical illnesses can have an impact on the brain and central nervous system.

What Are the Signs and Symptoms of Brain Injury?

Brain injuries are difficult to diagnose because there may be many different signs or symptoms that are present immediately after injury or that may not show up for hours or days. In the event of any type of head injury, it is important to gather as much information as possible about the accident. Anyone who witnessed the accident may be able to provide details about exactly what happened and how the injured person acted after the accident.

Temporary amnesia (am-NEE-zha), or loss of memory, is common with many brain injuries. It is typical for the injured person not to remember what happened immediately before, during, and immediately after the accident. Brief periods of amnesia may occur during the recovery period after brain injuries. Longer-term amnesia is not common, except when a head injury is severe.

Brain injuries can affect a person cognitively (intellectually), physically, and emotionally. The following symptoms may be present at the time of the accident. While it is less common, some symptoms may appear hours, days, or even longer after the accident:

- Cognitive effects of brain injury may include short-term or long-term memory loss, inability to learn new information, trouble concentrating or staying focused, speech or communication difficulties, disorientation in space, problems in organizing aspects of

The mechanics of whiplash and the resulting brain injury. © Nucleus Medical Art, Inc./Alamy.

daily living, impaired decision-making, and inability to perform more than one task at a time.

- Physical effects of brain injury may include seizures*, rigid limbs, muscle spasms, double vision*, dim vision, blindness, loss of the sense of taste or smell, slow or slurred speech, minor or severe headaches, balance problems, and tiredness.
- Emotional effects of brain injury may include anxiety (ang-ZY-e-tee), depression or mood swings, denial of having any problems, impulsive behavior, agitation (a-je-TAY-shun), and changes in personality.

What Are the Different Types of Brain Injury?

Minor Head Trauma Anyone who suffers minor head trauma without loss of consciousness or other associated neurological* symptoms still should be watched closely. The injury may or may not be followed by

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **double vision** is a vision problem in which a person sees two images of a single object.

* **neurological** (nur-a-LAH-je-kal) refers to the nervous system, which includes the brain, spinal cord, and the nerves that control the senses, movement, and organ functions throughout the body.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

* **subdural** (sub-DOO-ral) means under the dura, the covering of the brain.

symptoms such as vomiting, paleness of the skin, irritability, or sluggishness. If any of the symptoms last more than six hours or if they worsen, the symptoms may indicate a more severe injury. A doctor should be consulted immediately for a thorough evaluation.

Skull fracture A skull fracture, or injury to the bony structures protecting the brain, may or may not result in any neurological symptoms. In some cases the skull may have a noticeable depression (a “pushed in” appearance, like a dent), or there may be significant swelling or bleeding from the overlying scalp. Fractures may cause bruising or tearing of brain tissue, or blood vessels on the meninges. The injured person may have seizures as a result of the injury. A doctor should examine the person if there is any possibility of skull fracture.

Concussion A concussion (con-CUH-shun) is a bruise-like injury to brain tissue caused by a direct blow or violent shaking. A concussion usually is associated with amnesia or a change in level of consciousness that lasts a few seconds to a few minutes after the trauma. The patient typically shows no other signs of neurological problems immediately after the trauma, but a condition known as postconcussion syndrome might follow a minor head injury. Patients with persistent postconcussion symptoms sometimes enter the hospital for observation. These symptoms include headache, dizziness, difficulty concentrating, varying degrees of amnesia, depression, apathy (a lack of interest or feeling), nausea, and anxiety. Repeated concussions are dangerous and may put the person at risk of sudden death.

Contusions and lacerations Contusions (con-TOO-zhuns) and lacerations (la-se-RAY-shuns), which are bruises and cuts to tissue, are serious problems when the brain is affected. Brain contusions and lacerations often are associated with serious head trauma that causes severe surface wounds and skull fractures. The symptoms a person shows depend on the part of the brain that is affected. Severe contusions and lacerations generally are associated with brain swelling. The initial trauma may also cause paralysis or even coma* for several days to weeks.

Hematomas A hematoma is a localized mass of blood in tissue. The swelling and the black-and-blue appearance of a bad bruise are caused by just such a leakage of blood from damaged blood vessels in the injured area. Unlike most of the rest of the body, the skull restricts swelling, so the increased pressure caused by the bleeding is transferred to delicate brain tissues. In the brain, hematomas cause different symptoms depending on where they are located. Bleeding from injury to blood vessels within the brain tissues may cause an acute subdural* hematoma. This kind of hematoma begins forming immediately after injury and is common in severe head injuries. It causes growing pressure within the skull that eventually can lead to coma and even death. Some subdural hematomas are formed by very slow blood vessel bleeding, and so they may not produce

symptoms for several days or even weeks after the injury. The symptoms may be overlooked because of the time lapse between the injury and the appearance of symptoms. Symptoms may include daily headaches that slowly increase in severity, impairments in aspects of thinking and memory, changing levels of drowsiness and confusion, and gradual paralysis on one side of the body.

Epidural* hematomas occur when blood coming from arteries is trapped between the membranes covering the brain and the skull. The symptoms of an epidural hematoma usually develop within hours of the injury. Symptoms may include worsening headache, growing loss of consciousness, loss of motor skills*, and fixed gaze of one or both eyes, with dilated (widened) pupils. Epidural hematomas are less common than subdural hematomas, but they require prompt medical attention because the bleeding can quickly compress the brain and cause permanent or fatal brain damage.

How Do Doctors Diagnose and Treat Brain Injuries?

The severity of brain injuries may be difficult to determine accurately. Doctors must evaluate all the symptoms, listen to descriptions of the accident from both the injured person and witnesses, and rely on a variety of tests and procedures to make a diagnosis. The problems of diagnosis are even more complicated when the patient is unconscious or suffers from amnesia.

The diagnosis begins with physical examination. The doctor checks the state of consciousness, breathing patterns, pupil size and the pupils' reaction to light, and movement of the eyes and limbs. Doctors may perform x-rays to find fractures of the skull. In addition to x-rays, doctors use special imaging studies, such as computerized tomography* (CT) scans or magnetic resonance imaging* (MRI), to reveal detailed information about the brain itself. CT and MRI tests show whether there are structural changes in the brain, such as hematomas. A procedure called an angiogram, which is a kind of x-ray of the blood vessels, sometimes is used to see where blood vessels may be ruptured, or torn. In some cases, carefully observing the patient over several hours is important because in some neurological conditions symptoms can be delayed and then appear suddenly. A neurologist or neurosurgeon (a doctor who specializes in injuries and surgical problems of the brain) may review all of this information. Based on the details surrounding the accident and the results of the physical assessment and the various medical tests, the doctor chooses the best course of treatment.

Skull fractures themselves seldom require special treatment. In most cases, the fracture heals by itself over time. In severe or penetrating cases of skull fracture, surgery may be required to remove fragments of the skull that may have been pushed into the brain.

Surgery is one method of treatment for injuries such as hematomas. Attempts to stop the bleeding associated with epidural hematomas usually

* **epidural** (ep-I-DOO-ral) means above or outside the dura, the covering of the brain.

* **motor skills** are muscular movements or actions.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

Sports-Related Brain Injury

Every year more than 750,000 people in the United States are injured while playing recreational sports. About 82,000 of these are traumatic brain injuries. Players of almost any sport can be injured, but those who play football, soccer, or ice hockey and those who wrestle or box may be most in danger of severe brain injuries. In just one playing season, as many as 10 percent of college football players and 20 percent of high school football players may have serious head injuries. Sports participants who are hit in the head repeatedly, such as boxers, may have permanent disabilities as the result of many injuries to the brain.

Members of the American Medical Association assert that the danger is so grave that they have repeatedly called for a ban on boxing. Some professional boxers have a condition called punch-drunk syndrome, which slurs their speech and makes them unsteady on their feet. Boxers who are punch-drunk may also have memory impairment and difficulties in concentrating or communicating. Muhammad Ali (b. 1942), three-time world heavyweight boxing champion and Olympic gold medalist, developed parkinsonism, which may have resulted from his years in the ring. A person with parkinsonism usually has muscle rigidity, tremors, and twitches that may make it difficult to walk or even to talk. In severe cases, parkinsonism also may affect a person's mental abilities.

* **clots** are jellylike masses of congealed blood that stop blood flow.

are done as an emergency procedure to prevent further brain damage from increased pressure in the skull caused by the bleeding. Epidural hematomas may require repeated operations to remove blood clots*. Damage to brain tissue cannot be repaired by surgery or medicine. The harmful effects of brain injuries respond best to aggressive treatment by rehabilitation teams typically made up of specially trained physicians, psychologists, physical therapists, speech-language pathologists*, physical and occupational therapists*, and other professionals. Patients must be monitored constantly and their condition reevaluated as their behavior and symptoms change.

What Are the Long-Term Effects of Brain Injury?

Recovery from a minor brain injury, such as a concussion, usually takes a short period of time (three to six months), and the recovery often is complete. For more serious injuries, degrees of recovery vary. Factors that predict good recovery are the patient's age (younger is better), duration of coma (longer is worse), presence of bleeding in the brain, and the site and amount of trauma to the head and brain. Patients who survive severe brain injury often face a long recovery process (years) and are left with permanent disabilities.

Rehabilitation programs help patients regain their cognitive and emotional faculties. During the rehabilitation process, patients commonly have lapses of memory, behavioral changes, emotional problems such as anxiety or depression, changes in sleep patterns, declines in intellectual ability, and seizures. Psychological counseling and brain injury support groups are available to help patients and families deal with the long-term rehabilitation process.

Patients who end up in a coma or a persistent vegetative state (PVS) usually have the most severe types of brain injury. In these types of injury, the cognitive centers of the brain are badly damaged while the brain stem that controls bodily functions may remain intact. The PVS can last for many years. During the PVS, patients are not mentally aware of their surroundings, but they may still have basic reflexes and sleep cycles. Patients in a PVS that lasts longer than three months have a slight chance of some amount of recovery, whereas patients in a PVS for more than six months rarely recover.

How Can Brain Injury Be Prevented?

Most brain injuries are the result of accidents or falls. Wearing safety belts in cars and helmets when using wheeled vehicles, such as bicycles and skateboards, can help prevent many of these injuries. Observing safety practices is important. Wearing a safety belt in the front seat of a car prevents the wearer from hitting the dashboard, steering wheel, or windshield. Wearing seatbelts in the front seat or backseat keeps the wearer from being thrown around inside the vehicle or thrown out of the vehicle. Wearing a helmet while riding a bicycle or motorcycle or using a skateboard or skates helps protect the rider from injuries during falls. The

helmets should be tight fitting and padded and have a chin strap. It is also important to wear helmets while playing contact sports such as football. Even in sports such as baseball, helmets should be worn whenever there is a possibility that the ball could strike the head.

Brain Tumor

A brain tumor is a mass of abnormal cells growing in the brain. Despite its frightening name, not all brain tumors are cancerous or fatal.

What Is a Brain Tumor?

A brain tumor is a clump of abnormal tissue that can be found anywhere in the brain. The brain and spinal cord form the central nervous system, which controls bodily functions. Some of these, such as walking and talking, are voluntary or intentional actions. Others, such as food digestion and heart rate, are involuntary or automatic functions. The central nervous system manages the latter in conjunction with hormones secreted through numerous glands that are part of the endocrine system*. Besides these tasks, the central nervous system also controls people's senses, emotions, thoughts, memory, and personality.

Brain tumors are categorized in two ways: first, by how they look during imaging tests that create pictures of the brain and by how the tissue appears under a microscope; and second, according to whether they formed in the brain or spread there from another part of the body.

Benign brain tumors have clearly defined edges and contain cells that look healthy, just like normal cells. They tend to grow slowly, are not likely to spread, and rarely grow back once they are removed. The word "benign" means harmless or not cancerous. Benign tumors may cause impairment if they start to interfere with normal brain function.

* **speech-language pathologists** (pa-THAH-lo-jists) are professionals who are specially trained to test and treat people with speech, language, and voice disorders.

* **physical and occupational therapists** are professionals who are trained to treat injured people by means of activities designed to help them recover or relearn specific functions or movements and restore their abilities to perform the tasks of daily living.

* **endocrine system** is a system of ductless glands, including the thyroid and pituitary among others, that secrete hormones and control many bodily functions.

Brain scan, from the top of the head, showing a tumor (the red mass) in the right hemisphere. *Illustration by Argosy. Reproduced by permission of Gale, a part of Cengage Learning.*

Malignant brain tumors are also called brain cancer. They are made up of abnormally shaped cells and can have irregular borders. They tend to spread quickly by sprouting new “roots” into surrounding brain tissue, almost like a plant in the soil. While the tumors may also spread to the spinal cord, they generally do not spread to other parts of the body. In some cases, one tumor may contain a combination of nearly normal and extremely abnormal cells.

Primary brain tumors originate in the tissues of the brain and may be either benign or malignant. According to the American Brain Tumor Association, about 45,000 people in the United States receive a diagnosis of a primary brain tumor each year, and about 60 percent of these will be benign. Of the 45,000 total, approximately 3,400 occur in individuals less than 20 years of age.

Secondary brain tumors are actually formed from cancer cells that have traveled to the brain from another part of the body. For example, cells from tumors in the lung or breast can spread to the brain and cause new tumors to grow. Secondary brain tumors are always malignant.

In addition, brain tumors are classified by the type of brain cell that became a tumor, with medical names such as astrocytoma (as-tro-sy-TO-ma), glioma (glee-O-ma), ependymoma (e-pen-di-MO-ma), germinoma (jer-mi-NO-ma), medulloblastoma (med-yoo-lo-blas-TO-ma), meningioma (men-in-jee-O-ma), and neuroblastoma (noor-o-blas-TO-ma). Their common ending “-oma” means “tumor,” and the remainder of the word indicates the part of the brain where the tumor forms. For example, gliomas, the most common type of brain tumor, forms in the supportive tissue of the brain, called the glia. The second most common type, meningioma, forms in the meninges, which are the membranes that cover the brain and spinal cord.

Why Do People Develop Brain Tumors?

Doctors cannot explain why some individuals develop brain tumors. Even though a tumor can spread within the brain, it cannot spread from one person to another; in other words, brain tumors are not contagious.

Researchers have found that some brain tumors are more common in people who are frequently exposed to certain industrial chemicals used to manufacture rubber, pharmaceuticals, crude oil and petroleum, and nuclear fuel and weapons, as well as agricultural chemicals used on farms. They also have investigated whether certain viruses may contribute to brain tumor development.

Heredity is another possible cause. Because brain tumors sometimes occur in several members of the same family, researchers have investigated whether the tendency to develop them may be inherited.

In addition, some studies have linked cellular phone usage to increased risk, but many others have shown no such connection.

THE STORY OF JOHNNY GUNTHER

Brain tumors affect people of all ages. Among children and young adults who have tumors, the brain tumor is one of the more common types diagnosed. Still, childhood brain tumors are relatively rare. The American Brain Tumor Association estimates that only about four of every 100,000 children under age 20 develop a brain tumor.

In 1946 one such child was Johnny Gunther, whose father wrote the widely read book *Death Be Not Proud* about Johnny's experiences. At the age of 16, Johnny started experiencing some vision problems and a stiff neck. After a series of tests, he was diagnosed with glioblastoma, a fast-growing tumor that tends to spread quickly within the brain.

The book describes the diagnostic tests that Johnny underwent and his treatments, including surgery and radiation therapy, which was called x-ray therapy at that time. Johnny's father also recounts how the family coped with the disease and the eventual knowledge that Johnny would not get better. The boy died in 1947 at the age of 17.

Johnny's tumor is not typical of all brain tumors. Some grow much more slowly and do not invade the surrounding tissue. Gunther notes that while his son's tumor looked like a spider stretching out its legs, another type might look more like "a marble stuck in jelly."

Treatment methods for all types of brain tumors have advanced since 1946, making it easier for doctors to remove these tumors and control their growth. Johnny's doctors had to rely on x-rays, vision tests, and a brain wave test called an electroencephalogram to locate his tumor. In the early 2000s doctors use CTs, MRIs, and other computer technologies to create visual "maps" of the brain and pinpoint a tumor's exact location before and during surgery.

Neurosurgery and Brain Tumors

Neurosurgery has a principal role in the treatment of brain tumors and other tumors within the central nervous system, which includes the brain and spinal cord. It has come a long way since the work of Harvey Cushing (1869–1939), who pioneered the specialty of neurosurgery and post-operative care in the United States in the early 20th century.

Later neurosurgeons used a variety of tools to assist them in precisely locating and removing CNS tumor tissue in order to avoid or significantly decrease trauma to healthy cells that are vital to normal bodily functions. These tools, a number of which are at least partially computer-controlled, allowed the surgeons to maneuver carefully within the tight confines of the skull or backbone.

Through these techniques and the skill of the surgeons, an increasing number of people who have had brain and other CNS tumors removed, were alive and well years after surgery.

What Are the Symptoms of a Brain Tumor?

As the tumor grows, it exerts pressure on the brain that often causes headaches, drowsiness, blurred or double vision, or nausea and vomiting. Of course, most of the time these symptoms are *not* caused by brain tumors. Because different parts of the brain control specific functions in the body, a tumor's symptoms often depend on its location in the brain. Symptoms may include the following:

- Seizures, or sudden movements or changes in consciousness over which the person has no control
- Weakness or loss of feeling in the arms or legs
- Stumbling or lack of coordination in walking
- Abnormal eye movements or changes in vision
- Changes in personality or memory
- Speech problems

Stereotactic Surgery

Stereotactic surgery uses a frame attached externally to the skull. The frame allows the surgeon to attach surgical instruments and to position them precisely.

Before surgery, tumor locations are identified using computerized tomography (CT) or magnetic resonance imaging (MRI). The surgeon then drills a small hole in the skull and, using the CT or MRI data, inserts the instruments and navigates to an exact point in the brain. The surgeon can then remove a tumor or perform other procedures.

Doctors often use stereotactic surgery to steer biopsy needles and forceps, to direct electrodes for recording or marking lesions, to guide lasers, to insert endoscopes for looking inside the body, and to conduct gamma knife procedures, which use radiation to do surgery.

* **chemotherapy** (KEE-mo-THER- α -pee) is the treatment of cancer with powerful drugs that kill cancer cells.

How Do Doctors Diagnose Brain Tumors?

In addition to asking about symptoms, the doctor performs a neurological exam, which involves different tests of vision and eye movement, hearing, reflexes, balance and coordination, memory, thinking ability, and other functions controlled by the brain.

The doctor is also likely to order imaging tests such as a computerized tomography (CT) scan (a special x-ray that uses a computer to create pictures of the brain), or a magnetic resonance imaging (MRI) scan, which creates a picture of the brain by using a very strong magnetic field instead of x-rays. Another possible type of test, called angiogram imaging, involves injecting dye into a blood vessel and creating a series of images as the dye moves through the brain. This procedure helps doctors to visualize the tumor and the blood vessels leading to it.

Once a tumor is found, doctors often need to gather more information to figure out what type it is. In some cases, the doctor takes a sample of the cerebrospinal fluid that surrounds the brain and spinal cord, and then sends the fluid to be examined under a microscope. More commonly, surgeons remove part or all of the tumor in a process called a biopsy and then send the tissue to the laboratory for analysis. To get at the tumor, they open part of the skull (a procedure called craniotomy), or they may drill a small hole in the skull and use a needle to take a tissue sample. Both before and sometimes during the operation, surgeons use computerized images of the brain to help them locate the tumor and avoid the nearby healthy tissues that are essential for normal function.

How Do Doctors Treat Brain Tumors?

Surgery, radiation therapy, and chemotherapy* are the three most common treatments for a brain tumor, but the type of tumor, its location, and the person's age often determine how these treatments are used. Before the process starts, most patients receive medications to relieve any swelling in the brain and control the seizures that often occur with brain tumors.

Surgery During surgery, surgeons attempt to remove the entire tumor. However, if the tumor cannot be removed completely without damaging vital brain tissue, then they remove as much as they can. Surgery is usually the only treatment needed for a benign tumor.

Radiation therapy Radiation therapy (also called radiotherapy) is the use of high-powered radiation to destroy cancer cells or stop them from growing. It is often used to destroy tumor tissue that cannot be removed with surgery, or to kill cancer cells that may remain after surgery. Radiation therapy can be used when surgery is not possible. External radiation comes from a large machine, while internal radiation involves implanting radioactive material directly into the tumor. Even though the radiation is focused on the tumor, some of the surrounding healthy tissue is often damaged as well. Therefore, doctors avoid giving radiation to very young children, especially those under age three because their brains are

still developing. These children are often treated with chemotherapy until they are old enough to have the radiation therapy.

Chemotherapy During chemotherapy, doctors give anticancer drugs by mouth or by injection into a blood vessel or muscle. Because the body automatically tends to prevent chemicals and other foreign substances from entering the brain and spinal cord (a kind of “self-defense” mechanism), doctors may need to inject them right into the spinal fluid.

Research Efforts Research studies called clinical trials evaluate numerous other treatments for brain tumors. For example, researchers can test biological therapies that try to “supercharge” the body’s disease-fighting immune system against the tumor. They also test drugs that would prevent tumors from creating the new blood vessels they need to keep growing. In the United States, the National Cancer Institute formed groups of doctors nationwide who work together to find new treatments for brain tumors in children and adults.

Life after a Brain Tumor

Sometimes, the tumor or the treatment damages some of the nearby healthy brain tissue that controls physical and mental function. Patients need to work with a special therapist if they are having trouble using their arms or legs, maintaining balance, speaking, swallowing, or expressing their thoughts. They may feel tired or depressed, and they may experience personality changes. Children may find that they have problems with learning or remembering what they learn when they return to school.

Breast Cancer

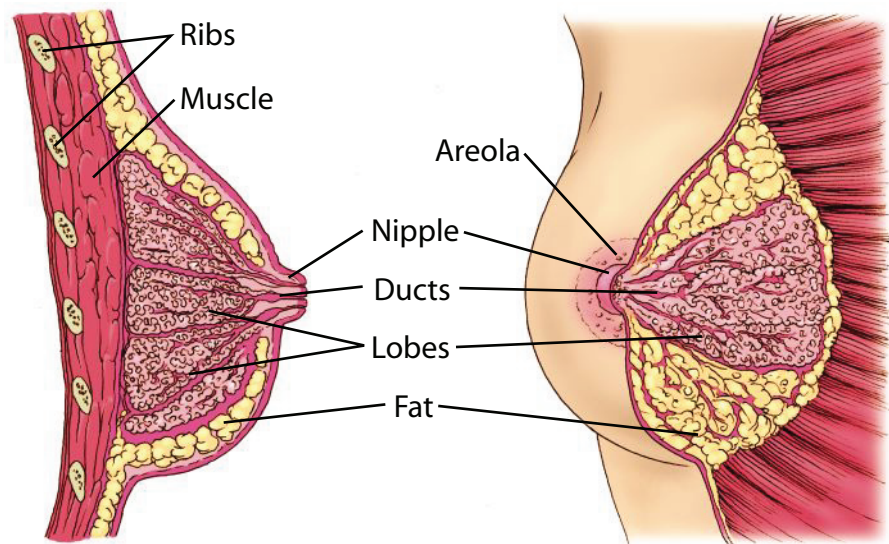

Breast cancer is a potentially dangerous tumor that develops in the cells of the breast. Cancer cells sometimes spread from the breast to other parts of the body.

How Common Is Breast Cancer?

In the United States, breast cancer is a very common cancer among women. Only skin cancer is more common. Breast cancer may occur in men, too, but is much rarer. Breast cancer is also the second leading cause of cancer death in women behind lung cancer, but deaths from breast cancer were reduced substantially in the late 1990s and the early 2000s because more effective treatments became available and because skilled health professionals using state-of-the-art equipment were able to find these cancers earlier when they are easier to treat.

How Does Breast Cancer Start?

A woman's breast contains millions of milk-producing glands called lobules (LOB-yools) that look like tiny bunches of grapes. When a woman is lactating after giving birth, milk from the lobules flows out through channels, or ducts, and to the nipple. Breast cancer begins when a single cell in a duct or lobule undergoes changes (mutations) that cause it to

Anatomy of the breast. Ducts carry milk from the lobules to the nipple. The lobules and ducts are surrounded by fatty tissue and ligaments called stroma. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

start growing out of control. At first, despite the prolific growth, the cells remain within the duct or lobule. At this stage the cancer is called “cancer *in situ*.” Later, the cells may break out of the duct or lobule into the fat and surrounding tissue, where they continue to divide and multiply. The cells form a mass called a tumor that sends out signals in the form of proteins to prompt new blood vessels to form. These vessels provide the nourishment a tumor requires to continue growing.

Metastasis Cancer cells may enter the bloodstream, where the body’s immune system (the body’s defense against disease) may kill them. If the immune system is not successful, the cancer cells may travel to distant organs of the body, settle there, grow, and divide. This spreading process is called metastasis (me-TAS-ta-sis). Breast cancer cells are most likely to spread to the lungs, liver, and bones.

Who Gets Breast Cancer?

Breast cancer is not contagious, and in the early 2000s no one yet knew exactly what causes breast cancer to start. It was known, however, that certain risk factors, such as smoking and obesity*, placed a person at higher risk of getting the disease.

Can Teenagers Get Breast Cancer? Breast cancer in teenagers is very rare. A girl whose breasts are developing may feel some discomfort from time to time, but these pains are a normal part of the body’s functioning and are not a sign of cancer.

Family history A woman whose mother, sister, or daughter has had breast cancer has twice the risk of getting the disease compared to a woman without the family history of breast cancer. Most women diagnosed with breast cancer, however, do not have such a family history.

BRCA1, BRCA2, and Estrogen Women who inherit certain mutated genes* are at higher risk of getting breast cancer. Two of the genes commonly implicated in this higher risk are BRCA1 and BRCA2 (BRCA is short for BReast CAncer). Each person inherits two copies of any given gene from their parents, one from the mother and one from the father. When only one copy of a gene is required to have an effect, it is known as an autosomal dominant gene. BRCA1 or BRCA2, as well as some genes associated with other cancers, are autosomal dominant genes. According to the National Cancer Institute, the presence of BRCA1 or BRCA2 genes can increase breast cancer risk by three to seven times. Although these two mutations account for no more than 10 percent of the overall number of breast cancer cases, women should learn their family history for the disease and report it to their health professionals.

Researchers suspect that natural substances in the body called hormones, especially the female hormone estrogen, play a role in promoting some types of breast cancer. Numerous research studies have linked high lifetime exposure to estrogen to an increased risk of breast cancer.

Women, Breast Cancer, and Mammograms

- All women are at risk for breast cancer. Most women diagnosed with breast cancer do not have a family history of the disease. In fact, according to a very large study compiled in 2001, eight of nine affected women did not have a mother, daughter, or sister with breast cancer.
- As of 2009, invasive (spreading) breast cancer occurs in one out of every eight U.S. women.
- The early detection of breast cancer by mammograms increases the chance of successful treatment.
- Some doctors believe that a woman should have her first mammogram by age 35. This first mammogram provides a baseline for comparison with future mammograms.
- The American Cancer Society recommends that women 40 years old and older have a mammogram every year. The National Cancer Institute recommends a mammogram screening for this age group every one to two years.

* **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person’s body structure and physical characteristics. Inherited from a person’s parents, genes are contained in the chromosomes found in the body’s cells.

Men and Breast Cancer

- About 1 percent of all cases of breast cancer occur in men.
- A family history of breast cancer is one of several risk factors for men as well as for women.
- Breast cancer in men usually shows up as a lump beneath the breast area, fixation of skin to the lump, and discharge from the nipple.
- While breasts are smaller in men, which makes any unusual lumps easier to feel, breast cancers in men typically spread much faster than they do in women. For this reason, breast cancer in men is often detected when the cancer is advanced and more difficult to treat.
- Treatment usually involves surgical removal of the lump and surrounding tissue in to which the cancer may have spread, followed by chemotherapy or radiation therapy to kill any remaining cancer cells in the body.
- The survival rates for men who are treated for breast cancer are similar to those for women at the same stage of the disease.

* **mammography** (mam-MOG-ra-fee) is x-ray examination of the breasts. A mammogram is used in the diagnosis of breast cancer. It may show changes that indicate a possibility of cancer, and medical professionals will then run other tests to check for other signs of the disease.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **benign** (be-NINE) refers to a condition that is not cancerous or serious and will probably improve, go away, or not get worse.

Estrogen levels may become elevated due to obesity, use of birth control pills or other estrogen-containing medications, possibly exposure to environmental chemicals, and other causes.

Age Older women have a higher risk of developing breast cancer. Another risk factor is early age for first menstrual period as well as late age for menopause. Women who have their first child after the age of 30, or who do not have any children, also have a slightly higher risk. In addition, a woman who has already had breast cancer in one breast is at higher risk of getting it in the other breast.

Diet and lifestyle Rates of breast cancer vary around the world, and these general differences appear to be related to diet or lifestyle. For example, women in Southeast Asia in the 1990s showed that they had only one-fifth to one-fourth the risk of getting breast cancer as women in the United States. Numerous studies have explored possible connections between diet and lifestyle and the threat of breast cancer.

Signs and Symptoms of Breast Cancer

The first sign of breast cancer is often a painless lump in the breast. In some cases, the shape, color, or texture of the breast or nipple may be different, or the nipple may be tender or have a discharge. Sometimes, medical professionals may find the cancer before symptoms occur. One method for doing so is the routine or “screening” mammography* (mam-MOG-ra-fee) (x-ray examination of the breasts). A mammogram may show changes that indicate a possibility of cancer, and medical professionals will then run other tests to check further for the disease.

Diagnosis If screening tests or a woman’s symptoms suggest cancer, the doctor may request a biopsy* (BI-op-see). In this procedure, a small amount of tissue is removed from the abnormal area of the breast and examined under a microscope. Most biopsies show that the tissue is benign*, which means that the tissue is cancer-free, and the woman may need no further treatment. A woman who receives a diagnosis of cancer, by contrast, should proceed to learn about the disease and discuss her options for treatment with her health professionals, as well as her friends and family.

Treatment Breast cancers that do not appear to have spread may be treated through lumpectomy (lump-EK-to-mee), which removes only the tumor. Sometimes, however, a mastectomy* (mas-TEK-to-mee) may be required, which is the surgical removal of the breast. The size and sometimes the kind of tumor will determine which is best.

Follow-up treatment may include radiation therapy and anti-cancer medication, called chemotherapy* (kee-mo-THER-a-pee), to kill any remaining cancer cells and to prevent them from returning. The choice of follow-up treatment depends on the kind of tumor and whether it appears to have spread to the lymph nodes* or other parts of the body.

3,000 YEARS OF BREAST CANCER RESEARCH AND TREATMENT

The history of breast cancer and its treatment goes back thousands of years.

- A description of “bulging tumors” being burned or cut out of the breast can be found in the Edwin Smith papyrus from Thebes, dated 1600 B.C.E.
- Ancient Greek women sought help from Aesculapius (es-ku-LA-pe-us), their mythical god of healing. Aesculapian temples were filled with offerings, including carvings of excised tumorous breasts. The women hoped their gifts would prompt an explanation of their disease or convey thanks to the god for his healing power.
- The Greek physician Hippocrates (c. 460–c. 375 B.C.E.) emphasized the importance of diet and the environment for the management of breast cancer. During the second century, the Roman physician Galen (130–200 C.E.) focused his research on a hypothesis that excess black bile caused cancer and that treatment required that the bile be removed by means of bloodletting.
- Bloodletting as a medical technique prevailed until the 1500s, when medieval doctors began returning to surgical treatment of breast cancer.

Support groups

For women with breast cancer, talking to other women who are living with the disease can be a very comforting experience. For women whose breast cancer has come back or spread, support can be even more beneficial. One study showed that women with metastatic breast cancer who participated in support groups lived an average of almost two years longer than women who did not.

Women who have just been diagnosed with breast cancer also may find it helpful to meet and to talk to women who had breast cancer 10 or 15 years earlier and who are now living happy, healthy lives.

Listings of support groups are available through many organizations, including the American Cancer Society.

Can Breast Cancer Be Prevented?

No guaranteed method of breast cancer prevention was available as of the early 2000s, but risk for the disease might be reduced by restricting alcohol consumption, by eating a healthy diet, by getting regular exercise, or by taking other measures. In addition, the early detection of breast cancer greatly improved recovery rates, so women aged 40 years and older were advised by many physicians to have regular screening mammograms and physical exams to check their breasts.

Will a Way to Prevent Breast Cancer Ever Be Found?

Besides focusing on ongoing studies to improve chemotherapy options for treating breast cancer, many researchers were working in the early 2000s on genetic tests that might help to determine who is more susceptible to the disease in the first place. These tests, which begin with a simple blood sample, search for mutated genes that may make a woman more likely to develop breast cancer. While the tests did not identify whether a woman definitely would or would not get breast cancer, they could show the presence of mutated genes, such as BRCA1 or BRCA2, that are related to breast cancer. Numerous studies were underway as of 2009 to investigate

* **mastectomy** (mas-TEK-to-mee) is the surgical removal of the breast.

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

how best to use the information from such genetic tests to help a woman lower her risk of getting breast cancer.

Tamoxifen research An effective treatment for many women with breast cancer is a drug called tamoxifen (tam-OX-ih-fen). This drug works against the hormones that stimulate the cells in the breast to grow which are likely factors in many breast cancers. In particular, tamoxifen fills the docking ports (known as receptors) on cancer cells where the hormone estrogen would otherwise fit. In other words, tamoxifen mimics the lock-and-key fit of estrogen into the cancer cell's receptors, and this blocking action stops the hormone from causing cancer growth. Tamoxifen was approved in the late 1990s for use by women who do not have breast cancer but who are at high risk of getting it. Because tamoxifen carries a risk for serious side effects, researchers investigated safer alternatives, including synthetic drugs that work as well as or better than tamoxifen. Scientists also studied other hormones, including progesterone, and their potential implications in either stimulating breast cancer or protecting against it.

What Is It like to Live with Breast Cancer?

Treatment for breast cancer can be very taxing emotionally and physically. Women who undergo mastectomy face emotional difficulties and may also experience serious post-operative swelling in their arms. Chemotherapy carries a set of side effects. If the cancer has spread, individuals face the challenges of recognizing, planning for, and coping with the prospect of dying. Even if the breast cancer was successfully treated, patients must learn to live with the fear that the cancer might someday return.

On the brighter side, treatment options and post-operative care continue to improve. Many women who have had mastectomies are able to have reconstructive surgery that can restore a more normal appearance following breast removal. In addition, support groups for women and men assist those dealing with the stresses of the illness, and love and understanding from family and friends may help to make even the most difficult situation bearable.

Broken Bones (Fractures)

The bones in the human body are very strong, but they can be broken (fractured) as a result of trauma. Breaks can range in severity from hairline fractures that require minimal treatment to shattered bones that require surgery and may result in permanent damage.

Ken's Elbow

Ken knew the steps to the attic were steep, but when his little sister ran off with his toy airplane, he took the stairs two at a time. Halfway down he slipped. Ken landed in a heap at the bottom and immediately howled in pain. When he got up, his arm was twisted in a funny way, and his elbow would not bend.

Ken's mother rushed him to the emergency room where doctors took x-rays of his arm. He had broken the bone in the upper part of his arm as well as his elbow. The breaks were so bad that Ken had to have surgery that afternoon. The doctor put a metal pin in his elbow to hold the bones together while they healed. After surgery, Ken's arm had to be in traction for two weeks, which means that he had to lie on his back in bed while his elbow was held in place by a special device hanging from the ceiling. This device put tension on his arm and elbow in just the right places to allow them to heal properly. After getting out of the hospital, Ken had a plaster cast on his whole arm for another eight weeks. Ken's arm and elbow healed completely, but every so often his elbow aches when he plays baseball.

Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.

What Are Bone Fractures?

Bone is the hardest tissue in the human body, but when bones are subjected to forces that exceed their strength, they may break. The terms “break” and “fracture” mean the same thing.

- A simple fracture is the most common type of break. The bone breaks but does not break through the skin.
- A compound (open) fracture occurs when the broken bone breaks through the skin. This type of break is serious because in addition to the damaged bone bacteria can infect the body through the break in the skin. Sometimes the jagged edges of bone break blood vessels and cause bleeding.
- A greenstick fracture is a type of incomplete fracture. Greenstick fractures often affect children, whose bones are springy and resilient. The best way to visualize a greenstick fracture is to think of trying to break a small branch off a growing tree. It will not snap off; rather it requires twisting. Twisting of the branch produces splinters. This effect is similar to what happens in a greenstick bone fracture: The bone cracks and splinters but does not break. If the bone does break into separate pieces, it is called a complete fracture.
- Stress fractures are tiny hairline cracks that can occur when a bone is repeatedly stressed.
- An impacted fracture occurs when a bone breaks and the two pieces ram into each other.
- A comminuted fracture is one in which a bone shatters into pieces.

- Fractures also can occur through joints.
- Sometimes, people tear ligaments (tough bands of connective tissue that hold joints and bones together) even when a bone is not broken. Torn ligaments frequently affect the ankles and knees.
- Dislocations are injuries in which the bones in a joint are pulled apart or displaced in relation to each other. Ligament injuries and fractures often occur with dislocations.

What Causes Breaks and Fractures?

Bones break when they are subjected to extreme force or stress. The likelihood that a bone will break depends on the location of the bone in the body, the thickness of the bone, and the circumstances under which the force is applied. The most commonly broken bones are those in the wrist, hip, and ankle.

Bone is living tissue, and like other living tissue in the body, bone is affected by genetics, hormones, diet, physical activity, disease, and drugs. All of these factors determine which bones are more or less prone to injury. In addition, the strength of bone and the forces acting on bone vary with age, so the types of fractures and the number of people affected by them vary with age as well.

Other factors that weaken bone and predispose individuals for bone fracture include those associated with low bone mineral density such as osteoporosis*, age (over 50 years of age), menopausal and post-menopausal women (due to low estrogen levels), previous fractures, ethnicity (Caucasian and Asian groups have a higher incidence of osteoporosis), long-term corticosteroid* therapy, rheumatoid arthritis*, elevated levels of parathyroid hormone (associated with hyperparathyroidism), and androgen deficiency* in men. In addition, some cancer treatments, immunosuppressants*, steroids, antipsychotics*, and anticonvulsants* may predispose individuals who use them to bone fracture. Some diseases associated with nutritional deficiencies and/or immobility may predispose to poor bone health such as Crohn's disease, rheumatoid arthritis, blood disorders, and endocrine disorders. Healing time also varies with a patient's general state of health and nutrition.

Many types of trauma (for example, skiing or car accidents) can cause a bone to break. However, some people are more prone to breaks because they have genetic conditions or bone diseases that weaken their bones, such as the following:

- Osteogenesis imperfecta, which means imperfect bone formation, is also called brittle bone disease. People with this condition have inherited genes that cause a defect in the production of bone. The result is weakened bones that break easily.
- Osteoporosis causes a thinning and weakening of the bones, making bones prone to fracture. It affects older adults, particularly women after they reach menopause.

Anatomy of Bone

The human skeleton consists of 206 bones that support the body and allow it to move. There are 29 bones in the skull, 27 in each hand, and 26 in each foot.

Bone is living tissue. It consists of cells, blood vessels, connective tissue, proteins, and fibers, as well as minerals such as calcium and phosphorus. Every bone contains both trabecular (tra-BEK-yoo-lar) and cortical (KOR-ti-kal) bone. Trabecular, or cancellous (KAN-sell-us) bone, looks like honeycomb. Despite being porous, it is very strong. Cortical bone is solid and dense. In cross-section, it reveals circular patterns like those seen in slice of a tree trunk. It forms the outer layer of bones. Many bones also contain bone marrow, where blood cells are made.

The ratio of trabecular to cortical bone varies depending on the type of bone. Trabecular bone surrounded by a thin layer of cortical bone makes up the spine, skull, ribs, and sternum (breast bone), whereas the bones of the arms and legs consist mostly of cortical bone, with only a small amount of trabecular bone at both ends.

* **osteoporosis** (os-te-o-por-O-sis) is the loss of material from the bone. This makes the bones weak and brittle.

* **corticosteroid** (KOR-ti-ko-STER-oid) is one of several medications that are prescribed to reduce inflammation and sometimes to suppress the body's immune response.

* **rheumatoid arthritis** (ROO-mah-toyd ar-THRY-tis) is a chronic disease characterized by painful swelling, stiffness, and deformity of the joints.

X-ray image showing a fracture of the fibula, a leg bone. Doctors use x-rays to confirm fracture diagnoses. *Scott Camazine/Photo Researchers, Inc.*

* **androgen deficiency** (AN-dro-gen de-fish-ens-see) is reduced male hormones in men, also called male menopause.

* **immunosuppressants** (im-yoo-no-su-PRES-ants) are substances that weaken the body's immune system.

* **antipsychotics** describes a type of medication that counteracts or reduces the symptoms of a severe mental disorder such as schizophrenia.

* **anticonvulsants** (an-tie-kon-VUL-sents) are medications that affect the electrical activity in the brain and are given to prevent or stop seizures.

* **bone marrow** is the soft tissue inside bones where blood cells are made.

RÖNTGEN AND THE DISCOVERY OF X-RAYS

X-rays are the result of the collision between electrons and protons. German physicist Wilhelm Conrad Röntgen (or Roentgen) (1845–1923) discovered what he called X-radiation in 1895. This form of radiation was noted to have properties allowing transparency and fluorescence that absorbed visible light and contrasting shadows. Experiments with this new form of radiation revealed the distinction between bone and soft tissues in the body, such as in the hand.

Röntgen's first x-ray was of his wife's hand, which showed bones, soft tissue, and metal from the ring she was wearing. His discovery of x-rays heralded a significant and valuable diagnostic tool used in the field of medicine.

Röntgen was awarded the Nobel Prize for Physics in 1901 for his discovery. He was the first recipient to be honored in this category. This Nobel Laureate was honored "in recognition of the extraordinary services he has rendered by the discovery of the remarkable rays subsequently named after him". They were called Röntgen Rays in many countries, but the scientist himself preferred to call them x-rays, as the letter *X* in mathematics stands for an unknown.

- Osteopetrosis is a rare hereditary disease that causes the bones to thicken. Osteopetrosis comes in several forms, some of which cause joint problems. Osteopetrosis congenita is discovered in infancy or childhood and it affects the bone marrow*; without a bone marrow transplant, this condition usually is fatal. Marble bone disease also is discovered in infancy. It causes short stature and mental retardation.
- Other diseases, such as bone cancer, osteomalacia (adult rickets), Paget's disease (in which the bones become enlarged, weak, and deformed), and exposure to radiation can weaken bones and make them susceptible to breaks.

How are Fractures Diagnosed and Treated?

Diagnosis A doctor may suspect a broken bone based on the appearance of the injured area. A fractured bone may cause swelling or bruising in the affected area. As in Ken's case, the affected limb might look deformed and it may hurt to move it. Sometimes a break is obvious because the bone has poked through the skin. By touching and pressing on the injured area, the doctor may be able to tell if a bone is broken. X-rays of the injured area usually confirm the diagnosis of a broken bone, although stress fractures or hairline fractures (these are fractures due to continued overuse associated with small amounts of repeated trauma causing the area to become weakened) can be difficult to detect on x-rays. Sometimes two or three x-rays may need to be taken from different viewpoints because

a fracture may be difficult to see from one angle, but easily seen from another x-ray view.

Treatment Broken bones may be treated by realigning the bones in their proper position, if necessary (a process called “reduction”), and then holding them in place while they heal.

How a broken bone is treated depends on where in the body it is located and how severe the break is. In the case of a stress fracture, a device called a splint may be used to immobilize the injured area while it heals. An arm sling may also be used to keep a person from using an injured arm. When a person has a simple fracture, the doctor guides the bones back into their proper place, if necessary, and then immobilizes the injured area with a cast made of plaster or fiberglass.

Other more serious types of fractures can require surgery. For example, in Ken’s case, realigning the bones was not a straightforward task. An orthopedic surgeon (bone specialist) needed to open the site of the fracture surgically and use metal pins and plates to hold the bones together while they healed. Ken’s injury required his arm to be in traction for several weeks before having a cast for an additional two months.

Healing The healing process for fractures takes place in three stages known as inflammation, repair, and remodeling. The first phase (inflammation phase) occurs as damaged soft tissue in the surrounding area becomes swollen and painful. This swelling and pain may last from a few days to a few weeks. The second phase (repair phase) may last from a few weeks to a few months, as bone regeneration occurs and the new soft bone without calcium (callus) moves from being soft to being hard and strong. The third stage (remodeling phase) may last for many months, as the bone builds itself back to its normal, hardened state.

Splints, casts, and slings are used to keep bones in place while they heal. Healing occurs when the bone tissues produce a substance called callus, which binds the broken pieces together. Healing time varies with age. A fracture that may take three weeks to heal in a four-year-old may take three months to heal in an adult. Casts for simple breaks usually stay on for six to eight weeks, but more severe breaks may require a cast for much longer time periods.

Bones, like other living tissue, maintain continuous states of renewal. Osteoblasts and osteoclasts are special types of cells that are responsible for the formation (osteoblasts) of new bone and the breakdown (osteoclasts) of bone material. Callus formation (created by the union of bone, blood, and cartilage material) allows for a bridge-like connection during repair of a bone fracture. During this time, bone-forming cells grow and surround the fracture to gradually renew and strengthen the bone and fracture site.

Many people recover completely from breaks and fractures. However, one possible complication that may increase recovery time is osteomyelitis*, an infection of the bone. Osteomyelitis may be acute or chronic, and it is

Is It Broken?

People can break bones anytime and anywhere. To assess the situation, doctors often look for signs of fractures and ask about symptoms. Among the signs doctors look for are the following:

- Swelling and bruising
- A limb hanging at an unusual angle
- A limb that appears out of place
- A bone sticking out through the skin

Doctors also ask about the following:

- Did the person feel or hear anything breaking?
- Can the person move the injured area?
- Does the area hurt when touched?

* **osteomyelitis** (ah-stee-o-my-uh-LYE-tis) is a bone infection that is usually caused by bacteria. It can involve any bone in the body, but it most commonly affects the long bones in the arms and legs.

* **trachea** (TRAY-kee-uh) is the windpipe—the firm, tubular structure that carries air from the throat to the lungs.

usually caused by bacteria entering the bone. The infection may occur at the fracture site or in another part of the body; in the latter case, the infection then travels to the bone via the bloodstream. Osteomyelitis may be a concomitant result when a person sustains a compound fracture (often from physical trauma) in which a break in the skin occurs. The open skin allows bacteria to enter, and osteomyelitis may result. Antibiotics are often prescribed for compound fractures in order to prevent or eliminate the infection and thus minimize the possibility of osteomyelitis. Compound fractures may take a long time to heal, necessitating prompt and aggressive antibiotic therapy.

Bronchiolitis and Infectious Bronchitis

Bronchiolitis (brong-kee-o-LYE-tis) is an infection that causes inflammation of the lung's smaller airways, also called the bronchioles (BRONG-kee-oles). It is common among very young children, particularly during the winter months. Bronchitis (brong-KYE-tis) is a disease that involves inflammation (irritation and swelling) of the larger airways in the respiratory tract. These airways, called the bronchial (BRONG-kee-ul) tubes or bronchi (BRONG-kye), extend from the windpipe to the lungs. Another name for the windpipe is the trachea to the lungs. Bronchitis and bronchiolitis can result from infection or other causes.*

Close-up view of the anatomy of the left lung and of one of its bronchial tubes, which is called a bronchus. Healthy bronchi bring air in and out of the lungs, but people with irritated and inflamed bronchi have mucus clogging up the inside of the tubes. The inflammation interferes with breathing and causes coughing that often brings up the mucus. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

What Are Bronchitis and Bronchiolitis?

In both bronchitis and bronchiolitis, the tissue lining the airways swells, narrowing the air passages and making breathing difficult. The inflamed airways produce larger amounts of a thick, slippery substance called mucus*, which can clog the air passages and complicate breathing even more. People who have bronchitis and bronchiolitis cough frequently to drive out this excess mucus.

Bronchitis and bronchiolitis can also affect the cilia, which are fine, hair-like structures on the surface of the cells lining the airways. Normally, the cilia help cleanse the airways of inhaled particles, but in individuals who have these conditions, the cilia become less able to clear impurities and bacteria from the airways, making it harder for the person to fight off lung infection.

What Causes Bronchitis?

Infection with viruses and sometimes with bacteria can cause bronchitis, but many people get it as the result of smoking or from living or working in areas that have heavy air pollution and/or dust. Bronchitis comes in three types: acute bronchitis, a persistent or recurring form called chronic (KRAH-nik) bronchitis, and asthmatic bronchitis.

Acute bronchitis Acute bronchitis comes on quickly and often results from an infection with a virus. Viruses that can cause acute bronchitis are

* **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.

* **respiratory syncytial virus** (RES-puh-ruh-to-re sin-SIH-she-ul), or RSV, is a virus that infects the respiratory tract and typically causes minor symptoms in adults but can lead to more serious respiratory illnesses in children.

* **parainfluenza** (pair-uh-in-floo-EN-zuh) is a family of viruses that cause respiratory infections.

* **influenza A** (in-floo-EN-zuh A) is one member of a family of viruses that attack the respiratory tract.

* **adenovirus** (ah-deh-no-VY-rus) is a type of virus that can produce a variety of symptoms, including upper respiratory disease, when it infects humans.

contagious. People can get a viral infection from someone who is infected if they come into contact with that person's respiratory fluids. The virus also can spread from person to person through the air by way of the droplets from a sneeze or cough. Acute bronchitis can also result from an allergy or from inhaling irritating substances in the air, such as smoke from a fire. In all, more than 12 million people have bouts of acute bronchitis every year, and most of them are children under five years of age, who typically get it in winter and early spring. Usually, acute bronchitis lasts about 10 days, but in severe cases, an individual may have a bad cough that lasts up to a month as the bronchi heal.

Chronic bronchitis No matter who they are, what their job is, or where they live, people who smoke cigarettes are more likely to experience chronic bronchitis. The American Lung Association reports that the disease develops in more than nine million people in the United States every year. People with chronic lung disease are also likely to experience chronic bronchitis. Generally, chronic bronchitis is not contagious. Rather, it results from persistent or repeated inflammation of the lungs over at least two to three months, which can continue or come and go over years. Individuals with chronic bronchitis typically have a bad cough and restricted airflow because of the excess mucus in their airways.

Asthmatic bronchitis Asthmatic bronchitis is seen in people with persistent asthma.

What Causes Bronchiolitis?

In the vast majority of bronchiolitis cases, a virus infects the bronchioles, the smallest airways that carry air through the lungs. The virus that most often causes bronchiolitis is called respiratory syncytial virus* (RSV). Other viruses, such as rhinovirus, parainfluenza* virus, influenza A*, and adenovirus*, also can cause bronchiolitis. These viruses are contagious.

Viral bronchiolitis occurs commonly in late fall, winter, and early spring. It typically affects younger children, with most cases occurring in children two years old or younger. Many may only get bad cold symptoms and nothing more, but others may need hospital care. In fact, bronchiolitis is a leading cause of hospitalizations for children under age five; more than 100,000 per year occur annually in the United States.

While most bronchiolitis results from viral infection, it sometimes has other causes. These types of non-infectious bronchiolitis may stem from the following:

- constrictive bronchiolitis (also called bronchiolitis obliterans), which sometimes occurs when the body of a lung-transplant patient rejects the new organ
- diffuse panbronchiolitis, a poorly understood condition that mainly affects Asian men
- respiratory bronchiolitis, which occurs mainly among smokers

What Are the Signs and Symptoms of Bronchitis and Bronchiolitis?

Chronic bronchitis usually is marked by a cough that lasts three months or longer, tightness in the chest, and trouble breathing. Acute bronchitis and bronchiolitis symptoms often mimic those of a cold. Common symptoms include coughing that brings up mucus, wheezing, tiredness, chest pain, a low fever, and difficulty breathing. Individuals who have difficulty breathing should see a doctor immediately to make sure they are getting enough oxygen. Signs of breathing difficulties may be blue skin or lips, very rapid breaths, or a noticeable inward movement, which is called a retraction, of the muscles between the ribs while breathing. Individuals who cannot drink and hold down fluid should also see a doctor right away. In that case, the doctor may check for signs of dehydration*.

In diagnosing these conditions, a doctor may start by listening to the person's breathing or ordering a chest x-ray to check for pneumonia or a lung function test to check for asthma. The doctor may also take a sample of the individual's nasal fluid and ask laboratory technicians to check it for the presence of RSV. They do this with an antigen* detection test.

How Are Bronchitis and Bronchiolitis Treated?

Most otherwise-healthy people who have bronchitis and bronchiolitis can recover at home. Doctors usually recommend that individuals drink lots of fluids, eat a well-balanced diet, and get plenty of sleep, preferably in a room that has a cool-mist vaporizer or humidifier running to ease breathing. For pain and fever, doctors typically suggest over-the-counter medications, such as acetaminophen*. For patients with acute bronchiolitis, a doctor may also prescribe bronchodilator* drugs to help open the airways. Bronchodilator drugs come either in pill form or in a spray inhaler.

The vast majority of bronchitis and bronchiolitis cases result from viruses, so doctors generally do not prescribe or recommend antibiotics. Although decongestants may seem like a good choice as a way of decreasing the amount of mucus, they often produce unwanted side effects in very young children and should not be given to them. Instead, a parent can clear the mucus from a child's nose with suction from a rubber bulb and saltwater nose drops. Occasionally children with bronchiolitis, especially those who were born prematurely or with heart or lung problems, may have to be hospitalized so that they can get extra oxygen and fluids, and if necessary, breathing treatments.

For people who have chronic bronchitis, the best treatments are preventative measures: stop smoking and avoid dust, fumes, and cold or dry air. Besides these preventative steps, individuals with chronic bronchitis may get some relief from their symptoms through cough medicine and vaporizers.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **antigen** (AN-tih-jen) is a substance that is recognized as a threat by the body's immune system, which triggers the formation of specific antibodies against the substance.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

* **bronchodilator** (brong-ko-DYE-lay-tor) is a medication that helps improve air flow through the lungs by widening narrowed airways.

Kicking Butts

When a smoker quits smoking, it takes only 20 minutes to feel better. Statistics from the American Lung Association show the following:

- **20 minutes after quitting** blood pressure decreases and pulse rate lowers
- **Eight hours after quitting** the oxygen level in the blood rises to normal and the carbon monoxide level in the blood returns to normal
- **One day after quitting** the chance of a heart attack drops
- **Two days after quitting** nerve endings begin to regrow, allowing the senses of taste and smell to improve
- **Two weeks to three months after quitting** circulation of the blood improves and both walking and breathing become easier
- **One to nine months after quitting** coughing, congestion, tiredness, and shortness of breath diminish
- **One year after quitting** the risk of heart disease becomes half that of a smoker

The long-term benefits are encouraging, too. After 5 to 15 years, the risk of stroke drops to that of someone who has never smoked. At 10 years after quitting, the risk of lung cancer can become just half of that of a continuing smoker and the risk of several other smoking-related cancers becomes lower, and at 15 years, the likelihood of having a heart attack drops to that of someone who has never smoked at all.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

What to Expect

Most symptoms of acute bronchitis and bronchiolitis clear up after a few days to a week, but the cough may last several weeks longer while the airways in the lungs heal. Chronic bronchitis symptoms last longer and may never resolve, because the damage to the lungs may be permanent. Because of the production of excess mucus, the body's natural reflex will be to cough it up, and this cough may come and go for a long time, flaring up, subsiding, and flaring up again.

Occasionally, people with bronchitis and bronchiolitis develop other conditions, which include pneumonia*, apnea*, and respiratory failure*. These are more common among individuals who have heart, lung, or other health problems, and among children who were born prematurely. Children who have had bronchiolitis are more prone to asthma* later in childhood. Chronic bronchitis, by contrast, can lead to heart failure, because it makes the heart work harder to compensate for the lack of oxygen. Severe respiratory problems can develop, and in some cases the disease can result in death.

How Can Bronchitis and Bronchiolitis Be Prevented?

Because the viruses that cause bronchitis and acute bronchiolitis—especially RSV—spread very easily from one person to another, people can reduce their chances of getting the diseases by washing their hands frequently. Parents should also instruct their children not to share drinks or eating utensils with other children. In addition, parents should keep their children home from school if they have either disease, so the children do not infect their classmates. As an added precaution, doctors may suggest infection-preventing immunizations against RSV for certain children who are at high risk of becoming seriously ill from bronchiolitis. These children include premature infants and those with chronic heart or lung disease.

For chronic bronchitis, the best preventative measure is to stop breathing cigarette smoke. In fact, if people did not smoke, most cases of chronic bronchitis would not develop. Doctors usually advise people with chronic bronchitis or other chronic lung diseases to get a yearly influenza* vaccination* (flu shot) to prevent symptoms from flaring up in response to infection with flu viruses.

Bulimia Nervosa

Bulimia Nervosa (bull-EE-me-a ner-VO-sa—often called simply “bulimia”), sometimes referred to as the “binge-purge” disorder, involves repeated episodes of excessive eating (bingeing) followed by attempting to rid the body of the food by vomiting, using laxatives or enemas (purging), or exercising excessively.*

Marlene’s Perfect Figure

To her friends and family, Marlene had a perfectly fine figure, and she seemed confident and self-assured. But privately, Marlene suffered from bulimia and could not seem to stop bingeing and purging. Several times per week, she would eat whole batches of cookies, packages of candies, and as much bread and muffins as she could find. Her guilt and fear of becoming overweight always led her to make herself vomit. Marlene stayed at a healthy weight for her size, but she was obsessed with her weight and body shape.

What Is Bulimia?

Eating disorders are habits or patterns of eating that are out of balance and may involve major health and emotional problems. Bulimia is a type of eating disorder in which a person binges, or consumes large quantities of food, and then purges, or attempts to rid the body of the food. When bingeing, people with bulimia often feel like they have little control over their behavior. After a binge, they feel guilty and fearful of becoming fat, so they try to rid the body of the food by vomiting or using laxatives or enemas. They may use diet pills or take diuretics, drugs to reduce the volume of fluids in the body. Some people with bulimia also exercise excessively in order to burn up some of the calories eaten during binges. People

* **apnea** (AP-nee-uh) is a temporary stopping of breathing.

* **respiratory failure** is a condition in which breathing and oxygen delivery to the body are dangerously altered. This may result from infection, nerve or muscle damage, poisoning, or other causes.

* **asthma** (AZ-mah) is a condition in which the airways of the lungs repeatedly become narrowed and inflamed, causing breathing difficulty.

* **influenza** (in-floo-EN-zuh), also known as the flu, is a contagious viral infection that attacks the respiratory tract, including the nose, throat, and lungs.

* **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.

* **enemas** (EH-nuh-muhz) are procedures in which liquid is injected through the anus into the intestine, usually to flush out the intestines.

* **body image** is a person's impressions, thoughts, feelings, and opinions about his or her body.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **anxiety** (ang-ZY-e-tee) can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person's physical or mental well-being.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

with bulimia have a distorted body image*; even though many people with bulimia stay at a fairly healthy weight, they are fixated on body shape and weight and feel like they are fat.

Most people who develop bulimia are girls and young women of European ancestry, although males and people of all ethnic groups can have it. Bulimia affects at least 1 to 3 percent of middle and high school girls and up to 5 percent of college-age women in the United States.

What Causes Bulimia?

Bulimia often starts with dieting after a binge, but once the purging begins, the situation worsens. A person eats too much, feels guilty about it, and purges. The purging provides some immediate relief but is followed by shame and guilt. People with bulimia begin to believe that the only way to control their weight is to purge. They often feel intense social and cultural pressure to be thin. Family problems and conflict are often present in the lives of people with bulimia. Poor self-esteem can also play a role. People with bulimia overemphasize the importance of body shape and size in their overall self-image.

What Are the Signs and Symptoms of Bulimia?

A person with bulimia can often hide it very well. A girl with bulimia is usually near a healthy weight but is preoccupied with eating and dieting. Bulimia and other eating disorders share many symptoms, such as fatigue, low blood pressure, dehydration*, preoccupation with food, and secretiveness about eating. However, because of the purging, bulimia can be associated with additional, serious symptoms that include:

- tooth and other dental problems caused by stomach acids damaging tooth enamel
- rips or tears in the esophagus (the tube that runs from the throat to the stomach) from frequent vomiting
- other gastrointestinal problems
- imbalances in electrolytes (essential body chemicals and minerals) that can lead to heart and other health problems
- feelings of loss of control, shame, depression, irritability, withdrawal, and secretiveness

How Is Bulimia Diagnosed?

Like Marlene, people often keep their bulimia hidden from family, friends, and healthcare professionals. The shame and embarrassment about purging can be profound. Sometimes a dentist will notice damage to the tooth enamel. A healthcare professional might ask about a person's weight, diet, nutrition, and body image, and the responses may reveal an eating disorder. If concerned, a physician might order lab tests to study nutritional and medical status. A mental health professional may uncover bulimia when a person is treated for a different symptom, such as anxiety* or depression*.

How Is Bulimia Treated?

Bulimia, like other eating disorders, is treated most effectively with a combination of therapies. The main treatment for bulimia is psychotherapy*. The focus of treatment is on changing eating behaviors and thinking patterns. To help a person overcome bulimia, a therapist also addresses the person's distorted body image and fear of being fat. Sometimes a physician prescribes an antidepressant medication* to relieve anxiety or depressive symptoms. Nutritional counseling, support groups, and family counseling can also be helpful.

Bunions

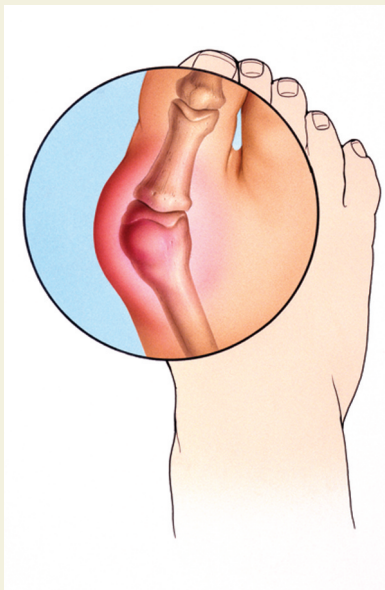

Bunions (BUN-yunz) are foot deformities caused by displacement of certain bones. A bunion is visible as a bump on the side of the foot at the joint at the base of the big toe.

The Price of Style

When Natalie began her job at the bank, she finally could afford to indulge her love of stylish shoes, the higher the heel and the more pointed the toe, the better. However, after several months, the inner side of Natalie's right

* **psychotherapy** (sy-ko-THER-a-pea) is the treatment of mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth.

* **antidepressant medications** are used for the treatment and prevention of depression.

▲ A bunion is formed when the first metatarsal bone (along the inner side of the foot) pushes out at the base of the big toe, and the big toe is displaced toward the smaller toes. The bump that characterizes a bunion is caused by joint inflammation and swelling. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

* **orthotic** is a support or brace for weak or ineffective joints or muscles.

foot, especially around the base of the big toe, began to swell and turn red. As it rubbed against her shoe, the bump on her foot grew bigger. After a few weeks, even sneakers hurt her foot. Natalie knew she had a bunion; she must have inherited the tendency for them since her foot looked just like her mother's and grandmother's feet. She counted the days until her appointment with a podiatrist (po-DY-a-trist), or foot specialist.

What Causes Bunions?

Hallux valgus The medical term for bunion is hallux valgus: Hallux means big toe, and valgus means a deformity pointing away from the middle of the body. A bunion is formed when the first metatarsal (MET-a-tar-sal), which is the long bone along the inner side of the foot, pushes out at the base of the big toe, and the big toe is displaced toward the smaller toes. The first metatarsal and one of the big toe bones meet at the first joint of the big toe; the bump characteristic of a bunion is caused by inflammation and swelling of this joint.

Anyone can develop a bunion Bunions are a very common and often painful foot deformity. Anyone, including children, can develop a bunion. However, bunions are most common in women over 30, possibly because of shoe choice. Narrow, pointy, high-heeled shoes can speed the formation of a bunion in people who are susceptible to developing them. People who have flat feet or low arches are more prone to develop bunions than people with higher arches.

Pronation and other foot abnormalities Foot abnormalities are a common cause of bunions. For example, people whose feet are rotated so that the inside edge of the foot hits the ground first when they walk (pronated feet) are prone to bunions. Many people have a genetic susceptibility to developing bunions, and bunions also may develop in association with arthritis.

How Are Bunions Treated?

Natalie had the classic symptoms of a bunion: The inner side of her foot was deformed by a red, swollen, painful lump the size of a large marble; she also had a big callus (an area of hard thick skin) along the inner side of her foot; her other toes overlapped one another; and sometimes the skin over the bunion became infected.

Before treating the bunion, Natalie's podiatrist took x-rays of her foot to examine the foot bones. She had a large and well-developed bunion, and he decided to inject medication into her big toe joint to reduce the swelling. He also prescribed a device called an orthotic* that fit into her shoes and helped reduce pressure and weight on her big toe. To help reduce swelling, the podiatrist told Natalie to take an over-the-counter pain reliever, put ice packs on her foot, and soak her foot in mineral salts. She also would have to give up the high heels.

Osteotomy These treatments did not work for Natalie, and ultimately she had bunion surgery. The podiatrist performed an osteotomy (os-tee-OT-o-mee), which means “cutting of bone.” After giving Natalie local anesthesia* to block pain in her foot, the podiatrist removed areas of the metatarsal that had thickened, and he used a small titanium (ty-TANE-ee-um) screw to hold the bones in their correct position. Like almost all bunion repairs, Natalie’s was successful. She was walking again the day of the surgery and was back to work in four days.

Burns

Burns are tissue injuries caused by direct contact with heat, such as fire, sunlight, steam, boiling fluids, heated objects, electricity, lightning, and radiation. Burns may cause a variety of problems ranging from minor discomfort to serious, life-threatening conditions.

* **local anesthesia** (an-es-THEE-zha) means using medicine to block or numb pain in one part of the body while patients remain awake. General anesthesia blocks pain over the entire body while patients sleep.

A first degree burn affects only the top layer of skin (the epidermis). A second degree burn affects the epidermis and the dermis. A third degree burn is the most serious as it affects deeper layers of tissue, including nerves, sweat glands, fat, and hair follicles. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

Did You Know?

The National Institute of General Medical Sciences and the American Burn Association report that in the United States, more than a million burn injuries require medical attention each year. Among those with burn injuries, the following applies:

- 45,000 require hospitalization, and about half of them require treatment in special burn units
- as many as 10,000 people die of burn-related infections
- burn research and burn treatments are greatly improving survival rates even among people with burns covering more than 90 percent of their bodies.

Sunburns

The discomfort of sunburns can be eased with the following:

- cool baths or cool compresses (ice should not be placed directly on a burn)
- soothing lotions
- over-the-counter pain medications such as acetaminophen.

Some products can make sunburns worse. These include the following:

- petroleum jelly
- butter
- harsh soaps
- over-the-counter sprays or lotions containing benzocaine or lidocaine.

Severe sunburn should be treated by a doctor.

What Is a Burn?

The skin is the protective external surface of the body. Its outer layer, the epidermis, comprises several layers of epithelial cells arranged like shingles on a roof. Its inner layer is the dermis, which contains many types of nerves that sense touch, pain, heat, and cold. Healthy skin renews itself and helps keep body fluids in and unwanted bacteria out. When burns injure the skin, they upset these processes. All burns result in skin cell injury, and the most serious burns can result in death.

Three Classes of Burns

Burns are categorized by the degree of severity.

First-degree burns These burns are the least severe. They affect only the top layer of skin, the epidermis, which turns red at the burn site and causes pain when it is touched. Small blisters and mild swelling sometimes accompany first-degree burns, but usually the blisters heal rapidly and the swelling recedes on its own.

Second-degree burns These burns affect both the dermis and the epidermis. They often cause pain, fever, swelling, chills, and blisters, which may be reddish or whitish in color. Severe sunburns often are second-degree burns, and a person with such a burn should consult a doctor about it.

Third-degree burns These are the most serious burns and require immediate medical treatment. They affect all layers of skin and cause damage and cell death to numerous kinds of tissues, including nerves, sweat glands, fat, and hair follicles. The burn area itself may be free from pain if its nerve endings have been damaged, but the area around the burn will often be extremely painful. The whitish or reddish blisters of second-degree burns usually will not be present, but the skin may be blackened or charred. Other complications of third degree burns may include the following:

- loss of body fluids (dehydration)
- respiratory (breathing) problems
- bacterial infections and pneumonia
- shock

How Do Doctors Treat Burns?

Treatment depends on how deeply the burn has injured skin tissue and underlying organs, the overall size of the burn, and the burn's location. For instance, a person with a sizeable burn to the hands, feet, face, joints, groin, or buttocks should consult a doctor.

Mild burns usually heal on their own when the injured area is kept clean and dry. More serious burns often require treatment in a hospital, and the most severe of these cases may necessitate care in a hospital's specialized burn unit or in an intensive care unit.

Doctors often treat second- and third-degree burns with an antimicrobial agent, such as a silver sulfadiazine cream. Externally applied, this agent kills a range of bacteria. These burns often demand skin graft surgery to replace the damaged tissue followed by a long healing period and physical therapy for the injured area. Often a patient may receive a “skin bandage” prior to a skin graft. These skin bandages, which usually come from pigs although they may also come from human cadavers, serve as temporary coverings for the burned area.

The best defenses against burns are following fire safety rules, being aware, and preventing accidents. Being informed about the sun’s harmful rays is also helpful.

Bursitis *See Arthritis.*

C

Caffeine-related Disorders

Caffeine-related disorders are a group of psychiatric disorders defined by DSM-IV that are caused by taking in large amounts of caffeine in foods, drinks, or over-the-counter medications. Caffeine is a stimulant* that also affects the muscles and the digestive tract. Some doctors include digestive problems caused by caffeine in the category of caffeine-related disorders.*

Keith's Story

Keith, a high-school student in Chicago, got into the habit of drinking Redline, a caffeinated energy drink that his friends recommended as a way of boosting his energy and endurance before basketball practice. Keith thought of Redline as much like a soft drink: a drink to quench thirst as well as improve sports performance. Before long he was drinking two or three cans per day.

One afternoon Keith felt sick after his basketball game. He could feel his heart beating, he was sweating heavily, and he could not stop vomiting. He was also very anxious. The coach took him to the emergency room of a nearby hospital, where the doctor diagnosed Keith with caffeine intoxication. Keith was surprised to learn how much caffeine he had been taking on a daily basis and how quickly it could affect his health.

What Is Caffeine?

Caffeine is a naturally occurring chemical compound that is classified as a xanthine (ZAN-then). Xanthines are nitrogen-based compounds that are found in both plant and animal tissue and have a stimulating effect on the nervous system. Caffeine itself is found in various amounts in the stems, leaves, and berries or beans of some plants, particularly the coffee plant and the leaves of tea bushes. Other natural sources of caffeine used by humans to make beverages include yerba maté, a shrub in the holly family that grows in South America; guarana, a climbing plant found in the Amazon rain forest; kola nuts, used to flavor cola beverages; and cacao pods, the source of cocoa and chocolate. The caffeine in all these plants acts as a natural pesticide that paralyzes and kills insects that would otherwise feed on their leaves and berries.

Caffeine was given its name in 1819 by Friedrich Ferdinand Runge, the first chemist to isolate it from plants. Runge named the white powder caffeine because he derived it from coffee beans. In its chemically pure state,

* **psychoactive** (sy-ko-AK-tiv) affecting a person's mood, behavior, perceptions, or consciousness.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

* **diuretics** (dye-yoor-EH-tiks) are medications that increase the body's output of urine.

caffeine is an odorless powder consisting of white crystals with a slightly bitter taste. It can be dissolved in alcohol and some other liquids as well as in water.

Caffeine is the most widely consumed psychoactive* substance in the world, although most people do not think of it as a drug. Unlike most other psychoactive substances, caffeine is legal and unregulated in almost all countries. The Food and Drug Administration (FDA) defined caffeine in 2003 as a "Multiple Purpose Generally Recognized as Safe Food Substance." An FDA publication from 2007, however, described caffeine as "both a drug and a food additive." This change in wording reflects a growing awareness around the world that caffeine can be addictive when it is overused and that it can have toxic side effects on people who take very high doses of it or who are unusually sensitive to its effects.

How Does Caffeine Affect Humans?

Human use of caffeine Humans have known for centuries about the effects of caffeine in improving alertness, fighting off drowsiness, and increasing physical endurance and muscular coordination. There is evidence from Stone Age burial sites that early humans (possibly as early as 10,000 B.C.E.) knew that chewing the leaves of plants containing caffeine relieved fatigue, enabled people to do hard physical work for longer periods of time, and helped to lift depressed moods. It was not until about 3000 B.C.E., however, that the Chinese discovered that soaking tea leaves in hot water produced a beverage containing more caffeine than the fresh tea leaves themselves. Brewed coffee appeared in the Arab world around the 9th century C.E. but did not reach Europe until the 17th century.

Cacao beans were used for their caffeine content by the Maya in southern Mexico as early as 600 B.C.E. The cacao beans were ground and flavored with vanilla and chili peppers to make a spicy drink to relieve tiredness. When the Spanish conquistadors came to Mexico in the 16th century C.E., they adopted the chocolate-flavored drink (minus the chili peppers), and brought it back to Europe. They planted cacao trees in the West Indies and the Philippines to supply the new European craving for chocolate.

In the 20th century, kola nuts were used by the Coca-Cola Company to flavor its well-known soft drink. Although most cola-flavored soft drinks use artificial flavoring as of 2009, some energy drinks use kola nuts as well as guarana berries to increase their caffeine content. These drinks became increasingly popular in the two decades following their introduction in the 1980s.

Caffeine in the body Caffeine is classified as a central nervous system* stimulant because it reduces drowsiness, increases alertness and the ability to focus, and speeds up the flow of thought. It is also a diuretic*, which means that it increases the loss of body water in the urine.

Caffeine usually enters the body through the mouth and is absorbed by the stomach and small intestine within 45 minutes. The half-life of

caffeine—the time it takes for the body to eliminate half the caffeine taken at one time—varies according to age, sex, the healthiness of a person's liver, and other medications the person may be taking, but in general the half-life of caffeine in a healthy adult is three to four hours. In pregnant women, however, the half-life of caffeine is 9 to 11 hours; in young children, it is as long as 30 hours; and in elderly adults with liver disease, it can be as long as 96 hours.

After being absorbed from the digestive tract, caffeine passes rapidly into other body tissues. It can affect the brain because it is able to cross the blood-brain barrier*. Once in the brain, caffeine acts primarily as an antagonist* of a brain chemical called adenosine (ah-DEN-oh-seen), a chemical that occurs naturally in the body and among its other functions promotes sleep and suppresses arousal. It is also involved in the sleep-wake cycle. Although the chemical reactions involved are complicated, caffeine's ability to increase alertness and physical endurance is largely due to its role as an adenosine antagonist.

In the digestive tract, caffeine stimulates the stomach to produce more gastric acid and reduces muscle tone in the (lower esophageal) esophago-gastric sphincter (the muscle ring that closes off the esophagus from the stomach during digestion), which is the reason why some people experience heartburn after drinking tea or coffee. Caffeine is metabolized (broken down) in the liver into three simpler compounds. One of these compounds is a diuretic; it increases the person's urine output. This pattern of caffeine metabolism* explains why drinks containing high levels of caffeine do not quench thirst as effectively as noncaffeinated beverages. The three compounds formed from the metabolism of caffeine in the liver are broken down still further and leave the body in the urine.

Other effects of caffeine on the digestive tract include stimulation of the gall bladder* and the colon*. In addition, caffeine relaxes the muscles of the anal* sphincter (SFINK-ter), the ring of muscles surrounding the anus that holds fecal matter inside the body. The effects of caffeine on the colon and anal sphincter help to explain why people with fecal incontinence* should not drink coffee or tea.

Tolerance and withdrawal People who drink large quantities of coffee, tea, or energy drinks develop tolerance* to the psychological and physical effects of caffeine. That means that people get used to the stimulant effects of caffeine and are not kept awake at night even after consuming several cups of tea or coffee. Tolerance to caffeine builds up quite rapidly; one study found that test subjects who took 400 mg of caffeine three times per day for seven days did not have any problems with sleep. Another study found that subjects who took in 300 mg of caffeine three times per day for 18 days developed complete tolerance to the psychological effects of caffeine.

The other side of caffeine tolerance is caffeine withdrawal*. Withdrawal refers to the symptoms experienced by heavy caffeine users when they suddenly stop taking large amounts of caffeine. The most common

* **blood-brain barrier** is a biological shield in the body that helps prevent germs or other potentially harmful materials in the blood from entering the brain and spinal cord.

* **antagonist** (an-TAG-oh-nist) a chemical that acts within the body to reduce or oppose the effects of another chemical.

* **metabolism** (meh-TAB-o-liz-um) is the process in the body that converts foods into the energy necessary for body functions.

* **gall bladder** is a small pear-shaped organ on the right side of the abdomen that stores bile, a liquid that helps the body digest fat.

* **colon** (KO-lin), also called the large intestine, is a muscular tube through which food passes as it is digested, just before it moves into the rectum and out of the body through the anus.

* **anal** refers to the anus, the opening at the end of the digestive system through which waste leaves the body.

* **incontinence** (in-KON-ti-nens) is loss of control of urination or bowel movement.

* **tolerance** (TALL-uh-runce) a condition in which a person needs more of a drug to feel the original effects of the drug.

* **withdrawal** a group of symptoms that occurs when a drug that causes physical or psychological dependence is regularly used for a long time and then suddenly discontinued or decreased in dosage.

* **antihistamines** (an-tie-HIS-tuh-meens) are drugs used to combat allergic reactions and relieve itching.

* **insomnia** abnormal inability to get adequate sleep.

symptoms of caffeine withdrawal are headache, nausea, drowsiness or difficulty sleeping, irritability, difficulty concentrating, and pain in the stomach, upper body, or joints. Some people also experience a psychological depression. Caffeine withdrawal begins within 12 to 24 hours after the last dose of caffeine and lasts anywhere from 1 to 5 days.

Medical uses of caffeine Although most people think of caffeine simply as an ingredient of certain beverages and a few solid foods such as chocolate, it is also used in some medications to improve the effectiveness of aspirin and other pain relievers, to treat migraine headaches, or to counteract the drowsiness caused by antihistamines*. A number of over-the-counter medications taken to relieve menstrual cramps or to help dieters control their appetite contain caffeine.

What Are Caffeine-related Disorders?

Caffeine-related disorders are a group of four mental disorders defined by DSM-IV. Some doctors also use the term loosely to refer to physical problems caused or made worse by consuming large amounts of caffeine.

Psychiatric disorders DSM-IV defines four caffeine-related psychiatric disorders:

- Caffeine intoxication. A diagnosis of caffeine intoxication is based on the patient's recent intake of 250 mg or more of caffeine and five or more of the following symptoms during or shortly after consuming the caffeine: restlessness, nervousness, insomnia*, excitement, flushed face, increased urine output, digestive disturbance, muscle twitching, rambling thought or speech, fast or irregular heartbeat, pacing the room, or working for hours without needing rest. In addition, the patient's symptoms are severe enough to interfere with study, work, or relationships.
- Caffeine-induced anxiety disorder. This diagnosis depends on anxiety being the primary symptom together with evidence that the anxiety is directly related to caffeine intoxication or withdrawal within the past month. Again, the patient's symptoms must be severe enough to interfere with functioning to make the diagnosis.
- Caffeine-induced sleep disorder. In this disorder, difficulty sleeping is the central symptom, is directly related to the patient's caffeine intake and is severe enough to interfere with daily functioning.
- Caffeine-related disorder not otherwise specified (NOS). This is a catchall category for symptoms of caffeine withdrawal or other problems related to caffeine intake that are not quite severe enough to meet the definitions of the first three disorders.

Other caffeine-related health problems The long-term use of high doses of caffeine has been linked to several digestive problems caused by increased secretion of stomach acid:

- Peptic ulcers
- Gastroesophageal (GAS-tro-ess-off-uh-JEE-ul) reflux disease (GERD). GERD is a disorder in which the acid contents of the stomach move back up into the esophagus* because the sphincter at the lower end of the esophagus has been weakened. GERD is also known as acid reflux disease.
- Chronic inflammation of the esophagus

There is less agreement among doctors about the effects of high doses of caffeine on miscarriage*. Some studies maintain that high caffeine intake doubles a woman's risk of miscarriage whereas several other studies found no connection. In addition, whereas children can experience the same symptoms of anxiety, speeded-up heart rate, and digestive disturbances as adults, there is no evidence that caffeine stunts children's growth.

How Common Are Caffeine-related Disorders?

It is difficult to find exact figures on the frequency of caffeine disorders, either in the United States or worldwide. One reason is that people vary considerably in their sensitivity to caffeine; age, sex, and body size make a difference too. Most adults do not experience significant side effects from caffeine until they are taking 300 mg or higher each day. Another is the widespread use of tea, coffee, and soft drinks on social occasions or during coffee breaks in the workplace. Because caffeine is such a common part of everyday social customs, most people do not think of it as a habit-forming substance. It is estimated that Americans consume on average 291 mg of caffeine per day, adults in the form of coffee or tea and children in the form of soft drinks or energy drinks. The worldwide average daily dose of caffeine is 76 mg.

In addition, the caffeine content of coffee or tea can vary from cup to cup, depending on the growing conditions at the time the coffee or tea was produced, the processing techniques that were used before the coffee or tea was marketed, and the method of preparation used. Even beans from the same coffee bush in the same growing season can show variations in caffeine content. One 5-ounce serving of coffee can range from 40 to 100 mg of caffeine per cup.

Another reason why it is difficult to gather accurate statistics about the frequency of caffeine-related disorders is that many people who are dependent on caffeine are also taking other psychoactive drugs. Using caffeine along with alcohol or other drugs makes it hard to tell how much the caffeine by itself contributes to the patient's symptoms. In addition, about 50 percent of people diagnosed with depression and other mood disorders* are dependent on caffeine. Moreover, many people with schizophrenia* also consume large amounts of caffeine. This overlap with other mental disorders also makes it hard to tell how many people in the general population have caffeine-related disorders. DSM-IV states simply that the frequency of caffeine-related disorders is unknown as of the early 2000s.

* **esophagus** (eh-SAH-fuh-gus) is the soft tube that, with swallowing, carries food from the throat to the stomach.

* **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.

* **mood disorders** are mental disorders that involve a disturbance in the person's internal emotional state. They include depressive disorders, bipolar disorders, and mood disorders associated with the use of drugs or medical illnesses.

* **schizophrenia** (skit-so-FREE-nee-ah) is a serious mental disorder that causes people to experience hallucinations, delusions, and other confusing thoughts and behaviors, which distort their view of reality.

ENERGY DRINKS: A PROBLEM FOR SOME PEOPLE

Energy drinks are soft drinks containing high levels of caffeine that have been advertised since the 1980s as improving athletic performance and mental concentration. Some contain guarana or yerba maté as well as caffeine derived from tea or coffee. The average energy drink contains about 80 mg of caffeine in an 8-ounce serving, with some containing higher levels. In addition, some energy drinks contain such other stimulants as ginseng, which increase the stimulant effect of caffeine.

An average-sized adult is not likely to have symptoms from a single energy drink; however, those who drink two or more in a short period of time can develop caffeine jitters and other symptoms of caffeine intoxication. According to a May 2008 article in the *New York Times*, hospitals across the United States have seen high school students come to the emergency room with heart palpitations, nausea, and severe sweating after drinking Redline, a popular energy drink. Several school districts in Oregon and Colorado have banned energy drinks from school properties. France and Denmark banned Red Bull, another popular energy drink, following the death of an 18-year-old Irish athlete, who consumed four cans of the drink and then played a basketball game.

Many doctors are concerned about the advertising campaigns for these drinks, which target high school- and college-age males by appealing to their need to appear masculine and adventurous.

How Are Caffeine-related Disorders Diagnosed?

People commonly experience one or more symptoms of a caffeine-related disorder if they take in large quantities of caffeine on a daily basis. They may not always draw a connection, however, between their symptoms and caffeine. One reason is that people vary in their sensitivity to caffeine. Another reason is that people do not always add up all the caffeine they take in from different sources in a short period of time. Individuals who drink a cup of coffee with each meal, take a caffeinated headache remedy, and drink a lot of cola consume much more caffeine than they realize. Common symptoms of high caffeine intake include:

- Nervousness and anxiety
- Muscle twitching or trembling, sometimes called “caffeine jitters”
- Flushing of the face
- Insomnia
- Increased urination
- Stomach or digestive disturbances
- Headache

- Faster breathing rate
- Rapid heart rate or heart palpitation*
- Irritability

Some people do not recognize that they may have a caffeine-related disorder until they try to stop drinking caffeinated beverages or using caffeinated over-the-counter medications. Some researchers at Johns Hopkins University found that some people can experience the symptoms of caffeine withdrawal when they are used to doses of caffeine as low as 100 mg per day, which is the caffeine equivalent of one 6-ounce cup of brewed coffee or two to three 12-ounce servings of caffeinated soft drink.

How Serious Are Caffeine-related Disorders?

Most people who experience the symptoms of caffeine withdrawal or caffeine jitters do not suffer any long-term consequences. The most serious consequences of caffeine-related disorders are found in individuals who combine caffeine with alcohol or other drugs and then drive under the influence or engage in other risky behaviors. One study of college students who were heavy drinkers of alcohol combined with energy drinks reported that these students had much higher than average rates of car accidents, being injured while riding with an intoxicated driver, date rape, and falls or other accidents that needed a doctor's attention.

Some rare cases have been reported of people who have died from extremely high doses of caffeine, usually from taking caffeine pills to stay awake. The lethal dose of caffeine in humans is estimated to be about 150 to 200 mg per kilogram of body mass; an average-sized adult would have to drink between 80 to 100 cups of coffee within 4 to 6 hours to take in that much caffeine. However, people can overdose on No Doz or similar pills to stay awake. Some have needed hospitalization after consuming only 2 grams of caffeine (about 0.07 ounces). When death does occur from a caffeine overdose, it is usually due to an abnormal heart rhythm brought on by the effects of caffeine on the heart and blood vessels.

How Are Caffeine-related Disorders Diagnosed and Treated?

Diagnosis The diagnosis of caffeine-related disorders begins with taking a careful patient history, including any other substances the patient may be using and other mental disorders being treated as well as the patient's use of caffeine. The reason for asking about other substance use (or abuse) and treatment for other psychiatric conditions is that the symptoms of caffeine-related disorders can be disguised by the symptoms of other substance abuse and mental disorders. In addition, caffeine interacts with some medications used to treat schizophrenia by increasing their side effects. Caffeine can also worsen the symptoms of depression and panic attacks*.

To narrow the diagnostic possibilities, the doctor may perform a mental status examination (MSE) in the office. This is a brief test in which the

* **palpitation** is the sensation of a rapid or irregular heartbeat.

* **panic attacks** are periods of intense fear or discomfort with a feeling of doom and a desire to escape. During a panic attack, a person may shake, sweat, be short of breath, and experience chest pain.

* **electrocardiogram** (e-lek-tro-KAR-dee-o-gram), also known as an EKG, is a test that records and displays the electrical activity of the heart.

patient is asked to answer a set of questions, follow simple instructions, and walk across the room while the doctor evaluates the patient's appearance, mood, speech patterns, coordination, thought processes, insight, judgment, and perceptions. A person with a caffeine-related disorder will often appear jittery, tense, having trouble making eye contact, and generally fidgety. The person would not, however, have hallucinations or memory problems, be disoriented, or talk about suicide or murder simply from the effects of caffeine. Any person with these symptoms has another mental or substance abuse disorder.

Caffeine can be detected in the blood, but blood tests are not useful in diagnosing caffeine-related disorders. The doctor might order a urine test to rule out other drug-related disorders or an electrocardiogram* to evaluate an irregular heartbeat if one is present.

Treatment Treatment of caffeine-related disorders consists of lowering daily caffeine consumption or stopping it altogether. Withdrawal symptoms can be treated by taking pain relievers containing small amounts of caffeine until the withdrawal is over.

Can Caffeine-related Disorders Be Prevented?

Caffeine-related disorders can be prevented by becoming knowledgeable about the caffeine content of favorite foods or over-the-counter medications and monitoring one's daily intake of caffeine. One can also prevent caffeine-related disorders by simply avoiding all products with significant amounts of caffeine. Some religious groups, such as the Mormons, Seventh-day Adventists, and some sects of Hinduism discourage their members from drinking caffeinated beverages.

* **diarrhea** (di-ah-RE-a) refers to frequent, watery stools (bowel movements).

* **feces** (FEE-seez) is the excreted waste from the gastrointestinal tract.

Campylobacteriosis

Campylobacteriosis (kamp-pi-lo-BAK-ter-ee-ob-sis) is an infection of the intestinal tract that is caused by the *Campylobacter* bacterium. The infection may cause diarrhea*, nausea and vomiting, and abdominal cramps.

What Is Campylobacter?

Campylobacter (kamp-pi-lo-BAK-ter) is a type of curved bacteria that is a normal inhabitant of the digestive tract of wild and domesticated animals. The bacteria are passed in feces*, which can lead to infection in humans. People, however, do not normally carry *Campylobacter*, and exposure to it usually causes an intestinal infection called campylobacteriosis (kamp-pi-lo-bak-ter-ee-O-sis).

The most common source of *Campylobacter* in the United States is chicken. When chickens (and other animals) are killed for food, the bacteria from their digestive tract can contaminate the meat. People get infected when they eat raw or uncooked meats and eggs (thorough cooking kills the bacteria), drink raw (unpasteurized) milk, or drink contaminated water. Oftentimes, juices from raw meats drip on and contaminate other foods. In rare cases, contact with people or animals who are infected spreads the illness.

Campylobacter is the most common bacterial cause of diarrhea in the United States, where more than 2 million cases occur each year. The illness most frequently affects infants and children younger than age 10, although anyone can get it. Most cases occur in the summer and fall.

What Are the Symptoms of Campylobacteriosis?

Within two to five days after exposure to *Campylobacter*, a person may develop diarrhea, fever, abdominal cramps, and blood in the stool. Most people with campylobacteriosis recover within about ten days without any treatment other than drinking lots of fluids to prevent dehydration (a dangerous loss of fluids and salts). Symptoms of dehydration that should be monitored closely may include: being thirsty, irritable or feeling restless and tired; having sunken eyes, dry mouth and tongue, dry skin; and urinating less frequently; and (in infants) a dry diaper for several hours.

* **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

More severe manifestations of campylobacteriosis included colitis (severe inflammation of the colon), bacteremia (bacterial infection of the blood), and meningitis (inflammation and infection of the layers of tissue that cover the brain). A form of arthritis and Guillain-Barré (gee-YAN-ba-RAY) syndrome, a disorder that causes temporary paralysis*, may also occur in individuals who have recently recovered from a campylobacter infection. This is thought to be due to an overreaction of the immune system*, in response to the presence of the campylobacter bacteria. As a result, the immune system overproduces cells that then attack and damage the individual's own tissues.

Treatment Most people who suffer from campylobacter infection do not require any medication to recover. Those with mild to moderate diarrhea without dehydration may be treated at home. They are given a normal diet and fluids are increased except for fruit juices and sodas. However, in serious cases, people with campylobacteriosis, especially very young children, may require intravenous* (IV) rehydration (fluid replacement).

Prevention The best way to prevent infection is to treat all meat and eggs as if they were contaminated: avoid letting meat drip on other food; always cooking meat thoroughly; always wash cooking utensils and cooking areas thoroughly; and always wash hands after using the bathroom, touching pets, and before handling food. The following are other ways of preventing campylobacteriosis:

- Always drink water that has been tested and approved for purity and drink milk that has been pasteurized. While hiking and camping, people need to avoid drinking water from streams and from sources that pass through land where animals graze.
- Eat foods while they are still warm.
- In caring for a family member who has diarrhea, individuals need to wash their hands before touching other people in the household. Clean and disinfect toilets after they are used by the person with diarrhea.
- In caring for a pet dog or cat that has diarrhea, individuals need to wash hands frequently and check with a veterinarian about treatment.

Cancer: Overview

Cancer is a group of diseases all caused by the out-of-control growth of abnormal cells.

An Ancient Affliction

The disease called cancer has been around as long as human beings have existed. Evidence of cancerous growths, or tumors, has been found among fossilized bones and in human mummies dating from Ancient Egypt. The ancient Greek physician Hippocrates (hi-POK-ra-tees) was the first to use the word “carcinoma” (kar-si-NO-ma) to describe various kinds of tumors. Hippocrates noted that parts sticking out from some tumors looked like the limbs of a crab. The word “cancer” comes from the Latin word for crab. In 1913, only one in nine people had a chance of being alive five years after a diagnosis of cancer. In the early 2000s, depending on the site of the cancer, more than 50 percent of people survive the disease for five or more years. For many types of cancer, early detection and treatment result in a normal lifespan. Despite this progress, however, cancer is the second leading cause of death in the United States.

What Is Cancer?

Cancer can arise almost anywhere in the body, but no matter where it occurs, it is characterized by three features: first, the appearance of abnormal cells, meaning cells that do not function as they should; second, their uncontrolled growth into a nonstructured mass (tumor); and third, their spread (metastasis) (meh-TAS-ta-sis) to surrounding tissues and distant parts of the body. Because cancer cells can spread (metastasize), cancer is also called a malignancy or a malignant* tumor, as opposed to a benign* tumor, which remains in the part of the body in which it starts and does not endanger life.

The main types of cancers are as follows:

- Carcinomas, the most common types of cancer, arise from the cells that cover external and internal body surfaces. Lung, breast, and colon are the most frequent carcinomas diagnosed in the United States.
- Sarcomas arise from cells found in the supporting tissues of the body, as for example in bone, cartilage, fat, connective tissue* is

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **bone marrow** is the soft tissue inside bones where blood cells are made.

the material that holds various body structures together, such as cartilage, tendons, ligaments, and blood vessels, and muscle.

- *Lymphomas* (lim-FO-mas) arise in the lymph nodes* and tissues of the immune system*.
- *Leukemias* (loo-KEE-mee-yas) are cancers of immature blood cells that grow in the bone marrow* and accumulate in large numbers in the blood stream.

A cancer is generally named for the site of the body where it starts and no matter where it spreads to later, it retains the name of the initial site.

Almost everyone knows someone who has had cancer, and it is natural for children to worry that they might get it. However, cancer in children is very rare. Some cancers are more common than others. The cancers that adults get most frequently are cancers of the skin, lungs, and colon and rectum. Breast cancer is common among women and prostate cancer among men. Childhood cancers include leukemias, lymphomas, brain cancer, and osteosarcomas (os-tee-o-sar-KOME-as) (bone cancer).

How Does Cancer Begin?

A healthy body is home to more than 10 trillion cells (at least 100 times as many stars as there are in the entire Milky Way galaxy). Just as neighbors cooperate to maintain an orderly community, cells usually grow, divide, and die in a controlled fashion. In infants and young people, normal cells divide more rapidly than in adults. In adults, most body cells divide only to replace worn-out, dying cells and to repair injuries. The operating instructions for everything that cells do are contained in the genes*, the

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

CANCER IN THE UNITED STATES AND THE WORLD

- The National Cancer Institute (NCI) estimated that 1,444,920 Americans (766,860 men and 678,060 women) might be diagnosed with cancer and 559,650 might die of cancer of all types in 2007. The American Cancer Association also estimated that one out of every two American men and one out of every three American women would develop a cancer at some point during their lifetime.
- In the United States, the death rates for most major cancers steadily declined after the 1970s due to improved screening, earlier detection, and more effective treatment. They decreased by 2.1 percent per year from 2002 through 2004, nearly twice the annual decrease of 1.1 percent per year recorded from 1993 through 2002.
- Still cancer killed 550,270 Americans in 2004, or 187 people per 100,000, making it the second leading cause of death after heart disease. From 2000 to 2004, the average age at death for cancer of all types was 73.
- The overall five-year relative survival rate reported by the NCI for the 1996–2003 period was 64.9 percent. The breakdown of these rates by race and sex were: 65.5 percent for white men, 66.2 percent for white women, 58.6 percent for black men, and 53.8 percent for black women.
- The 2005 NCI Cancer Trends progress report stated that the death rates for the four most common cancers (prostate, breast, lung, and colorectal), as well as for all cancers combined, continued to decline and that the rate of cancer incidence had been relatively stable since the mid-1990s. However, the incidence of non-Hodgkin's lymphoma and cancers of lung and bladder and brain in women, prostate and testis in men, as well as leukemia, myeloma, melanoma of skin, and cancers of the thyroid, kidney, pancreas, liver, and esophagus were rising. Childhood cancer increased slightly. Cancer-related health differences were observed in population subgroups. For example, Blacks and people with low socioeconomic status had the highest rates of both new cancers and cancer deaths.
- The World Health Organization (WHO) reported that, worldwide, 7.6 million people died of cancer out of 58 million deaths in 2005. More than 70 percent of cancer deaths occurred in low- and middle-income countries, due to a lack of resources for prevention, diagnosis, and treatment.
- Population studies showed that cancers arise with different frequencies in different parts of the world. For example, stomach cancer was especially frequent in Japan, lung and colon cancer in the United States, skin cancer in Australia, leukemia in Canada, and lung cancer in the United Kingdom.
- According to the WHO, worldwide cancer deaths were expected to rise in with an estimated 9 million people dying from cancer in 2015, and 11.4 million dying in 2030. Reasons included increased smoking and pollution in developing nations, unhealthy diets, and more people living into old age, when cancer risk is higher. A link was also established with uncontrolled infection rates. For example, more than 400,000 cases of liver cancer were tied to infection with hepatitis in the mid-1990s. Parasites in food also can lead to stomach cancers.

* **carcinogens** (kar-SIH-no-jenz) are substances or agents that can cause cancer.

* **lymphatic system** (lim-FAH-tik) is a system that contains lymph nodes and a network of channels that carry fluid and cells of the immune system through the body.

packets of information inherited by offspring from their parents. Genes are made of DNA, a large molecule that stores the information needed for growth and development. Genes make proteins, the molecules required for the structure, function, and regulation of the body's cells, tissues, and organs. When a gene inside a cell is switched on, the cell starts producing the required protein. Sometimes genes undergo changes called mutations. Mutations in a gene can affect how it works; for example, a mutated gene might produce too much of a protein or perhaps none at all or protein that will not be able to function.

Life proceeds by cell growth and division, and this process is directed by a collection of genes whose proteins work like traffic police to encourage growth or to halt it. When these genes are mutated, the proteins they make may erroneously tell cells to continue growing, like a traffic light stuck on green. Such mutated genes are called oncogenes because they are capable of transforming normal cells into cancer cells. Normal genes that regulate cell growth and proliferation but which can cause cancer when mutated are called proto-oncogenes. In the late 20th century, dozens of proto-oncogenes were identified in human cancer. Normal cells with damaged DNA die if the body cannot repair the DNA, but cancer cells produced by oncogenes do not die. They keep growing.

Many tumors need 30 to 40 years to develop, which explains why children rarely get cancer. However, it is possible for a person to inherit a mutant cancer-causing gene, in which case the onset of cancer will be at an earlier age.

Genes can undergo mutations as a result of cancer-causing substances called carcinogens* (kar-SIN-o-jens) that are found in the environment and in chemicals in human cells. Another source of mutations is mistakes in the information copying that occur when DNA is replicated during cell division. Cells normally have repair systems to correct such errors. When the repair system slips up, however, the damage becomes a permanent part of that cell and its descendants. If a person has a faulty repair system, mutations in the genes build up rapidly, making the cells more likely to become cancerous. Faulty repair plays a role in certain kinds of colon, skin, and breast cancers.

How Does Cancer Spread?

The process by which cancer cells spread to other parts of the body where they again begin to grow and replace normal tissue is called metastasis. During this process, cancer cells break away from the primary tumor and enter the blood stream or lymphatic system*, which can carry them to almost any part of the body. Carcinomas metastasize primarily through lymphatic channels, whereas sarcomas metastasize primarily through the blood stream. Cancer cells frequently first spread to the regional lymph nodes, meaning those near the primary tumor, which is called regional disease (or involvement). Cancer that spreads to other organs or to lymph nodes distant from the primary tumor is called metastatic disease. New tumors

resulting from metastasis are called metastatic tumors and their cells are the same as that of the primary tumor. The most common sites of metastasis from solid tumors are the lungs, bones, liver, and brain.

New techniques show that abnormal cells from a tumor often are circulating even when doctors can find no evidence of spread, which is referred to as undetectable spread micrometastasis (MY-kro-meh-TAS-ta-sis). Once a cancer cell has found a new site, it must reverse all the steps it took in liberating itself from the primary site. It has to attach to the inner lining of a blood or lymph vessel, cross through it, invade the tissue beyond, and multiply. Probably fewer than 1 in 1 million of these cancer cells are able to survive to take up residence elsewhere. Much of how cancer spreads remained a mystery in the early 2000s. Some tissues—for example, cartilage and brain tissue—seemed more resistant to cancer. And some animals almost never have cancer.

What Causes Cancer?

A risk factor is anything that increases a person's chance of getting a disease. However, having a risk factor does not mean that a person will get the disease for sure. People usually get cancer as a result of a complex set of interactions between many risk factors, and this is why it is often called a multifactorial disease. While science could not as of 2009 provide all the answers, many of the causes of cancer had been identified. Besides factors such as heredity, diet, and hormones, studies point to key external factors that promote cancer such as carcinogens, pollution, radiation, and viruses or bacteria.

Exposure to chemical carcinogens Carcinogens are substances that directly cause or can help cause cancer. Thousands of chemicals used in farming and industry can cause cancer in humans or animals after prolonged or excessive exposure. Notorious chemical carcinogens include asbestos (az-BES-tos), and several insecticides* (e.g., DDT, ethylene dibromide (EDB), and kepone) that have a long history of having caused cancer. Other examples include industrial workplace chemicals such as the fumes of the metals cadmium, nickel, and chromium, known to cause lung cancer. Leukemia can result from chemically induced changes in bone marrow from exposure to benzene (BEN-zeen) and cyclophosphamide. Government regulations control the use of these chemicals, but not the use of other chemicals considered by many research scientists to be probably carcinogenic in humans because they are powerful carcinogens in animals.

Tobacco, food, and alcohol Tobacco contains chemicals that are lethal carcinogens, and its use is responsible for 30 percent of all cancer deaths every year in the United States, which affect the lungs and other organs of the body. In Western countries, diet has also been associated with certain cancers, particularly diets containing high amounts of animal (saturated) fat and red meat. Eating insufficient quantities of fruits and vegetables appears to contribute to cancer, for reasons no one understood as of 2009. It may be that fruits and vegetables help to block cancer-causing

* **insecticides** are chemicals used to kill insects and prevent infestation.

Cancer-fighting foods

Foods	Effects on cancer
Avocados	May attack free radicals in the body by blocking intestinal absorption of certain fats; may be useful in treating viral hepatitis (a cause of liver cancer)
Beans	May prevent or slow genetic damage to cells, prevent prostate cancer, and lower the risk of digestive cancers
Berries	May help prevent skin, bladder, lung, and breast cancers and slow the reproduction of cancer cells
Cabbage and cauliflower	May slow cancer growth and development and help to reduce the risk of lung, prostate, and bladder cancers
Broccoli	May prevent some types of cancer, including stomach, colon and rectal
Carrots	May reduce a wide range of cancers including lung, mouth, throat, stomach, intestine, bladder, prostate and breast
Chili peppers and jalapeños	May prevent cancers such as stomach cancer
Cruciferous vegetables (broccoli, cauliflower, kale, Brussels sprouts, and cabbage)	May help decrease prostate and other cancers
Dark green leafy vegetables	May reduce the risk of lung and breast cancer
Figs	May shrink tumors
Flax	May reduce the risk of breast, skin, and lung cancer
Garlic	May increase the activity of immune cells that fight cancer and indirectly help break down cancer causing substances. May help block carcinogens from entering cells and slow tumor development. May render carcinogens in the liver inactive. May lower risk of a variety of cancers including stomach, colon, lung and skin
Grapefruits	May prevent cancer by sweeping carcinogens out of the body and inhibit the proliferation of breast-cancer cells in vitro
Grapes	May inhibit the enzymes that can stimulate cancer-cell growth and suppress immune response
Kale	May help stop the conversion of certain lesions to cancerous cells in estrogen-sensitive tissues, suppress tumor growth, and block cancer-causing substances from reaching their targets
Licorice root	May prevent the growth of prostate cancer
Mushrooms	May help the body fight cancer and build the immune system
Nuts	May suppress the growth of cancers
Oranges and lemons	May stimulate cancer-killing immune cells like lymphocytes that may function in breaking down cancer-causing substances
Papayas	May reduce absorption of cancer-causing nitrosamines from the soil or processed foods. May minimize cervical dysplasia and certain cancers
Red wine	May inhibit cell proliferation and help prevent cancer
Rosemary	May inhibit the development of breast and skin tumors
Seaweed and other sea vegetables	May help in the fight against breast cancer
Soy products like tofu	May help to prevent breast and prostate cancer by blocking and suppressing cancerous changes
Sweet potatoes	May prevent cancer cells from dividing, reduce the risk of cancer of the stomach, lung, colon, rectum, liver and pancreas, and protect against various types of cancer
Tomatoes	May combat prostate cancer and protect against breast, lung, mouth, stomach, and pancreatic cancer. May reduce risk of breast, prostate, pancreas and colorectal cancer. May prevent cellular damage that leads to cancer.
Turmeric	May inhibit the production of the inflammation-related enzyme cyclo-oxygenase 2 (COX-2), which reaches abnormally high levels in certain inflammatory diseases and cancers, especially bowel and colon cancer
Whole grains	May help decrease the risk of developing most types of cancer

effects. Drinking large amounts of alcohol increases the risk of cancer of the upper respiratory and digestive tracts, and alcoholic liver disease can lead to liver cancer. Even moderate drinking may contribute to breast and colon and rectal cancer. Meats cooked at high temperatures are known to form small quantities of many potent carcinogens, comparable to those found in cigarette smoke.

Some research focused on trying to answer more questions about diet and cancer. One European study, called EPIC, involved 500,000 people

in 10 countries and aimed to produce detailed, reliable information about diet and cancer. The first results, published in 2001, confirmed that a high-fiber diet reduces colorectal cancer and that eating red or processed meat increases colorectal cancer risk whereas intake of fish decreases it.

Pollution In the early 2000s there was mounting evidence that toxic pollution causes cancer, especially in children. Polluters dumped more than 175 million pounds of cancer-causing chemicals into U.S. air and water systems in 1996, and this amount increased sharply during the early 2000s when many environmental regulations were relaxed. Many believe that carcinogenic industrial pollution was severely under-reported because the Environmental Protection Agency (EPA) did not report on carcinogenic chemicals from cars, trucks, buses, mines, power plants, airports, incinerators, and other small polluters.

The EPIC study also focused on the relation between air pollution or environmental tobacco smoke (ETS) and incident cancers of the bladder, lung, oral cavity, pharynx, larynx or leukemia.

Natural and human-made radiation Some forms of radiation have been shown to cause cancer, especially ionizing radiation which has been proven to cause genetic damage leading to cancer. X-rays, gamma rays, cosmic rays, and particles released by radioactive materials such as alpha particles and beta rays are examples of ionizing radiation. Leukemia was at one time thought to be the major cancer to arise from high-dose radiation exposure, based on the experience of people exposed to the atomic blasts in Japan in 1945. It was later determined that other cancers can result from radiation exposure, although they may take 10 to 15 years to develop.

Most cancer deaths are caused by non-ionizing radiation from natural sources such as the sun's ultraviolet* rays. For example, sunburns during childhood are a key factor in causing a kind of skin cancer called melanoma (mel-a-NO-ma) and most skin cancers are a direct result of sunlight exposure. But electric power lines, household appliances, and cellular telephones had as of 2009 not been proven to cause cancer. In the late 1990s and early 2000s, questions were raised about possible cancer risk associated with the use of video display terminals, but research did not provide definite evaluations as of 2009.

Viruses Viruses have also been shown to help trigger some cancers. These findings do not mean, however, that these cancers can be caught like a flu infection. What happens is that the virus can cause genetic changes in cells that make them more likely to become cancerous. For instance, links have been established between the following pairs:

- Cervical cancer and the genital wart virus (HPV)
- Primary liver cancer and the Hepatitis B virus
- T-cell leukemia in adults and the Human T-cell leukemia

* **ultraviolet** light is a wavelength of light beyond visible light; on the spectrum of light, it falls between the violet end of visible light and x-rays.

Eating for Health

The American Cancer Society recommended the following general nutritional guidelines that may help people prevent cancer:

- Choosing most foods from plant sources such as vegetables, fruits, and grains
- Limiting intake of high-fat foods, especially from animal sources
- Staying physically active
- Maintaining a healthy weight
- Limiting consumption of alcoholic beverages

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

How Do People Know They Have Cancer?

Many symptoms of cancer such as weight loss, fever, fatigue, and various kinds of lumps could also be caused by other diseases. Some cancers may cause no symptoms until they have spread. Based on the most commonly occurring cancers, the American Cancer Society published a list of seven warning signs of cancer:

- Change in bowel or bladder habits (for instance diarrhea that does not go away or pain during urination)
- A sore anywhere on the skin that does not heal
- Unusual bleeding or discharge from the nose, mouth, skin, nipple, or vagina
- A thickening or lump in the breast or elsewhere
- Indigestion or difficulty in swallowing
- Obvious changes in a wart or mole
- Nagging cough, particularly if these symptoms occur in a cigarette smoker.

How Is Cancer Diagnosed and Treated?

Diagnosis Diagnosing cancer involves removing some tissue for evaluation. This procedure is called a biopsy* (BY-op-see). Once the diagnosis is made, a treatment plan is put together. To do that, the doctor must determine how widespread and how serious the disease is. Staging the disease means assigning letters and numbers to it as a way of indicating whether it has spread and if so how far. There are several systems for staging, depending on the type of cancer. Generally speaking, the smaller the tumor, the more curable it is, although some cancer can be unpredictable. The outlook for some cancers, for example, leukemia and lymphoma, is judged according to other criteria. Cancer is classified according to the part of the body in which it begins and by how it looks under a microscope.

Treatment Various treatment for cancer are surgery, radiation therapy, and chemotherapy* (kee-mo-THER-a-pee), either prescribed alone or together. Other treatment methods such as immunotherapy and anti-angiogenesis treatment are also used. Because cancers vary in how fast they grow, where they spread, and how they respond to treatment, treatment is specifically tailored to the specific cancer a person has.

- Surgery performed to remove tumors is the oldest form of treatment for cancer, and it offers the greatest chance of cure for many kinds of cancer. About 60 percent of patients with cancer have some type of surgery.
- Radiation therapy uses high-energy radiation to kill cancer cells that surgery cannot remove because they are too small.

- Chemotherapy uses anticancer drugs to treat cancer. Chemotherapy drugs are given through a vein (also called an intravenous or IV line) or by mouth as pills. These drugs enter the blood stream and reach places in the body that surgery and radiation cannot reach. Chemotherapy is often given for cancer that has spread.
- Immunotherapy uses the body's own immune system to fight cancer. This therapy can be applied either by stimulating the immune system or by prescribing human-made immune system proteins.
- Anti-angiogenesis therapy prevents the creation of new blood vessels, as its name implies (from the Greek *anti*, meaning “against” *angio* meaning “blood vessel” and *genesis* meaning “beginning”). As the human body grows, it requires new blood vessels to distribute blood to all of its cells. Adults also need new blood vessels to heal wounds and repair damaged tissues. In people with cancer, however, this same process also creates new blood vessels that provide a tumor with its own blood supply to grow and spread. Anti-angiogenesis uses drugs to stop tumors from making new blood vessels.

Can Cancer Be Prevented?

Many cancers could be prevented by changes in a person's lifestyle. For example, cancers caused by cigarette smoking and drinking a lot of alcohol could be prevented completely. Limiting certain kinds of foods, such as red meats and animal fats, and eating lots of fruits and legumes (such as peas and lentils) may also help reduce the risk of getting many cancers. Physical activity helps to avoid obesity* and is believed to have other protective effects against cancer. Most of the 1 million skin cancers that are diagnosed each year could be avoided by staying out of the sun.

Regular cancer checks, called screenings, for cancer of the breast, colon, rectum, cervix, prostate, testes, mouth, and skin are an effective way of detecting cancer early enough so that it can be treated successfully. In addition, self-examination for breast and skin cancers may also help to detect tumors at earlier stages. The American Cancer Society estimates that if all Americans participated in regular cancer screenings, survival would be dramatically improved.

However, cancer prevention efforts would be more successful with improved federal regulation of pollution and carcinogenic substances. Such regulation would require industry to stop dumping cancer-causing chemicals and chemicals of unknown risk in the environment, where they can lead to carcinogenic exposure or leach into the food chain. The federal government should require polluting industries to conduct community cancer studies to determine danger near major pollution sites, such as power plants, highways, and airports. It should also strictly enforce the Superfund law to clean up toxic waste sites, and the Clean Water Act to keep pollution out of drinking water while enforcing

Clinical Trials and New Cancer Treatments

Studies of new or experimental treatments in patients are known as clinical trials. Research in cancer could not move forward without them because drugs may work very differently in people than in the animals in which the drugs first proved successful.

Clinical trials seek to answer such questions as the following:

- Does this new drug or treatment work?
- Does it work better than other treatments already available?
- Do the benefits outweigh the risks, including side effects?

Although there are risks to new treatments, clinical trials are done only when there is some reason to believe that the treatment will be of value to the patient.

Participating in a clinical trial is completely up to the patient. The doctor may suggest it, or patients can request information about clinical trials from the National Cancer Institute.

* **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

urban air pollution standards to protect people from cancer-causing pollution.

Through much of the 20th century commercial cigarette manufacturers increased concentrations of nicotine in cigarettes while company executives pursued aggressive marketing that denied tobacco's addictive nature and its connection to cancer. Similarly industrial chemicals such as U238 (so-called depleted uranium) munitions, and other profitable cancer-causing chemicals went unregulated in the second half of the 20th century and contributed to cancer rates. There is a recognized need for education on what carcinogens are and how to avoid them. Government oversight and increased regulation are key for the protection of both the environment and the public; they are also essential in the fight to control and even reduce the incidence of cancer in the 21st century.

Living with Cancer

A cancer diagnosis is usually shocking and frightening. A person's life is suddenly disrupted by visits to the doctors, surgery, treatment, and changing personal relationships. Children with cancer may have to miss school for a time or to give up sports or other activities. Children especially may feel incorrectly that something they did caused the cancer, especially if it is a brother or sister who is sick. Family, physician, friends and organizations, religious clergy, and self-help groups may be important sources of support. Each person's way of dealing with cancer is unique. Even with life-threatening cancers, a person may live for many years. And more than 70 percent of children and adolescents with cancer are successfully treated.

Alternative and complementary therapies Many patients seek alternative therapies during their treatment. These therapies generally are of two kinds:

- Alternative therapies are often advertised as cancer cures. Patients should be aware that these therapies have either not been tested for safety and effectiveness or have been tested and found to be ineffective.
- Complementary therapies, by contrast, are used in addition to standard medical therapy. They may help to relieve symptoms of the disease or side effects of treatment, or they just may make patients feel better. Examples of complementary therapies are meditation to relieve stress and peppermint or ginger tea to combat nausea (stomach upset) from chemotherapy.

Canker Sores (Aphthous Ulcers)

Canker sores, or aphthous (AF-thus) ulcers, are small, round sores in the mouth that quickly turn white and usually are painful.

Ashley's Story

Ashley first noticed a slight tingle in her mouth one morning as she was brushing her teeth before school. It was inside her lower lip, on the soft, fleshy part in front of her bottom teeth. By the next morning, she felt a bump that hurt when her tongue touched it and when she tried to drink orange juice with her breakfast. By dinner time, when Ashley pulled down her lip (gently) to look at the small, round blister in her mouth, she saw that it was white and rimmed with a red ring that looked like a halo. It was Ashley's first canker sore, but it probably would not be her last.

What Is a Canker Sore?

Canker sores are small, round sores that are found where Ashley discovered hers: inside the mouth. They may occur on the inside of the lips, on the tongue, on the roof or floor of the mouth, or inside the cheeks. They may appear as one small sore or in groups, and they can be quite irritating and painful to even the slightest touch. Contact with acidic, salty, or spicy foods and fluids, such as chips or orange juice, can be particularly painful for people with canker sores.

Canker sores are not contagious*. They cannot be passed along from one person to another by kissing or by sharing food. It is important, however, to distinguish canker sores from other kinds of mouth sores, which may be caused by viral infections*, trauma, vitamin deficiencies, and sometimes, but not often, cancer. If a mouth sore has not healed within a week or two, it is important to see a doctor.

What Causes Canker Sores?

No one is sure what causes canker sores, although they occur more frequently when people are experiencing stress. Often, the first sores appear as children near middle-school age. Canker sores are more common among women.

How Are Canker Sores Treated?

Ashley's canker sore disappeared on its own two weeks after she first noticed that sore feeling inside her mouth. Most canker sores clear up the same way, without treatment, although some people use over-the-counter

medications to numb canker sores during the first four or five days when they are most painful. It also helps to avoid the sore while brushing teeth and to eliminate foods that aggravate the pain, such as salty chips, citrus fruits, or spicy foods.

If canker sores recur or return or if they do not heal on their own within two weeks, they may need to be seen by a doctor or dentist. Usually, canker sores go away on their own.

People with AIDS and other severe immunodeficiency states can develop severe and prolonged episodes of canker sores that may require medical attention and treatment.

Carbon Monoxide Poisoning

Carbon monoxide is a colorless, tasteless, odorless gas that results from incomplete burning of solid, liquid, and gaseous fuels. This gas can cause dizziness, nausea, coma, or death if breathed in sufficient amounts.*

A Close Call

The neighbors could set a clock by Dr. Smith's morning routine. He turned off the porch light at 6:00 a.m., picked up the newspaper from the driveway at 6:15, and took the dog for a walk at 6:30. One winter morning, Dr. Smith's next-door neighbor noticed that none of these activities had occurred. He knew the Smiths were home, but they did not answer the doorbell or the telephone.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

Carbon monoxide detectors for the home look like smoke detectors and can be installed to monitor for CO fumes.

AP Images.

* **hemoglobin** (HE-muh-glo-bin) is the oxygen-carrying pigment of the red blood cells.

* **acute** describes an infection or other illness that comes on suddenly and usually does not last very long.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

The neighbor called the police, who broke into the house and found four unconscious people. The gas heater had shut off during the night and had been giving off carbon monoxide gas for many hours. The Smiths were rushed to the hospital and treated for carbon monoxide poisoning. Dr. Smith and his wife and children were lucky; they were found in time and recovered completely after several weeks.

What is Carbon Monoxide (CO) Poisoning?

Carbon monoxide (CO) is a chemical created when some fuels, such as coal and gas, are burned. CO is toxic because it reduces the amount of oxygen received by the body's cells. Red blood cells contain a protein called hemoglobin* that carries oxygen to the body's cells. Because CO binds much more easily and tightly to hemoglobin than oxygen does, CO will replace oxygen in the bloodstream when inhaled. When that happens, the cells that need lots of oxygen, such as those of the heart, skeletal muscles, and central nervous system, cannot operate properly.

Acute CO poisoning Dr. Smith and his family suffered acute* CO poisoning, in which a large amount of CO was breathed at one time. This kind of poisoning can lead to death: It kills 25 to 40 percent of those exposed. Survivors may feel symptoms for days, months, or years.

Chronic CO poisoning CO poisoning also can be chronic*. A small amount of CO inhaled continuously or frequently over a long period of time does not kill, but it does impair oxygen flow to the brain and may cause long-term nervous system problems, such as headaches, dizziness, weakness, sleepiness, nausea, and vomiting. Low-level chronic exposure to CO is especially serious for people with heart, lung, or circulatory problems, and for infants and older adults. Developing fetuses also can be affected by CO poisoning.

Carbon Monoxide and the Environment

CO is one of the most prevalent poisons in the environment. It can get into buildings, homes, and vehicles in many ways. Sources of CO include car exhaust, gas or oil furnaces, kerosene lamps, space heaters, improperly installed appliances, wood stoves, wood-burning fireplaces, and tobacco smoke. CO poisoning most often occurs during winter months, when people use heaters and fireplaces.

How Is CO Poisoning Treated?

A person with acute CO poisoning requires extra oxygen as soon as possible. The individual may be given pure oxygen to breathe. A hyperbaric (hy-per-BARE-ik) oxygen chamber also may be used to treat CO poisoning. This is a large chamber that holds the patient and sometimes the

medical team. The chamber is filled with 100 percent oxygen, and the pressure is increased to three atmospheres (three times the pressure of the air near the Earth's surface, or the pressure the body feels about 90 feet under water). Pressure and pure oxygen help the oxygen molecules displace the CO attached to hemoglobin. Diagnosis and treatment of chronic CO poisoning may be more difficult because its symptoms are similar to flu and many other conditions.

Can CO Poisoning Be Prevented?

CO poisoning is usually preventable. Basic safety guidelines include the following:

- Never burning charcoal in a tent or camper to keep warm.
- Installing water heaters and gas appliances properly and checking them often to make sure they are operating correctly.
- Keeping chimneys and wood-burning fireplaces clean.
- Never letting a car idle inside a garage, especially if the garage is attached to the house.
- Installing commercial CO detectors (similar in design to smoke detectors) for the home.

- * **ligaments** (LIG-a-ments) are bands of fibrous tissue that connect bones or cartilage, supporting and strengthening the joints. Ligaments in the mouth hold the roots of teeth in the tooth sockets.
- * **ergonomics** (er-go-NOM-iks) is a science that helps people to know the best postures and movements to use while working, in order to avoid injury and discomfort.
- * **synovitis** (sin-o-VY-tis) is inflammation of the membrane surrounding a joint.
- * **arthritis** (ar-THRY-tis) refers to any of several disorders characterized by inflammation of the joints.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

Carpal Tunnel Syndrome

Carpal tunnel syndrome is a repetitive stress disorder caused by the compression of the median nerve in carpal tunnel in the wrist that causes pain and numbness in the hand and fingers.

Rodney's story

Rodney loved coaching his son John's Little League team. Shortly before the season began, though, Rodney took a new job on a small appliance assembly line. After a few weeks, his fingers began to tingle and hurt. When he was at baseball practice, he experienced pain while gripping the bat properly. When the pain did not get better, Rodney went to the doctor and complained that it hurt to cross his thumb over the palm of his hand and that the pain and tingling came and went but was worse at night.

What Is Carpal Tunnel Syndrome and Who Gets It?

The median nerve extends through the forearm into the palm of the hand where it divides and sends branches to the thumb and first three fingers. To reach the hand, the nerve passes through a narrow space, or tunnel, in the wrist formed by ligaments* and the carpal bones of the wrist. Carpal tunnel syndrome (CTS) occurs when this space becomes narrowed and the median nerve is compressed or irritated. Pressure on the median nerve causes numbness, weakness, and pain. If not corrected, CTS can result in permanent damage and loss of feeling in some fingers.

It is hard to estimate how many people develop CTS because many people with mild CTS do not see a doctor. One study found that as many as half the people in high-risk occupations develop CTS. Another study estimated that 10 percent of people in the United States would have CTS at some point during their lifetime. Most people do not develop CTS until after age 35. Women are at least three times more likely to develop the condition than men. Researchers hypothesize that is because the space in the wrist that the median nerve must pass through is smaller in women to begin with, so it takes less narrowing to put pressure on the nerve.

Carpal Tunnel Syndrome is common, especially among people who perform repeated motions with their hands and wrists or who use them in ways that are not ergonomically* correct. There are other causes of CTS, and often the cause is not clear. CTS affects some people who have synovitis*, arthritis*, diabetes*, thyroid disease, and acromegaly*. Injury to the wrist is another cause of CTS. Pregnant women sometimes retain fluid, making the ligaments in the carpal tunnel swell and causing CTS.

What Happens When People Have Carpal Tunnel Syndrome?

The doctor can usually diagnose CTS by having the patient do certain manipulations with his or her hands and noting whether these are painful. Another clue to CTS is that the little finger is not painful, because the median nerve does not send a branch to this finger. More extensive testing can be done to rule out other conditions, for example x-rays may be done to rule out a fractured wrist bone. Sophisticated tests can measure the speed at which the median nerve transmits impulses if a diagnosis of CTS is uncertain.

Mild CTS is usually treated by resting the wrists and then splinting them. However, the best way to treat CTS caused by repetitive motion is to eliminate the cause, which could mean allowing assembly line workers to switch jobs frequently during their shift or purchasing ergonomically correct office equipment and computer keyboards.

Advanced CTS may be treated by the injection of cortisone* or a related medication into the wrists. In severe cases of CTS, the doctor may recommend a surgical procedure called carpal tunnel release. This surgery cuts a band of tissue in the wrist so that the space for the median nerve is widened. The procedure is usually done as day surgery and does not require hospitalization. If left untreated, CTS can cause permanent nerve damage. With early treatment and lifestyle modifications most people achieve pain relief.

Cat Scratch Disease

Cat scratch disease is an infectious illness that can cause flu-like symptoms and swelling of lymph nodes. It is caused by bacteria carried in cat saliva. The bacteria usually enter the body from a cat scratch or a bite that breaks the skin.*

What Is Cat Scratch Disease?

Cat scratch disease (also called cat scratch fever) is caused by the bacterium *Bartonella henselae* (bar-tuh-NEH-luh HEN-suh-lay), which is found in the saliva of cats and kittens all over the world. About 3 to 10 days after a person is bitten or scratched by a cat, a blister or small bump may develop. This is called an inoculation (ih-nah-kyoo-LAY-shun) lesion, which means that it appears at the site where germs entered the body. Usually about two weeks later, there is inflammation of nearby lymph nodes. If the scratch or bite is on the arm, the lymph nodes on the arm or in the armpit will become swollen. Swelling also can develop in the lymph nodes in the neck or groin, depending on the site of the scratch or bite.

Who Gets Cat Scratch Disease?

People of any age can get the disease, but most cases occur in children and teens. It is estimated that there are about 24,000 cases of cat scratch disease each year in the United States. Members of the same household can become ill if they are scratched or bitten by the same infected cat. Cat scratch disease affects 9 of every 100,000 persons each year worldwide. People can get the disease only from infected cats and kittens. It cannot be transmitted from person to person, but it can spread among cats. It is thought that cats and kittens can become infected with *Bartonella henselae* from fleas.

What Are the Signs and Symptoms of the Disease?

The most common symptoms of cat scratch disease are a bite or scratch that does not heal normally; painful or swollen glands (lymph nodes), especially in the armpit or near the inside of the elbow; fever; headache; fatigue; joint pain; and sometimes a rash. Less common symptoms are weight loss, sore throat, and draining lymph nodes. If a person is suspected of having cat scratch disease, the doctor will ask about any recent

contact with a cat and will look for signs of a cat scratch or bite, swollen lymph nodes, or an inoculation lesion. Sometimes a person with cat scratch disease does not recall having had contact with a cat. Blood tests can rule out other causes of swollen nodes and check for the presence of antibodies* to the bacteria that cause the disease. In some cases, a doctor will use a needle to take a sample (a piece of tissue) from a swollen lymph node for examination under a microscope.

How Do Doctors Treat Cat Scratch Disease?

Antibiotics may be prescribed for cat scratch disease, but some doctors advise taking these medications only in severe cases. Most people eventually get well without treatment. If the patient is otherwise healthy, rest and over-the-counter medicines, such as acetaminophen* to relieve pain and fever, are all that are needed while waiting for the disease to run its course. If a lymph node becomes very swollen and painful, the doctor may decide to drain it. Treatment with antibiotics often is recommended for patients who have weakened immune systems as the result of other illnesses. The symptoms in most patients usually resolve after several weeks of treatment with antibiotics and within three months without antibiotic treatment. Swollen lymph nodes may take several months to return to normal size. Most people recover completely from the illness. After an episode of cat scratch disease, people are usually immune to it, meaning that they cannot get the disease again.

Complications

Generally, cat scratch disease is not serious in people who are healthy. However people with weak immune systems, such as those with human immunodeficiency virus* (HIV) infection or poorly controlled diabetes* and those receiving chemotherapy* for cancer, have a greater risk of complications and need to be watched closely by their healthcare providers. These complications include hepatitis*, osteomyelitis*, encephalitis*, and retinitis*. Sometimes cat scratch disease can appear in the form of Parinaud oculoglandular syndrome (PAH-rih-nod ok-yoo-lo-GLAN-dyoo-ler-SIN-drome). In this condition, a small sore and inflammation develop in the membrane lining the inner eyelid, called the conjunctiva (kon-jung-TIE-vuh), accompanied by swollen lymph nodes around the ear. Rubbing one's eyes after handling an infected cat can transmit the infection to the conjunctiva because the bacteria can be present on the cat's coat wherever it licks itself.

Prevention

About 30 percent of American households have pet cats. Keeping cats indoors and free of fleas may help prevent them from contracting the infection. It is a good idea to avoid stray or unfamiliar cats and not to provoke any cat or kitten to the point that it scratches or bites. Thoroughly cleaning any wounds inflicted by a cat may help prevent infection.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

* **human immunodeficiency virus** (HYOO-mun ih-myoo-no-dih-FIH-shen-see), or HIV, is the virus that causes AIDS (acquired immunodeficiency syndrome), an infection that severely weakens the immune system.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

* **hepatitis** (heh-puh-TIE-tis) is an inflammation of the liver. Hepatitis can be caused by viruses, bacteria, and a number of other noninfectious medical conditions.

* **osteomyelitis** (ah-stee-o-my-uh-LYE-tis) is a bone infection that is usually caused by bacteria. It can involve any bone in the body, but it most commonly affects the long bones in the arms and legs.

* **encephalitis** (en-seh-fuh-LYE-tis) is an inflammation of the brain, usually caused by a viral infection.

* **retinitis** (reh-tin-EYE-tis) is an inflammation of the retina, the nerve-rich membrane at the back of the eye on which visual images form.

Cataracts

Cataracts develop when the lens of the eye becomes cloudy. They usually impair vision and sometimes occur as people get older.

What Are Cataracts?

Many people who live to an old age develop cataracts, often without noticing the effects until they are past age 70. For some, it might mean only a slight change in vision. Others, however, find they need surgery to remove the cloudy lens.

A cataract results when the clear lens in the eye becomes cloudy. Like frost on a window, the cataract makes it more difficult to see clearly. The reason is that the light passing through the cloudy lens is distorted

▶ Cataracts develop slowly, causing the eye's clear lens to become cloudy. Cataracts can be removed surgically. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

before it reaches the visual receptors in the retina* at the inside rear of the eyeball.

What Happens When People Get Cataracts?

Researchers believe that cataracts develop because the proteins in the eye change as people age. The changes cause the lens to become cloudy. Other factors, such as smoking, poor nutrition, eye injury, exposure to excessive sunlight, and certain medical conditions such as diabetes*, also may be factors that put people at higher risk of developing cataracts.

Cataracts develop slowly. At first, people notice difficulty reading the newspaper, or they experience blurry vision. The eyes become more sensitive to light, and seeing at night becomes especially difficult. People with cataracts often say they feel they have a film over their eyes, as if they are looking through a piece of gauze.

For a short time, the condition actually may benefit some people who always had trouble seeing objects that are near them, such as the words on a page. The cloudiness of a cataract changes how light is focused and temporarily results in better vision for such people. They may find themselves able to read for the first time without eyeglasses, a condition sometimes called “second sight.” As the cataracts worsen, however, eventually these people experience increasing visual difficulties.

How Do Doctors Diagnose and Treat Cataracts?

An ophthalmologist* examines the eye to detect a cataract and follow its progress. When cataracts are detected, the doctor can evaluate the symptoms and decide on the best course of treatment.

Many people can live with the condition untreated. For others, surgery may be recommended to remove the cloudy lens and to replace it with a clear artificial lens that is smaller in size than a dime. Cataract surgery improves vision in 90 to 95 percent of cases. It is one of the most common operations, with more than 1 million performed each year. Surgery generally is done when the lens has become so opaque or cloudy that reading, driving, or watching television are major problems.

Can Cataracts Be Prevented?

Some studies suggest that vitamins C and E may lower the likelihood of developing cataracts. That is because these vitamins appear to reduce damage to the proteins that are linked to the development of cataracts. Also, using sunglasses that block ultraviolet* light may lower a person’s risk of developing cataracts because studies strongly suggest that sunlight plays a role in their development. Avoiding cataracts is another important reason to avoid smoking, as smokers appear to have an increased risk of developing cataracts.

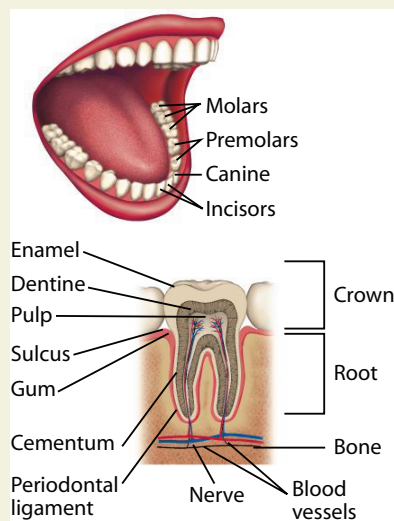

* **retina** (RET-i-na) is the tissue that forms the inner surface of the back of the eyeballs; it receives the light that enters the eye and transmits it through the optic nerves to the brain to produce visual images.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body’s pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **ophthalmologist** (off-thal-MOLL-o-jist) is a medical doctor who specializes in treating diseases of the eye.

* **ultraviolet** light is a wavelength of light beyond visible light; on the spectrum of light, it falls between the violet end of visible light and x-rays.

Cavities

Cavities are areas of tooth decay caused by bacteria.

Grin, Don't Bear It

Michael's friend Ashley always said that she loved his smile, and Michael wanted to keep it that way. However, Michael was unaware that he had a small cavity starting in one of his front teeth. Even though Michael had felt a little twinge now and then when he ate ice cream and candy, his favorite foods, he had not paid much attention. Michael never would have known that he had a cavity if he had not gone to the dentist for a regular checkup. Luckily, the dentist was able to drill out the decay and fill the cavity before it got worse. Michael vowed to do a better job in the future of brushing, flossing, and cutting back on sugary snacks.

What Are Cavities?

Cavities, also known as caries (KARE-eez), are areas of decay on the teeth that are caused by bacteria*. They are one of the most common of all human diseases. Almost half of American children have had a cavity by age four. Not only children have cavities, however. Teenagers and adults also are prone to tooth decay. Fortunately, most cavities can be prevented by taking good care of the teeth, eating a healthy diet, and getting regular dental care.

What Causes Cavities?

The human mouth is home to a host of bacteria. The type of bacteria that causes cavities most often is *Streptococcus mutans* (strep-to-KOK-us MU-tanz), but other types play a role, too. Such bacteria in the mouth change the sugars and starches in food to acid. The bacteria and acid combine with mucus* and food particles, forming a sticky mass called plaque on the teeth. Plaque is the rough substance that people feel when running their tongue over their teeth several hours after brushing.

The acid in plaque can eat a hole in a tooth's enamel, the hard substance that covers and protects the outside surfaces of the tooth. People hardly notice the cavity at this stage, or they might feel a slight twinge when eating foods that are sweet or very cold or hot. However, bacteria that enter the hole in the enamel can make their way through the softer inside parts of the tooth. Eventually, the bacteria may reach the tooth's pulp, the soft tissue in the center of the tooth that contains nerves and blood vessels. When this happens, the blood vessels can swell and press on the nerves, causing a painful toothache. Left untreated, infection of the pulp by bacteria can cause the blood vessels and nerves in the tooth to die.

Plaque sticks best in the pits and grooves of the back teeth, just above the gums, between the teeth, and around the edges of earlier fillings. Cavities are most likely to form in these areas.

Who Gets Cavities?

Anyone can get cavities. They are most common in children, young adults, and the elderly. People who eat a diet filled with sugary foods also have a high risk of developing cavities, because the more sugar people eat, the more cavity-causing acid they make. People who already have a lot of fillings have an increased risk as well, since the area around fillings is an ideal spot for decay to start.

How Are Cavities Treated?

Cavities are usually painless during the early stages. Most are found during regular dental checkups. A dental x-ray can find cavities that are hard to see. Treating cavities early can prevent later pain and tooth loss.

If a cavity is found, the decay process can be stopped by removing the decayed part of the tooth with a special drill. If there is a lot of decay, or if a tooth is very sensitive, the dentist may give the person a shot of anesthetic* or have the person breathe an anesthetic gas before drilling. The decayed material is then replaced with a filling. Such fillings can be made from a number of materials. The most common is silver amalgam (a-MAL-gam), an alloy of silver and other metals, which is used mainly in back teeth. Fillings in the front usually are made of other materials that match the color of the teeth.

Sometimes, there is so much decay that removing it all leaves a tooth weak and easily broken. In that case, the dentist may fit the person with a crown, an artificial replacement for the part of the tooth above the gum. The crown is made in a laboratory, and then it is cemented to what is left of the tooth.

If the tooth is very seriously decayed or infected, the dentist may perform a root canal. In this procedure the pulp is removed from the root, which is the part of the tooth that anchors it to the gums. The empty space is then cleaned and filled with a special material. The root and the tooth stay in place, but the tooth structure is not as strong as before. To strengthen it, the person may need a crown.

* **anesthetic** (an-es-THET-ik) is a medicine that decreases the sensation of pain.

A Flurry of Fluoridation

Fluoride is a mineral that occurs naturally in all water sources. Many areas, especially in the southern states, have a water supply that is well fluoridated naturally.

Scientists as far back as the early 1900s noted fluoride's role in preventing tooth decay. Fluoride can even reverse the early decay process. Since the 1940s, some communities in areas where natural fluoride is low have been adding extra fluoride to their water. This is a very effective and inexpensive way to help prevent cavities on a large scale.

In the early 2000s, about 60 percent of the U.S. water supply is fluoridated. In places where the water is not fluoridated, or in families who drink unfluoridated bottled water instead of tap water, dentists may prescribe fluoride supplements for children.

How Can Cavities Be Prevented?

People can take several steps to stop most cavities. They can brush twice per day and floss every day. Brushing and flossing help remove plaque. They can use a soft-bristled toothbrush. People should pick a brush that feels comfortable and will reach all the teeth, even those in back. They should replace the toothbrush when the bristles show signs of wear. People should use toothpaste that contains fluoride (FLOOR-eyed), a mineral that helps protect against tooth decay. To clean the teeth, they should brush with a short, gentle, back-and-forth motion. People should not forget the inside surfaces, the back teeth, and the tongue. They should floss to reach plaque between the teeth and under the gum line, where a brush cannot go. Finally, people should cut down on sweets and between-meal snacks. Damaging acid forms in the mouth each time a person eats a sugary or starchy food. The acid continues to affect the teeth for at least 20 minutes afterward. The more often people eat these kinds of food, the more times they feed the bacteria that cause cavities. In addition, some sugary foods do more harm than others. Sticky or chewy sweets may cling to the teeth, staying in the mouth and causing problems longer than other foods.

People should see their dentist regularly for checkups and cleanings. Dentists may apply extra fluoride in the form of a gel, foam, or rinse. In addition, dentists may apply dental sealants, thin plastic coatings that are put on the chewing surface of back teeth. Such sealants are painted on as a liquid, but they quickly harden to form a shield over the teeth that keeps out the food and bacteria that cause decay. Dentists say that children should get sealants on their permanent back teeth as soon as they come in. In some cases, sealants are also put on baby teeth or on the teeth of teenagers or adults.

Celiac Disease

Celiac disease is a digestive disease that adversely affects people when they eat foods that contain the protein gluten.

What Is Celiac Disease?

Celiac disease (CD)—also spelled “coeliac” and also called by such names as gluten sensitive enteropathy, celiac sprue, and gluten intolerance—is a digestive disease that adversely affects both children and adults when they eat foods that contain the protein gluten. The inability of some people to digest gluten completely is the reason behind celiac disease. Although it resembles a food allergy*, celiac disease is not one. Instead, it is an autoimmune disease* (an adverse reaction of antibodies* within the body) of the small intestine. The primary difference between the two conditions is that people sometimes resolve their food allergies, but people with celiac disease will not outgrow it. They will always be intolerant to gluten.

The Celiac Disease Foundation states that about one person in 133 in the United States is affected with CD. Moreover, a person is at an increased risk (about 5–10%) when an immediate family member has celiac disease. Without proper diagnosis and treatment of the disease, people with celiac disease may develop medical complications such as cancer or osteoporosis*.

What Are the Symptoms of Celiac Disease?

The symptoms experienced by people with celiac disease vary widely. Moreover, they may appear for the first time at any point during a person’s life. In fact, some people with the disease do not have symptoms. Other people mistake their symptoms for an intestinal problem, such as irritable bowel syndrome or lactose intolerance. Medically, the disease is thought to be brought on by a stressful physiological event such as pregnancy, childbirth, major surgery, or a viral infection*, or by some psychologically stressful event. Severity of the symptoms, along with when they first appear, may be caused by the severity of the particular stressful event. For instance, a minor viral infection may initiate less severe symptoms of CD than a major infection.

The range of symptoms may in part be determined by the length of time that individuals were breastfed as a baby, the age in childhood at which they were first fed gluten-containing food, or the amount of gluten-containing foods that they eat as an adult. Another factor that can influence the severity of the symptoms is the length of time before a person is diagnosed, with the longer period without diagnosis increasing the risk of more severe symptoms.

Symptoms of celiac disease usually, but not necessarily, involve the digestive tract. The more common digestive-based symptoms include the following:

- Abdominal pain, cramping, and bloating
- Frequent or long-lasting diarrhea (frequent, watery bowel movements)

▲ Celiac disease is an intolerance to gluten that usually occurs in young children. Symptoms include abdominal distention, diarrhea, and fatigue. Home testing kits require a small blood sample to be taken. *Cordelia Molloy/Photo Researchers, Inc.*

* **allergy** (AL-uhr-jee) is an immune system-related sensitivity to certain substances, for example, cat dander or the pollen of certain plants, that cause various reactions, such as sneezing, runny nose, wheezing, or swollen, itchy patches on the skin, called hives.

* **autoimmune disease** (aw-toh-ih-MYOON) is a disease in which the body’s immune system attacks some of the body’s own normal tissues and cells.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body’s immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **osteoporosis** (os-te-o-por-O-sis) is the loss of material from the bone. This makes the bones weak and brittle.

* **viral infections** cause mouth sores that are called fever blisters or cold sores. These are often caused by the herpesvirus, and they usually appear on the gums or around the mouth and lips. Unlike canker sores, fever blisters and cold sores are contagious.

* **failure to thrive** is a condition in which an infant fails to gain weight and grow at the expected rate.

* **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.

* **epilepsy** (EP-i-lep-see) is a condition of the nervous system characterized by recurrent seizures that temporarily affect a person's awareness, movements, or sensations. Seizures occur when powerful, rapid bursts of electrical energy interrupt the normal electrical patterns of the brain.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **small intestine** is the part of the intestines—the system of muscular tubes that food passes through during digestion—that directly receives the food when it passes through the stomach.

- Constipation (hard, dry stools that are difficult to pass)
- Weight loss
- Vomiting
- Pale colored, foul smelling, or fatty stools
- In infants, failure to thrive*
- In children, lack of growth, especially in height; lateness of puberty; problems with dental enamel and discoloration of teeth; and behavioral issues

Non-digestive symptoms in adults include the following:

- Anxiety, leading often times to depression
- Unexplained anemia
- Skin rash
- Fatigue, weakness, lack of energy
- Depression, irritability
- Arthritis (swollen, painful joints)
- Joint and/or bone pain
- Osteoporosis (brittle bones)
- Canker sores (ulcers) within the mouth
- Numbness of the extremities, especially the feet and hands
- Seizures (convulsions)
- In women, missed or irregular menstrual periods
- In women, spontaneous miscarriages*
- Infertility

Because people with celiac disease are malnourished, the disease can lead to neurological problems such as epilepsy* and chronic diseases such as liver and gastrointestinal cancers, thyroid disease, and Type 1 diabetes.

What Causes Celiac Disease?

Celiac disease results from an intolerance to gluten. Actually called gliadin, gluten is found in certain grains, such as all types of barley, rye, triticale, and wheat. Gluten is an ingredient in many common foods, such as bread, pizza, pasta, breakfast cereal, cakes and cookies, and beverages such as beer. However, it is also contained in less common products such as certain vitamins and medicines.

When digested, gluten is modified so the body's immune system* reacts abnormally to it in the intestines, creating a toxic (inflammatory) reaction, which interferes with the absorption of nutrients such as vitamins and minerals. The digestive system is unable to absorb the necessary nutrients. Even small amounts of ingested gluten cause health problems and can eventually flatten the lining of the small intestine*. This flattening, which is called villous atrophy, damages the

small intestine, reducing the ability of the body to absorb nutrients (malabsorption).

The small intestine is compromised because the modified gluten damages, and sometimes destroys, millions of microscopic-sized, finger-tip-like protrusions called villi, which line it. Under normal conditions, the villi allow nutrients to be absorbed through the walls of the small intestine and into the bloodstream. However, individuals with celiac disease do not obtain all of these nutrients so they become malnourished regardless of the quantity or quality of food they eat.

The risk of developing celiac disease may be genetically determined. Africans and Asians are less likely to get celiac disease, and Caucasians of northern European descent are more at risk for developing it. Individuals may be predisposed to the disease when they are born. Then a specific physical or emotional event may cause the disease to become apparent. A similar stressful event may also trigger celiac disease in the offspring of these parents. Having one parent with celiac disease increases the risk of the disease by 5 to 15 percent in the children. People with autoimmune disorders such as type 1 diabetes and rheumatoid arthritis* are 25 percent more at risk for celiac disease than other people.

How Is Celiac Disease Diagnosed?

To detect celiac disease several blood serum (serologic) tests must be performed. These show if levels of gluten-sensitive antibodies and certain proteins are abnormally high within the body. Tests for the following antibodies are usually performed:

- IgA antigliadin antibody
- IgG antigliadin antibody
- IgA antiendornysial antibody
- IgA antitransglutaminase antibody

If the results are “positive,” then a biopsy* is usually performed on the small intestine. The doctor performs a procedure called endoscopy*, a procedure that involves inserting a long, thin, fiber-optic tube through the mouth and stomach into the small intestine. The doctor takes a small tissue sample from the small intestine for analysis in the laboratory. The biopsy reveals the amount of damage to the villi in the lining of the intestine.

If these tests and the biopsy are inconclusive, then two genetic tests—HLA-DQ2 and HLA-DQ8—should be run to identify human leukocyte antigen (HLA) genes, which are present in people with celiac disease. These tests are not conclusive because one-third of all people in the United States have these genes without having celiac disease. However, people with these genes are considered to be highly susceptible to the disease. By contrast, if these genes do not appear in the tested person, then their absence essentially rules out celiac disease as the problem. Other tests can be performed in order to reach a definite diagnosis.

Saliva Test May Reveal Celiac Disease

As of 2009, medical researchers were evaluating the use of saliva to test the progress of celiac disease. The test could one day help patients who try to improve their celiac disease condition by following a gluten-free diet. The test was also anticipated to assist people who are at increased risk for getting celiac disease.

* **rheumatoid arthritis** (ROO-mah-toyd ar-THRY-tis) is a chronic disease characterized by painful swelling, stiffness, and deformity of the joints.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **endoscopy** (en-DOS-ko-pee) is a type of diagnostic test in which a lighted tube-like instrument is inserted into a part of the body.

How Is Celiac Disease Treated?

The basic treatment for CD is a gluten-free diet. After gluten is removed from the diet, the small intestine is able to repair itself and return to normal function. Many, if not all, symptoms disappear over a few months. Any lingering imbalances in the body can be corrected with nutritional supplements. Physicians usually do not prescribe medicines; however, regular examinations are highly recommended so the progress and health of the patient can be monitored. According to the Celiac Disease Foundation, the most common medical complication is osteoporosis; three-fourths of all diagnosed people with CD have some degree of bone loss.

The gluten-free diet is challenging to maintain. Grains are common ingredients, second only to sugars, in the average diet. Gluten in tiny amounts may be present and yet not listed in food labels. Obvious foods that must be avoided are those including the following ingredients: binders, fillers, extenders, malt, modified food starch, and unidentified starch.

All types of wheat, such as durum, einkorn, farina, faro, kamut, emmer, semolina, and spelt, contain gluten. Cracked wheat, hydrolyzed wheat protein, wheat bran, wheat germ, and wheat starch also contain gluten. Other grains such as barley, rye, and triticale (a wheat-rye blend) include gluten. Oat may not cause a CD reaction; however, it is wise to avoid oat products as well.

Basic foods that do not contain gluten include buckwheat, chia seed, corn (maize), flax, legumes, millet, nuts, quinoa, rice, and wild rice. Non-cereals that do not contain gluten include potatoes and bananas.

Many processed foods contain gluten. These include candy, luncheon meats, potato chips and french fries, rice mixes, sauces and gravies, soups, and many others. People with celiac disease should discuss their gluten-free diet with their family doctor, along with a dietitian. Such experts can recommend and guide patients in their food selections.

Although a gluten-free diet is essential for all celiac sufferers, the bright side is that most foods containing gluten can be made by substituting ingredients. Many grocery stores carry gluten-free foods, and some restaurants carry gluten-free meals. Online health-food stores sell gluten-free foods. For celiac sufferers, local and national support groups provide information and a sense of community with others facing the same problem.

Cerebral Palsy

Cerebral palsy (sa-REE-brul PAWL-zee) is a group of several conditions characterized by a loss or limitation of movement or other nerve functions caused by brain injuries that typically occur before, during, or shortly after birth.

Marsha's Story

Marsha could not help comparing her baby to the others at the park. At 10 months old, Sam could hardly sit up on his own, but most of the other babies Sam's age were crawling and pulling up to a standing position. Marsha also noticed that Sam often felt stiff when she picked him up. When Marsha took Sam to the doctor and described his symptoms, the doctor suspected that Sam had a form of cerebral palsy. Sam's doctor explained that cerebral palsy occurs when parts of the brain that control movement are injured or fail to develop properly during pregnancy.

What Is Cerebral Palsy?

Cerebral palsy is not a single condition but instead identifies a group of movement disorders caused by a brain injury. The period before birth and shortly after birth is typically defined as the perinatal period. At some point during this time the developing brain tissue may be injured by

- * **trauma** refers to a wound or injury, whether psychological or physical. Psychological trauma refers to an emotional shock that leads to lasting psychological damage.
- * **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.
- * **encephalitis** (en-seh-fuh-LYE-tis) is an inflammation of the brain, usually caused by a viral infection.
- * **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.
- * **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

trauma* or by diseases such as meningitis* or encephalitis*. Brain damage may also result from severe dehydration*, lack of oxygen, or a variety of other problems. In some cases, ill health in the mother while she is pregnant may lead to cerebral palsy in her child. In addition, infants who are born prematurely have a higher risk of developing cerebral palsy.

According to the United Cerebral Palsy Research and Educational Foundation, 1.5 to 2 million U.S. children and adults have cerebral palsy, and 10,000 new cases of cerebral palsy are diagnosed in the United States each year.

What Are the Signs and Symptoms of Cerebral Palsy?

Cerebral palsy is divided into three main types based on symptoms, although many people may have symptoms that span more than one type.

Spastic (SPAS-tik) syndromes are the most common form of cerebral palsy and account for 70 to 80 percent of cases. People with spastic syndromes move in a stiff or jerky way. Spastic movements may affect one limb, one side of the body, both legs, or both arms and legs, and the affected limbs are usually underdeveloped and have rigid muscles. For those people with mild cases, the symptoms may only become obvious during certain activities such as running, whereas those with severe cerebral palsy may require a wheelchair. People with spastic syndromes also may experience seizures*, partial or full loss of movement (paralysis), sensory abnormalities, and problems with speech, hearing, and vision.

Athetoid, or dyskinetic, cerebral palsy affects 10 to 20 percent of patients. Individuals with this form of the disease experience slow, writhing, involuntary muscle movements in the arms and legs, meaning their movements happen automatically as in a reflex rather than by choice.

CEREBRAL PALSY AND WILLIAM JOHN LITTLE

William John Little (1810–1894) developed a deformity in his foot at a young age as a result of polio infection. At the age of 16, Little decided to pursue a career in medicine, hoping to find a cure for his condition. Although Little never found his cure, his research did lead to the description of another disease. In 1853, Little published *On the Deformities of the Human Frame*, in which he first described cerebral palsy. Little's medical practice focused on the musculoskeletal system, and his research contributed to advances in both neurology and orthopedics.

“Little's Disease” is the name now used to designate a congenital form of cerebral palsy.

The symptoms usually increase with stress and disappear when the person is sleeping.

Ataxic cerebral palsy is the least common form, affecting about 5 to 10 percent of people with the disease. This form is characterized by weakness, uncoordinated movements, and shaking, and often leads to difficulties with rapid and fine motor movements.

Many people with cerebral palsy, even some who experience very severe physical disabilities, have normal intelligence, but about two-thirds have intellectual impairments, according to the National Institute of Neurological Disorders and Stroke. Some of these children may attend regular classes but have trouble with reading or math, while others may need special learning assistance.

How Is Cerebral Palsy Diagnosed and Treated?

As of 2009 there was no assessment to test for cerebral palsy before a baby is born. In fact, physicians are often unable to make a clear diagnosis until a child is six months to two years old, and this is frequently aided by a parent's own observations and concerns. A doctor will typically perform a physical examination that includes a test of the child's reflexes, often by tapping specific tendons in the body with a reflex hammer, to see if the child's brain and nervous system are functioning properly. In individuals with spastic symptoms of cerebral palsy, the reflex responses are more pronounced. In some instances, simple bending of a leg or arm can trigger it to jump. The exaggerated reflex response may arise from damage to the upper motor neurons, nerve cells that run from an area called the motor cortex, which lies within the brain's cerebral cortex—the main thought-processing region—to the spinal cord. The neuronal damage affects the ability of the motor cortex to control voluntary muscle movements*. The doctor's exam may also include an evaluation of the child's gait, or walking pattern, detailed inquiries about perinatal* health history, and various diagnostic tests, by such means as x-rays, magnetic resonance imaging, or computed tomography.

In addition, because children who are born with very low birth weights (less than two pounds) are more prone to cerebral palsy, physicians and parents should be vigilant in monitoring the children's progress over time.

Treatment for cerebral palsy is tailored to each individual's specific symptoms. Doctors and therapists work together to set up a treatment program that will help the patient deal with the challenges of day-to-day living, such as dressing, grooming, and eating. Glasses and hearing aids may improve sight and hearing. Children may have mild to significant communication difficulties that require a range of care from visits to a speech therapist to communication tools, such as alphabet boards they can use to point to letters or specially designed computers. For mobility problems, leg braces, walkers, wheelchairs, and other equipment are available. Some patients may also need special positioning aids for sitting, standing, and even lying. In addition, physical therapy can

* **voluntary muscle movements**

are those physical actions, such as moving a hand or blinking an eyelid, over which an individual has conscious muscle control

* **perinatal** (per-ee-NAY-tal) means existing or occurring around the time of birth, with reference to the fetus.

Tools That Help

Many different kinds of equipment are available to help people with cerebral palsy to do everyday things. Wheelchairs with and without motors help those who cannot walk to get around, whereas walkers assist those who can walk but are unsteady on their feet. Spoons, toothbrushes, and pencils with special handles and shapes make it easier to hold and use them. Alphabet and picture boards make it possible for people who have trouble speaking to communicate. A computer is even available to talk for people who cannot.

help people with cerebral palsy build strength and improve function in their limbs.

Again depending on the symptoms, a doctor may prescribe muscle relaxants to reduce muscle tone and the related spastic movements or medications to control seizures. Occasionally, a doctor may recommend surgery to treat disease-related muscle, hip, or extremity problems.

Is Cerebral Palsy Preventable?

Because the cause of cerebral palsy is unknown in the majority of cases, no definite prevention methods are available. Nonetheless, an expectant mother can increase the chances that her baby will be healthy by eating properly, getting regular checkups, and refraining from activities such as smoking, drinking alcohol, or drug use, that may harm the fetus. After giving birth, a parent can take steps to provide the child with a safe environment that reduces the potential for accident or injury.

Living with Cerebral Palsy

Cerebral palsy is a lifelong disorder. The extent of disability caused by cerebral palsy varies with the severity of the symptoms. Some people have mild forms that are barely noticeable. For example, a child may have a limp when walking or running. Other people have more severe symptoms and may require a wheelchair to get around and/or experience severe mental retardation. While severely affected persons may need long-term care, such as institutionalization, a large proportion of people with cerebral palsy lead full and happy lives. Most children with cerebral palsy engage in many of the activities their friends enjoy, including attending school, participating in summer camp, reading, listening to music, talking on the phone, using the computer, and playing sports. As they grow older, many continue their education at college, enter the job market, form personal relationships, and raise their own children.

Cervical Cancer

Cervical (SER-vi-kal) cancer is a highly curable condition that occurs in the female reproductive tract.

◀ Anatomy of the female reproductive system showing cervical and uterine cancers. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

▲ Cells from Pap smears like the ones seen here help to find cancerous cells in the cervix. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

* **cancer** is a condition characterized by abnormal overgrowth of certain cells, which may be fatal.

* **tumors** (TOO-morz) are abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **carcinoma** (kar-sih-NO-muh) is a cancerous tumor that arises in the epithelium (eh-puh-THEE-lee-um), the sheets of cells that line body surfaces, such as the insides of hollow organs and cavities.

What Is Cervical Cancer?

Cervical cancer develops in the part of a woman's reproductive tract called the cervix. The uterus is the hollow, pear-shaped organ in which the fetus develops when a woman is pregnant. The cervix is the lower, narrow part of the uterus (cervix is Latin for "neck"). The cervix lies between the main body of the uterus and the vagina (va-JY-na), or birth canal, which opens to the outside of the body.

Cancer* is a condition in which cells undergo abnormal changes and start dividing without control or order, usually forming tumors*. Scientists are not exactly sure why these changes happen, but they believe that something occurs in the abnormal cells that turns off certain genes* that control orderly cell growth. When these genes are turned off, abnormal cells are free to grow wildly. In some cases, these abnormal cells are cancerous; in other cases, they are not.

Cancers are named for the type of cell that becomes abnormal. There are two main types of cervical cancer. Between 80 and 90 percent of all cervical cancers are squamous cell carcinomas*. Squamous cells are a layer of cells that cover the outside of the body (e.g., skin cells) and the internal surface of the body (e.g., the lining of the cervix). The other type of cervical cancer is called adenocarcinoma. This type of cancer begins in cells of the mucus glands that line the cervix.

How Does Cervical Cancer Develop?

Cervical cancer generally develops slowly. At first, certain cells, called precancerous cells, begin to show abnormalities. These cells are not yet cancers, and in many women they change back into normal cells without any treatment. In some women, however, the precancerous cells continue to change and turn into cancer cells. This process usually takes several years, although it can happen in a shorter period. Precancerous cells look

DETECTING CERVICAL CANCER WITH A PAP TEST

In the late 1920s, the scientist George Papanicolaou (1883–1962) developed a simple method for examining cells of the cervix for precancerous abnormalities. To perform this test, later called a Pap test, the doctor scrapes some of cells from the surface of the cervix and places them on a microscope slide. Under a microscope, a trained examiner can tell the difference between normal, precancerous, and cancerous cells.

When found early, cervical cancer is highly curable. Therefore, doctors recommend that women have their first Pap test within three years of the time when they start having sex or at age 21, whichever comes first. Women should then have a repeat Pap test every year.

different from normal cells under the microscope and can be detected in a Pap smear*, also called a Pap test or cervical smear.

About 6 percent of Pap tests show that abnormal cells are present. Not all of these abnormalities become cancer. However, if a Pap test comes back as abnormal, the doctor is inclined to do further tests. One test, called colposcopy (kol-POS-ko-pee), involves applying a vinegar-like solution to the cervix and then using a very thin, lighted instrument to examine the cervix closely. Doctors may also remove a small amount of tissue from the cervix and have it examined under a microscope, a procedure called biopsy (BY-op-see).

Having a Pap test is particularly important because even when cervical cells become cancerous, a woman often has no symptoms until the cancer is far advanced and has grown through the wall of the uterus or spread to other parts of the body. Symptoms of advanced cervical cancer are similar to symptoms caused by many other diseases and disorders. They include:

- Abnormal vaginal bleeding
- Increased vaginal discharge
- Pain during sexual intercourse

What Causes Cervical Cancer?

Scientists know that cancer is caused by the faulty regulation of cell growth. They are not exactly sure what happens to trigger cervical cancer, but they do know that it appears to be related to becoming infected with the human papilloma virus (HPV), a group of about 100 viruses, not all of which cause cancer. In fact, about two-thirds of all cancers are caused by only two viruses, HPV 16 and HPV 18. Most HPV infections occur in women between the teenage years and age 30.

What is confusing to scientists about the relationship between HPV and cervical cancer is that a great many women are infected with the HPV virus, but only a very few develop cancer. In most cases, the body's immune system* fights the HPV infection and the body shows no ill effects of the infection. In some women, however, infection with certain HPV viruses triggers a change in cervical cells, which then become cancerous. A test is available that can tell whether a woman has been infected with the HPV virus. This test is not routinely used, but may be done on women who have abnormal Pap tests.

Who Gets Cervical Cancer?

The American Cancer Society estimated that in 2008 about 11,000 new cases of cervical cancer would be diagnosed in the United States and that about 3,900 women would die of the disease that year. Cervical cancer does not occur evenly throughout the population; some women are more likely to develop it than others. For example, in the United States Hispanic women are twice as likely to develop cervical cancer as non-Hispanic women, and African American women are more likely to develop the disease than white women. Most cervical cancers are diagnosed in women between the ages of 20 and 50, but 20 percent occur in

What Is a Papilloma?

A papilloma is what people ordinarily call a wart. Human papilloma virus got its name because some of these viruses cause small warts to grow around the anus and the male and female genitals. Other HPV viruses cause warts in other parts of the body, including the hands, feet, and mouth.

* **Pap smear** is a common diagnostic test used to look for cancerous cells in the tissue of the cervix.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

Cervical Cancer Is Decreasing

In the United States, the death rate from cervical cancer decreased 74 percent between 1950 and 1992. The rate was expected to continue to decline given that a vaccine that protects against the some of the viruses that trigger cervical cancer is available.

* **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).

* **chlamydia** (kla-MIH-dee-uh) are microorganisms that can infect the urinary tract, genitals, eye, and respiratory tract, including the lungs.

* **malignant** (ma-LIG-nant) refers to a condition that is severe and progressively worsening.

* **lesions** (LEE-zhuns) is a general term referring to a sore or a damaged or irregular area of tissue.

* **chemotherapy** (KEE-mo-THER-ah-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

women over age 65. Other factors that increase the chances of developing cervical cancer are as follows:

- Infection with the HPV virus
- Infection with the HIV* virus
- Infections with the chlamydia* bacteria
- Smoking
- Long-term use of oral contraceptives (birth control pills)
- Poverty that results in poor diet and lack of access to routine health care
- Family history of cervical cancer

How Is Cervical Cancer Treated?

Cervical cancer is staged using an international system (Federation of International Gynecology and Obstetrics or FIGO system) that classifies cancer according to stages of its development, from stage 0 to stage IV. The stages are determined by the extent of the spread of malignant* cells from the primary lesion to other locations in the body. The stage is determined primarily by a doctor's examination and the results of several tests. The lower the stage number, the less advanced and more curable the cancer is.

The recommended treatment depends on the stage of the cancer. It is wise to get a second opinion from an independent doctor before beginning treatment. Some lesions* that have a close-to-normal appearance do not require treatment, but they do need to be checked regularly. Other growths that appear likely to develop into cancer may need to be removed, which is often done by using a special instrument to freeze them off, a procedure called cryosurgery (KRY-o-sur-jer-ee), to burn them off by cauterization (kaw-ter-i-ZAY-shun), or to direct high-energy laser beams at them. These procedures can destroy the abnormal areas without affecting nearby healthy tissue.

These procedures also may be used to remove tumors that definitely are cancerous but have remained on the surface of the cervix. However, if the cancer has penetrated or grown into the wall of the cervix or has spread, surgeons either need to remove the tumor and the surrounding tissue, or they need to remove the entire uterus and cervix, an operation called a hysterectomy (his-ter-EK-to-mee). Surgery is the most common treatment for cervical cancer, but it also may be used together with radiation therapy and chemotherapy*. These treatments can help kill any cancer cells that remain after surgery or they help destroy cancer cells that already have traveled to other parts of the body. Radiation therapy uses high-energy rays to damage cancer cells and stop them from growing. Chemotherapy involves giving powerful anticancer drugs either by injection into a vein or by mouth.

How Can Cervical Cancer Be Prevented?

In 2006, the Food and Drug Administration approved a vaccine (Gardasil) that prevents infection against four types of HPV infection that cause about 90 percent of all cervical cancers. The vaccine is designed to be

given to young women ages 9 to 26 who are not pregnant or breastfeeding. Immunization requires three injections of the vaccine over a six-month period. Two months after the first injection, a second injection is given. A third injection is given four months after the second injection. All three injections must be given for the vaccine to be effective. As of 2009, questions about potentially dangerous side effects of the vaccine remained unanswered and concerns about the safety of this vaccine remained.

Because cervical cancer is so closely connected with the sexually transmitted virus called HPV, not having sexual intercourse is an effective way to prevent HPV infection. When engaged in sexual intercourse, men should always use a condom, which helps to protect their partner from possible infection. A condom offers good, but not total, protection against both the HPV virus and the HIV virus. Maintaining a healthy lifestyle by not smoking, eating a balanced diet, and maintaining a healthy weight also reduce the risk of developing cervical cancer.

Reduviid bugs, like this assassin bug, live in the cracks and crevices of poorly built houses. Reduviid bugs can pick up the *Trypanosoma cruzi* parasite that causes Chagas' disease when they bite an infected person or animal. They pass along the parasite to the next person they bite. *Image copyright Bidouze Stéphane, 2008. Used under license from Shutterstock.com.*

* **parasite** (PAIR-uh-site) an organism such as a protozoan (one-celled animals), worm, or insect that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. A parasite lives at the expense of the host and may cause illness.

* **blood transfusions** (trans-FYOO-zhunz) are procedures in which blood or certain parts of blood (such as specific cells) are given to a person who needs them due to illness or blood loss.

* **host** is an organism that provides another organism (such as a parasite or virus) with a place to live and grow.

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

Chagas' Disease

Chagas' disease is a parasitic infection common in South and Central America that is spread to people by blood-sucking insects called reduviid bugs.

What Is Chagas' Disease?

Chagas' disease is a parasitic infection common in South and Central America. It is chronic (long-lasting) and can seriously damage the heart and the digestive system many years after infection. Another name for Chagas' disease is American trypanosomiasis (tri-pan-o-so-MY-a-sis).

What Is Infection with Trypanosomiasis?

Chagas' disease is an infection with a protozoan (pro-to-ZO-an), a tiny parasite* called *Trypanosoma cruzi*. This parasite infects many kinds of mammals in South and Central America. It is spread to people by blood-sucking insects called reduviid (re-DOO-vi-id) bugs. These insects, also called kissing or assassin bugs, pick up the parasite when they bite an infected person or animal. The parasites multiply inside the insect and are excreted in their feces and urine. When the insects bite people, they deposit parasite-laden feces and urine on the skin at the end of their blood meal. If the feces get into the bite or are accidentally rubbed into a cut or scratch, the eyes, or the mouth, the person may be infected with the parasite. Approximately 80 percent of infections are through this route. Other routes of infection include contaminated food or water or anything that introduces the parasite into the blood such as blood transfusions* or organ transplantation from an infected donor.

The parasite must invade the cells of a mammalian host* such as humans in order to complete its lifecycle. Once the parasite invades the cells of a human host, it multiplies within those cells. The cells contain the multiplying parasites until they rupture, releasing chemicals that cause inflammation* as well as the new parasites. This process of cells rupturing and inflammation causes much damage to the body tissues and consequent health problems. When a damaged area is able to heal, the remaining scar tissue may also cause health problems. The most commonly affected organs are the heart, esophagus, and colon.

Reduviid bugs tend to live in the cracks and crevices of poorly built houses in rural South and Central America and in Mexico. Chagas' disease used to be largely an illness of the rural poor in those areas. But in the 1970s and 1980s, many people moved from the countryside to Latin American cities, bringing the parasite and disease with them. In the cities, from 5 to 20 percent of cases are caused from ingesting contaminated food, transfusions of contaminated blood, and organ transplants. More rarely, it can also be transmitted to the fetus at a rate of 2 to 10 percent

of infected pregnant women. Chagas' disease is estimated to kill up to 50,000 people per year.

What Are the Symptoms of Chagas' Disease?

Chagas' disease has incubation, acute, indeterminate, and chronic phases. Upon infection, the incubation phase passes without symptoms and lasts seven to ten days when infected by the insect, 20 to 40 days when infected by blood transfusion.

Acute and indeterminate phases Symptoms most often appear in infected children and usually resolve within three to eight weeks. Symptoms include fever, headache, muscle pain, general malaise, lost appetite, rash, and lethargy. When an insect bites the skin it causes a characteristic lesion called a chagoma. When the insect bites the eye it causes swelling around the eye known as the Romana sign, present in 20 to 50 percent of acute cases. In rare cases, there may be heart damage even as early as the acute phase. In people with weakened immune systems*, such as those with AIDS*, the acute stage can recur later, in a very severe form. In the indeterminate phase, the parasite is still present in the body but causes no symptoms. This stage lasts a lifetime in many infected people. There are blood tests that can identify infection in this phase.

Chronic phase In about one-third of infected people, serious symptoms develop 10 to 20 years or more after infection occurred. The most common problems are enlargement and weakening of the heart, a condition called cardiomyopathy, which can make a person feel tired, weak, and short of breath; ventricular dysrhythmias, a form of irregular heartbeat that can cause sudden death; and heart failure, which may lead to death. Heart failure due to Chagas' disease is the most common form of cardiovascular death in patients who are 30 to 50 years old and live in areas of South America where Chagas' disease is prevalent. Other complications include megacolon, an enlargement of the colon (large intestine) that can cause extreme constipation and require surgical treatment, and enlargement and inflammation of the esophagus, which can make eating difficult and lead to severe weight loss.

Where Does Chagas' Disease Occur and Who Are Affected?

Chagas' disease occurs only in the Americas, mainly in South and Central America and in Mexico. It is believed to create a greater economic burden than any other tropical disease except malaria and schistosomiasis. In South and Central America, about 16 million to 18 million people are infected with Chagas' disease. Many live in thatch, mud, or adobe houses in poor areas. In the United States, many people who emigrated from South and Central America are thought to be infected with Chagas' disease, chiefly in the indeterminate or chronic stages. However, it is extremely rare for someone to catch the disease in the United States. Between about 1980

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

and 2000, fewer than 20 newly acquired U.S. cases were reported, including three from blood transfusions. About 50,000 people die each year from the disease. The World Health Organization (WHO) reports that about 100 million people are at risk of developing Chagas' disease. Illness and death are most common in black individuals as opposed to white or mixed race in the acute phase. There is no difference between genders for the acute phase, but males tend to have more severe cases of cardiomyopathy in the chronic phase.

How Is Chagas' Disease Diagnosed and Treated?

In the acute stage, the parasites can be seen when blood is examined under a microscope. In the later stages, diagnosis is more difficult, and an array of different blood tests are used. In the acute stage, the parasites often can be eliminated by prescription medication taken for several months. In later stages, there is no proven cure. Instead, doctors try to treat the symptoms of the organ damage the parasites cause.

How Is Chagas' Disease Prevented?

In Latin America, many countries took part in a campaign to wipe out Chagas' disease. They used pesticides to kill the insects that transmit the disease, and they upgraded housing so the insects could not hide in cracked walls and thatched roofs. They also tried to screen blood supplies more thoroughly. This campaign progressed best in the countries of the Southern Cone: Argentina, Brazil, Chile, Paraguay, and Uruguay. In this area, new infections of children and young adults reportedly were reduced by almost 70 percent in the late 1990s. Travelers to areas where Chagas' disease is common should use insect repellent. If possible, people should avoid sleeping in thatch, mud, or adobe homes, or should use bed nets at night.

Charcot-Marie-Tooth Disease

Charcot-Marie-Tooth disease is an inherited nervous system disorder which causes progressive degeneration of the nerves that supply the muscles of the limbs, resulting in gradually increasing muscle weakness.

What Is Charcot-Marie-Tooth Disease?

Named for the three physicians who discovered the disorder in 1886, Charcot-Marie-Tooth disease is the most common inherited nervous system (neurological*) disorder. About 2.6 million people have the condition. The disease causes progressive degeneration of the nerves that supply the muscles of the limbs, resulting in gradually increasing muscle weakness.

What Causes Charcot-Marie-Tooth Disease?

Charcot-Marie-Tooth disease runs in families and is caused by a genetic defect. genes* (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes* found in the body's cells. Under normal circumstances, long nerve fibers (called axons) that carry signals from the brain and spinal cord to the muscles are covered with a special sheath called myelin. Myelin allows the electrical signal to travel quickly and efficiently along the nerve, and it also provides some nutrition for the continued health of the nerve. In Charcot-Marie-Tooth disease, defective genes do not produce the appropriate proteins necessary for the normal composition of the axons or of the myelin sheath. Abnormal axons result in weaker than normal transmission of electrical signals; abnormal myelin results in slower than normal transmission of electrical signals. This genetic disease causes weakness in limbs, generally beginning in the legs and then affecting the arms.

Who Gets Charcot-Marie-Tooth Disease?

Most forms of Charcot-Marie-Tooth disease are inherited in an autosomal dominant fashion. This means that an individual only has to have one parent with the disorder in order to inherit the disease. A couple in which only one member has the disorder has a 50 percent chance of passing it on to their offspring. A few forms of Charcot-Marie-Tooth disease are inherited in an autosomal recessive fashion, meaning that an affected individual has to receive a copy of the defective gene from each parent. Type 1X is x-linked, which means that it is passed by the mother to the son, on the X chromosome, and only males will display symptoms of the disorder. In some cases, Charcot-Marie-Tooth disease can occur as a spontaneous mutation, in which case neither parent of the affected individual had the disorder, but offspring of the affected individual are at risk of inheriting the defective gene.

* **neurological** (nur-a-LAH-je-kal) refers to the nervous system, which includes the brain, spinal cord, and the nerves that control the senses, movement, and organ functions throughout the body.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **chromosomes** (KRO-mo-somz) are threadlike chemical structures inside cells on which the genes are located. There are 46 (23 pairs) of chromosomes in normal human cells. Genes on the X and Y chromosomes (known as the sex chromosomes) help determine whether a person is male or female. Females have two X chromosomes; males have one X and one Y chromosome.

* **neurologist** (new-RHAL-eh-jist) a physician who specializes in diagnosing and treating diseases of the nervous system.

* **electromyogram** (ee-lek-tro-MY-eh-gram) (EMG) a visual record made by an electromyograph, which measures the electrical activity associated with functioning muscle.

What Are the Symptoms of Charcot-Marie-Tooth Disease?

About 10 to 20 percent of all people with Charcot-Marie-Tooth disease do not develop any symptoms of the disorder at all. The other 80 to 90 percent experience gradually increasing muscle weakness. Muscles grow smaller, walking becomes difficult, and balance is affected. There may be decreased sensation or painful numbness and tingling (paresthesias) in the feet, lower legs, hands, and forearms. If the muscles become abnormally tight, joints may become stiff. In some cases, people with Charcot-Marie-Tooth disease develop a curved spine (scoliosis) or foot sores (ulcers) that do not heal. Although most people with Charcot-Marie-Tooth disease live a normal lifespan, the disease can be associated with significant disability, particularly by the time afflicted individuals reach their 60s or 70s.

How Is Charcot-Marie-Tooth Disease Diagnosed?

The diagnosis of Charcot-Marie-Tooth disease is straightforward among people who already know the disorder runs in their family. Others are examined by a neurologist* who takes a detailed family history, does a thorough examination (such as observing walking and testing reflexes). Electro-diagnostic testing may be performed, including an electromyogram* (EMG) to test how strong the electrical signals are in the muscles and a nerve conduction velocity test, to see how quickly and strongly the electrical signal travels along nerves. Some forms of Charcot-Marie-Tooth disease can also be diagnosed through genetic testing.

How Is Charcot-Marie-Tooth Disease Treated?

As of 2009 there was no known cure for Charcot-Marie-Tooth disease. Treatment in the early 2000s addressed the weakness and deformity that may be caused by the disease. Braces and appropriate footwear may improve mobility, and physical therapy and an appropriate exercise program may help optimize muscle strength and flexibility. Occupational therapy can also help people learn how to function better, despite their impairment. In some cases, an orthopedic surgeon may recommend surgery to help improve tight heel cords, lower the arch of the foot, fuse the ankle joint, or straighten toes that have been deformed by the condition. Pain medications or consultation with a pain specialist may be helpful for people with paresthesias.

Can Charcot-Marie-Tooth Disease Be Prevented?

Charcot-Marie-Tooth disease cannot be prevented, but genetic counseling can help an affected individual understand the risk of passing the defective gene on to his or her offspring.

Chemical Poisoning

Chemical poisoning is the state of a person who has been poisoned with chemicals, which may include household cleaners, drugs, pesticides, herbicides, environmental toxins, such as radon and carbon monoxide, and others.

What Is Chemical Poisoning?

Chemical poisoning occurs when individuals have been exposed to and are harmed as a result of chemicals having made their way into their bodies. This may occur because the person has eaten, drunk, or inhaled chemical toxins or has absorbed them through the skin. A child who drinks a poisonous household cleaner, a person who takes an overdose of a drug, a worker who inhales a toxic gas at a work site, all are victims of chemical poisoning.

Poisoning is divided into two types: acute and chronic. Acute poisoning occurs following a single exposure to a toxin, and the person has symptoms shortly after the exposure. Chronic poisoning develops slowly, often over many months or even years of exposure. Because the symptoms of chronic poisoning can occur quite a long time after the exposure has stopped, medical professionals may have difficulty diagnosing the illness and treating patients. An example of chronic chemical poisoning is radon exposure. Radon is a colorless, odorless gas that may be present at very low levels in buildings, especially in basements. After long-term exposure, individuals may develop lung cancer. Lung cancer, however, can have many causes, so doctors may not be able to pinpoint radon as the culprit.

How Widespread Is Chemical Poisoning?

Chemical poisoning is a common form of poisoning. It may occur accidentally or intentionally. An accidental poisoning happens when a person ingests a poison by mistake, such as when an adult grabs the wrong bottle

* **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

* **chronic fatigue syndrome** (KRON-ik fat-TEEG) a debilitating and complicated disorder in which individuals feel intense fatigue that lasts six months or longer. Symptoms may include insomnia, muscle pain, and impaired concentration. Since other illnesses have these symptoms, doctors must rule out a number of conditions in order to make a diagnosis.

* **Parkinson's disease** is a disorder of the nervous system that causes shaking, rigid muscles, slow movements, and poor balance.

of medicine or when a toddler gets into a cupboard and drinks a household cleaner. Intentional poisoning occurs when individuals ingest or inhale a poison deliberately and with the intent of self-harm. When individuals attempt to commit suicide by overdosing on a drug, the chemical poisoning is called intentional. By contrast, if individuals overdose on a drug but did not mean to harm themselves, the poisoning is called accidental. Poisoning with chemicals, whether intentional or accidental, makes up 95 percent of all poisonings in the United States. About 90 percent of all chemical poisonings are accidental, and most of these involve toddlers and small children who swallow household cleaners. In fact, poison control centers in the United States respond to hundreds of thousands of calls each year regarding poisoning of children younger than six years of age.

Are Some Diseases Associated with Chemical Poisoning?

Researchers have linked many diseases to chemical exposure, particularly low level chemical exposure that occurs over long periods of time. These diseases include the following:

- Breast cancer, which has been associated with a variety of chemicals, including some that mimic female hormones* or that are found in certain plastics
- Lung cancer, which has been associated with exposure to asbestos or to radon, among other chemicals
- Gulf War illness, which affects many soldiers and has been tied to chemicals that are found in pesticides and nerve agents, as well as pills designed to protect against nerve agents
- Chronic fatigue syndrome*, which has been associated with insecticide exposure
- Asthma attacks and other respiratory allergies, which can be triggered by or worsened by cigarette smoke, pollutants, and other chemicals
- Parkinson's disease*, which some studies have connected to long-term, low-dose exposure to certain pesticides

Various studies have also linked certain chemicals to memory loss, infertility, learning disorders, behavioral disorders, birth defects, and many other conditions and diseases.

What Are Some Common Toxic Household Chemicals?

Common toxins household chemicals include the following:

- Volatile organic hydrocarbons
- Carbon monoxide
- Lead and other heavy metals
- Insecticides and other pesticides
- Radon

Volatile organic hydrocarbons Volatile organic hydrocarbons (VOCs) are chemicals that are found in paint and paint strippers, carpet backing, plastics, wood preservatives, and other household products. VOCs typically become airborne and may especially accumulate in a building that is undergoing construction or renovation. Typical symptoms of exposure to VOCs are headaches; eye, nose, and/or throat irritation; dizziness and/or nausea; a dry cough; and fatigue. These symptoms usually disappear once the person leaves the building. This collection of symptoms is sometimes called “sick building syndrome.”

Carbon monoxide Carbon monoxide is a colorless, odorless gas that may accumulate in a house due to a faulty appliance, such as a furnace, or to improper use of an appliance, which may include the use of a space heater without adequate ventilation. Symptoms of carbon monoxide poisoning include headaches, nausea, and fatigue. After prolonged exposure, carbon monoxide poisoning can cause brain damage and death. In some cases, entire families have died in their sleep of carbon monoxide poisoning.

Lead and other heavy metals Lead poisoning is more common in children than in adults, and typically it results when children put a lead-containing item, such as paint, toys, or art supplies, into their mouths. Although paint in the early 21st century no longer contains lead, older homes sometimes still have lead paint on their walls or on windowsills. When the paint peels, toddlers may pick up pieces of the paint and eat them. If they swallow these low doses of lead over a prolonged period of time, they may experience serious health conditions that affect the development of the brain or the nervous system. This exposure can lead to slow development of the body, hearing problems, behavioral problems, kidney damage, and other problems. Symptoms of lead poisoning include aggressiveness, lack of appetite, low energy, headaches, trouble sleeping, constipation and/or abdominal cramps, and in some cases, seizures* and coma*.

Other dangerous heavy metals are arsenic, mercury, cadmium, and thallium, as well as such elements as zinc, copper and iron. It is best to read the contents of all substances in the house and store those with dangerous contents in safe locations, especially out of reach of children.

Insecticides and other pesticides Insecticides and other pesticides are chemicals used to kill insects and other pest animals, such as mice. Poisonings can occur when people eat or breathe pesticides or absorb them through their skin. Typical symptoms of insecticide and pesticide poisoning include headache; runny nose and watery eyes; considerable saliva in the mouth; diarrhea; abdominal pain, cramps, and/or vomiting; fatigue; dizziness and/or shallow breathing; twitching muscles and/or seizures; loss of consciousness; constricted (small) pupils; and heavy sweating. Exposure to rat poison has different symptoms, some of which may occur hours or even days after exposure. These include easy bruising,

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

* **leukemia** (loo-KEE-me-uh) is a form of cancer characterized by the body's uncontrolled production of abnormal white blood cells.

* **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.

AGENT ORANGE AND VIETNAM

During the Vietnam War, at various times from the late 1950s until 1975, the U.S. government used a powerful herbicide, which is a chemical that causes plants to lose their leaves, to uncover the enemy hiding in the jungles of Vietnam and Laos and also to destroy crops the enemy was using for food. That herbicide was called Agent Orange. After studies showed that the herbicide caused birth defects in laboratory animals, the government stopped using Agent Orange. But by that point, the U.S. military had already sprayed nearly 19 million gallons of the chemical on millions of acres and exposed many U.S. soldiers and thousands of citizens in Vietnam and Laos to it. After that, U.S. soldiers and their families were concerned about the health effects of that exposure, and many believed it led to an increased risk of cancer later in life and birth defects in children of exposed parents. Moreover, Agent Orange contaminated soil and ground water, making affected areas toxic for decades after the war ended.

The American Cancer Society reported that some studies showed an association between a father's exposure to Agent Orange and the later occurrence of acute myeloid leukemia* in biological children he subsequently fathered. Other studies suggested that exposure may be associated with various forms of cancer in soldiers, such as Hodgkin's disease, multiple myeloma, prostate cancer, and lung cancer. Additionally, research linked exposure to increased incidence of diabetes in soldiers. Ongoing studies are being conducted to verify these results and to determine whether Agent Orange exposure was associated with any other illnesses.

Increased rates of miscarriage* and birth defects, along with higher than normal rates of other diseases, were experienced for decades among citizens who lived in contaminated areas in Vietnam and Laos. Environmental damage in these areas was acute and long-lasting, with the rain forest not able to grow back and long-term contamination of ground water.

nosebleeds, bloody urine and/or bloody diarrhea, hair loss, shortness of breath, and fatigue.

Radon Radon is a radioactive material that occurs naturally in the soil and seeps into the air. Outdoors, it is typically at such low concentrations that it causes no health problems. When it seeps through walls and into buildings, however, it can reach unhealthy levels. It is typically most concentrated in basements, although not all basements have levels of radon that present a health concern. Radon produces no short-term symptoms, but prolonged exposure to high enough levels can cause lung cancer. According to the Environmental Protection Agency, radon is the second leading cause of lung cancer after smoking, and it is the number one cause of lung cancer among non-smokers. Overall, it causes approximately 21,000 lung-cancer deaths each year, including nearly 3,000 to non-smokers.

How Is Chemical Poisoning Treated?

In the event of any acute poisoning that happens anywhere in the United States, an immediate call should be made to the Poison Help Hotline at 1-800-222-1222. If possible, callers should have information about the chemical that caused the poisoning. This information helps hotline personnel determine the best course of action. Sometimes, people think the first response in the case of acute chemical poisoning should be to induce vomiting, but medical professionals recommend against it. Some chemicals burn the esophagus (e-SOF-uh-gus), so making the victim vomit may only serve to damage the esophagus again. Hotline personnel explain the best way to care for the victim, and if professional help is needed, they will call an ambulance as well as the hospital, and provide both with the needed information to assure the best care for the patient.

If a patient requires hospital care, the specific treatment depends on the type of poison and the extent of exposure. Some patients require stomach pumping, in which medical professionals use a tube to remove the contents of the stomach, but others may need more extensive care. Doctors may also perform blood tests or other exams if the cause of the poisoning is unknown.

How Is Chemical Poisoning Used as a Weapon?

An especially disturbing type of poisoning can result from chemical weapons. These are toxic chemicals that are used as weapons, such as the mustard gas used in World War II by the Nazis. Although the production, stockpiling, and use of chemical weapons was made illegal by the Chemical Weapons Convention, some countries, including the United States, did stockpile them, and the possibility of their use remained. As a result, many government agencies around the world take steps to prepare for the possible use of these weapons. In the United States these include the Centers for Disease Control and the Federal Emergency Management Agency.

Chicken Pox See *Varicella (Chicken Pox) and Herpes Zoster (Shingles)*.

Childhood Disintegrative Disorder (Heller's Syndrome)

Childhood disintegrative disorder (CDD) is a rare medical disorder that occurs in children usually after the first three years of life. Also called Heller's Syndrome, CDD also goes by such names as childhood disintegration disorder, disintegrative psychosis, and social development regression. The progressively deteriorating condition is characterized by severely slowed mental developmental especially in the areas of cognitive skills (such as language), motor skills (such as walking), and social functions (such as interest in playing with other children). Often classified as a pervasive developmental disorder (PDD), a cure for CDD had as of 2009 not been discovered.

Why Do Some Children Lose Abilities Once Learned?

Children who eventually contract CDD do so after having developed normally, or almost normally, for the first couple years of life. They suddenly, in some cases, begin to regress, losing skills that they had already learned successfully. In these situations, childhood disintegrative disorder, as the name implies, can be the cause of such regression of skills.

Sometimes CDD is mistaken for autism-spectrum disorder (ASD), what is commonly called autism*. For this reason, the medical community generally considers autism to be a similar condition to CDD. But unlike autism, CDD is not present at birth and appears later. CDD may occur any time between two to ten years of age.

Who Discovered Childhood Disintegrative Disorder?

Australian educator and remedial teacher Theodor Heller (1869–1938) first described the syndrome in 1908. Heller studied six children in Vienna, Austria, who after normal childhood development suddenly developed

severe mental problems that began between the ages of three and four years. Heller used the name *dementia infantilis* to identify this group of similar problems. However, little notice was made of his discovery within the medical community. At that time, the group of problems was associated with specific problems involving the nervous system*.

What Are the Signs and Symptoms of Childhood Disintegrative Disorder?

Children with CDD generally have normal developmental skills until two years of age. However, around this time, their ability to communicate, socialize, and perform other such skills begins to deteriorate and, in some cases, is totally lost. Sometimes this regression is slow acting (over several years), but in other cases, it is abrupt, occurring over only a few days or weeks. Often, children with CDD have higher incidences of seizures and related disorders.

Children with CDD tend to lose skills and abilities in at least two of the following areas:

- Motor skills
- Toileting, including bladder and bowel movements
- Social interaction and self-care skills
- Receptive behavioral skills, along with interest in the surrounding environment
- Language and communication skills
- Play skills

For instance, a child with CCD may not be able to say words and sentences that they were able to earlier. They may lose the ability to understand verbal and nonverbal communications. The child with CDD is often mistakenly thought to have autism. However, the occurrence of CDD is less frequent than autism. Boys, rather than girls, are more likely to be affected with CDD.

What causes Childhood Disintegrative Disorder?

The exact medical or neurological cause for CDD had as of 2009 not been found. Some scientific evidence with CDD points toward problems with the central nervous system*. Other studies show that children with CDD possess excessive deposits of lipids (fats) within the brain and nervous system. CDD has also been associated with chronic infections of the brain and various tumors* within the brain and major body organs. Although CDD children are more likely to have seizures, they are not considered a cause of the condition.

How Is Childhood Disintegrative Disorder Treated?

No cure was known for childhood disintegrative disorder as of 2009. Treatment for CDD involves behavior therapy*, which helps children to relearn skills lost by the disease. Medications indirectly alleviate some of

* **nervous system** is a network of specialized tissue made of nerve cells, or neurons, that processes messages to and from different parts of the human body.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

* **tumors** (TOO-morz) are abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.

* **behavior therapy** is a type of counseling that works to help people change their actions.

* **antipsychotic drugs** are medications that counteract or reduce the symptoms of a severe mental disorder such as schizophrenia.

* **anticonvulsants** (an-tie-kon-VUL-sents) are medications that affect the electrical activity in the brain and are given to prevent or stop seizures.

* **microorganism** is a tiny organism that can be seen only by using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

the symptoms but do not treat the disease directly. Medications commonly prescribed include antipsychotic drugs* (to control behavior problems) and anticonvulsants* (to control seizures). Many children with CDD are left with permanent and serious disabilities that need long-term care.

Chlamydial Infections

Chlamydial (kla-MID-ee-al) infections are caused by three species of microorganism. Chlamydia trachomatis can cause eye or lung infections and can also infect the urinary and genital areas of both men and women. Chlamydia pneumoniae causes infections of the respiratory tract, and Chlamydia psittaci causes ornithosis, known as parrot fever, that is similar to the flu.*

What Diseases Are Caused by Chlamydial Infections?

Chlamydia trachomatis In the United States, Chlamydia trachomatis (tra-KO-ma-tis) is responsible for more cases of sexually transmitted diseases (STDs) than any other organism. Sexually transmitted diseases are passed from one partner to another during sexual activity. It is estimated that between 4 and 8 million people are annually infected in the United States by Chlamydia trachomatis.

Chlamydia trachomatis also causes an eye infection called trachoma (tra-KO-ma). This inflammation of the membrane covering the eye

causes the eye to become irritated and red with a thick discharge. Infants whose mothers' have chlamydial infections may become infected during birth. These infants can develop eye infections a few days after birth or pneumonia several weeks after birth.

Chlamydia pneumoniae *Chlamydia pneumoniae* (noo-MO-nee-eye) can cause infections in the respiratory tract. The result can be bronchitis*, pneumonia*, or pharyngitis*. In the United States, chlamydia pneumoniae is one of the leading causes of pneumonia in people between the ages of 5 and 35.

Chlamydia psittacosis The illness psittacosis (sit-a-KO-sis), also called ornithosis or parrot fever, is caused by *Chlamydia psittaci* carried by birds (mainly parrots, parakeets, and lovebirds). In human beings, it causes an illness that is like the flu. Only people who work closely with birds, such as pet-store employees or trainers of carrier pigeons, are liable to contract this disease.

How Are Chlamydial Infections Transmitted?

Chlamydial infections are passed from one person to another through direct contact. Sexually transmitted chlamydia is passed from one person to another by direct sexual contact, and the people at most risk are those who have unprotected sex (sexual intercourse without use of a condom) or multiple sex partners.

Parrot fever is caused by inhalation of dust from feathers and droppings or by the bite of an infected bird. Trachoma is transmitted by eye-to-eye or hand-to-eye contact, eye-seeking flies, or by sharing contaminated articles such as towels, handkerchiefs, or eye makeup.

Who Are at Risk for Chlamydial Infections?

Those at greatest risk for chlamydia trachomatis infections include sexually active individuals, especially those with partners who have the infection. Unborn babies of mothers with the disease are also at risk for infection during birth. People who work with birds that are illegally brought into the United States are at risk of infection with *Chlamydia psittaci*.

What Are the Symptoms of Chlamydial Infections?

The most common symptom of chlamydia trachomatis infections in men or women is a burning sensation during urination. Unfortunately, many women who are infected do not have any symptoms. If they are pregnant and do not know that they have been infected, they may unknowingly pass the disease to their baby during birth. Besides a burning sensation when urinating, a person with chlamydia trachomatis may have an abnormal discharge from the genital area. The genital area may become inflamed, and in women the inflammation can spread to the internal reproductive organs. Women may then develop pelvic inflammatory disease (PID), a condition that cause a woman to become infertile (unable to become pregnant and give birth).

▲
A microscopic image of a smear of material taken from the cervix of a woman infected with chlamydia shows the presence of the bacteria. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

* **bronchitis** (brong-KYE-tis) is a disease that involves inflammation of the larger airways in the respiratory tract, which can result from infection or other causes.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

* **pharyngitis** (far-in-JI-tis) is inflammation of the pharynx, part of the throat.

* **cornea** (KOR-nee-uh) is the transparent circular layer of cells over the central colored part of the eyeball (the iris) through which light enters the eye.

* **incubation** (ing-kyoo-BAY-shun) is the period of time between infection by a germ and when symptoms first appear. Depending on the germ, this period can be from hours to months.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

* **endemic** (en-DEH-mik) describes a disease or condition that is present in a population or geographic area at all times.

* **quarantine** is the enforced isolation (for a fixed period) of apparently well people or animals who may have been exposed to infectious disease.

Trachoma (chlamydial eye infection) is found in poor areas of the southeast United States and in poor areas of other countries around the world. This eye infection is closely associated with poor nutrition and inadequate hygiene. Trachoma infection causes eyelid swelling, tearing, and sensitivity to light. Seven to ten days after the symptoms start, small lumps develop inside the eyelid and gradually increase in size and number. If not treated, scarring of the cornea* occurs, and vision is diminished or completely lost.

Parrot fever has an incubation* period of one to three weeks. There is then a sudden onset of fever, chills, loss of appetite, and fatigue. Later a cough develops, which progresses to pneumonia. Up to 30 percent of people who have untreated parrot fever die.

How Are Chlamydial Infections Treated?

Chlamydial infections can be successfully treated with antibiotics*. Because untreated chlamydial infections can lead to serious and permanent problems, possible infections should be treated and evaluated by a doctor as soon as possible. While being treated for genital infections due to chlamydia, individuals should inform their sexual partners who should be tested and treated, if necessary. Parents of newborn children should be alert to the condition of the baby's eyes. If they become red, swollen, or have a thick discharge, a physician should be contacted immediately. Persistent coughing by a newborn is also a signal to call a doctor.

Can Chlamydial Infections Be Prevented?

The best prevention for genital infection by chlamydia is to avoid sexual contact with an infected person. Abstaining from sexual relations is the only certain way to avoid contracting chlamydia trachomatis because it is common for infected people not to know they have the infection.

Blindness due to trachoma infection can be prevented by giving a single dose of the antibiotic azithromycin to individuals who live in areas where the condition is endemic*.

Parrot fever can be prevented by buying birds from reputable pet stores or breeders who sell imported birds that have been quarantined*, examined, and fed antibiotic-treated bird feed for 45 days.

Cholera

Cholera (KAH-luh-rub) is an acute infection of the small intestine* that can cause severe diarrhea (dye-uh-REE-uh).*

What Is Cholera?

Cholera is an illness caused by the bacterium *Vibrio cholerae*, which is contracted by eating contaminated food or drinking contaminated water. The bacteria can cause severe diarrhea* by producing a toxin that makes the intestines release more water and minerals than usual. The disease has a one- to five-day incubation period (the time between infection and when symptoms appear) and progresses very quickly. Most cases of cholera are mild, but in about one of 20 cases, the disease is serious. If left untreated, severe cholera can lead to death from dehydration* within hours. With treatment, the death rate is less than 1 percent.

Is Cholera Common?

Cholera has been rare in industrialized (or highly developed) countries such as the United States since the early 1900s, thanks to improved sanitation and water treatment. However, cholera is still common in other parts of the world, including India and southern Asia, parts of Africa, and Latin America.

In 1991 an epidemic* of cholera occurred in South America and some cases appeared in the United States shortly thereafter. Most cases of cholera reported in the United States can be traced to travel to an area where cholera is endemic*.

* **acute** describes an infection or other illness that comes on suddenly and usually does not last very long.

* **small intestine** is the part of the intestines—the system of muscular tubes that food passes through during digestion—that directly receives the food when it passes through the stomach.

* **diarrhea** (di-ah-RE-a) refers to frequent, watery stools (bowel movements).

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **epidemic** (eh-pih-DEH-mik) is an outbreak of disease, especially infectious disease, in which the number of cases suddenly becomes far greater than usual. Usually epidemics are outbreaks of diseases in specific regions, whereas widespread epidemics are called pandemics.

* **endemic** (en-DEH-mik) describes a disease or condition that is present in a population or geographic area at all times.

* **feces** (FEE-seez) is the excreted waste from the gastrointestinal tract.

In 2008 an epidemic of cholera occurred in Zimbabwe, a country in the southern part of Africa. The World Health Organization reported that as of December 1, 2008, a total of 11,735 cholera cases with 484 deaths had been reported since the previous August. Given widespread deterioration in water and sewage systems and crowded living conditions in the country, cholera outbreaks occurred frequently during the early 1990s. Large outbreaks also occurred in 1999 and 2002.

How Do People Contract Cholera?

Cholera is spread when people eat food or drink water that has been contaminated with feces* containing *Vibrio cholerae*. Risk factors for epidemics of cholera include unsanitary and crowded living conditions, war, famine (scarcity of food), and natural disasters that disrupt clean water delivery. For example, following a natural disaster such as a hurricane or flood, supplies of drinking water can become contaminated. The disease is most frequently spread in areas with poor sanitation and water treatment facilities.

During outbreaks of the disease, cholera may spread by contact with the feces of an infected person; *Vibrio cholerae* can live in feces for up to two weeks. It also spreads when people use contaminated water for cleaning or waste disposal. Eating raw or undercooked shellfish can be another way of contracting the disease because the bacteria can survive in slow-moving rivers and coastal waters. The few cases in the United States are typically caused by contaminated seafood from the Gulf of Mexico or seafood brought home by people who have traveled to other countries.

What Happens to People Who Have Cholera?

Signs and symptoms The major symptom of cholera is diarrhea, which can be severe and cause up to a quart of fluid loss per hour from the body. Diarrhea caused by cholera is painless, with stools that are fishy smelling

CONCERN OVER CHOLERA

Until the late 1800s, cholera was a serious threat in the United States, and the numbers of cases often reached epidemic proportions. In 1849, the immigrant boat *John Drew* brought cholera to Chicago, where 678 people died of the disease that year.

By 1870 cholera was no longer a major threat in the United States due to improved sanitation and water treatment. However, the disease continued to be a significant concern in other parts of the world. In 1961 a pandemic (an epidemic that occurs over a large geographic area) that began in Indonesia spread to Bangladesh, India, Iran, and Iraq by 1965. In 1970 cholera appeared in West Africa, where it had not been seen in 100 years. It eventually became endemic to most of the continent.

and watery, often with flecks of mucus* in them (these are sometimes called “rice water” stools, because they look like rice floating in water).

Most cases of cholera are mild or moderate, and disease can be difficult to distinguish from other ones that cause diarrhea. More serious cases can cause severe diarrhea, vomiting, and dehydration. Signs of dehydration include decreased urination, extreme tiredness, rapid heartbeat, dry skin, dry mouth and nose, thirstiness, and sunken eyes.

Diagnosis Because the symptoms of cholera are often identical to those of other illnesses that cause diarrhea, knowing that a person has traveled to a country where cholera is endemic is important in helping a doctor make the diagnosis. Blood and stool samples can be taken to look for evidence of the bacteria.

Treatment Treatment of cholera can be simple and effective, especially if it is given soon after symptoms appear. Rehydration, or replenishing the body with fluids, is the most important part of treatment. People can rehydrate effectively by drinking a mixture of sugar, salts, and clean water, known as an oral rehydration solution. The World Health Organization has an oral rehydration solution that is distributed worldwide through the efforts of the United Nations. In the United States, solutions can be bought or mixed at home. Such solutions replenish the fluid and salts lost by the body due to diarrhea and vomiting.

More serious cases of cholera may require intravenous (in-tra-VEE-nus) fluids, or fluids injected directly into a vein. Antibiotics, which are given in severe cases, can shorten the time that the symptoms last and help prevent spread of the disease to others. But widespread use of antibiotics for large populations is discouraged.

* **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.

◀ Cholera bacteria live in water. At this crossroads near Capetown in South Africa, human waste contaminates the drinking water and the water used for cleaning and cooking food.
M. Courtney-Clarke/Photo Researchers, Inc.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **shock** is a serious condition in which blood pressure is very low and not enough blood flows to the body's organs and tissues. Untreated, shock may result in death.

* **kidneys** are the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

* **vaccines** (vak-SEENS) are preparations of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.

Complications from cholera are usually the result of severe dehydration. Seizures*, abnormal heart rhythms, shock*, damage to the kidneys*, coma*, and death can occur. Children, especially infants, are more likely to develop complications than adults because they are more prone to developing severe dehydration and body mineral imbalances.

How Can Cholera Be Prevented?

Steps people can take to prevent contracting cholera when traveling or after a natural disaster include the following:

- Drinking only bottled water, water that has been boiled or treated with chlorine or iodine, or bottled, carbonated beverages
- Eating only food that has been thoroughly cooked and is still hot
- Not eating raw fruit or vegetables unless they have been peeled
- Avoiding food and drinks sold by street vendors
- Avoiding raw or undercooked seafood
- Not bringing seafood from abroad back to the United States

Vaccines* for cholera exist, but their effectiveness is short lived, and none is provided or recommended in the United States.

Chronic Fatigue Syndrome

Chronic fatigue syndrome (KRAH-nik fuh-TEEG SIN-drome), or CFS, is a condition that makes people feel exhausted and affects their participation in normal activities, such as work or school. The cause of the syndrome was not fully understood in the early 2000s, and researchers were investigating the possibility that an infection might trigger the condition in some cases.

Keith Jarrett's Story

In November 1996, the enormously popular American jazz pianist and composer Keith Jarrett found himself completely drained of energy in the middle of a concert tour in Italy. The only way he could get through his performances was to stay in bed most of the day and get up just for the concert at night. Too tired even to cross the street, Jarrett did not play in public again for two years. The illness was so severe that he said he felt as though aliens had entered his body. He was eventually diagnosed with chronic fatigue syndrome.

What Is Chronic Fatigue Syndrome?

Chronic fatigue syndrome is a condition that causes almost constant exhaustion. People with CFS typically cannot get more sleep to feel better, because their fatigue does not improve with rest. In addition, physical or mental work may make the fatigue worse. Doctors and scientists do not know what causes CFS. In the mid-20th century, people with CFS were often told their symptoms were psychological*.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **mononucleosis** (mah-no-nuklee-O-sis) is an infectious illness caused by a virus with symptoms that typically include fever, sore throat, swollen glands, and tiredness.

* **hepatitis** (heh-puh-TIE-tis) is an inflammation of the liver. Hepatitis can be caused by viruses, bacteria, and a number of other noninfectious medical conditions.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **hypoglycemia** (hi-po-gly-SEE-mee-uh) is a condition that occurs when the amount of glucose, or sugar, in the blood becomes too low. Symptoms can include dizziness, trembling, sweating, and confusion.

* **candidiasis** (kan-dih-DYE-uh-sis) is an overgrowth of *Candida*, a type of yeast, in or on the body.

* **Lyme disease** (LIME) is a bacterial infection that is spread to humans by the bite of an infected tick. It begins with a distinctive rash and/or flu-like symptoms and, in some cases, can progress to a more serious disease with complications affecting other body organs.

Then in the 1980s, healthcare professional began to recognize CFS as a medical condition associated with the physical symptoms of severe fatigue and weakness.

CFS affects all racial groups and occurs in teens and adults. According to the National Institutes of Health, females are at least two to four times more likely than males to develop CFS. Some studies have estimated that as many as one million people in the United States have the syndrome.

What Are the Symptoms of Chronic Fatigue Syndrome?

For a diagnosis of CFS, individuals must have a sudden onset of exhaustion that continues for six months or recurs during that length of time. For a doctor to diagnose CFS according to guidelines from the Centers for Disease Control and Prevention, individuals must also have experienced at least four of the following eight symptoms after the fatigue began:

- Malaise, such as intense exhaustion, that occurs after physical activity and lasts more than 24 hours
- Feeling of tiredness despite having slept
- Difficulty in concentrating or short-term memory problems
- Muscle pain
- Pain in more than one joint, but without accompanying redness or swelling
- Headache
- Tender lymph nodes*
- Sore throat

Just because individuals experience the symptoms of CFS does not necessarily mean they have this condition. Other medical problems may be the cause of the symptoms. For this reason, medical professionals order many tests in order to rule out other health conditions. If these tests are negative, the CFS is considered as the diagnosis.

What Causes Chronic Fatigue Syndrome?

Doctors do not know what causes CFS. Because many people first experience the symptoms of CFS after an illness caused by a virus (such as mononucleosis* or hepatitis*), some scientists think that a viral illness can trigger the condition. Some researchers have also suggested toxins (poisons), stress, and physical or emotional injury as possible causes of CFS. In addition, some researchers think that CFS stems from a problem in the immune system*, which helps the body fight disease. Because many people with CFS experience depression, other doctors believe that a psychological condition produces the physical symptoms of CFS. Previously CFS was blamed on many other conditions, such as allergies, hypoglycemia*, infection with Epstein-Barr virus (the virus that causes mononucleosis), candidiasis*, and Lyme disease*.

How Is Chronic Fatigue Syndrome Diagnosed and Treated?

CFS is diagnosed if a person has at least four of the specified symptoms, described above, and medical professionals have ruled out other causes, such as multiple sclerosis*, hypothyroidism*, or heart or kidney disease.

Individuals need to undergo blood tests and physical examinations to eliminate other possible causes of symptoms, because no specific laboratory tests can confirm the diagnosis of CFS. A diagnosis of CFS often is made when nothing else is found to account for the symptoms.

Because the cause of CFS was unknown as of 2009, treatment for CFS involved relieving the symptoms. Treatment or recommendations for handling symptoms include engaging in moderate exercise, such as yoga or tai chi; taking a prescribed antidepressant (medication to ease depression); and taking a nonsteroidal over-the-counter anti-inflammatory drug, such as ibuprofen. People with CFS should also watch their stress levels, because mental, physical, or emotional overexertion can aggravate CFS symptoms. Some patients with CFS may respond to drinking extra fluids and eating extra salt. Some people also find cognitive behavioral therapy* and rehabilitative therapy* helpful in decreasing or coping with their symptoms. For most patients, the symptoms of CFS are most severe in the beginning, and later they may come and go. Some people recover completely from CFS, although it is not clear why this happens. Most CFS patients recover gradually within five years after symptoms begin.

Chronic Illness

A chronic illness is a mental or physical disorder that lasts for a long time, perhaps even a lifetime.

What Is Chronic Illness?

Chronic (KRAH-nik) illnesses are different from illnesses such as flu or chicken pox, in which a person becomes sick for a short time and then returns to health. These short-term illnesses are called acute (a-KYOOT) illnesses. Unlike people with acute illnesses, people with chronic illnesses usually do not return completely to normal health. The illness does not go away, even when the symptoms are controlled.

What Are Different Types of Chronic Illness?

There are many types of illnesses that are chronic, each with its own symptoms, causes, and course. Some chronic illnesses affect people of any age or ethnic background, whereas others are more likely to appear in a particular age or ethnic group. Some chronic illnesses are present at birth, whereas others develop later in life. Chronic illnesses are sometimes inherited. Diseases that are inherited develop because a person has certain genes*, the material in the body that helps determine physical and mental characteristics, such as hair and eye color. An example of an inherited chronic illness is sickle-cell anemia. This disease affects the blood's ability to carry oxygen through the body. Sickle-cell anemia is more likely to occur in people of African descent who carry the gene for the disease. Sometimes the symptoms of inherited chronic illnesses appear early in childhood. At other times, symptoms of an inherited chronic illness do not show up until much later in life.

Some chronic illnesses are caused by environmental factors such as exposure to pollutants. Coal miners may breathe so much coal dust in the air that they begin to show symptoms of a chronic lung disorder called black lung disease. Bacteria* or viruses* can cause chronic illnesses. For example, Lyme disease, a bacterial disease spread by the bite of ticks, causes an acute flu-like illness at first, but it also can cause longterm joint, heart, and nervous system problems that may not show up for months or years. Some chronic illnesses are progressive. Progressive illnesses such as muscular dystrophy*, cystic fibrosis*, multiple sclerosis*, Parkinson disease*, or Alzheimer (ALTS-hy-mer) disease* can get worse as time passes.

How Is Chronic Illness Treated?

When doctors diagnose a chronic illness, they also recommend treatments that can relieve symptoms or keep the body functioning at its healthiest. Sometimes treatments involve medications the doctor prescribe. Sometimes managing the illness also depends on behaviors the ill person can do to remain as healthy as possible, such as making changes in diet, quitting smoking, or exercising more. People with chronic illness seem to do best when they work as partners with their doctors to take an active role in caring for their health.

The symptoms of many chronic illnesses can be controlled with medication or changes in diet and activity. For example, people with diabetes (dy-a-BEE-teez) are unable to process sugars properly for use by the body. By taking insulin* or other medications and by eating properly, people with diabetes can lead very active, normal lives. Bobby Clarke, who played professional ice hockey for many years, is an example of a person with diabetes who has had a vigorous and demanding career, even though he has needed to take insulin every day.

Some people with chronic illnesses have symptoms that appear only under certain conditions. For example, some people with asthma (AZ-ma), a chronic illness that affects the lungs, may experience difficulty breathing only when they exercise, breathe in pollutants, or are under stress. Others with asthma may need to take medications or use inhalers daily to prevent wheezing. When the symptoms of a chronic illness are not present or are minimal, the illness is said to be in remission (ree-MI-shun). Having an illness that is in remission is not the same as being cured because the disease that causes the illness is still present.

Coping with Chronic Illness

Accepting that one must live with the limitations of a chronic illness can be difficult. How people react to the diagnosis of a chronic illness and how they cope depend partly on the nature of the illness and the age and resilience of the person. The changes they believe the illness will make in their lives and how the illness will change their family and social support also influence how people cope. Many people go through a process of grieving for the health and freedom of activity that they have lost. They may also feel anger, depression, and worry when they find out that they have a chronic disease.

Self-image and self-esteem* may suffer when a person must cope with a chronic illness, especially if that illness is painful or imposes limitations that interfere with social activities, school, or work. Chronic illness may be difficult for other family members, who frequently must take on additional responsibilities at home. Many chronic illnesses may get better or go into remission, only to reappear unexpectedly, sometimes with worse symptoms. Uncertainty about the course of the illness can be stressful. This uncertainty also may make planning for vacations or special activities difficult.

Support groups dedicated to specific illnesses are often effective in helping the person with a chronic illness and that person's caregivers make

* **insulin** is a kind of hormone, or chemical produced in the body, that is crucial in controlling the level of glucose (sugar) in the blood and in helping the body use glucose to produce energy. When the body cannot produce or use insulin properly, a person must take insulin or other medications.

* **self-esteem** is the value that people put on the mental image that they have of themselves.

emotional and physical adjustments to the disease. Counseling and therapy for both the chronically ill person and caregivers or family members may help people find ways of dealing with the stress of chronic illness. Many people with chronic illness, even children, cope well with their condition and find ways of adjusting to their disease and leading full and meaningful lives.

Chronic Obstructive Pulmonary Disease (COPD)

Chronic obstructive pulmonary disease, or COPD, known as the thief of breath, causes long-lasting obstruction of the respiratory airways, resulting in damaged lungs and making it hard to breathe. Emphysema and chronic bronchitis are forms of COPD.

Daughter Knows Best

Chrissy's father had been smoking cigarettes since he was a teen. In the past few years, though, her father had developed a nasty cough that never seemed to go away. Her father said it was just a "smoker's cough" and nothing to worry about, but Chrissy was concerned. Finally, she convinced her father to see a doctor. The doctor said that her father had an

early stage of chronic obstructive pulmonary disease or COPD, an illness that affects a large number of smokers. The doctor pointed out that too many smokers do not take this condition seriously until the lungs have been badly damaged. At that point, smokers can develop life-threatening breathing problems or heart failure. Surprised by what he had learned, Chrissy’s father thanked his daughter for urging him to get help before it was too late. The next day, he joined a group for smokers who want to stop smoking.

How Does the Respiratory System Work?

Air reaches the lungs through a series of ever-smaller tubes that appear like an upside-down tree. As people breathe air in through their nose and mouth, it passes through the long pipe called the trachea (TRAY-kee-a), which passes from the throat down the neck. Then the trachea branches into two large tubes or bronchi (BRONK-eye), and then into even

Did You Know?

- Approximately 11.2 million adults have been diagnosed with COPD in the United States; an additional 14 million may have COPD but are not diagnosed.
- Since 1982, the number of people with COPD has increased 41.5 percent.
- An estimated 9.1 million people were diagnosed with chronic bronchitis in 2002.
- An estimated 3.1 million have emphysema.
- An estimated 8 to 17 percent of American men and 10 to 19 percent of women suffer from some type of chronic airway obstruction.
- Death rates for female patients with COPD have been consistently higher than death rates for males with COPD. In 2002, 61,422 women with COPD died compared to 59,133 men.

* **emphysema** (em-fuh-ZEE-mah) is a lung disease in which the tiny air sacs in the lungs become permanently damaged and are unable to maintain the normal exchange of oxygen and other respiratory gases with the blood, often causing breathing difficulty.

smaller bronchi called bronchioles (BRONK-kee-olz) that branch still further deep into the lungs. The bronchioles end in tiny air sacs called alveoli, which have very small blood vessels called capillaries that run in the walls.

The thousands of tiny alveoli provide a surface about the size of a football field for the exchange of oxygen and carbon dioxide. It is here that the body takes in oxygen to nourish the body cells and gives off carbon dioxide, which is exhaled. Normally, the airways and air sacs are elastic and spring back to their original shape after filling with air, acting like a new rubber band or balloon. This flexibility allows the oxygen and carbon dioxide exchange to take place efficiently. A slice of a normal lung looks like a pink sponge filled with tiny bubbles or holes.

What Happens in COPD?

In COPD causes less oxygen-laden air gets in and less air gets out for the following reasons:

- Airways and air sacs lose elasticity and become like old rubber bands or worn out balloons.
- Walls between many of the alveoli are destroyed.
- Walls of the airways become thick and inflamed or swollen.
- Cells in the airways may produce more mucus or sputum than usual and block airways.

In the emphysema* type of COPD, the bronchi and bronchioles are inflamed and continually swollen and clogged. This condition causes the alveoli to swell, burst, and merge. Instead of the healthy pink tissue with small holes, the lungs look like a dirty sponge with many large bubbles or holes in it. Deposits of tar from smoking make the tissue dark and spotted. Because there is less air surface, the damage to the alveoli makes it more difficult for the transfer of oxygen and carbon dioxide to take place and for the person to breathe.

There are three types of emphysema depending on the location of the inflammation. Panlobular or panacinar emphysema is characteristic of a weakening and inflammation of alveoli at the end of the bronchioles. When destruction is severe, the lungs appear like a spider web in x-rays. A mild version of this type of emphysema occurs in aging; in younger people it is caused by the body's ability to produce sufficient amounts of the protein Alpha-1 antitrypsin (ATT). The second type, centrilobular or centriacinar emphysema, affects single alveoli, destroying them and causing the airway walls to enlarge. This type is commonly associated with chronic bronchitis. A third type, distal acinar emphysema or paraseptic, is rare.

An acute type of bronchitis is one that anyone can get, usually from contact with viruses or bacteria. With rest and care, it disappears after a brief period of time. However, in chronic bronchitis the lining of the bronchial tubes become inflamed and swell up inside. This interferes

with the flow of air into and out of the lungs. The swollen and inflamed tissues also make large amounts of a thick, slippery substance called mucus*. People with bronchitis bring up mucus when they cough. Chronic bronchitis lasts for a long period of time, and it can come and go over several years.

What Are the Causes of COPD?

COPD, including emphysema, are very rare in young people, but the incidence* steadily increases as people grow older, particularly during or after middle age. The repeated breathing of cigarette smoke is the most common irritant that causes COPD; however, pipe, cigar, and other types of tobacco smoke can also cause COPD, especially if the smoke is inhaled. Secondhand smoke that is in the air from other people’s smoking cigarettes can also play a part in developing COPD, due to the cumulative effect on the lungs of breathing tobacco smoke. However, one person cannot catch COPD from another.

Emphysema is more common in men than in women, probably because more men smoke cigarettes than women. However, it is believed that this difference will become smaller because more teenage girls and young women are smoking cigarettes in the early 2000s than in years before. Heavier smoking among men over the last several decades of the 20th century is believed to account for the imbalance in numbers in the early 2000s. COPD occurs in 15 percent of cigarette smokers, and tobacco use accounts for a much as 90 percent of the risk for developing the disease.

In some cases, a rare gene for a condition called Alpha-1 antitrypsin deficiency may play a role in COPD. In normal and healthy individuals, the protein Alpha 1 antitrypsin (ATT) protects the lungs from an enzyme that may attack lung tissue. Without ATT lung tissue may be destroyed. The gene carrying ATT is recessive, and the American Lung Association

300 YEARS AGO: NO SMOKING PLEASE

Sir John Floyer (1649–1735), an English physician who had asthma, first described emphysema in the 17th century. Floyer was studying pulmonary (lung) disorders and described the characteristic prolonged expiration and progressive nature of emphysema.

Floyer warned his patients to avoid tobacco smoke, metallic fumes, and other potential irritants because he believed that they caused pulmonary disorders. He was right.

estimates that about 100,000 Americans in the early 2000s were born with the deficiency. If these people smoke, their risk of developing emphysema is increased. The onset of Alpha-1 related emphysema symptoms often appear between the ages of 32 and 41. It is estimated that 25 million Americans carry the gene, and most carriers are not aware of it.

The lungs and airways are very sensitive, and other irritants can inflame them and destroy the elasticity of the sensitive structures. Such activities as working around certain kinds of chemicals and breathing those fumes for many years, working in dusty areas over the years, and heavy exposure to air pollution can cause COPD. Environmental air pollution may also make a person more likely to develop chronic bronchitis and emphysema. With on-the-job exposure to mineral dusts, such as coal dust in a mine, emphysema may occur as part of a disease known as pneumoconiosis (noo-mo-ko-nee-O-sis).

Emphysema may also accompany diseases such as asthma and tuberculosis that can obstruct the airways in the lungs. A less serious form of emphysema sometimes develops in elderly people whose lungs have lost elasticity only as a part of the aging process. Another usually mild form, called compensatory emphysema, results when a lung overexpands to occupy the space of another lung that has collapsed or has been removed surgically. However, the effect of all these groups or conditions is small compared to cigarette smoking.

The great majority of emphysema cases are associated with cigarette smoking. It has been found that people who are heavy smokers of cigarettes are 10 to 15 times more likely to develop emphysema than are nonsmokers.

What Are the Signs and Symptoms of COPD?

COPD is usually not diagnosed until about the sixth decade (between the ages of 50 and 59) in a person's life. Most of these people have smoked at least 10 to 20 cigarettes per day for 20 or more years before experiencing any symptoms. The signs of COPD are as follows:

- Cough and chest illness are common. The cough is usually worse in the morning and produces a small amount of colorless sputum. The irritated bronchial tubes also are an ideal breeding ground for repeated infections.
- Shortness of breath is common but does not occur until about the sixth decade.
- A whistling or squeaky musical-like sound occurs when breathing, especially after exercise or exertion.
- As the condition worsens, shortness of breath occurs more frequently.
- Discoloration of the skin and failure of the right side of the heart may occur.
- Anorexia and weight loss often develop.

With any of the above symptoms, the person is encouraged to seek medical attention.

How Is COPD Diagnosed?

The healthcare provider asks about symptoms and whether the person has smoked, currently smokes, or is exposed to second-hand smoke or air pollutants. The physician first takes a medical history, physical exam, and listen to the lungs. A sample of sputum may be collected and sent to a laboratory for analysis.

Tests for the chest and breathing A chest x-ray or a high-resolution computerized tomography (CAT) scan may be taken. The CAT scan provides more detail than a chest x-ray and is useful especially in diagnosing emphysema.

Spirometry (speh-ROM-eh-tree) is an easy and painless breathing test to help determine the working of the lungs. This pulmonary function test detects and assesses the severity of the disease. In this test, the person breathes as hard as he or she can into a large hose connected to a machine called a spirometer. When the person breathes out, the machine measures how much air the lungs can hold and how fast he or she can blow air out of the lungs after taking a deep breath. Spirometry measures the amount of air that the person can exhale—the forced expiratory volume or FEV in one second (FEV1). The test, which shows the narrowing of airways, bases the normal value at 70 to 80 percent of the forced volume capacity (FVC). The device is quite sensitive and can detect COPD before serious symptoms appear. Based on the result of tests, doctors divide COPD into three categories according to severity:

1. Mild COPD or Stage 1 is FEV1 in which breathing is equal or more than 50 percent of the predicted normal value of 70 to 80 percent. The breathing test shows mild airflow limitation. Signs may include a chronic cough and sputum productions.

2. Moderate COPD or Stage 2 is FEV1 in which breathing is 35 to 49 percent of the predicted value. The breathing test shows a worsening airflow limitation. Usually the symptoms have increased, including shortness of breath that develops when the person is working hard, walking fast, or doing strenuous activities. The person begins to realize that he or she must seek medical attention.
3. Severe COPD or Stage 3 is FEV1 in which breathing is less than 35 percent of the predicted value. Breathing test shows severe airflow limitation. The person is exhausted after little activity. Other complications such as signs of heart or respiratory failure may develop. Now the person has a greatly impaired quality of life. The worsening symptoms become life threatening.

The test is also used to diagnose the severity of asthma and to assess the suitability of patients for treatment, such as oxygen therapy.

The doctor may recommend other tests to rule out conditions that may have similar signs and symptoms. The tests may include an arterial blood gas test that measures how well lungs are transferring oxygen into the blood and how efficient the lungs are removing carbon dioxide. Another test uses a pulse oximeter, which is attached to a finger, to measure the percentage of oxygen saturation in the blood.

How Is COPD Treated?

The goals of COPD treatment are to improve the quality of life of the person by preventing symptoms of the condition, to slow the progress of the disease, to prevent complications and sudden onset of problems, and to improve overall health. COPD treatment is different for each person, and the general practitioner may recommend a pulmonologist (pull-mon-OL-o-gist), a specialist who works with diseases and disorders of the respiratory system. Three types of treatment are self-help at home, medications, and surgery, and treatment may depend on whether the symptoms are mild, moderate, or severe.

Self-care At Home The most important step that a person with COPD can take is to stop smoking in order to possibly reduce the progress of the disease. A plan to stop smoking is essential, and help from outside sources may be necessary. However, most patients have trouble stopping their habit of smoking. The addictive power of nicotine, the conditioned response to smoking-associated stimuli, and psychological problems, which may include depression, the tobacco industry's forceful promotional campaigns, and poor education about the nature of nicotine make it difficult for individuals to stop smoking. A smoking cessation program may involve the following techniques and tools:

- Patient education, which involves revealing the harmful effects of smoking and what is happening in COPD.
- A designated date for quitting.

- Follow up support. This encouragement may be individual or in a group setting
- Relapse prevention. This support system tries to catch the signs and symptoms that indicate the person may relapse into smoking and act immediately.
- Advice for healthy lifestyle changes. Good nutrition and the value of exercise—although limited in advanced stages—are important for the person's well being.
- Social support systems. The encouragement of family and friends helps individuals stop smoking.
- Other adjuncts to treatment such as medication that replaces nicotine.

Several nicotine replacement therapies are available. Nicotine polacrilex is a chewing gum, which comes in two strengths and are designated for those who smoke less than one pack per day and those who smoke more than a pack per day. The person may chew hourly and as needed for any initial cravings within the first two weeks and then gradually reduce the amount of use over the next three months. Transdermal nicotine patches are available and generally well tolerated; these products are scheduled for decreased use over 6 to 10 weeks. The antidepressant bupropion is a non-nicotine aid for stopping smoking and may also be effective for those people who have not been able to stop with other nicotine replacement therapies. Some people have had success with hypnotherapy.

Withdrawal from nicotine may cause unpleasant side effects, such as anxiety, irritability, difficulty concentrating, anger, fatigue, drowsiness, depression, and sleep disruption. If the person requires the first cigarette within 30 minutes of waking up, he or she is highly addicted and likely would benefit from nicotine replacement therapy. A nicotine replacement program is an important part of smoking cessation but must be used only under the supervision of a physician.

Medications for COPD Several types of medication are used to treat COPD. Following are medications that may be recommended depending on the nature and progress of the disease:

- Inhaled steroids. Some people with mild to moderate COPD respond to inhaled steroids, also called glucocorticosteroids or corticosteroids. (Corticosteroids are different from the anabolic steroids that athletes may use for bodybuilding.) Inhaled corticosteroids act to reduce airway inflammation and have fewer side effects than oral steroids, although they might not be as effective even at high doses.
- Oral steroids. Oral steroids are sometimes used to improve symptoms and lung function when inhaled drugs do not work. They are not recommended for long-term use because of potential side effects.

* **aerosolize** (AIR-o-suh-lize) is to put something, such as a medication, in the form of small particles or droplets that can be sprayed or released into the air.

- **Bronchodilators.** Prescription bronchodilators work by relaxing muscles around the airways to make breathing easier. Most of these are inhaled and the medicine goes directly into the lungs where it is needed. There are many kinds of inhalers, and they can be either short or long acting. Short-acting bronchodilators last about 4 to 6 hours and are used only when needed. Long-acting dilators last about 12 hours and are used every day.

Several types of medication are bronchodilators. The first group, the Beta 2 agonists, is quickly taken into the lungs and is the first treatment of choice, especially for acute symptoms such as coughing or shortness of breath. Two long-lasting beta 2 agonists, formeterol and salmeterol, may be especially effective for people who have symptoms at night. A second group of bronchodilators, the anticholinergic agents, such as ipratropium bromide, are aerosolized* to deliver the medication in tiny droplets and open breathing passages with minimal side effects. A group of long-acting bronchodilators use methylxanthines, chemicals related to the caffeine family. Caution is recommended with this group due to unwanted side effects.

- **Antibiotics.** In people with COPD chronic infection is common. Use of antibiotics helps people who have shortness of breath and increased sputum production.
- **Oxygen therapy.** People with COPD have worsening levels of oxygen in their bloodstream, especially during periods of exercise. Home oxygen supplements are often recommended. A tube inserted in the nose delivers oxygen from small portable tanks. Because oxygen is flammable, people who have these devices must be cautious about fire and never smoke around the oxygen tank.

Surgery for COPD Surgical approaches are probably the last measure to consider in treating COPD. Three major surgical approaches emerged in the late 1990s: bullectomy, lung volume reduction surgery (LVRS), and lung transplantation:

- **Bullectomy.** Giant bullae are air-filled spaces that form when the walls of the air sacs break to join together to form a large space. Removing them surgically is called bullectomy, an approach that has been standard for many years. Bullae in patients can range in size from 1 to 4 centimeters in diameter and occupy more than 33 percent of a lobe of the lung on one side of the chest. The giant bullae can push against surrounding lung tissue, reducing blood flow and ventilation to healthy tissue. Surgical removal can reduce the pressure and improve lung function.
- **Lung volume reduction surgery (LVRS).** In this type of surgery first performed in the 1950s, surgeons remove 20 to 30 percent from the upper part of each lung, the area most damaged by cigarette smoking. Early successes led to rapid spread of the procedure. The basic assumption behind this type of surgery is that removal of part of the diseased lung increases the airway flow to the remaining

lung and reduces the symptoms. This procedure is mostly used on people with severe emphysema. The National Emphysema Treatment Trial (NETT) supported by the National Heart, Lung, and Blood Institute (NHLBI) and two other government agencies was the first multi-center clinical trial designed to determine the role, safety, and effectiveness of LVRS in the treatment of emphysema. The massive trial took five years to complete and results were presented in May 2003 at a meeting of the American Thoracic Society. The study revealed that patients who received LVRS, along with rehabilitation efforts and counseling, were more likely to function better than those who just received medical treatment.

- Lung transplant. This relatively new surgery may be suggested for those with advanced COPD and a life expectancy of only two years. This procedure involves taking a lung from a healthy donor to replace the diseased lung.

How Can COPD Be Prevented?

Because the damage that COPD, emphysema, and bronchitis do cannot be undone, it is especially important to prevent this disease from developing in the first place. Adopting healthy habits early in life—especially not smoking—is very important. Avoiding exposure to second-hand smoke and staying clear of wood and cooking smoke are also wise. Trying to limit air pollutants in the home is wise, too. It is very important to avoid respiratory infections during cold and flu seasons. Vaccines for flu and pneumonia are recommended for those who are prone to chest disorders and for those older than 65. People can take an active role in fighting for clean air laws to prevent air pollution.

The Global Initiative for Chronic Lung Disease (GOLD) works with healthcare professionals and public health officials around the world to raise awareness of COPD and to improve prevention and treatment of the disease. GOLD works to improve the lives of people with COPD around the world. Launched in 1997 in collaboration with the NHLBI, the National Institutes of Health, and the World Health Organization, the program recommends effective COPD strategies for use in all countries. A major initiative is sponsoring World COPD Day each year in November.

Cirrhosis of the Liver

Cirrhosis (sir-RO-sis) damages liver cells and replaces them with scar tissue that prevents the normal flow of blood through the liver and interferes with many of the liver's vital functions.

Who Gets Cirrhosis of the Liver?

Many people believe that only heavy drinkers can get cirrhosis of the liver. Although it is true that the number one cause of cirrhosis in the United States is drinking alcohol, a person need not be a heavy drinker to get the disease. The chance of developing cirrhosis depends on the amount and frequency that individuals drink, as well as their weight and height, and their body's ability to metabolize, or process, alcoholic products in the blood stream.

What Is Cirrhosis of the Liver?

Cirrhosis is a chronic* liver disease in which normal liver cells are damaged and replaced by scar tissue. The disease prevents the normal flow of blood through the liver and prevents the liver from functioning properly. It is most often (but not always) the result of severe liver damage or chronic liver disease. Although some liver tissue can regenerate or repair itself when injured, the extent to which damaged cells are able to regenerate varies with each person. If cirrhosis is not treated, it can eventually lead to liver failure, or death.

The liver is a large, complex organ, about the size of a football and weighing around three pounds. It is located beneath the ribs in the upper right side of the abdomen* and is connected to the small intestine by the bile duct, which transports bile* from the liver to the intestines. A healthy liver is soft and smooth.

A healthy adult liver (left) weighs about 3 pounds. A liver damaged by alcoholism shows a buildup of fatty tissue (middle). A liver with cirrhosis is enlarged and swollen (right). *A. Glauber/Photo Researchers, Inc.*

The liver is one of the most important organs, serving as the body's most comprehensive chemical factory and refinery. Almost all of the blood that leaves the stomach and intestines passes through the liver. The liver is responsible for cleansing the body of toxic or poisonous substances; processing nutrients, hormones, and medications; and for making proteins and clotting* factors that are crucial to healing. In a person with cirrhosis, toxic substances and bile remain in the bloodstream because the liver has not removed them.

What Causes Cirrhosis?

Cirrhosis is not contagious; it cannot be passed on from one person to another. Cirrhosis has many possible causes:

- Drinking alcohol, the most frequent cause. About one-third of all heavy drinkers eventually develop cirrhosis; the rest may suffer from other forms of liver disease, but not cirrhosis.
- Chronic viral hepatitis (inflammation of the liver). Hepatitis (usually types B, C, and D) is the second most common cause of cirrhosis.
- Wilson's disease, which causes a buildup of copper in the liver, brain, kidneys, and eyes.
- Cystic fibrosis, which causes a buildup of mucus in the lungs, liver, pancreas, and intestines.
- Hemochromatosis (he-mo-kro-ma-TO-sis), which causes a buildup of iron in the liver and other organs.
- Blockages or inflammation of the bile ducts, called biliary (BIL-ee-ar-ee) cirrhosis.
- Congestive heart failure.

* **clotting** is a process in which blood changes into a jellylike mass that stops the flow of blood.

Did You Know?

- Almost 800,000 people die from cirrhosis each year worldwide.
- Cirrhosis is the fourth disease-related cause of death in the United States for people aged 24 to 44.
- Alcohol-related cirrhosis of the liver more than doubled among 25 to 34-year-olds from 1997 to 2007.
- Experts estimate that more than half of all liver diseases could be prevented if people acted upon knowledge that is already available.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be woken up, and cannot move, see, speak, or hear.

- Glycogen storage disorders, which prevent the body from using sugars properly.
- Parasitic infections.
- Reactions to prescription drugs, environmental toxins, and inhalant abuse (sniffing toxic substances).

What Are the Signs and Symptoms of Cirrhosis?

In the early stages, cirrhosis is considered a “silent” disease because people show few symptoms. Over time, however, people with cirrhosis begin to experience fatigue, weakness, exhaustion, and loss of appetite. Weight loss and nausea are common. As cirrhosis worsens, the liver manufactures fewer of the proteins that the body needs and other symptoms develop:

- As less of the protein albumin (al-BYOO-min) is made, water accumulates in the person’s legs, a condition called edema, or abdomen, a condition called ascites (a-SITE-eez).
- A slowing down of the production of plasma proteins such as fibrinogen (fy-BRIN-o-jen), essential for blood to clot, makes it easier for a person with cirrhosis to bruise or to bleed.
- Jaundice, a yellowing of the whites of the eyes or skin, may occur in a person with cirrhosis. This is caused by the buildup of bilirubin (bil-e-ROO-bin) or bile pigment that is normally passed by the liver into the intestines.
- Some people with cirrhosis also experience intense itching due to the bile products deposited in the skin.
- Cirrhosis prevents the liver from cleansing toxins, poisons, or drugs from the bloodstream. As these build up, they can lead to changes in mental function and personality. Early signs of cirrhosis may include neglect of personal appearance, forgetfulness, trouble concentrating, or changes in sleeping patterns. Later signs may include loss of consciousness or coma*.
- Cirrhosis also can affect abdominal blood vessels. Normally, the huge portal vein transports blood from the intestines and spleen through the liver. Cirrhosis blocks the flow, causing a condition called portal hypertension. As the spleen swells, the body attempts to divert blood through other blood vessels. But these new vessels are often not strong enough for the job. If they break, people can vomit blood, a highly dangerous situation.

How Do Doctors Diagnose and Treat Cirrhosis?

Diagnosis Doctors always begin with a medical history and a physical exam. Evidence of an enlarged or swollen liver; evidence of edema or ascites; and signs of mental confusion caused by the buildup of toxic substances in the brain all can lead a doctor toward a diagnosis of cirrhosis.

The doctor also may order CT scans* or ultrasound* scans of the liver to see if it is scarred. A needle biopsy*, in which a needle is put through the skin to take a sample of tissue from the liver, can be useful in diagnosing cirrhosis. The liver also can be inspected through a laparoscope (LAP-a-ro-scope), a viewing device inserted through a tiny incision in the abdomen. The presence of telangiectasia (tel-an-je-ek-TAY-ze-a), which are tiny, expanded, “spidery” blood vessels in the skin, particularly in the face and upper chest, may indicate cirrhosis.

Treatment Treatment depends on the type and stage of the cirrhosis. The goal is to stop the progress of the disease while trying to reverse damage to the liver. If the cirrhosis is caused by alcohol, stopping drinking is the first step.

As of 2009, there is no one treatment to cure cirrhosis. Symptoms such as itching can be treated with medications. Diuretics (drugs that help remove excess salt and water from the body) also may be prescribed to treat edema or ascites. In severe cases of liver failure, when the liver cells have completely stopped working, a liver transplant may be the only solution.

How Is Cirrhosis Prevented?

Adults who eat a nutritious diet and limit their alcohol consumption can help prevent destruction of healthy liver cells. Other tips that can help prevent the disease include:

- Never mixing drugs, in particular alcohol and over-the-counter medications.
- Closely following label directions when using chemicals: ensuring good ventilation, never mixing chemicals, avoiding inhaling any chemical products, avoiding getting chemicals on the skin, promptly washing any accidentally exposed area, and wearing protective clothing.
- Avoiding any type of inhalant abuse.
- Avoiding intravenous drug use by which hepatitis B, C, and D may spread.

Living with Cirrhosis

People with cirrhosis can live for many years. Even when complications develop, they usually can be treated. Many people with cirrhosis have undergone successful liver transplantation and gone on to live healthy lives.

People recovering from cirrhosis are advised not to drink alcohol. Poor nutrition, particularly associated with alcohol or drug abuse, is believed to play a role in how cirrhosis develops, although physicians did not understand this completely as of 2009. In the meanwhile, eating a healthful, well-balanced diet is recommended.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **biopsy** (Bl-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

Cleft Palate

A cleft palate is a gap or split in the roof of the mouth (the palate). It occurs when the palate of a fetus does not develop properly during the first months of pregnancy.

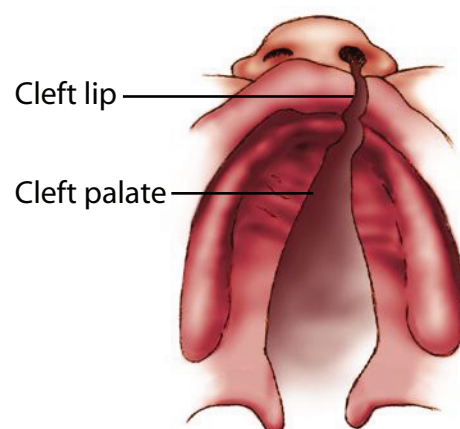

Mixed Feelings

Tonya and Phil were excited to hear their newborn son's first cry, but they were shocked when they saw him for the first time. Baby Philip's upper lip was split up the middle. The doctor told them that Philip had a cleft palate as well as a cleft lip and that both are fairly common birth defects. The doctor reassured Philip's parents that their son was otherwise a healthy baby: The cleft lip and palate would cause Philip some problems, but none that could not be overcome. A plastic surgeon would repair Philip's lip and palate, and a team of specialists would work on related problems with his teeth, ears, and speech.

Normal palate in infant

Partial cleft palate

Complete cleft palate and cleft lip

What Is a Cleft Palate?

Cleft means gap or split, and the palate is the roof of the mouth. A cleft palate occurs when the roof of the mouth in a fetus* does not develop properly, leaving a hole between the nose and the mouth.

The palate extends from the top teeth to the uvula (YOOV-u-la), which is the little piece of tissue that hangs in the back of the throat. A bony hard palate can be felt just behind the top teeth and a muscular soft palate is located just behind the hard palate. A fully formed palate is necessary to close off the nose and throat from the mouth. It keeps food from going up the nose, and it pushes food and saliva to the back of the throat when a person is eating and swallowing. The palate also is important for speaking because it keeps air from going out of the nose instead of the mouth.

The mouth and nose develop early during pregnancy, between the fifth and twelfth weeks of gestation. Three developing areas must fuse (close) together to form the face. The pieces that form the palate usually unite like a zipper. When the growth process is disturbed for some reason, the “zipper” does not close all the way, leaving a cleft. Formation of the palate and the upper lip are separate but linked processes, and many children born with a cleft palate also have a cleft lip. A cleft lip impairs sucking, speech, and appearance. The size and severity of a cleft depends on how much of the palate or lip has not fused together. Clefts can consist of one split down the middle (a unilateral cleft) or two splits (a bilateral cleft).

Why Are Babies Born with Cleft Palates and Cleft Lips?

Cleft palates and lips probably are the result of a number of factors acting together. One in five cases is inherited, probably through the interaction of many different genes*. In most cases, however, clefts seem to result from

▲ A cleft palate is a gap or split in the roof of the mouth (palate). The palate fuses closed as a normal part of fetal development (left). If the palate does not fuse correctly, it can result in a partial cleft palate (middle), or a complete cleft palate and cleft lip (right). *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

The United States and the World

- Worldwide clefts are one of the most common birth defects. Approximately one in 700 babies is born with a cleft palate and/or cleft lip.
- More than 5,500 babies are born in the United States each year with these problems.
- Among people with clefts, 50 percent have both a cleft palate and a cleft lip; 30 percent have only a cleft palate; and 20 percent have only a cleft lip.
- Boys are twice as likely as girls to have a cleft lip or a cleft lip and palate, whereas girls are twice as likely as boys to have just the cleft palate.
- People of Asian, European, and Native American ancestry are more prone to clefts than other ethnic groups.
- Clefts are least likely to occur in people of African ancestry.

Operation Smile

Cleft palate repair requires multiple surgeries, and many people do not have access to or money for the needed medical care. In 1982, plastic surgeon William P. Magee and his wife Kathleen, a nurse and social worker, founded Operation Smile to help make a difference.

Operation Smile and its volunteers provide free reconstructive (repair and rebuilding) surgery and other medical services for children in the United States and in 20 developing countries. Operation Smile volunteers have treated more than 100,000 children since 1982. Even so, many children go untreated, which can lead to medical complications later in life.

environmental factors to which the fetus is exposed early in gestation. The German measles (rubella) virus, other infections, vitamin deficiencies, some medications, and maternal alcohol and drug use during pregnancy all seem to increase the risk that a child will be born with a cleft lip or palate. Prevention efforts are focused on teaching people about these risk factors regarding pregnancy.

What Happens to Children with Cleft Palate and Cleft Lip?

Symptoms An improperly formed palate and/or upper lip affects a child's physical and emotional health in many different ways:

- A cleft lip is a highly visible disfigurement, and a cleft palate can cause abnormal growth of the face. Uncorrected, this abnormality can lead to serious self-esteem problems.
- When a person speaks, sounds result from air that is directed through the nose or the mouth. A complete upper lip also is required to make certain noises. A cleft palate allows air to escape from the nose all of the time, resulting in unusual sounds.
- A hole in the palate can allow food or liquid to come out of the nose. Usually, the normally formed palate acts as a barrier and prevents this problem.
- Because a cleft palate allows liquid to invade the sinuses (facial air cavities) and ear tubes, children with cleft palates are prone to ear and sinus infections.
- Many children with cleft palates and/or cleft lips have dental problems such as missing bone, missing or malformed teeth, and malocclusion (an incorrect bite, meaning top and bottom teeth do not fit together properly). Such problems interfere with chewing and cause facial disfigurement.
- Some children with clefts also have congenital heart problems, growth disorders, or learning problems.

Treatment Fixing Philip's cleft lip and palate requires several surgeries, the first two of which occurred during the baby's first year. In the first surgery when Philip is three months old, a plastic surgeon repairs the lip by stitching together its edges using flaps of skin from other parts of Philip's mouth. In the second surgery when Philip is six months to a year old, the surgeon repairs the cleft palate. If Philip is prone to ear infections, the doctor puts tubes in the baby's ears to help drain them of the fluid that otherwise may lead to infection. These repairs, which are done as early as possible, help prevent hearing and speech problems.

Philip also may require several cosmetic surgeries to adjust his facial features as he grows older. He may need dental work to encourage jawbone growth and to straighten his teeth. He will have his hearing checked frequently by a hearing specialist (an audiologist), and he will need to

work regularly with a speech therapist to learn how to train his palate muscles to work properly.

Philip and his parents will have a lot to deal with over several years, but his prognosis is good. The doctor expects that when Philip enters first grade, he will be speaking well, and he will have barely a scar where his cleft lip once was.

Not all children are as lucky as Philip, who had good medical coverage. Many other children in the United States and elsewhere in the world do not, which leaves a great number of children with no access to medical care. Without proper treatment, cleft palate and cleft lip can lead to myriad health, social, and emotional challenges, and these birth defects can also limit an individual's ability to become a productive member of society. Medical professionals and other advocates often point to this treatable condition as a strong argument for universal healthcare coverage.

Clubfoot

Clubfoot congenital condition in which the foot is abnormally formed and twisted toward the toe. The type of treatment necessary depends on the specifics and the severity of the deformity.

What Is Clubfoot?

Clubfoot (also called Talipes Equinovarus) is a congenital* condition in which the foot is abnormally formed and rigidly twisted toward the toe. Clubfoot occurs when the bones, muscles, tendons, and blood vessels develop abnormally during the first 8 to 12 weeks of fetal development.

What Causes Clubfoot?

The tendency to develop a clubfoot is thought to be multifactorial, meaning that it occurs when there are multiple risk factors for the condition. For example, there may be genetic reasons (it may run in a family), and there may be environmental reasons (for example, an exposure in the uterus to a particular substance that predisposes to the condition).

THE CLUBFOOT IN FICTION

Of *Human Bondage*, the 1915 novel by English author W. Somerset Maugham (1874–1965), has as its main character Philip Carey, who is born with a clubfoot. Like Philip, Maugham was orphaned in childhood and raised in the vicarage of his relative. During his early years the author developed a stutter (called a stammer in England). In writing this novel, Maugham drew on his own experience of disability and the social unease it caused, along with his grief over the loss of his parents. He created a sympathetic portrait of a child born with a clubfoot, one who is orphaned early and socially disadvantaged as he grows up. Maugham's novel is considered his masterpiece.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

Who Gets Clubfoot?

About one in 1,000 babies is born with clubfoot. A baby is more likely to be born with clubfoot if a parent and/or a sibling also has this defect. Boys are about two times more likely than girls to be born with this defect, and about half of all children with the condition are born with both feet affected.

What Are the Symptoms of Clubfoot?

The clubfoot has a characteristic appearance. The foot is often smaller than normal, and the front of the foot is twisted and drawn stiffly towards the big toe. The heel cord (Achilles tendon) may be abnormally short and tight, pulling the foot backwards towards the heel. Some people describe its appearance as “kidney-shaped.” The sole of the foot is also twisted into a more upward position than normal; if walking were to occur, weight would be born by the side of the foot, rather than the sole. Because this deformity occurs very early in fetal development (within the first trimester of pregnancy), at birth the foot is held very rigidly in this position.

Untreated, clubfoot can result in significant disability, since walking is difficult and abnormal. Without treatment, the child is forced to walk on the outside of the foot, rather than flat on the foot's sole. Other bony changes occur over time in the untreated clubfoot, which can be further disabling.

How Is Clubfoot Diagnosed?

The diagnosis of clubfoot at birth is quite simple given the characteristic appearance of the foot. Additionally, because clubfoot occurs so early in fetal development, clubfoot can sometimes be diagnosed during a routine 16-week prenatal ultrasound*.

How Is Clubfoot Treated?

Treatment usually begins almost immediately after birth. The type of treatment necessary depends on the specifics and the severity of the deformity. Most treatment entails a combination or series of casts, braces, special shoes, and therapeutic manipulation of the affected foot and leg. In some cases, surgery is necessary in order to release or reposition the overly tight tendons and/or ligaments that are keeping the joints in an abnormal position or to renovate or stabilize the bones and/or joints.

With treatment, children with clubfeet can go on to grow, develop, and function quite normally. Well-known athletes have gone on to do very well, despite having been born with clubfeet, including the Olympic gold medalist skater Kristi Yamaguchi, and the Olympic gold medalist soccer player Mia Hamm.

Can Clubfoot be Prevented?

Clubfoot cannot be prevented, but genetic counseling can help an affected individual understand the risk of passing the condition on to his or her offspring. Additionally, the general risk of birth defects is decreased in women who do not smoke, drink alcohol, use drugs or medications, or experience other potentially toxic exposures during pregnancy.

Coccidioidomycosis

Coccidioidomycosis (*kok-sih-dee-oyd-o-my-KO-sis*), also known as *Valley fever*, *San Joaquin valley fever*, or *San Joaquin fever*, is a disease that can occur after breathing in the spores* of a fungus found naturally in the soil of dry regions, such as the southwestern United States.

What Is Coccidioidomycosis?

During World War II, American trainees sent to Arizona and parts of Southern California for flight training took thousands of days of sick leave due to coccidioidomycosis, a disease caused by *Coccidioides immitis* (*kok-sih-dee-OYD-eez IH-mih-tus*), a fungus that hibernates a few inches beneath semi-dry soil. The disease's other name, S.J. valley fever, comes from the San Joaquin Valley region of California, where the fungus was first identified.

After regular rainfall, the *coccidioides* fungus blooms into tiny mold spores. If the soil is stirred by events such as dust storms, earthquakes, farming, excavation, or construction work, these microscopic spores spring into the air, where they are easily breathed into the lungs of people and animals.

Coccidioidomycosis cannot be passed from person to person. People must inhale the spores of the fungus in order to contract the disease. Most people who inhale the spores develop only a mild case of disease, in which the infection results in symptoms similar to those of a cold or the flu that go away on their own. Many people are not even aware that they are infected when the symptoms are mild. People with weakened immune systems develop more serious cases. Moreover, North and Central American people with African, Filipino, or Siberian ancestry are especially susceptible. These populations get more severe forms of the disease, in which cases coccidioidomycosis can spread from the lungs to other parts of the body and even to the brain. Severe cases may result in meningitis*. *Coccidioides* infection that has spread throughout the body and occurs with arthritis* is sometimes called desert rheumatism (*ROO-muh-tih-zum*). In general, the more fungal spores inhaled by a person, the more serious the disease tends to be.

Is Coccidioidomycosis Common?

The fungus that causes coccidioidomycosis is found mainly in the desert climates of the southwestern United States, parts of Mexico, and Central and South America. The infection is considered endemic* in these regions. People who live in or visit “cocci country” and who often spend time outside for work or play are more likely to develop the disease, especially near areas of development and construction during the summer and fall.

Light micrograph of a section of human lung tissue infected with a spore (centre) of the soil fungus *Coccidioides immitis*, which causes coccidioidomycosis.

CNRI/Photo Researchers, Inc.

* **spores** are a temporarily inactive form of a germ enclosed in a protective shell.

* **meningitis** (*meh-nin-JY-tis*) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.

* **arthritis** (*ar-THRY-tis*) refers to any of several disorders characterized by inflammation of the joints.

* **endemic** (*en-DEH-mik*) describes a disease or condition that is present in a population or geographic area at all times.

- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.
- * **culturing** (KUL-chur-ing) means being subjected to a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.
- * **sputum** (SPYOO-tum) is a substance that contains mucus and other matter coughed out from the lungs, bronchi, and trachea.
- * **biopsies** (BI-op-seez) are tests in which small samples of skin or other body tissue are removed and examined for signs of disease.
- * **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.
- * **antifungal drugs** (an-ty-FUNG-al drugs) are medications that kill fungi.
- * **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

Up to 50 percent of people living in such areas have antibodies* against *Coccidioides immitis* in their blood, which indicates that they have been exposed to the fungus, although many of them never developed signs of the disease. Furthermore, climate changes that bring winds can spread spores and thereby deliver the infection to new geographic areas.

Signs and symptoms About 60 percent of people infected by *Coccidioides immitis* develop no symptoms. When symptoms do occur, they are usually mild and include fever, aches, chills, headache, and tiredness. Those with weakened immune systems, such as people with AIDS*, certain types of cancer, and diabetes*, have a greater risk of developing a more severe form of the infection.

Diagnosis A doctor diagnoses coccidioidomycosis by culturing* a patient's sputum* or by doing a skin test. If injecting the test material into the skin of the forearm causes a large circular welt to appear on the arm within two days, it is considered a positive test for the fungus. Blood tests may show antibodies to the fungus, which helps confirm the diagnosis. Examination of lung or skin biopsies* may reveal the fungi. A chest x-ray is sometimes taken to look for signs of infection or inflammation in the lungs.

Treatment Most mild cases of the disease can be managed with bed rest, over-the-counter pain relievers such as acetaminophen*, and sometimes oral (by mouth) antifungal medication*. In more serious cases in which the fungus has spread throughout the body, intravenous (in-tra-VEE-nus, or given directly into a vein) anti-fungal medicines and hospitalization may be necessary. Mild cases of coccidioidomycosis last about two weeks, but recovery may take up to six months in more severe cases.

Complications Pneumonia*, arthritis, meningitis, and other serious problems can result if the infection spreads throughout the lungs or to other parts of the body, such as the liver, heart, brain, bones, or joints.

Can Coccidioidomycosis Be Prevented?

No specific activities can prevent a person from becoming infected with the *coccidioides* fungus, other than avoiding the regions where it is found. Planting grass and paving roads may reduce dust in problem areas but will not kill the fungus.

▲ The white, speckled skin on these fingers indicates frostbite injury. *SIU/Photo Researchers, Inc.*

Cold-Related Injuries

Cold-related injuries, such as hypothermia and frostbite, occur when low temperatures damage the body. In cases of hypothermia, the body's internal temperature falls, causing blood flow and breathing to get dangerously slow. In cases of frostbite, outer parts of the body, such as fingers and toes, start to freeze. Other cold-related injuries include chilblains and trench foot.

Who Is at Risk for Cold-Related Injuries?

Anyone who spends time outdoors in cold weather can be at risk for cold-related injuries. That includes people who fish, hunt, or hike, especially in the mountains, where temperatures can drop quickly, and icy rain or snow can blow in with little warning. In snowstorms, people trapped in their cars can suffer permanent injury or even death if they cannot keep warm until help arrives.

In cities, homeless people who remain outdoors in the cold are at special risk. Likewise, poor people who cannot afford to heat their homes or whose landlords do not provide heat face dangers from the cold.

WEATHER AND WARFARE

Throughout history armies faced the perils of winter weather. George Washington lost many men to the cold during an encampment at Valley Forge (1777–1778). Napoleon, after first successfully invading Russia in 1812, was forced to retreat from Moscow when his army faced the severe Russian winter.

The Wind-Chill Factor

The wind-chill factor can increase heat loss from the body. If the skin is wet, there is an even greater transfer of heat to the surrounding air from the body. Those who are at risk from these circumstances are people who fish on ice, hunters, skiers, campers, and hikers in the mountains. Anyone exposed to wind and low temperatures can develop serious frostbite.

The actual temperature and the wind speed determine the wind-chill temperature. The lower the wind-chill temperature, the greater risk to human beings.

Examples of wind-chill temperatures using the formula actual temperature (in degrees Fahrenheit) plus wind speed (in miles per hour) equals the wind-chill temperature (in degrees Fahrenheit):

■ $35^{\circ}\text{F} + 10 \text{ mph} = 27^{\circ}\text{F}$

■ $15^{\circ}\text{F} + 20 \text{ mph} = -2^{\circ}\text{F}$

■ $0^{\circ}\text{F} + 30 \text{ mph} = -26^{\circ}\text{F}$

■ $-15^{\circ}\text{F} + 45 \text{ mph} = -51^{\circ}\text{F}$

* **platelets** (PLATE-lets) are tiny disk-shaped particles within the blood that play an important role in clotting.

Indoors or outdoors, elderly people, the very young, and those who abuse alcohol or drugs also are at extra risk. Hypothermia, in which body temperature falls, is most common in cold, wet weather. In some cases, however, people who are elderly or who have diabetes, hypothyroidism, or other underlying diseases can become hypothermic while indoors even if the heating is adequate. In these cases, hypothermia may develop gradually over days. With elderly people, in particular, it can occur at temperatures as high as 65 degrees Fahrenheit (18 degrees Celsius). This situation develops because aging can reduce the body's ability to conserve heat and to maintain an internal (core) temperature of about 98.6 degrees (37 degrees Celsius). In addition, elderly people may not feel the cold as much, so they may not take steps to get warm.

In the United States, 600 to 700 people die each year from hypothermia, but doctors suspect that thousands of elderly people may be hospitalized each year for problems caused by undiagnosed hypothermia.

What Is Frostbite?

Frostbite is the freezing of any part of the body. Ice crystals form within or between the cells. Red blood cells and platelets* clump and restrict blood flow, especially to the ears, fingers, toes, and nose. These areas usually are the first to turn cold, white, hard, and numb. Frostbite can be deceptive; because it causes numbness, rather than pain, people may not know it is happening in time to prevent serious damage, which may lead to amputation of all or a portion of the affected body part.

How Is Frostbite Treated?

In dealing with frostbite, doctors usually recommend that the affected body parts be warmed rapidly in warm, but not hot, water. Doctors warn against rubbing the frostbitten parts by hand or with snow because this action can cause more tissue damage.

The affected part begins to become pink or red when it is thawing. If it remains white, the body part requires more time to thaw adequately.

After the rapid thawing, small blisters will appear. They will break in about a week, and a black scab will form after the blisters rupture. Normal tissue may have already formed below. Treatment at this point typically involves protecting the thawed part to avoid both refreezing and excessive heat. Usually, medical professionals advise that the area be cleaned with mild soap, but they do not suggest that either bandages or dressings be used.

Doctors recommend exercises to preserve joint motion in hands and feet. In some cases, a patient may require early surgical removal of the dead tissue to save the entire part from amputation. If necessary, medical professionals may also prescribe antibiotics.

What Is Hypothermia?

Hypothermia (hy-po-THER-mee-a) is the lowering of the body temperature below 95 degrees Fahrenheit (35 degrees Celsius). This condition usually results from prolonged exposure to cold when the body heat loss

is greater than heat production. In some people, including the elderly and those with certain underlying diseases, hypothermia can occur even indoors and at temperatures that would otherwise be sufficient. Hypothermia can be life-threatening. As in cases of frostbite, the sooner a person with hypothermia receives treatment, the better the chances for survival.

What Are the Symptoms of Hypothermia?

Some symptoms of hypothermia are slurred or incoherent speech, irritability, slowed rate of breathing, and a drop in awareness. Another common symptom is violent shivering, which is the body's response to cold as it attempts to warm itself. Without treatment, a person may become exhausted and stop shivering, which leads to an even more rapid decline in body temperature. Children and the elderly are particularly susceptible to hypothermia because their body temperature lowers especially quickly.

Irritable behavior may be a sign of hypothermia. Hypothermia symptoms may emerge as anger or inability to perform physical movements. Severe hypothermia may produce rigid muscles, dark and puffy skin, irregular heart and respiratory (breathing) rates, unconsciousness, and eventually death.

How Is Hypothermia Treated?

Treatment for hypothermia includes keeping the patient warm while seeking immediate medical attention. If the clothing is wet, it should be removed carefully. Although myths exist about the value of rubbing the skin, medical professionals do not advise this tactic. If the person is unconscious and not breathing, someone who has been trained in cardiopulmonary resuscitation (CPR) should use this revival technique.

What Are Trench Foot and Chilblains?

Trench foot is a painful disorder of the foot involving damage to the skin, nerves, and muscle that is caused by prolonged exposure to cold or dampness or by prolonged immersion in cold water. World War I soldiers fighting in the trenches developed this painful condition because they did not have access to clean, dry socks and boots.

Chilblain (CHILL-blain; often referred to in the plural, "chilblains") usually affects the fingers and is characterized by redness, swelling, and itchiness caused by exposure to damp cold. Tissue damage is less severe with chilblain than with frostbite, in which cases the skin is actually frozen. Chilblain does not cause permanent damage.

Can Frostbite and Hypothermia Be Prevented?

One of the best ways to prevent cold-related injuries is to dress properly in cold, damp weather. Doing so requires wearing several layers of dry, loose-fitting clothing that allow perspiration to evaporate, and keeping gloves and socks dry. People in the cold should also protect exposed flesh from the wind. Face masks, hoods, and ear muffs are helpful. Hats are

A COLD RIDE

A description of what it might feel like to freeze can be found in *These Happy Golden Years* by Laura Ingalls Wilder (1867–1957), a memoir about living in the Dakota Territory in the early 1880s. The author describes how Almanzo Wilder (1857–1949), the young man who would eventually become her husband, picked her up from the place where she taught school to drive her home for the weekend in his horse-drawn sleigh. Unfortunately, a storm was brewing. The wind blew hard, and the thermometer dropped to 40 degrees below zero Fahrenheit (–40 degrees Centigrade). As they rode along, the cold crept through the buffalo robe covering her, her woolen coat, dress, and stockings, and her flannel undergarments. Despite all she did, Laura could not stop shivering nor could she get warm.

Almanzo does not become worried about her until she starts to feel sleepy and a sense of euphoria engulfs her. Almanzo keeps talking to Laura to keep her awake, for they both feared that were she to fall asleep, she would freeze to death.

In reality, going to sleep in the cold does not cause a person to freeze to death, although moving the body, which is more likely to occur when a person is awake, helps generate body heat. The sleepiness is a symptom of severe hypothermia (low body temperature), and asleep or not, Laura and Almanzo were certainly in danger of freezing.

One reason that Laura Ingalls Wilder excelled at describing the cold realistically is that her stories are true: She was recording her own experiences. Another one of her books is called *The Long Cold Winter*.

important because up to 40 percent of the body's heat is lost through the head. In addition, consuming adequate amounts of food and fluid helps the body to generate heat.

Another important prevention rule is to listen to highway department advisories about driving during snowstorms, because getting caught in a stalled car in a snowstorm can easily lead to frostbite and hypothermia. Safety supplies to carry along on a car trip during severe cold weather include a small shovel and rock salt, a blanket, high-energy foods such as granola bars, and a coffee can with some candles and matches. A lighted candle propped inside a large can provides a good source of heat.

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

* **colon** (KO-lin), also called the large intestine, is a muscular tube through which food passes as it is digested, just before it moves into the rectum and out of the body through the anus.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

Colitis

Colitis (ko-LY-tis) is inflammation of the internal wall of the colon*.*

What Is Colitis?

Colitis is one form of inflammatory bowel disease that can occur at one point in time (acute) or continue for some time (chronic). Depending on the type of colitis, symptoms can include diarrhea, cramps, pain, nausea, vomiting, and bleeding or a bloody stool. Some types primarily affect older adults; others affect all ages. Treatment varies with type; in some cases the cause is not clear.

Ischemic (is-KEE-mik) (meaning to hold back blood) colitis occurs when blood flow to the colon is limited, often by blood clots in the arteries (acute) or atherosclerosis (fat deposits) in the blood vessels (chronic). It is a common intestinal problem among those 50 or older, especially those at risk for heart disease. If left untreated, it can damage the colon and become life threatening. Pain is often centered on the left side of the abdomen*.

Another type of colitis strikes adults over 60 by inflaming the collagen (connective tissue) inside the colon wall. This condition may progress, giving rise to an abundance of white blood cells in the colon (lymphocytic colitis). Researchers believe these two conditions are phases of the same disease, both caused by an overreaction of the body's immune system. In both, the main symptom is watery diarrhea.

People who have been treated with antibiotics for other diseases may develop colitis caused by harmful bacteria in the intestines. Normally

* **Crohn's disease** an often inherited, chronic inflammatory disease that typically affects the small and/or large intestine but which can affect any part of the digestive system. The disease causes crater-like ulcers or sores in the inner surface of the bowel. Mild cases may be treated with medication; serious cases may be treated with surgery.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **corticosteroids** (kor-tih-ko-STIR-oyds) are chemical substances made by the adrenal glands that have several functions in the body, including maintaining blood pressure during stress and controlling inflammation. They can also be given to people as medication to treat certain illnesses.

present, these “bad” bacteria are usually kept in check by “good” bacteria that have been, in this case, neutralized by the antibiotic. Common symptoms include watery and bloody diarrhea, a high fever, pain and cramps, and pus or mucus in the stool. It can appear a few days or several weeks after taking antibiotics. Older people are at higher risk for antibiotic-associated colitis, and those taking antibiotics prior to surgery.

Ulcerative colitis inflames long stretches of the inner lining of the intestines, often starting just above the rectum. It can be misdiagnosed as Crohn's disease*, which also causes ulcers (bleeding, open sores) but may appear anywhere in the digestive system, not just the colon. The cause of ulcerative colitis is not clear as of the early 2000s, but heredity (family history), the immune system, and unintended effects of antibiotics appear to play a role. Many researchers assert that stress can aggravate it, but does not cause it. Studies show that individuals are at greater risk for ulcerative colitis if they are white, live in industrial areas or northern climates, eat processed foods, and are young, in their late 20s or 30s. Ulcerative colitis can be acute or chronic. Some extreme cases increase the risk of colon cancer by one-third.

How Is Colitis Diagnosed?

Symptoms provide a general idea of what is wrong. However, because some colitis symptoms are similar to those of other conditions, physicians may test blood and stool samples or conduct a colonoscopy (viewing the colon through a flexible tube using a miniature camera that delivers images to a computer screen). During the colonoscopy a tissue sample may be removed for testing (biopsy*).

How Is Colitis Treated?

Mild cases of colitis may be treated by changing diet; eating frequent smaller meals; and avoiding caffeine, carbonated drinks, and spicy, high fat, or gassy foods. Often medications are used to slow intestinal contractions or stop diarrhea. Anti-inflammatory drugs (traditionally sulfa-based drugs or mesalamine, which has fewer side effects) are prescribed. Corticosteroids* may be an alternative to reduce swelling, but these also have side effects. In cases in which colitis originates with the immune system, immune-system suppressors are used. Infliximab has been used successfully for some hard-to-treat cases of ulcerative colitis. Antibiotic-activated colitis is treated with antibiotics (metronidazole) to fight the “bad” bacteria and allow the “good” bacteria to recover. In severe cases persons may be hospitalized and fed intravenously (through the veins) to give the colon a chance to rest and heal. In cases in which damage cannot be reversed (usually ischemic or ulcerative colitis), sections of or the entire colon may be surgically removed.

- * **antigen** (AN-tih-jen) is a substance that is recognized as a threat by the body's immune system, which triggers the formation of specific antibodies against the substance.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

Collagen Vascular Diseases

Collagen vascular diseases are a diverse group of diseases in which the body reacts against its own tissues, often causing joint pain and inflammation, fever, rash, fatigue, and difficulty swallowing.

What Are Collagen Vascular Diseases?

Collagen vascular diseases, sometimes called connective tissue diseases (CTDs) or autoimmune diseases, include a wide array of disorders in which the body's natural immune or self-protection system fails to recognize its own tissues and attacks itself. Some of these diseases limit their damage to a single organ, and others create problems throughout the body.

Immune responses to foreign bodies In a healthy immune system, antigens* (foreign bodies such as viruses and bacteria) are recognized as different from regular body tissues. When an antigen enters the bloodstream, it triggers the production of antibodies*, substances that attack the alien substance. Lymphocytes (LIM-fo-sites) and leukocytes (LOO-ko-sites) are the special white blood cells responsible for creating these antibodies.

Lymphocytes include two major subtypes (T cells and B cells), which have the unique ability to recognize the invading alien and alert the immune system to destroy it. The process is highly specialized: each

- * **inflammation** is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.
- * **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.
- * **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.

lymphocyte recognizes a specific antigen and produces an antibody against only that particular antigen.

Autoimmune responses In collagen vascular diseases, this immune system malfunctions. Rather than responding to foreign antigens, the body produces antibodies (autoantibodies) against its own antigens and normal proteins. Researchers do not understand what gets this autoimmune process started, but they have a fairly good idea of how it proceeds once it begins. Rheumatoid arthritis and systemic lupus erythematosus (er-i-thee-ma-TO-sis) are two types of collagen vascular disease.

Rheumatoid arthritis Rheumatoid arthritis is a chronic inflammatory* disease that causes stiffness in the joints (places where bones meet) and can lead to disfigurement. It is an ancient disease; archeologists have found skeletons thousands of years old that have bone changes showing this condition.

In rheumatoid arthritis, the autoimmune process begins in connective tissue and the cushiony membranes that surround joints and the ends of bones. Collagen (KOL-a-jen) is the tough glue-like protein that gives joints their support and flexibility, and it represents 30 percent of the body's protein. Rheumatoid arthritis is thought to begin when T cells mistake the body's own collagen cells for foreign antigens and alert B cells to produce antibodies to fight the invader. The leukocytes rush in and produce cytokines (SY-to-kines), small proteins that are essential in healing the body but which can cause serious damage in large doses. The inflammation and joint damage that result can lead to joint deformities and can spread throughout the body to other sites of connective tissue.

Systemic lupus erythematosus Systemic lupus erythematosus (SLE) is one of the major types of the chronic (long-lasting) disease known as lupus. Lupus, which was first described in 1828, causes inflammation of connective tissue, the material that holds in place the various structures of the body. While the cause or causes of lupus are uncertain, the disease was believed as of 2009 to be an autoimmune disorder. SLE affects the skin but also involves other tissues and organs. Symptoms may include a butterfly-shaped rash over the bridge of the nose and cheeks, hair loss, skin lesions that may spread and cause damage to the mucous membranes and other tissues, arthritis, weakness, extreme fatigue, fever, sensitivity to sunlight, and loss of weight. Some patients have problems with kidney function and uremia (yoo-REE-me-a), or the buildup of toxic substances in the blood due to kidney failure. These problems can be fatal. SLE can affect the nervous system and cause psychological problems, seizures, or other symptoms. The lungs, heart, liver, and blood cells may also be involved. In the blood, certain antibodies can interfere with the normal function of the blood vessels and can bring on a stroke* or heart attack. In pregnant women, the presence of these antibodies can cause a miscarriage*.

Frequently, people who have SLE also have another collagen vascular disease: scleroderma. A chronic autoimmune disease, scleroderma causes skin to thicken and tough fibrous tissue to form in the internal organs of the digestive tract, kidneys, heart, and lungs.

Raynaud's Disease Often, people who have collagen vascular diseases are also diagnosed with Raynaud's disease, although not everyone who has Raynaud's disease has a collagen vascular disease. Raynaud's disease is a disorder in which the vessels that supply blood to the fingers and toes respond to cold or other stimuli by going into spasm (contracting), which reduces the supply of blood and causes the digits to turn white, feel numb, tingle, or burn. In rare, severe cases, the restriction of the arteries may cause the fingers to thicken, which can lead to ulcerations (loss of tissue) at the finger tips as well as changes in the fingernails. Sometimes, gangrene (tissue death) can occur.

Causes Some autoimmune diseases have strong genetic components and may be passed down from parents to children. Environmental factors may act to trigger these diseases in some way. Fatigue, stress, and higher levels of certain antibodies may also lead to these diseases. Some researchers have even suggested that ultraviolet* rays of sunlight may be a contributing cause. Collagen vascular diseases are not contagious; people cannot catch these diseases from one another.

What Happens When People Have Collagen Vascular Diseases?

Signs and symptoms Signs and symptoms differ depending on the illness, but they often include joint pain, fever, rash, recurrent infections, fatigue, mouth ulcers, dry mouth and dry eyes, hair loss, difficulty swallowing, swollen glands, or fingers and toes that get overly cold when exposed to cooler temperatures. In addition to systemic lupus erythematosus, rheumatoid arthritis, and scleroderma, collagen vascular diseases include:

- **Sjögren's syndrome:** This causes dry mouth, dry eyes, and other symptoms.
- **Polymyositis and dermatomyositis:** These are inflammatory muscle disorders that may also affect the skin, heart, and lungs.
- **Mixed connective tissue diseases:** These combine features of lupus, scleroderma, and polymyositis.
- **Polyarteritis nodosa:** This disorder can damage small and medium-sized arteries of almost any organ, including the kidneys, heart, and intestines.

Diagnosis A complete medical history and a physical examination are the basis for the diagnosis of autoimmune disease. Doctors may also order a number of laboratory tests to help diagnose collagen vascular diseases. Blood tests can check levels of autoantibodies. Other tests include

* **ultraviolet** light is a wavelength of light beyond visible light; on the spectrum of light, it falls between the violet end of visible light and x-rays.

* **remission** is an easing of a disease or its symptoms for a prolonged period.

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

rheumatoid factor tests, urinalysis, blood counts, liver and kidney tests, and a sedimentation rate, which gives a nonspecific indicator of inflammation. Doctors may also order a chest x-ray and other tests of specific lung function, since collagen vascular disorders not uncommonly produce breathing difficulties.

Treatment As of 2009, no cures existed for autoimmune diseases. Some, however, may go into remission* as symptoms disappear for periods of time. Treatment depends on the extent of the disease. Doctors may prescribe steroid creams or anti-inflammatory medications to ease discomfort. In advanced cases, immunosuppressant drugs may help lessen the immune system's overreaction. Available therapies include chemotherapy*, such as mycophenolate mofetil or other agents that affect the body's immune system.

Living with Collagen Vascular Diseases

These serious diseases often require adjustments in activities of daily living. People with rheumatoid arthritis often have early morning stiffness that lasts for about an hour, after which they can go on about their activities. Avoiding certain foods and reducing physical and emotional stresses also seem to reduce symptoms for some people.

Colon Cancer See *Colorectal Cancer*.

Color Blindness

Color blindness is a condition caused by a defect in the eye that makes an individual unable to identify various colors and shades.

What Is Color Blindness?

Red means stop. Green means go. It is one of the earliest lessons a child learns. For more than 10 million people in the United States, however, telling the difference between these two colors is not as simple as it sounds. These people usually are called color blind, although it is more accurate to say that they have poor color vision, since only a few people are unable to see any color at all.

How Does Color Blindness Happen?

Color blindness is almost always inherited from the mother's genes*. It affects boys most often, as girls usually have additional genetic material that overrides the vision problem. According to the Sight and Hearing Association, about one in seven males in the United States has some degree of color blindness, but fewer than one in 100 U.S. females have it. People with color blindness often have no other vision problems, but color blindness sometimes results from other eye diseases and vision problems.

Eight million colors As light passes through the eye, the image is focused on the retina. The retina contains layers of cells at the inside rear of the eyeball and acts a little like the photographic film in a camera. The retina contains millions of receptors called rods that help see light and cones that help see light and colors. Although humans typically have about seven million cones, the cones come in only three types, each of which is particularly sensitive to a different color range: blue, green, or red. These colors are also known as primary colors in the scientific community. When cones respond, they release light-sensitive chemicals that trigger electrical signals to travel along nerves, called optic tracts, and to the part of the brain known as the visual cortex (also sometimes called the striate cortex). Rather like an artist mixes different paint colors to create a vast array of hues, the visual cortex combines the information it receives from the cones and the rods to produce the large range of colors—about eight million of them—that humans can see.

Red and green People with poor color vision have cones that do not function properly, because they do not release some of the light-sensitive chemicals when light strikes them. As a result, these people see only certain colors and shades. The most common form of color blindness is a difficulty in seeing red and green correctly or the same way most people see them. Some people with this type of color vision deficiency can tell blue hues from yellow ones but cannot distinguish reds, greens, and yellows. Others

▲ Color blindness test. People with color blindness cannot distinguish the 25 in the green circle. *Image copyright Vilmos Varga, 2008. Used under license from Shutterstock.com.*

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

are able to tell red from green but only because green appears to be a little lighter rather than an entirely different color. Red-green color vision deficiency is more common among males because they only need to inherit the gene for the problem from one parent. Females, by contrast, only have the color deficiency if they get a defective gene from both parents.

Other types of color blindness Although they are much rarer than red-green color blindness, other forms of color blindness sometimes occur. One is called blue-yellow color blindness, which affects males and females equally. In this condition, a person cannot tell blues from yellows. Only a small number of people are unable to identify any colors at all. They see the world in shades of black, white, and grays—rather like a black-and-white photograph or movie. In addition, people with complete color blindness are usually very sensitive to bright light and have overall poor vision.

How Is Color Blindness Diagnosed and Treated?

The first signs of poor color vision often appear when a child enters school and begins to learn to identify colors. A simple vision test can determine if the problem is color blindness. This test involves showing a child an image made up of dots, for instance, a number made up of green dots on a background of yellow and orange dots. If the child cannot see the green number distinctly because it appears to blend in with the background, he or she may have color blindness.

Although no treatment or cure for color blindness exists, people often learn to cope with their color blindness in various ways; for example, they note that traffic lights usually have the red light on top and green on the bottom.

Colorectal Cancer

Colorectal cancer is caused by a growth that starts in the colon and/or rectum of the large intestine and may spread. The large intestine is part of the digestive tract.

A Painful Surprise

In October 1998, New York Yankees outfielder Darryl Strawberry had pain in his stomach and went to see his doctor. Surprisingly, the cause turned out to be colon cancer. Many people believe colon cancer affects only older people or only men, but anyone can get the disease. Colorectal cancer is the second leading cause of cancer death, with 55,000 Americans dying from this disease each year. When discovered early, colorectal cancer is frequently curable, and most deaths due to the disease could have been prevented by early screening and follow-up medical care. Colon cancer is not contagious.

Human digestive system. ©1999.

Learning, a division of Cengage Learning.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

What Is Colorectal Cancer?

The colon and rectum Colorectal cancer begins in either the colon or the rectum. Both are part of the digestive tract, which consists of a series of tubes and organs that process food. Digestion begins in the stomach. From the stomach, partly digested food passes into the small intestine, the longest section of the digestive tract, which absorbs most of the nutrients. The food then continues into the large intestine (the colon), which is a muscular tube approximately five feet long. In the colon, the remaining water and nutrients are extracted from the food and the remaining matter is stored as waste. The waste moves from the colon into the rectum and then passes through the anus and out of the body during a bowel movement.

The American Cancer Society estimated that in 2008 there would be 108,070 new cases of colon cancer and 40,740 new cases of rectal cancer in the United States, and about 49,960 people would die from colorectal cancer. The number of people who die from colorectal cancer declined between 1993 and 2008.

Polyps and adenocarcinoma Colorectal cancer does not happen suddenly. It can take many years to develop, and it usually is preceded by changes in the lining of the colon or rectum that occur over several years. One of these changes is a growth of tissue into the center of the colon or rectum, called a polyp (POL-ip). Not all polyps develop into cancer; those that do are called neoplastic polyps, or neoplastic lesions. Removing a neoplastic polyp early prevents it from later becoming cancerous. Moreover, not all colon cancer begins with polyps. In the case of hereditary nonpolyposis colon cancer, polyps do not form.

Ninety-five percent of colorectal cancers are of the particular kind called adenocarcinoma (AD-e-no-kar-si-NO-ma). These cancers begin in the lining of the colon or rectum and can grow either into the center of the colon or rectum or outward through the wall. If the cancer is not treated, cancerous cells can break away into the circulatory system and travel to other parts of the body. When a cancer spreads in this way, it is said to have metastasized (me-TAS-ta-sized).

What Happens When People Have Colorectal Cancer?

Signs and symptoms Darryl Strawberry had gnawing pains in his abdomen*, and these pains caused him to go to the doctor. Another symptom is a change in bowel habits, for example, diarrhea or constipation that lasts for more than a few days. Or individuals might feel the need to have a bowel movement even after they have had one or they might notice bleeding from the rectum or blood in the stool. Some people, however, have no noticeable symptoms.

Diagnosis Just because people have symptoms does not mean that they have colorectal cancer. The only way for them to be sure is to have a medical examination. It also is possible for people to have colon or rectal cancer and not have any symptoms. Because older people are more likely to develop colorectal cancer, medical professionals recommend that all people aged 50 years and older have regular colon cancer screening tests.

The simplest test is a digital rectal exam. The doctor inserts a gloved finger into the rectum to feel for anything that is not normal. People often are uncomfortable at the thought of such a test, but it is very effective in detecting certain kinds of cancers. Other tests use special instruments to examine parts of the colon. If the doctor finds anything unusual, he or she may remove a small amount of tissue for examination under the microscope to see whether the tissue is cancerous or benign (harmless). This microscopic examination of tissue is called a biopsy.

How Is Colorectal Cancer Treated?

If cancer is found, the next step is to do tests to see whether it has spread. Doctors use a four-level system of numbers or letters to stage, or classify, the cancer. The lower the number or letter, the less the cancer has spread. A higher number, for example, stage IV, means a more serious stage of the disease.

The three main types of treatment for colorectal cancer are surgery, radiation therapy, and chemotherapy:

- **Surgery** is the main treatment for both colon and rectal cancer. In some more advanced instances of rectal cancer, a person may need to have a colostomy*. Colostomies usually are not needed in colorectal cancer.
- **Radiation therapy** uses high-energy radiation to kill cancer cells. It is used to destroy small areas of cancer that might not have been removed during surgery.
- **Chemotherapy** (kee-mo-THER-a-pee) refers to the use of anti-cancer drugs to kill cancer cells. The drugs may be given through a vein in the arm or as pills. Through either method, the drugs can enter the bloodstream and can reach any area of the body where metastasized cancer cells may have traveled.

Can Colorectal Cancer Be Prevented?

People can take steps to reduce their risk and in many cases to prevent colorectal cancer from developing.

Screening and other precautions Because finding colorectal cancer early often means it can be cured, people age 50 and older should follow the screening guidelines established by the American Cancer Society. Younger people whose close relatives (mother, father, sister, or brother) have had colorectal cancer or physical conditions that increase the risk for colorectal cancer should begin screening earlier than

* **colostomy** (ko-LOS-to-mee) is a surgical procedure in which a part of the large intestine is removed, and the end of the intestine is attached to an opening made in the abdomen. The stool is passed through this opening into a special bag.

age 50. Younger people who have had colorectal cancer already must be particularly careful to follow up with their doctors regularly to make sure the cancer does not return.

Two tests are used to detect polyps that have the potential to develop into colon cancer; the earlier these are detected and removed the more likely cancer can be prevented. In sigmoidoscopy (sig-moyd-OS-ko-pee), the doctor uses a slender, lighted tube linked to a video camera to examine the rectum and lower part of the colon, areas where most cancers and polyps are found. Another test is the colonoscopy (ko-lon-OS-ko-pee), in which a long, thin, flexible tube linked to a video camera allows the doctor to examine the entire length of the colon. If polyps are found, they can be removed using a wire loop. Because polyps take 6 to 10 years to develop into cancers, removing them early can prevent them from becoming cancerous. Colorectal cancer is highly curable if it is caught early.

Eating a healthy diet, getting plenty of exercise, and never smoking are other precautions people can take to decrease their risk.

What Is It Like to Live with Colorectal Cancer?

Caught in the early stages, colorectal cancer is one of the most curable cancers. People recover from surgery and resume their normal lives. Many people are embarrassed about having colorectal cancer, however, because it involves a part of the body they do not usually talk about. Moreover, people who have had permanent colostomies may feel different from everyone else and embarrassed by the colostomy bag. Everyone's reaction to cancer and to treatment is different. There is no single right way to handle it. Support groups can be particularly helpful for people who are living with this very curable form of cancer.

Coma See *Stupor and Coma*.

Common Cold

The common cold is a nickname for a group of commonly occurring viral infections of the upper respiratory tract.*

What Is the Common Cold?

More than 200 different viruses* can cause colds. Rhinoviruses are responsible for up to one-third of all upper respiratory (RES-puh-ruh-tor-e) infections. Other common viruses that lead to stuffy heads and runny noses include adenoviruses*, coronaviruses (ko-ro-nuh-VY-rus-sez), parainfluenza (pair-uh-in-floo-EN-zuh) viruses, respiratory syncytial (sin-SIH-she-ul) virus, coxsackieviruses (kok-SAH-kee-vy-ruh-sez), echoviruses* (EH-ko-vy-rus-sez), and influenza (in-floo-EN-zuh) viruses (although influenza may also trigger more serious complications). Children get colds most frequently, in part due to their close contact with so many other children in daycare or school. Younger children are more likely to cough without covering their mouths and not wash their hands.

In North America, young children in daycare may catch several (sometimes as many as 10 or more) colds each year. People tend to get fewer colds as they grow older because they develop immunity* to some of these viruses after being infected with them. For this reason, healthy adults average two to four colds a year, and those over age 60 tend to get even fewer (as few as one cold per year, or less).

How Common Is the Common Cold?

As many as a billion colds occur each year in the United States. The National Center for Health Statistics, part of the Centers for Disease Control and Prevention, notes that on a yearly basis close to 22 million school days are lost due to illness from colds, and 45 million days are spent resting while recovering from colds.

Is the Common Cold Contagious?

Colds are very contagious. In general, they are most contagious during the first few days of illness, when symptoms such as congestion (stuffy nose) and sneezing are starting. Cold viruses often spread through direct

- * **respiratory tract** includes the nose, mouth, throat, and lungs. It is the pathway through which air and gases are transported down into the lungs and back out of the body.
- * **viruses** (VY-rus-sez) are tiny infectious agents that can cause infectious diseases. Viruses can only reproduce within the cells they infect.
- * **adenoviruses** (ah-deh-no-VY-ruh-sez) are a type of viruses that can produce a variety of symptoms, including upper respiratory disease, when they infect humans.
- * **echoviruses** a group of viruses found in the intestinal tract. The word echo in the name is acronym for enteric cytopathic human orphan viruses. When these viruses were named, they were not associated with any disease, hence the use of the word orphan. However, later these viruses were associated with various diseases, including meningitis and encephalitis.

Common Cold Myths

Colds are so common that everyone seems to have a theory on what brings them on and how to cure them. Below are two common cold myths (and some myth-busting explanations):

Myth: Running around in the cold and having a wet head or wet feet can bring on a cold.

Reality: These two beliefs probably stem from the accurate observation that more colds seem to occur in the cold, wet weather that often accompanies winter months in the United States. In fact, neither the cold nor wet brings on the illness. During colder weather people stay indoors and have increased close contact with each other, which makes them at higher risk for colds.

Myth: Taking large doses of vitamin C prevents colds.

Reality: Vitamin C may have other body-boosting benefits, but there is no scientific proof that it prevents the common cold. Although garlic (which may have antiviral properties) and chicken soup appear to have some beneficial effects, studies of other widely touted cold remedies such as echinacea (eh-kih-NAY-see-uh), a plant product, and zinc supplements have mostly yielded negative, inconsistent, or unconvincing results.

A sneeze in action. Virus-packed droplets are expelled from the respiratory system and can spread widely to contaminate surfaces. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

contact. Shaking the unwashed hand of someone with a cold (who has just touched his or her face) can easily spread the virus. When an infected person laughs, sneezes, or coughs, virus-packed droplets of moisture from the person's mouth and nose can become suspended in the air, where they can be inhaled by others. Sometimes these drops of respiratory secretions land on a surface such as a kitchen or bathroom counter, where they can infect the next person who touches the surface.

What Happens to Someone Who Has a Cold?

Signs and symptoms Cold symptoms usually appear within two to three days after the person becomes infected. They often include a runny or stuffy nose, watery eyes, coughing, mild muscle aches, tiredness, headache, low fever, and a scratchy sore throat. Sneezing and coughing up mucus* are also common.

Diagnosis Doctors diagnose colds based on a history of symptoms and findings from a physical examination. Cultures* and other tests for the viruses are available but are not done in most situations. However, the doctor will want to distinguish a cold, caused by a virus, from bacterial infections of the sinuses or throat, such as strep throat.

Treatment As of 2009, there was no known medical cure for the common cold. People who come down with colds can help themselves feel better by taking care of themselves at home until the infection goes away on its own. Bed rest helps tiredness, and inhaling mist in a steamy bathroom or running a humidifier in the bedroom to moisten dry air can relieve congestion and make it easier to breathe. Drinking plenty of clear or warm fluids may also reduce congestion, and tea with honey can soothe a scratchy throat. Over-the-counter medicines such as acetaminophen* can

ease headaches and body aches and lower fever. Over-the-counter cold medicines may also help relieve symptoms. Symptoms of a cold can last several weeks, but most people recover within a few days.

Because viruses cause colds, antibiotics are not useful in fighting these infections. Some antiviral drugs may be effective in fighting some cold-causing viruses (such as rhinoviruses). Research in the early 2000s on these medicines may change the treatment of colds in the future.

Complications Sometimes colds can cause swelling and irritation in the nasal passages, eustachian tubes*, and airways leading to the lungs. Bacteria that invade the body can flourish in these areas, causing additional infections. This is why it is not uncommon for someone to develop sinusitis*, an ear infection (otitis, o-TIE-tis), or bronchitis at the end of a bad cold. For those with weaker immune systems, such as the very young, the elderly, or those with chronic illnesses, these secondary infections can lead to severe bronchitis or pneumonia, which may sometimes be life threatening. Colds can also trigger flare-ups or worsening of respiratory symptoms in people who have asthma*.

Can Colds Be Prevented?

To lower the risk of catching (or spreading) a cold, people should wash their hands frequently and cover their mouth with a tissue when coughing or sneezing. Avoiding touching the eyes or nose as much as possible, regularly cleaning bathroom and kitchen surfaces to get rid of germs, and avoiding close, extended contact with anyone who has a cold are also helpful.

Researchers have explored the idea of a cold vaccine, but many different viruses can cause colds, making the development of a single, effective vaccine a great challenge.

* **immunity** (ih-MYOON-uh-tee) is the condition of being protected against an infectious disease. Immunity often develops after a germ has entered the body. One type of immunity occurs when the body makes special protein molecules called antibodies to fight the disease-causing germ. The next time that germ enters the body, the antibodies quickly attack it, usually preventing the germ from causing disease.

* **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.

* **cultures** (KUL-churz) are tests in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

* **eustachian tubes** (yoo-STAY-she-un) are the tiny channels that connect and allow air to flow between the middle ears and the throat.

* **sinusitis** (sy-nyoo-SY-tis) is an infection in the sinuses, which are hollow cavities in the facial bones near the nose.

* **asthma** (AZ-mah) is a condition in which the airways of the lungs repeatedly become narrowed and inflamed, causing breathing difficulty.

* **brain stem** is the part of the brain that connects to the spinal cord. The brain stem controls the basic functions of life, such as breathing and blood pressure.

Complications of Pregnancy *See Pregnancy.*

Concussion

Concussion, or brain concussion, is an injury to the brain caused by a blow to the head or by violent jarring or shaking. It is a form of head trauma that often involves loss of consciousness, which may be momentary or may last for several hours. Brain concussion is a common injury that sometimes has serious consequences.

What's Happening on the Playing Field?

Most people who watch sporting events on television have seen team physicians run out to the playing field to examine athletes who receive blows to the head. The doctors often ask the injured players if they know where they are or what day of the week it is. That is one way that doctors find out whether people have concussion.

What Causes Concussion?

A blow to the head, an injury, a fall, or sudden severe shaking may cause the brain to hit the inside of the skull. If the impact affects the consciousness centers in the brain stem*, then the person with concussion loses consciousness. This effect may occur if, for example, one boxer's knockout

Concussions may result from sudden traumas, such as motor vehicle accidents or sports injuries, that cause the brain to hit the inside of the skull. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

punch makes the other boxer's head accelerate sharply, or if someone's head decelerates suddenly, as when it strikes the ground during a fall.

Participating in sports is a common cause of concussion, and engaging in sports with the most physical contact, such as football, boxing, and hockey, carries a high risk of head injuries that involve concussion. Concussions may also occur when people collide or fall while playing basketball, soccer, and baseball or while riding motorcycles or bicycles.

Motor vehicle accidents cause about half of all head injuries. A large percentage of these accidents involve drivers who have been drinking alcohol. Other causes include fights and industrial accidents.

What Happens to People with Concussion?

Concussion does not always cause complete loss of consciousness. People who get mild concussions may be temporarily stunned or dazed. They may feel dizzy, light-headed, or confused for a brief time. With loss of consciousness may also come nausea or vomiting, numbness, blurred vision or temporary blindness, or amnesia, which means loss of memory for events just before or just after the injury that caused the concussion.

The longer the period of unconsciousness, the more severe the symptoms may be, which is why a doctor should examine people with concussion as soon as possible. The symptoms of concussion usually do not last long, but in rare cases they may persist for several weeks or longer.

Do People with Concussion Need Medical Treatment?

Permanent brain damage does not normally result from a single mild concussion. A doctor must first, however, make sure that a more serious head injury, such as contusion (bruise) or laceration of the brain, has not occurred. The doctor usually gathers information about the injury that caused the concussion and notes the person's signs and symptoms.

Sometimes people worry that it is unsafe to fall asleep after a concussion, but doctors usually advise a period of bed rest, either at home or in a hospital, and not engaging in sports or riding a bicycle until recovery is complete. If headache is a symptom, the doctor may suggest pain medication. People with concussion should not drink alcohol or take sedatives*.

If unconsciousness, headache, or drowsiness returns several hours or days after the injury, the injured person should see the doctor again. The doctor may recommend hospital treatment or may diagnose postconcussion syndrome. People who have had a concussion are at higher risk of severe injury, or even sudden death, if they get a second concussion within a short time after the first injury. Under these circumstances, avoiding possible head trauma becomes vitally important.

What Is Postconcussion Syndrome?

Headache, dizziness, and other symptoms of concussion usually go away in a few minutes or days. Occasionally, however, they may persist much longer, even for years. The person may complain of a group of symptoms

* **sedatives** (SAID-uh-tivs) are drugs that produce a calming effect or sleepiness.

What Does “Punch Drunk” Mean?

Boxers are sometimes called “punch drunk” if they develop slurred speech and poor concentration after receiving repeated punches and blows to the head during their careers. Repeated concussions can cause an accumulation of injuries to the brain and may result in permanent damage.

* **syndrome** is a group or pattern of symptoms or signs that occur together.

that not only includes headache and dizziness, but also confusion, poor memory, anxiety, sleeplessness, irritability, lack of energy, and depression. A person with this group of lasting symptoms following a concussion is said to have postconcussion syndrome*. Although it is not overly common, some people who experience concussion can develop a subdural hematoma, which can be very dangerous. Caused by a torn blood vessel, a subdural hematoma is a blood clot or a collection of blood on the surface of the brain. When it occurs rapidly, usually from a very serious blow to the head, it is called an acute subdural hematoma and it can be deadly. Minor head injuries can also produce a so-called chronic subdural hematoma that seeps blood more slowly and over a several days to several weeks. These are more common in elderly people. Symptoms of subdural hematoma are like those for concussion, but also may include slurred speech or an inability to speak at all, or seizures.

Although postconcussion syndrome is not well understood, many medical researchers believe it may be the result of subtle changes in the brain that do not show up in medical tests. Because brain tests are normal, people sometimes believe that postconcussion syndrome is due to psychological factors or that people with postconcussion syndrome are faking their symptoms, especially if they are attempting to win damages in a lawsuit. This situation may be the case in some instances, but often postconcussion symptoms exist in the absence of a lawsuit or persist after a settlement has been reached.

How Do People Prevent Concussion?

Wearing a helmet Wearing a helmet is the best way to prevent a concussion in most situations in which it might occur. Boxers are at high risk for receiving this type of injury, and that is why they always wear protective headgear during training matches. The same is true for people playing football, hockey, and other sports in which frequent physical contact occurs or where falls are likely. Bicycle and motorcycle riders also need to wear helmets to protect against serious head injury in case of a fall or collision.

Seat belts, air bags, and designated drivers In automobile accidents, seat belts and air bags can prevent riders from banging their heads against the windshield or dashboard. In addition, many accidents are preventable if adults who drink alcohol designate (choose) a non-drinking friend to drive them home after they have been drinking; this person is called a “designated driver.”

* **antisocial behavior** is behavior that differs significantly from the norms of society and is considered harmful to society.

* **bullying** is when a person repeatedly intimidates or acts aggressively toward those with less power or ability to defend themselves.

* **truancy** is staying out of school without permission.

Conduct Disorder

When children or adolescents show an ongoing pattern of aggressive or destructive behavior that violates the rights of others and the basic rules of society, they may be diagnosed as having conduct disorder.

Joe's Story

Joe always seems to pick fights on the school bus. He intimidates and bullies others and has few friends. Serving detention does not seem to help Joe learn to behave. Last year he was caught writing graffiti on school property, and he was suspended once for throwing rocks at a school bus. Although he was never caught, Joe stole money from the teachers' lounge, and he was suspected of setting a fire in the school dumpster. This year, he often cuts school and hangs out behind the local convenience store smoking cigarettes that he steals from his father.

What Is Conduct Disorder?

While all children and adolescents sometimes misbehave, some individuals seem to do so all the time. Conduct disorder refers to serious and frequent antisocial behavior* in young people. Conduct disorder involves any of four types of behaviors:

- Aggression, such as cruelty toward people or animals, bullying*, threatening, physical fights, or using weapons to hurt others
- Destruction of property, such as writing graffiti, setting fires, or slashing automobile tires
- Lying (purposefully telling an untruth) and stealing, such as cheating, shoplifting, or burglary
- Violating major age-appropriate rules, such as staying out all night, running away, or school truancy*

Individuals with conduct disorder will have demonstrated three or more of these serious behaviors over the past year. In the United States,

* **delinquent** is a legal term that refers to a juvenile (someone under the age of 18) who has committed an illegal act. Delinquent behavior includes any behavior that would be considered a crime if committed by an adult as well as specific behaviors that are illegal for youth, such as school truancy, violating curfew, or running away.

* **empathy** the action of being aware or understanding the feelings of others without having those feelings explained.

* **bipolar disorder** a group of mood disorders that are characterized by alternating episodes of depression and mania.

* **post-traumatic stress disorder** (post-trau-MAT-ik STRES dis-OR-der) is a mental disorder that interferes with everyday living and occurs in people who survive a terrifying event, such as school violence, military combat, or a natural disaster.

LEARNING TO BE AGGRESSIVE: ALBERT BANDURA'S EXPERIMENTS

In the 1960s, social psychologist Albert Bandura (b. 1925) wanted to find out whether children would learn and perform aggressive behaviors simply by watching someone else behave in aggressive ways. Learning a certain behavior by watching someone else do it is called modeling, or observational learning. Bandura conducted a series of experiments that demonstrated that aggressive behavior is indeed learned simply by observation. Whether a child actually went on to behave aggressively depended on what happened to the person the child observed. If a child saw that the other person was scolded or punished for acting aggressively, the child was not likely to perform the aggressive behavior, even though he or she had learned how. Children who saw that the other person's aggressive behavior was met with no consequence were more likely to perform the aggressive behavior they had observed as well as other aggressive behaviors.

about 9 percent of young men and 2 percent of young women are diagnosed with conduct disorder.

Young people with conduct disorder may act alone or in groups. Many become involved in gang violence or other criminal or delinquent* behaviors. When caught violating rules of conduct, these young people often deny their guilt and may shift blame onto others, trying to make themselves look as if they are the victim of the unfairness of others. They often lack remorse for their actions and lack feeling or empathy* for people or animals they have hurt. Conduct disorder may be associated with other problems such as drug abuse, mood disorders (e.g., depression, bipolar disorder*), attention deficit, post-traumatic stress disorder*, risky sexual behavior, and learning disabilities.

For some, conduct disordered behavior begins early in childhood. The earlier and more frequently the antisocial behavior occurs, the more likely it is to develop into a serious and difficult to solve problem. Other children do not develop antisocial behaviors until adolescence. Although still serious, their behavioral problems are sometimes more temporary and more successfully treated.

Young people who have conduct disorder do not necessarily go on to have serious problems in adulthood, although for some adolescent conduct disorder develops into a lifelong pattern of aggressive, antisocial behavior. In adults, a pattern of aggressive and antisocial behavior that disregards the rights of others may be diagnosed as antisocial personality disorder. All adults who have antisocial personality disorder have had symptoms of conduct disorder in their youth.

How Does Conduct Disorder Develop?

Many different theories exist about what causes conduct disorder, but there appears to be no one single cause; a number of factors seem to contribute to its development. However, conduct disorder and related antisocial behaviors tend to run in families, which may be due in part to inherited genes* that affect behavioral development, but there also is strong evidence that antisocial behavior is learned and modeled in the family environment.

Genetics and behavior Many researchers have tried to determine how genetics and biology contribute to conduct disorder. Some studies found that youth with conduct disorder may crave an unusually high amount of stimulation. They also have trouble with self-awareness and goal setting, and lack skills for forethought and planning. Other studies found that youth with conduct disorder have problems with social learning, which includes the skills needed to learn social rules and to interact well with others. Young people with conduct disorder also appear to have less empathy than do others their age. Empathy is a type of emotional feeling for others; it involves the ability to see another person's point of view and to understand how someone else might feel in a given situation.

Children who have deficiencies in empathy, social learning, planning, and self-awareness may have a harder time developing behavioral controls, good problem-solving skills, and respect for others. Because they have fewer skills to solve problems in socially acceptable ways, they may be more likely to develop conduct problems. Children who have conditions that cause them to be impulsive* may have difficulty learning social rules and developing the behavior controls to follow these rules. However, to what extent these deficiencies are part of a person's genetic makeup or are tendencies that are learned by example and behavior in the family remains unclear.

Learned behavior There is evidence that aggression, a major trait in people with conduct disorder, can be a learned behavior. People who observe others behaving in aggressive ways (and this includes watching aggression and violence on television, movies, and video games) are more likely to demonstrate the aggressive behaviors they have witnessed. Children who witness aggressive behaviors at home, such as physical fighting, pushing, and shoving, and other forms of domestic violence are at increased risk for developing conduct disorder. Children with conduct disorder often live in families in which there is a high level of conflict that takes physical form.

Certain parenting practices increase the risk that a child will develop conduct disorder. For example, parents who do not provide adequate supervision, do not consistently enforce rules for behavior, and do not administer age-appropriate discipline contribute to conduct disorder. Parents who use overly harsh or abusive discipline may contribute to the development of conduct disorder.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **impulsive** means acting quickly before thinking about the effect of a certain action or behavior.

Peers can also influence a child's behavior. Many young people with conduct disorder are rejected by their peers, which may make their conduct problems worse, particularly when conduct disorder is associated with other mental health or learning problems. Social rejection may cause these children to associate with others like themselves who have social and behavioral conduct problems, a choice that tends to reinforce unacceptable behaviors.

How Is Conduct Disorder Treated?

The earlier treatment begins for a conduct problem, the more likely it is to be cured. However, many young people with conduct disorder do not receive treatment until they come to the attention of school authorities or the juvenile justice system. Individual or group treatment for young people with conduct disorder often involves helping them to learn social skills they may be lacking, especially empathy and problem-solving skills. Good behaviors are rewarded and antisocial behaviors are punished. Parent training is an important part of many treatment programs. Training helps parents replace harsh and coercive parenting behaviors or lax, inconsistent parenting with consistent rules, appropriate consequences, and positive attention to children's good behaviors. Studies have shown that these treatment methods can be effective in reducing conduct problems. Medication may also be helpful, especially if other mental health problems, such as depression, are present. Treatment works best when it begins soon after the child or adolescent has started to show antisocial behaviors, and it is more effective when the family also participates.

Congenital Heart Disease See *Heart Disease, Congenital*.

Congenital Infections

Congenital infections are transmitted from mother to child, either before birth across the placenta* or perinatally—after the protective membranes rupture (waters break) or during labor and delivery when the infant is exposed to maternal blood. Perinatal* transmission is more likely to occur if the membranes rupture prematurely.*

What Are Congenital Infections?

The developing fetus* and newborn are protected from most infections by antibodies* in the mother's blood. Thus, most congenital infections result from either a serious untreated maternal infection or a common—usually mild—infection for which the mother lacks antibodies.

Congenital infections can be caused by viruses*, bacteria*, or parasites*. The mother may have few or no symptoms and be unaware that she is infected. However the consequences for the fetus or newborn may be disastrous: miscarriage*, preterm labor, fetal or neonatal* death, birth defects, or serious illness. Often an infection in early pregnancy is more damaging to the developing fetus.

Sexually transmitted infections (STIs) Worldwide, HIV* is the most dangerous congenital infection. An HIV-infected mother can transmit the virus to her baby through the placenta, during labor and delivery or through her breast milk. About 15 percent of HIV-infected newborns develop serious symptoms or die of AIDS* within the first year. Almost one-half of these children die by the age of 10.

Hepatitis* B and C viruses can be transmitted to the infant during birth. In rare cases, hepatitis B can also be transmitted through the placenta and may increase the risk of premature birth*.

Genital* herpes* is caused by Type 2 herpes simplex* virus (HSV-2) or, less frequently, by HSV-1 that usually causes cold sores. A first episode of genital herpes during pregnancy can be passed to the fetus because the mother does not yet have protective antibodies. It can cause preterm birth. If a mother has active genital herpes during childbirth, the infant may be born with facial or genital herpes, which in some cases has serious effects on the neonate.

* **congenital** (kon-JEH-nih-tul) means present at birth.

* **placenta** (pluh-SEN-ta) is an organ that provides nutrients and oxygen to a developing baby; it is located within the womb during pregnancy.

* **perinatal** (per-ee-NAY-tal) means existing or occurring around the time of birth, with reference to the fetus.

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **viruses** (VY-rus-sez) are tiny infectious agents that can cause infectious diseases. A virus can only reproduce within the cells it infects.

* **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.

* **parasites** (PAIR-uh-sites) organisms such as a protozoan (one-celled animals), worm, or insect that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. A parasite lives at the expense of the host and may cause illness.

* **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.

* **neonatal** (ne-o-NAY-tal) means pertaining to the first 4 weeks after birth.

- * **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).
- * **hepatitis** (heh-puh-TIE-tis) is an inflammation of the liver. Hepatitis can be caused by viruses, bacteria, and a number of other noninfectious medical conditions.
- * **premature birth** (pre-ma-CHUR) means born too early. In humans, it means being born after a pregnancy term lasting less than 37 weeks.
- * **genital** (JEH-nih-tul) refers to the external sexual organs.
- * **herpes** (HER-peeZ) is a viral infection that can produce painful, recurring skin blisters around the mouth or the genitals, and sometimes symptoms of infection elsewhere in the body.
- * **herpes simplex** (HER-peeZ SIM-plex) is a virus that can cause infections of the skin, mouth, genitals, and other parts of the body.
- * **chlamydial infection** (kla-MIH-dee-ul) can occur in various forms in which the bacteria can invade the urinary and genital systems of the body, as well as the eyes and lungs. One of its most common forms is a sexually transmitted disease (STD), usually passed from one person to another through unprotected sexual intercourse.

Chlamydial infection*, caused by the bacterium *Chlamydia trachomatis* (truh-KO-mah-tis), and gonorrhea*, caused by the bacterium *Neisseria gonorrhoeae* (nye-SEER-e-uh gah-no-REE-eye), can be transmitted to the infant during passage through the birth canal, causing conjunctivitis*. Chlamydial infection can also cause premature membrane* rupture and labor.

During pregnancy, if a woman is infected with syphilis*, which is caused by the bacterium *Treponema pallidum* (trep-o-NEE-mah PAL-id-um), or was inadequately treated for a previous infection, the bacteria can be transmitted either prenatally or perinatally. Unless the woman is treated with antibiotics*, almost half of all fetuses infected during gestation die before or shortly after birth.

Other common infections Cytomegalovirus* (CMV), a member of the herpesvirus family*, is the most common virus transmitted through the placenta to the fetus. CMV infection in early pregnancy can cause miscarriage and, in later pregnancy, preterm labor or stillbirth*. CMV can also be transmitted during birth or through breast milk; however, infection by these routes is less likely to cause severe problems.

If a woman contracts chicken pox—caused by the varicella zoster (var-uh-SEH-luh ZOS-ter) virus, another member of the herpesvirus family—during the first 20 weeks of pregnancy, there is a 2-percent risk that her newborn will have congenital varicella syndrome*, including multiple birth defects. However, the greatest risk is if the mother contracts the virus just before delivery, when she has not yet produced antibodies to protect the newborn. In this case the baby may develop severe or even fatal chicken pox.

If contracted early in pregnancy, rubella* virus infection—German measles*—can be passed to the fetus through the placenta. Rubella infection during the first 10 weeks of pregnancy may cause miscarriage, fetal death, or premature delivery*. More than 50 percent of infected newborns have severe birth defects.

Parvovirus B19 causes fifth disease in children, an acute disease that causes rash on cheeks and extremities with fever and malaise. About one-third of infants whose mothers contract fifth disease during pregnancy show signs of infection at birth. Although it is not usually dangerous, fifth disease contracted early in pregnancy can cause miscarriage or severe fetal anemia* that can lead to congestive heart failure* and fetal death.

Although invasive group B streptococcal (GBS) infection usually has no symptoms, in pregnant women it can cause uterine infections called amnionitis (am-nee-o-NYE-tiss) or stillbirth. GBS bacteria also can be passed from mother to child shortly before or during birth.

Toxoplasmosis* is caused by the one-celled parasite *Toxoplasma gondii*, which is commonly found in cats. Most cats that have toxoplasmosis are only infectious through their droppings for a several week period during initial infection. Most people infected with toxoplasmosis have no symptoms and most pregnant women have antibodies that protect the fetus. However, women who become infected for the first time shortly

before or during pregnancy can pass it to their fetuses, causing congenital toxoplasmosis. If maternal infection occurs during the third trimester*, the fetal infection rate is highest. However, the most severe fetal complications occur with first-trimester infections.

How Common Are Congenital Infections?

HIV About 20 to 25 percent of pregnant women with untreated HIV transmit the virus to their fetuses or newborns. However, in the United States, widespread HIV testing and antiretroviral (ARV) therapy (drugs used against any single-strand RNA viruses) have dramatically reduced the number of congenital HIV infections.

Worldwide, an estimated 420,000 children under age 15 became infected with HIV in 2007. Most were infected by their mothers before, during, or shortly after birth. An estimated 2.5 million children under age 15 were living with HIV in 2007, almost 90 percent of them in sub-Saharan Africa. About 330,000 children under age 15 died of AIDS in 2007. However, new HIV infections and AIDS deaths among children were declining. By 2007 nearly 35 percent of HIV-positive pregnant women worldwide were receiving ARV treatment.

Other common infections CMV affects about one out of every 150 newborns. Some 50 to 80 percent of women of childbearing age have antibodies that protect against CMV. However, 1 to 4 percent of American mothers have their first or primary CMV infection during pregnancy and about one-third of these infections are transmitted to fetuses. Each year about 8,000 American children develop permanent disabilities due to congenital CMV infection.

Because most adults have chicken pox as children or are vaccinated against the disease, it is estimated that an American woman's risk of contracting varicella during pregnancy is less than one in 1,000. Likewise, in the past rubella was a major cause of birth defects; however, routine vaccinations* have made prenatal* infection rare in the developed world.

About 50 percent of all women are infected with parvovirus as children or adolescents and have protective antibodies. Miscarriage due to parvovirus occurs in less than 5 percent of women who are infected during pregnancy.

GBS disease is the most frequent cause of life-threatening infection in newborns. Up to 20 percent of women carry GBS in their vaginas during the last trimester of pregnancy, with the potential of infecting the infant during birth. However, the use of antibiotics during delivery has decreased the rate of congenital GBS infections in the United States to 0.4 per 1,000 live births.

The CDC estimates that 25 to 45 percent of childbearing-age women carry the parasite that causes toxoplasmosis. In one-third of women infected for the first time during pregnancy, the parasite infects the

How Many Children Are at Risk for Congenital STIs?

The Centers for Disease Control and Prevention (CDC) estimates that each year among pregnant American women infections are communicated to fetuses and neonates in the following numbers:

- 6,400 infected with HIV
- 16,000 infected with hepatitis B
- 880,000 infected with HSV-2
- 100,000 infected with chlamydia
- 13,200 infected with gonorrhea
- Fewer than 1,000 infected with syphilis, although as of 2008, rising syphilis rates seen among infants born with congenital syphilis

* **gonorrhea** (gah-nuh-REE-uh) is a sexually transmitted disease (STD) spread through all forms of sexual intercourse. The bacteria can also be passed from an infected mother to her baby during childbirth. Gonorrhea can affect the genitals, urethra, rectum, eyes, throat, joints, and other tissues of the body.

* **conjunctivitis** (kon-jung-tih-VY-tis), often called pinkeye, is an inflammation of the thin membrane that lines the inside of the eyelids and covers the surface of the eyeball. Conjunctivitis can be caused by viruses, bacteria, allergies, chemical irritation, and other conditions or diseases that cause inflammation.

* **membrane** (MEM-brain) is a thin layer of tissue that covers a surface, lines a cavity, or divides a space or organ.

* **syphilis** (SIH-fih-lis) is a sexually transmitted disease that, if untreated, can lead to serious life-long problems throughout the body, including blindness and paralysis.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

* **cytomegalovirus** (sy-tuh-MEH-guh-lo-vy-rus), or CMV, infection is very common and usually causes no symptoms. It poses little risk for healthy people, but it can lead to serious illness in people with weak immune systems.

* **herpesvirus family** (her-pee-z-VY-rus) is a group of viruses that can stare themselves permanently in the body. The family includes varicella zoster virus, Epstein-Barr virus, and herpes simplex virus.

* **stillbirth** is the birth of a dead fetus.

* **syndrome** is a group or pattern of symptoms or signs that occur together.

* **rubella** (roo-BEH-luh) is a viral infection that usually causes a rash and mild fever.

* **measles** (ME-zuls) is a viral respiratory infection that is best known for the rash of large, flat, red blotches that appear on the arms, face, neck, and body.

* **premature delivery** is when a baby is born before it has reached full term.

* **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.

* **congestive heart failure** (kon-JES-tiv) or heart failure, is a condition in which a damaged or overworked heart cannot pump enough blood to meet the oxygen and nutrient needs of the body. People with heart failure may find it hard to exercise due to the insufficient blood flow, but many people live a long time with this condition.

How Do Women Get Transmissible Infections?

Women get transmissible infections in various ways.

- Women contract STIs primarily through sexual contact with infected men. HIV and hepatitis B and C can also be contracted through contact with infected blood, such as by sharing needles for injecting drugs.
- CMV is transmitted through infected blood, saliva, urine, or other body fluids.
- Varicella and rubella are commonly spread through coughs and sneezes.
- Parvovirus is spread by direct contact with infected nasal* secretions, such as by sharing eating utensils or cups.
- GBS bacteria live in the human intestine, rectum*, and vagina*, where they do not normally cause disease.
- The protozoan that causes toxoplasmosis produces eggs in cat intestines. The eggs are shed in cat feces* and can survive for up to 18 months in the soil. Human infection occurs from handling contaminated soil or cat litter or by ingesting raw or undercooked meat from infected animals.

placenta and enters the fetal circulation. Congenital infection occurs in one out of every 800 to 1,400 infants born to infected mothers.

What Are the Symptoms of Congenital Infections?

Viral STIs Many HIV-infected infants do not have symptoms at birth. However, the children, especially those infected before birth, generally develop symptoms of AIDS faster than adults. They may be sick from birth or fail to grow and develop at a normal rate.

Newborns with congenital hepatitis B may initially have no symptoms. However, without vaccination about 90 percent eventually develop symptoms of chronic* hepatitis.

Congenital HSV infection may be limited to the skin or involve various organs. Widespread infection can result in permanent brain damage, mental retardation*, or death. Initial symptoms of congenital herpes usually appear within four weeks of birth and may be mild:

- Skin blisters
- Fever

- Fatigue
- Loss of appetite

More serious symptoms of congenital HSV infection include the following:

- Chronic or recurring eye and skin infections
- Cataracts*
- Widespread infection affecting many organs, including the lungs and liver*
- A life-threatening brain infection called herpes encephalitis*.

Bacterial STIs Chlamydial infection can cause newborn pneumonia*. Conjunctivitis caused by chlamydia usually appears 5 to 12 days after birth, although it may take six weeks to develop. Conjunctivitis caused by gonorrhea usually appears two to seven days after birth. Newborns with gonorrhea can also develop an eye infection called gonococcal ophthalmia (gah-nuh-KOH-kul opf-THAL-me-uh). In rare cases, gonorrheal infection may cause meningitis* or blindness.

Congenital syphilis can cause premature birth and is a severe, disabling, and often life-threatening disease. If not treated early, it may cause facial deformity, blindness, deafness, neurological* conditions, and death.

A surviving newborn with untreated congenital syphilis may have no initial symptoms but may gain little weight and, during the first month of life, may develop the following:

- A rash or small blisters on the palms and soles of the feet
- Raised bumps around the nose, mouth, and diaper region
- Cracks around the mouth
- Nasal discharge
- Enlarged lymph nodes*, liver, and spleen*
- Bone inflammation*
- Meningitis

Other early-stage symptoms of congenital syphilis include the following:

- Failure to thrive*
- Fever
- Severe congenital pneumonia
- Rash and lesions* around the mouth, genitals, and anus*
- Bone lesions
- Nose cartilage infection or saddle nose (lacking a bridge)

Common viral infections* Most infants with congenital CMV have neither symptoms nor long-term problems. However, CMV infection in early pregnancy can cause birth defects and is a leading cause of congenital deafness. In later pregnancy CMV infection may cause serious newborn illness.

* **toxoplasmosis** (tox-o-plaz-MO-sis) is a parasitic infection that usually causes no symptoms in healthy people, but it can cause serious problems in unborn babies and people with weak immune systems.

* **trimester** (tri-MES-ter) is any of three periods of approximately 3 months each into which a human pregnancy is divided.

* **nasal** (NA-zal) of or relating to the nose.

* **rectum** is the final portion of the large intestine, connecting the colon to the outside opening of the anus.

* **vagina** (vah-JY-nah) is the canal, or passageway, in a woman that leads from the uterus to the outside of the body.

* **feces** (FEE-seez) is the excreted waste from the gastrointestinal tract.

* **vaccinations** (vak-sih-NAY-shunz), also called immunizations, are the giving of doses of vaccines, which are preparations of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself.

* **prenatal** (pre-NAY-tal) means existing or occurring before birth, with reference to the fetus.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **mental retardation** is a condition in which people have below average intelligence that limits their ability to function normally.

* **cataracts** (KAH-tuh-rakts) are areas of cloudiness of the lens of the eye that can interfere with vision.

* **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.

* **encephalitis** (en-seh-fuh-LYE-tis) is an inflammation of the brain, usually caused by a viral infection.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

* **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.

* **neurological** (nur-a-LAH-je-kal) refers to the nervous system, which includes the brain, spinal cord, and the nerves that control the senses, movement, and organ functions throughout the body.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **spleen** is an organ in the upper left part of the abdomen that stores and filters blood. As part of the immune system, the spleen also plays a role in fighting infection.

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

* **failure to thrive** is a condition in which an infant fails to gain weight and grow at the expected rate.

* **lesions** (LEE-zhuns) is a general term referring to a sore or a damaged or irregular area of tissue.

* **anus** (A-nus) is the opening at the end of the digestive system, through which waste leaves the body.

About 10 to 15 percent of infants with congenital CMV infection have symptoms at birth that may include the following:

- Low birth weight*
- Rashes
- Small bruises
- Hernias* in the groin
- Respiratory* problems
- Jaundice*
- Enlarged liver and spleen
- Retinitis*
- Microcephaly*
- Brain damage

Over the first few years of life, 0.5 to 15 percent of CMV-infected infants develop growth, development, hearing, vision, and/or neurological problems.

A fetus infected with varicella zoster early in gestation may develop pocks that can cause limb deformities. Congenital varicella syndrome is characterized by the following:

- Small limbs and head
- Scarring
- Eye damage
- Mental retardation

Rubella infections contracted later in pregnancy do not cause congenital defects, although the newborn may become seriously ill and eventually develop diabetes*. Rubella infections early in pregnancy can result in congenital rubella syndrome (CRS), which is associated various birth defects, including the following:

- Deafness
- Cataracts
- Bone marrow* abnormalities
- Heart defects
- Microcephaly
- Mental retardation

Newborns with CRS also may have the following:

- Low birth weight
- Bruising
- Bluish-red skin lesions
- Enlarged lymph nodes, liver, and spleen
- Brain inflammation
- Pneumonia

Although not usually dangerous, symptoms of congenital fifth disease include the following:

- A bright red rash on the cheeks
- Lacy red rashes on the neck, trunk, and legs
- Joint* pain
- Fatigue
- Malaise

GBS and toxoplasmosis Maternal infection with GBS at conception or within the first two weeks of pregnancy may lead to hearing and vision loss and mental retardation. GBS transmitted perinatally is the most common cause of sepsis* and meningitis in newborns and is a frequent cause of newborn pneumonia.

Although symptoms of congenital toxoplasmosis usually are very mild or absent, it can cause premature birth, low birth weight, or severe illness or death shortly after birth. Infection occurring early in fetal development can cause learning and motor* disabilities and other neurological symptoms. Other problems that may be present at birth or may not be apparent for months or years include the following:

- Slow growth
- Fever
- Skin rashes
- Easy bruising
- Anemia
- Microcephaly or macrocephaly*
- Hydrocephaly*
- Inflammation of the brain, heart, or lungs
- Seizures*
- Severe or prolonged jaundice
- Enlarged liver and spleen
- An eye inflammation called chorioretinitis, which can lead to blindness
- Hearing loss
- Mental retardation

How Are Congenital Infections Diagnosed and Treated?

Diagnosis of maternal, fetal, and congenital infections can be difficult. An obstetrician may diagnose a maternal infection based on a woman's symptoms and blood tests. Sometimes a fetal infection can be diagnosed using ultrasound*. In newborns congenital infections may be diagnosed based on a physical exam, symptoms, and blood or urine tests. Ultrasound may

* **viral infections** cause mouth sores that are called fever blisters or cold sores. These are often caused by the herpesvirus, and they usually appear on the gums or around the mouth and lips. Unlike canker sores, fever blisters and cold sores are contagious.

* **low birth weight** means born weighing less than normal. In humans, it refers to a full-term (pregnancy lasting 37 weeks or longer) baby weighing less than 5 pounds.

* **hernias** (HER-nee-ah) are protrusions of organs through connective tissue or cavity walls.

* **respiratory** (RES-pi-ra-tor-ee) refers to the breathing passages and lungs.

* **jaundice** (JON-dis) is a yellowing of the skin, and sometimes the whites of the eyes, caused by a buildup in the body of bilirubin, a chemical produced in and released by the liver. An increase in bilirubin may indicate disease of the liver or certain blood disorders.

* **retinitis** (reh-tin-EYE-tis) is an inflammation of the retina, the nerve-rich membrane at the back of the eye on which visual images form.

* **microcephaly** (my-kro-SEH-fah-lee) is the condition of having an abnormally small head, which typically results from having an underdeveloped or malformed brain.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

How Can STIs Be Prevented?

To reduce the risk of contracting an STI, pregnant women should do the following:

- Abstain from sexual contact outside a mutually monogamous relationship
- Use latex condoms correctly and consistently
- Avoid blood-contaminated needles, razors, or other items

* **bone marrow** is the soft tissue inside bones where blood cells are made.

* **joint** is the structure where two or more bones come together, allowing flexibility and motion of the skeleton.

* **sepsis** is a potentially serious spreading of infection, usually bacterial, through the bloodstream and body.

* **motor** relates to body movement.

* **macrocephaly** (ma-kro-SEH-fah-lee) means having an abnormally large head.

* **hydrocephaly** (hi-dro-SEH-fah-lee) means having an abnormally large amount of cerebrospinal fluid in the brain, resulting in an enlarged skull and brain atrophy.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

be used to image the newborn's brain and an echocardiogram* may diagnose heart problems.

Infants born with serious infections are treated in a neonatal-care unit with intravenous* (IV) drugs. Infants born to infected mothers may be treated with medications even if they show few or no signs of infection.

Viral STIs Most infants born to HIV-infected mothers test positive for maternal antibodies against HIV for 6 to 18 months after birth. Therefore, additional tests are performed to determine whether an infant is truly infected with HIV. Tests performed within 48 hours of birth detect only about 40 percent of HIV infections, so testing is repeated after one and six months. Treatment of congenital HIV infection with combination ARV drugs reduces child mortality by up to 67 percent.

Pneumonia caused by *Pneumocystis carinii* is often the first AIDS-related illness to appear in HIV-infected infants and is a major cause of death during the first year. The CDC recommends that all babies born to HIV-infected mothers be treated with anti-pneumonia drugs beginning at four to six weeks and continuing until the infant is found to be HIV-negative.

Infants born to mothers infected with hepatitis B are given both the first dose of hepatitis B vaccine* and hepatitis B immune globulin* within 12 hours of birth. The second and third doses of vaccine are given at one and six months of age.

Maternal HSV infection can be diagnosed by a culture* from an affected genital site, preferably on the first day of an outbreak, or a blood test. Newborns with congenital herpes are treated immediately with intravenous antiviral medications. Eye infections are treated with trifluridine drops. Although immediate medication may prevent or reduce the damage from HSV, one-half of infants born with severe HSV infections die and the other one-half may suffer brain damage.

Bacterial STIs Congenital chlamydial infection is treated with erythromycin eye ointment and oral* tablets. Conjunctivitis and pneumonia in newborns usually respond well to treatment with antibiotics.

An antibiotic ointment such as silver nitrate is placed under the eyelids of all newborns as preventative treatment for congenital gonorrhea. An infant born to a gonorrhea-infected mother is treated with intravenous antibiotics.

Congenital syphilis is identified during routine newborn blood testing and is treated with antibiotics. Syphilis in an older infant may be diagnosed by the following means:

- Lumbar puncture to look for signs of syphilis in the brain and central nervous system*
- An ophthalmologic* examination
- Dark-field microscopy to visualize the spirochete bacteria that cause the disease
- Bone x-rays

Other viral infections Prenatal diagnosis of CMV may include blood tests for maternal antibodies and fetal ultrasound. Symptoms of congenital CMV, including retinitis, are treated with antiviral medications. With treatment most infants with congenital CMV survive, although almost all suffer from its effects.

Congenital chicken pox is treated immediately to prevent serious complications or death. There is no specific treatment for CRS; rather, infants are treated for specific conditions.

Prenatal diagnosis of fifth disease may include blood tests for maternal antibodies and fetal ultrasound. The mother may receive medication that passes through the placenta to the fetus. Fetal anemia caused by fifth disease may resolve on its own. If the fetus is at risk for heart failure*, a fetal blood transfusion* may be performed.

GBS and toxoplasmosis GBS can be diagnosed by culturing the bacteria from the blood, spinal fluid, skin, vagina, or rectum. Newborns infected with GBS are treated immediately with intravenous antibiotics. Although antibiotic treatment is very effective, about 5 percent of newborns with congenital GBS die.

Prenatal tests for toxoplasmosis include:

- A blood test for maternal antibodies
- Testing of the amniotic fluid and fetal blood
- Fetal ultrasound

It has been suggested that all pregnant women and newborns be screened for toxoplasmosis.

Postnatal diagnosis of congenital toxoplasmosis may be based on the following:

- Antibody tests of the cord blood and cerebrospinal fluid*
- An ophthalmologic examination
- A neurologic exam*
- CT scans*

Fetal toxoplasmosis may be treated by giving the mother pyrimethamine and sulfonamides during the later second and third trimesters of pregnancy. Newborns with symptoms of toxoplasmosis are treated with the following:

- Pyrimethamine and sulfadiazine for one year
- Leucovorin for one year to protect the bone marrow from pyrimethamine toxicity
- Corticosteroids* for heart, lung, or eye inflammations

Can Congenital Infections Be Prevented?

Although the consequences of congenital infections can be devastating, they are often relatively easy to prevent, because maternal treatment with antiviral medications or antibiotics reduces the risk to the fetus. The

* **echocardiogram** (eh-ko-KAR-dee-uh-gram) is a diagnostic test that uses sound waves to produce images of the heart's chambers and valves and blood flow through the heart.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

* **vaccine** (vak-SEEN) is a preparation of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.

* **immune globulin** (ih-MYOON GLAH-byoo-lin), also called gamma globulin, is the protein material that contains antibodies.

* **culture** (KUL-chur) is a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

* **oral** means by mouth or referring to the mouth.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

* **ophthalmologic** (off-thal-MOLL-o-jik) means related to the function, structure, and diseases of the eye.

Should Pregnant Women Be Vaccinated?

Vaccinations can prevent varicella and rubella. Women of childbearing age who have not had chicken pox or rubella and have not been vaccinated previously should be vaccinated prior to becoming pregnant. Because these vaccines contain live viruses, women cannot be vaccinated during pregnancy due to the risk to the fetus. However, vaccinations for family members and others in close contact with a pregnant woman can help protect her from infection. Other vaccines, such as flu vaccine, which does not contain live-virus, are recommended after the first trimester of pregnancy.

* **heart failure** is a medical term used to describe a condition in which a damaged heart cannot pump enough blood to meet the oxygen and nutrient demands of the body. People with heart failure may find it hard to exercise due to the insufficient blood flow, but many people live a long time with heart failure.

* **blood transfusion** is the process of giving blood (or certain cells or chemicals found in the blood) to a person who needs it due to illness or blood loss.

* **cerebrospinal fluid** (seh-ree-bro-SPY-nuhl) is the fluid that surrounds the brain and spinal cord.

* **neurologic exam** refers to systematic tests of how well various parts of the nervous system are functioning.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

CDC recommends that on their first prenatal visit all pregnant women be screened for the following:

- HIV
- Hepatitis B and C
- Chlamydia
- Gonorrhea
- Syphilis

STIs Women who test negative for HIV early in pregnancy but are at high risk for HIV infection due to new or multiple sexual partners or intravenous drug use should be retested later in pregnancy. Women who were not tested for HIV during pregnancy may be screened during labor or delivery with a rapid test for HIV antibodies in the blood. If an HIV-infected woman is treated with ARV drugs during pregnancy and delivery and the newborn is treated immediately after birth, the baby's risk of HIV infection drops from about 25 percent to about 6 percent. If the mother's viral load (the amount of HIV in her blood) is high or if there is a prolonged period between membrane rupture and delivery, the risk of HIV transmission increases. If the mother receives ARV treatment during pregnancy and delivers by cesarean section* before labor begins and the membranes rupture, the risk of HIV infection in the newborn drops to 1 percent or less. Feeding formula* to infants prevents transmission of the virus through breast milk.

Sometimes pregnant women who are at high risk for hepatitis B infection are vaccinated. More than 95 percent of infants born to hepatitis B-infected mothers can be protected by administering the first dose of vaccine and immune globulin within 12 hours of birth.

Prevention of maternal-to-fetal HSV transmission includes the following:

- Abstaining from sexual activity during the last trimester of pregnancy or if there are signs of an outbreak or visible sores
- Using a condom even if no symptoms are present
- Postponing membrane rupture
- Avoiding a fetal monitor that makes tiny punctures in the fetal scalp
- Avoiding vacuum or forceps deliveries, which cause breaks in the infant's scalp.

An examination or HSV test can indicate whether a pregnant woman has active genital herpes near the time of delivery. Outbreaks just prior to delivery may be prevented by treatment with antiviral drugs. Women with active herpes lesions are likely deliver by cesarean section to reduce the risk of transmission.

Screening pregnant women for gonorrhea is important because women often do not know that they are infected, and antibiotic treatment can prevent congenital infection. Because women often are infected

with both gonorrhea and chlamydia, a combination of antibiotics is used to treat the infections simultaneously. Likewise, adequate antibiotic treatment of a syphilis-infected pregnant woman protects the fetus from congenital disease.

Preventing other congenital infections Pregnant women should be tested for immunity to rubella at their first prenatal visit. Exposure to chicken pox or rubella by a non-immune pregnant woman may be treated with an injection of immune globulin to help prevent fetal transmission.

Good hygiene can help protect pregnant women from infection with CMV, parvovirus, *Toxoplasma gondii*, and other infectious microorganism*. This is particularly important for women who have or work with young children and may be at risk for CMV and parvovirus. Good practices include the following:

- Frequent and thorough hand washing, especially after handling diapers or bodily fluids
- Not sharing food or drink
- Contacting a healthcare provider immediately upon exposure to a transmittable infection

Pregnant women should be tested for GBS between the 35th and 37th weeks of pregnancy to determine whether the bacteria are likely to be present during delivery. Pregnant women with GBS in their urine are treated with penicillin. Intravenous antibiotics may be administered from the moment following membrane rupture through labor and delivery. Antibiotic treatment reduces the risk of congenital GBS infection from 1 in 200 to 1 in 4,000.

Treatment with spiramycin for toxoplasmosis occurring within the first or early second trimester of pregnancy can prevent transmission to the fetus. However, it is important that pregnant women take measures to avoid *Toxoplasma* infection by taking the following measures:

- Keeping cats indoors and washing after handling them
- Using rubber gloves to handle cat litter and washing thoroughly afterwards
- Disinfecting cat boxes with boiling water for five minutes
- Covering sandboxes
- Wearing gloves for handling soil or gardening and washing afterwards
- Avoiding insects that may have been exposed to cat feces
- Avoiding raw or undercooked meat and poultry, unwashed fruits and vegetables, raw eggs, and unpasteurized* milk
- Killing *Toxoplasma* by freezing food or cooking it thoroughly

Should Women Be Tested Before Pregnancy?

Women who are considering becoming pregnant can be screened for antibodies to CMV and toxoplasmosis. If tests show that they have these antibodies, there is no risk of infection during pregnancy. If they do not have antibodies, women can take extra precautions to avoid exposure to these common pathogens.

* **corticosteroids** (kor-tih-ko-STIR-oyds) are chemical substances made by the adrenal glands that have several functions in the body, including maintaining blood pressure during stress and controlling inflammation. They can also be given to people as medication to treat certain illnesses.

* **cesarean section** (si-ZAR-ee-an SEK-shun) is the surgical incision of the walls of the abdomen and uterus to deliver offspring in cases where the mother cannot deliver through the vagina.

* **formula** is a prepared, nutritious drink or a dry drink mix designed specifically for infants.

* **microorganism** is a tiny organism that can be seen only by using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

* **unpasteurized** (pas-CHUR-ized) refers to foods that have not undergone the process of pasteurization (pas-chu-rih-ZAY-shun), in which food is heated to a certain temperature over a period of time to kill organisms and help make the food safer to consume.

▲ Iranian conjoined twins Ladan (left) and Laleh Bijani, smiling during a press conference in Singapore, June 11, 2003. Both women died July 8, 2003, when the operation to separate them was unsuccessful. *AP Images*.

* **identical twins** are twins produced when a single egg from the mother is fertilized and divides to form two separate embryos of the same sex with nearly identical DNA.

* **embryo** (EM-bree-o), in humans, is the developing organism from the end of the second week after fertilization to the end of the eighth week.

* **spina bifida** (SPY-nuh BIF-ih-duh) is a condition present at birth in which the spinal column is imperfectly closed, leaving part of the spinal cord exposed and often leading to neurological and other problems.

Conjoined Twins

Conjoined twins are identical twins in which the two embryos* fail to separate completely before birth. It is thought that the condition results from incomplete splitting after the twelfth day of development. If a fertilized human egg divides into two embryos before the twelfth day, the identical twins are born normally as two separate infants. A hundred years ago conjoined twins were often called Siamese twins, after Chang and Eng Bunker (1811–1874), a pair of male conjoined twins who were born in Thailand, then called the Kingdom of Siam.*

Meet the Schappell Sisters

George (born Dori) and Lori Schappell are conjoined sisters born in Reading, Pennsylvania, in 1961. They are craniopagus conjoined twins who cannot be separated because they share about 30 percent of their brain tissue. Dori disliked having a name that rhymed with her sister's, so she changed it first to Reba and then in 2007 to George.

The Schappell sisters are an example of the physical differences that can exist between conjoined twins. Lori is physically healthy, but George was born with spina bifida*. It was this physical condition that caused the sisters to be removed from their parents by court order in the early 1960s and placed in an institution for the mentally disabled even though

neither sister has a learning impairment. After they became adults, the sisters fought to be released from the institution. They were able to attend college after their release.

The two sisters took turns working while the other attended school or began a career. George worked in a hospital while Lori finished college. Lori worked in a laundry and helped to manage George's career as a country music singer. George (who still called herself Reba when she began to sing) performed in Germany and Japan as well as in the United States, and won the L. A. Music Award for Best New Country Artist in 1997. She also worked as a designer of support equipment for disabled humans and pets and designed the custom wheelchair that she needs to use to avoid straining Lori's back and neck. George's spina bifida means that she is much shorter than her sister and must be raised to her sister's height in order to move around easily. George used a bar stool as the base of the wheelchair.

The Schappell sisters have maintained their individual personalities. Although they share an apartment, they have separate rooms, and George has pets whereas Lori does not. They have different groups of friends and attend different churches. Lori cuts her hair short and enjoys an occasional drink whereas George has colored her hair and avoids alcohol. Lori speaks in the Pennsylvania Dutch accent of the Reading area, but George has adopted a Southern drawl from her work in country music.

What Are Conjoined Twins?

Conjoined twins are identical twins that fail to separate completely during the mother's pregnancy. Identical twins are also known as monozygotic* because they are formed when a single fertilized egg from the mother divides to form two separate embryos during pregnancy. Conjoined twins are a rare subtype of identical twins that result from incomplete splitting after the twelfth day of embryonic development. The longer the delay in the separation of the two embryos, the more complicated the connections between the conjoined twins are likely to be.

The other major category of twins are fraternal* twins, who are formed when two eggs from the mother are fertilized by two different sperm from the father and implant inside the uterus, the organ in which the unborn babies develop. Fraternal twins are also known as dizygotic* twins. Dizygotic twins are more common than identical or monozygotic twins.

How Common Are Conjoined Twins?

In general, about 1 in every 90 human pregnancies results in twins. About 40 percent of all twins born are fraternal twins in which one baby is male and the other female. The next most common type is female fraternal twins, followed by male fraternal twins, female identical twins, and male identical twins. Conjoined twins are the rarest form of identical twins, occurring once in every 50,000 to 200,000 pregnancies. They are

* **monozygotic** (mah-no-zye-GOT-ik) derived from a single fertilized egg.

* **fraternal** twins are born at the same time but develop from two separate fertilized eggs. Unlike identical twins, who develop from only one fertilized egg that splits into two and who look exactly alike, fraternal twins may not look the same at all or be the same gender. Identical twins have the same genes, but fraternal twins are no more likely to share genes than non-twin siblings.

* **dizygotic** (dye-zye-GOT-ik) derived from two different fertilized eggs.

more likely to occur in Southwest Asia and Africa than in Europe or North America, but the reason for this geographical difference is not yet known.

Conjoined twins are at considerable risk of death during pregnancy; doctors estimate that between 40 and 60 percent of conjoined twins are stillborn or die shortly after birth. Male conjoined twins are more likely than females to die before birth. Of conjoined twins that are born alive, females outnumber males by a ratio of three to one. In the United States, about one live birth in every 200,000 is a set of conjoined twins.

How Are Conjoined Twins Classified?

Conjoined twins are categorized in two major ways. Some doctors distinguish between symmetrical or equal conjoined twins, a condition in which both infants are well developed, and asymmetrical or unequal conjoined twins, in which an incomplete twin is joined to a fully developed sibling. The incomplete twin is sometimes called a parasitic twin because it depends on the overall health and body functions of the complete sibling. About 10 percent of conjoined twins are asymmetrical twins.

Conjoined twins are also classified according to the points at which their bodies are joined. This system goes back to a French biologist named Étienne Geoffroy Saint-Hillaire (1772–1844), who based his terms on the medical terms for parts of the body. The conjoined twins may share tissues, organ systems, or both, depending on the areas in which their bodies are fused:

- **Thoracopagus:** 40 percent of conjoined twins are joined at the chest. These twins always share a heart. Many conjoined thoracopagus twins are also joined at the abdomen and are called thoracophalopagus twins.
- **Omphalopagus:** 10 percent of conjoined twins are joined only at the abdomen. These twins often share a liver and digestive system but not a heart.
- **Pygopagus:** 18 percent of twins are joined back to back at the buttocks. These twins sometimes share the lower part of the digestive tract or the genital organs.
- **Ischiopagus:** 6 percent of twins are joined at the pelvis or lower spine with the lower half of the bodies fused. They have four arms but may have between two and four legs.
- **Craniopagus:** 2 percent of conjoined twins are fused at the head but the bodies are separate. In some cases these twins share part of the brain as well as the skull.
- **Xiphopagus:** A rare type of conjoined twins are those joined at the xiphoid cartilage, which runs from the breastbone to the navel in infants and turns into bone by adulthood. Chang and Eng Bunker were xiphopagus conjoined twins.

How Serious Is the Conjoined Condition?

In general, as has already been noted, conjoined twins are likely to die before or shortly after birth, although the degree of risk depends on how many organs they share and how well-developed their organs are. One side effect of the incomplete separation of the two embryos in conjoined twinning is that the babies' vital organs are likely to be incomplete or abnormal in some other way. Xiphopagus twins such as the Bunkers usually share only the liver and have a higher chance of survival; craniopagus twins with shared brain tissue or thoracopagus twins with a shared heart have a much poorer outlook.

Between 40 and 80 percent of conjoined twins who need emergency surgery after birth die in intensive care following the operation. In some cases, particularly those involving asymmetrical twins, the parents must make the painful decision to allow one of the twins to die if the other is to have any chance of survival. Conjoined twins who are born alive and are healthy enough to have surgery postponed until they are older have a survival rate of 80 percent.

THE ORIGINAL SIAMESE TWINS

Chang and Eng Bunker (1811–1874) were conjoined twins whose country of origin, then called Siam, led to their being called Siamese twins, a term later considered inappropriate for the condition. Chang and Eng were joined at the breastbone by a band of cartilage, but their vital organs functioned independently. They could have been easily separated by modern surgical techniques and equipment, but 19th-century surgeons did not have the specialized diagnostic techniques, blood banks, and other equipment necessary for such operations. The boys were fortunate that their parents did not abandon them; the midwife who delivered the boys was afraid to touch them for fear that she would be cursed; and when the King of Siam heard about the unusual birth, he condemned the twins to death. Luckily, he never carried out the sentence.

Like other sets of conjoined twins in the 19th century, Chang and Eng were exhibited as a medical curiosity. They were discovered by a British business promoter in 1829 and taken on tour in England and the United States. The twins then joined P. T. Barnum's traveling circus after their contract with the Englishman expired. They left the circus in 1839 and settled in a town in North Carolina. Taking the surname Bunker, they became citizens of the United States and married two sisters in 1843. Chang had ten children by his wife while Eng had eleven. The two wives did not get along, however, and the brothers set up two separate households, spending three days a week in each home.

The twins' health grew worse in the early 1870s, partly as a result of heavy drinking and financial worries following the Civil War. Chang died on January 17, 1874, most likely from a stroke; Eng died an hour later. The twins have been the subject of several novels, plays, and short stories, as well as a musical produced in Singapore in 1997.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **electrocardiogram** (e-lek-tro-KAR-dee-o-gram), also known as an EKG, is a test that records and displays the electrical activity of the heart.

* **electroencephalogram** an instrument that records the electrical activity of the brain.

* **cesarean section** (si-ZAR-ee-an SEK-shun) is the surgical incision of the walls of the abdomen and uterus to deliver offspring in cases where the mother cannot deliver through the vagina.

How Conjoined Twins Diagnosed and Treated?

Diagnosis In some cases the mother's doctor may suspect the presence of conjoined twins early in the pregnancy by finding that the mother's uterus is larger than expected and hearing two fetal heartbeats when listening through a stethoscope. Conjoined twins can be diagnosed by ultrasound* as early as the eighth week of pregnancy. Ultrasound imaging is also useful in planning for the birth, as many conjoined twins are not in the usual head-down position before birth and the doctor needs to be prepared.

Magnetic resonance imaging* can be used to identify which organ systems are shared between the twins and which organs are abnormal or incompletely developed. In every set of conjoined twins, one will be smaller than the other and will usually have more abnormal organs as well. CT scans* are primarily useful in evaluating the bony structures of twins fused at the hips or pelvis.

An electrocardiogram* and an electroencephalogram (EEG)* may be used to evaluate the extent of shared heart or brain function, and to determine whether surgical separation of the twins will be possible after birth. Although the number of successful separations of conjoined twins increased after the first attempt in Paris in 1888—about 250 long-term successes had been reported as of 2009—some conjoined twins cannot be separated.

Treatment The treatment of conjoined twins is highly individualized. It almost always requires complicated surgery in one of a small number of medical centers (three in the United States, one in the United Kingdom, one in New Zealand, and one in South Africa). Doctors classify conjoined twins for treatment in one of three categories: those who are likely to die shortly after birth; those who require immediate emergency surgery; and those who will survive until they are old enough for surgery to have a higher chance of success (usually 6–12 months). Twins who share a heart or brain usually cannot be separated without causing the death of both twins. Emergency surgery is needed when one twin dies shortly after birth in order to save the other twin.

Conjoined twins are usually delivered by cesarean section* rather than waiting for the mother's due date, in part because conjoined twins are more likely than other babies to be born prematurely. The operation is usually scheduled for two to four weeks before the expected date of birth. Surgery to separate the twins may be performed immediately after delivery if one or both twins have a life-threatening emergency. These operations are complicated and may take as long as 35 hours to complete. Two complete surgical teams are required to care for the twins after the separation is complete. In most cases, conjoined twins who survive separation need further surgery at intervals during childhood as their bodies grow and change.

Complications Complications following the separation of conjoined twins are common in spite of the number of imaging studies and careful

planning that takes place before the operation. The younger the infants at the time of surgery, the more likely they are to have complications related to blood loss, changes in blood pressure, or the use of general anesthesia*.

Some complications related to the separation of conjoined twins concern the legal system rather than surgery. In 2000 there was a controversial case in Great Britain in which conjoined girls were separated shortly after birth by order of the High Court over the objections of the twins' parents even though it was certain that the weaker twin would die as a result of the surgery. This case raises questions about a government's right to overrule parents' wishes as well as the ethics* involved in sacrificing one child's life for the sake of the other. In the United States as of 2009, the parents' decision regarding separation was considered final.

Can Conjoined Twins Be Prevented?

As of 2009, conjoined twinning cannot be prevented because the cause of the incomplete separation of the two embryos around the twelfth day of pregnancy is not known. Avoiding the small number of medications that have been associated with conjoined twinning in a few cases may help. Although twin births in general are known to run in families, conjoined twinning is considered to be a random occurrence; the parents of conjoined twins do not have an increased risk of having a second set in a later pregnancy.

Parents can choose to terminate the pregnancy if the mother has had an ultrasound or other diagnostic examination and is known to be carrying conjoined twins. As of the early 2000s, parents were increasingly choosing to end their pregnancy.

Living as Conjoined Twins

It is possible for conjoined twins who are not separated to have productive and satisfying lives, as the example of the Schappell sisters indicates. Daisy and Violet Hilton (1908–1969) were pygopagus conjoined twins born in England who moved to the United States and worked as vaudeville singers and dancers, including a tap-dancing routine with Bob Hope. Later, a set of conjoined twins in Minnesota completed high school in 2008, began college, and obtained a driver's license. They told a *Newsweek* reporter in 2008 that they expect to marry and have children after completing their education. Alice Dreger, a medical historian from Michigan, wrote in her book that many conjoined twins are satisfied with their lives, and—contrary to popular opinion—do not feel sorry for themselves or see their lives as not worth living. The Schappell sisters, for example, are opposed to separation surgery because they do not want to risk the possibility that one of them might die.

Conjoined twins who are not separated commonly state that being stared at by strangers, regarded as objects of pity, or asked intrusive questions about their bathroom habits or sexual activities are more bothersome than the physical inconveniences of their shared lives. Although a

* **general anesthesia** (an-es-THE-zha) means using drugs or inhaled gases to create a state of unconsciousness and muscle relaxation throughout the body to block pain during surgery. Local anesthesia blocks or numbs pain in one part of the body while patients remain awake.

* **ethics** is a guiding set of principles for conduct, a system of moral values.

number of pairs of conjoined twins in the 19th and early 20th centuries ended up in circuses or other forms of show business in order to earn a living, changes in employment legislation and the widespread use of computers in schools and workplaces have made it possible for contemporary conjoined twins to go to college and enter other occupations.

Conjoined twins who are not separated, however, have shortened life expectancies; most pairs die in their twenties or early thirties. The oldest known living set of conjoined twins is a pair of brothers in Ohio born in 1951; they are also the only set of adult male conjoined twins anywhere in the world as of 2009.

Conjunctivitis

Conjunctivitis (kon-jung-tih-VY-tis), often called pinkeye, is an inflammation of the conjunctiva (kon-jung-TIE-vuh), the thin membrane that lines the inside of the eyelids and covers the surface of the eyeball. Conjunctivitis can be caused by viruses, bacteria, allergies, or chemical irritation.

What Is Conjunctivitis?

Conjunctivitis is an inflammation of the thin membrane that lines the inside of the eyelids and covers the white surface of the eye. The inflammation can produce redness, burning, or itching of the eyes and sometimes a discharge. Bacterial or viral infections most often cause conjunctivitis. Many different bacteria can be the culprit, most commonly *Streptococcus*

In conjunctivitis, the membrane that lines the eyelids and covers the eye becomes inflamed and swollen. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

pneumoniae (strep-tuh-KAH-kus nu-MO-nye), *Haemophilus influenzae* (he-MOH-fih-lus in-floo-EN-zuh), and *Staphylococcus aureus* (stah-fih-lo-KAH-kus ARE-ree-us). Infections with adenovirus* and influenza viruses are common causes of conjunctivitis. About 80 percent of all cases of conjunctivitis result from viral or bacterial infection.

Rarely, parasite* and fungal infections can cause conjunctivitis. The condition also can stem from various allergies, irritants, chemicals, and pollutants. Reactions to smoke, dust, makeup, contact lenses, and pollen all can produce symptoms in some people as can contaminated contact lens solution in contact lens wearers.

The sexually transmitted diseases chlamydia* and gonorrhea*, which can be passed from infected mothers to their babies during birth, are the most common causes of conjunctivitis in newborns. These two diseases can lead to conjunctivitis in adults as well. Conjunctivitis usually does not cause problems with vision.

How Does Conjunctivitis Spread and Who Gets It?

Conjunctivitis, especially of viral origin, typically is seen in children and adults who are caregivers of children, such as parents or day-care workers. Bacterial conjunctivitis is less common in healthy older children and adults. Both the bacterial and viral forms of the condition are contagious. The germs that cause conjunctivitis may be present in nasal secretions and in the discharge from the eyes. People can become infected simply by touching the face of someone with the disease and then rubbing their own eyes without first washing their hands. Sharing contaminated towels or eye makeup also can spread the infection. Infectious conjunctivitis can spread quickly through child-care and school settings and among members of the same family. Bacterial conjunctivitis can remain contagious until treatment with antibiotics is started. The viral form is usually contagious before the symptoms appear and for as long as symptoms, including any discharge from the eye, last.

* **adenovirus** (ah-deh-no-VY-rus) is a type of virus that can produce a variety of symptoms, including upper respiratory disease, when it infects humans.

* **parasite** (PAIR-uh-sites) is an organisms such as a protozoan (one-celled animals), worm, or insect that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. A parasite lives at the expense of the host and may cause illness.

* **chlamydia** (kla-MIH-dee-uh) are microorganisms that can infect the urinary tract, genitals, eye, and respiratory tract, including the lungs.

* **gonorrhea** (gah-nuh-REE-uh) is a sexually transmitted disease (STD) spread through all forms of sexual intercourse. The bacteria can also be passed from an infected mother to her baby during childbirth. Gonorrhea can affect the genitals, urethra, rectum, eyes, throat, joints, and other tissues of the body.

▲
Antibiotic eyedrops or ointments are applied to the eye to treat bacterial conjunctivitis. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

* **herpesvirus** (her-pee-z-VY-rus) is a member of a family of viruses that can store themselves permanently in the body. The family includes varicella virus, Epstein-Barr virus, and herpes simplex virus.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

* **cornea** (KOR-nee-uh) is the transparent circular layer of cells over the central colored part of the eyeball (the iris) through which light enters the eye.

What Are the Signs and Symptoms of Conjunctivitis?

The first symptoms typically appear within a few days or up to a week after infection. A person may feel discomfort, a gritty sensation under the eyelids, or a feeling that there is something in the eye. Redness develops in the eye, and the eyelids may swell. Bacterial infections usually produce a thick yellowish or greenish discharge. When the person wakes up in the morning, the eyelids might stick together as the result of dried discharge. In viral conjunctivitis, the discharge is often thin, watery, and clear. Viral infections are more likely to affect both eyes and can be accompanied by other symptoms of viral infection, such as cold or flu symptoms.

How Is Conjunctivitis Diagnosed?

Eye discharge and inflammation (redness) of the conjunctiva are the hallmarks of conjunctivitis. The doctor also will ask whether the person has had recent contact with someone with conjunctivitis and will examine the eyes, making sure the person's vision is normal. Sometimes the doctor will swab the inside of the eyelids to obtain fluid for laboratory testing to determine the type of infection. This procedure is more likely to be done in newborn babies or someone at risk of a sexually transmitted disease, such as chlamydial infection or gonorrhea.

How Do Doctors Treat Conjunctivitis?

Treatment depends on the cause of conjunctivitis. If bacterial conjunctivitis has been diagnosed, antibiotic eye drops usually are prescribed for about a week. An antibiotic ointment is used for babies. Viral conjunctivitis disappears by itself and does not typically require treatment. (One exception is conjunctivitis caused by herpesvirus* infection, which is treated with antiviral eye drops.) Over-the-counter pain relievers, such as acetaminophen*, and warm compresses placed over the eyelids several times a day may ease the discomfort. Conjunctivitis usually clears up within a week. Cases of viral conjunctivitis can take longer to resolve than bacterial conjunctivitis.

Are There Complications?

Complications of conjunctivitis are rare. In newborns, untreated gonorrheal infection of the conjunctiva can cause a spreading infection of the eye that can lead to blindness. A few viruses cause conjunctivitis that affects deeper parts of the eye, resulting in keratitis (kare-uh-TY-tis), an inflammation of the cornea* that causes changes in vision and sometimes permanent scarring of the cornea. Trachoma (truh-KO-mah), a type of chlamydial conjunctivitis seen in developing countries, also can lead to blindness.

Can Conjunctivitis Be Prevented?

Good hygiene is the best way to help prevent infectious conjunctivitis. People should wash their hands frequently, especially after touching the face of someone who has the infection. Eye cosmetics should be replaced

regularly, and contact lenses should be handled and cleaned properly. It is a good idea for people with infectious conjunctivitis to wash their hands often to avoid spreading the infection. It is also wise not to share makeup; disposable items, such as paper towels and cotton balls; or towels. Washing towels and clothing in hot water can disinfect them.

Consciousness

Consciousness is a person's awareness of his or her inner world, the most private place where thoughts and feelings are formed and impressions and experiences are processed.

Automatic Tasks Versus Conscious Choices

Here is a test: Try to write down all the steps you followed in getting dressed this morning. Did you put on your pants or your top first? Which shoe went on first? What steps did you take to tie your shoes? This is likely to be a tough test because getting dressed, brushing teeth, or tying shoes are automatic tasks that can be done without much thought. Other examples of automatic tasks include riding a bike, playing a sport, and dialing a phone number from memory. These tasks may seem difficult when people learn them for the first time, but the tasks soon become so familiar that individuals do not have to focus their conscious minds on them. Without even realizing it, people rely on learned routines to complete lots of tasks efficiently.

- * **cerebral cortex** (suh-REE-brul KOR-teks) is the part of the brain that controls functions such as conscious thought, listening, and speaking.
- * **vegetative state** a state of extreme mental impairment in which only involuntary bodily functions are sustained.
- * **psychologists** (sy-KOL-o-jists) are mental health professionals who treat mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth. Psychologists also study the brain, behavior, emotions, and learning.
- * **ethics** is a guiding set of principles for conduct, a system of moral values.

Mindfulness

Automatic processing is not always enough for what someone needs to do. In such cases the conscious mind takes over. Whether a person is mastering a new concept, focusing on a challenging book, writing a school paper, deciding how to spend the afternoon, or reacting to criticism from a friend, for example, that person is mindful, or conscious, of what he or she is thinking, feeling, saying, or doing. These and other tasks require the mind to be aware of the inside and the outside world, instead of relying on set automatic routines. It appears that “consciousness” gives human beings the awareness to be flexible in dealing with new situations and an ever-changing environment. Consciousness is a state of being aware and paying attention to thoughts, feelings, ideas, and actions at a given moment.

Cerebral Cortex

It is generally believed that the mechanisms of consciousness are controlled by the cerebral cortex*, the upper wrinkled layer of the brain where higher functions, such as perception, memory, intelligence, and control of skilled movements, are also carried out. As of the early 2000s, however, scientists were unable to explain consciousness fully as a solely physical process carried out within the brain. Whether consciousness is solely a physical process has been debated intensely. Consciousness has proved to be one of the most difficult functions to define, even though everyone experiences it.

Philosophy, Psychology, and Neuroscience: The “Hard Problem” of Consciousness

Scientists, physicians, and psychologists who are specially trained to study the structure, function, and biology of the brain and nervous system have learned about different brain regions and how brain chemicals are involved in producing emotions such as anxiety, sadness, fear, and happiness. Using advanced brain imaging techniques, they also have gained more understanding of how different portions of the brain play a part in speaking, listening, processing information, and other activities. In addition, some medical professionals have used imaging tests to search for even slight conscious activity in the brains of patients who have suffered brain injury and appear to be in a completely vegetative state*. Further research may eventually lead to a better understanding about how to use imaging tests to determine which of these patients will eventually “wake up” and again become aware of their surroundings. As of 2009, however, even positive test results cannot predict whether a particular patient will ever regain consciousness.

Some researchers in the emerging field known as consciousness studies speculate that one day people will understand consciousness more fully in this way as well. They include not only psychologists* and scientists, but also some philosophers. Philosophy is the study of the nature of the mind and of the role of thought in how people experience and deal with the world around them, including ethics*, morality, decision making,

motivation, and beliefs. These researchers believe that eventually people will be able to “map” the process they understand as consciousness within the brain, explaining it in terms of the connections and messaging among nerve cells of the brain. They believe that consciousness will come to be understood as the product of the sophisticated machinery of the human brain, just as emotions have begun to be understood in this way.

Other researchers disagree. They contend that the so-called hard problem of consciousness will remain something of a mystery. The “hard problem” of consciousness refers to the question of how the physical brain can give rise to the unique experiences that individuals have in relation to the external world. These experts do not dispute the brain’s role in taking in, processing, and interpreting concrete information from the outside world. For example, two people at the same concert hear the same music thanks to the inner ear’s auditory nerve, which sends along impulses to the brain, where they are processed in the region that controls hearing. This statement does not, however, explain the inner aspect of thought and perception or the way the music “feels” for each person. When listeners explain their innermost thoughts while hearing the music, they describe very different responses based on personal experiences. For this reason, some experts contend that people will never be able to locate consciousness entirely within the structures and chemical processes of the brain. For them, consciousness is too complex to explain fully in terms of gray matter and brain chemicals. Instead, they argue that consciousness also draws on experiences and thoughts that are the essence of being human (and cannot be defined or measured).

The field of consciousness studies has brought together philosophers, psychologists, neuroscientists*, physicians, and other researchers to discuss this and other issues related to consciousness. Their first major gathering was held in Tucson, Arizona, in 1994, and many meetings occurred after that. This young field of study and research holds great promise for furthering people’s understanding of the mind.

Constipation

Constipation is a condition that involves difficulty in having a bowel movement or involves having stools (solid waste material from the body) that are dry and hard.

What Is Constipation?

Normal bowel movement patterns vary from person to person. Some people move their bowels as often as after every meal. Other people may move their bowels every three days or so. Both of these patterns may be normal.

With constipation a person feels discomfort and has irregular bowel movements. The difficulty comes from the dry, hard condition of the stool. Constipation may be associated with many medical illnesses.

What Causes Constipation?

Several factors can contribute to constipation, such as not eating enough fiber or drinking enough fluids, inactivity, or not developing regular toilet habits. Certain medical conditions such as irritable bowel syndrome or hypothyroidism* are associated with constipation. Sometimes the medicine people take for other illnesses causes them to become constipated. Pregnant women frequently develop constipation, also.

Constipation can occur when a person withholds stool and the intestines reabsorb the water in the stool, causing it to become harder. Withholding the stool can happen if a person is not comfortable having a bowel movement, for example, when traveling or if the toilet area is considered unsafe or unpleasant.

What Is the Treatment for Constipation?

Although many people take laxatives (LAK-sa-tivs) for constipation, doctors warn that these should not be taken regularly because the intestines may become sluggish and dependent on laxatives. Instead, it is recommended that people eat a diet that is rich in fiber. Foods that have fiber are whole grains, such as bran or whole wheat, beans, fruits, and vegetables. Eating mostly foods that contain a lot of starch or sugar, as in cookies and cakes, does not give the body enough fiber for good

digestion and proper elimination. Also, it is important to drink sufficient amounts of water.

In serious cases of constipation, a person may need to be examined by a doctor and possibly be given an enema (EN-e-ma), which is a process of putting fluid into the rectum to loosen the stool. The doctor also may prescribe medication to help the patient regain regular bowel habits.

For a child who develops a serious case of constipation, the doctor may help by providing a habit-training program. In addition to being instructed about proper diet and increased water intake, the child may be given medicine to help develop regular toilet habits.

Can Constipation Be Prevented?

Most people can prevent constipation by following a regular routine for bowel movements. Here are some habits that help prevent constipation:

- Eating foods rich in fiber
- Avoiding junk foods
- Drinking sufficient water every day
- Having regular toilet habits
- Engaging regularly in exercise
- Getting plenty of rest

- * **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.
- * **psychoanalysis** (sy-ko-a-NAL-i-sis) is a method of treating a person with psychological problems, based on the theories of Dr. Sigmund Freud. It involves sessions in which a therapist encourages a person to talk freely about personal experiences, and the psychoanalyst interprets the patient's ideas and dreams.

Conversion Disorder

Conversion disorder is a psychological condition in which a person loses physical abilities such as seeing, hearing, or speaking, or becomes paralyzed, but doctors can find no physical cause to explain the symptoms. Symptoms of conversion disorder often begin after some stressful experience, and the medical community traditionally has considered them an expression of emotional conflict or need.

What Is Conversion Disorder?

Conversion disorder is a mental disorder in which psychological symptoms are converted to physical symptoms, such as blindness, paralysis*, or seizures*. Seizures may involve sudden episodes of eye staring; twitching or thrashing of arms and/or legs; and may or may not involve loss of consciousness. Unlike malingering, in which a person fakes an illness or injury, a person with conversion disorder does not intentionally produce symptoms.

Conversion disorder is rare, occurring in only about one to three out of 10,000 people. It is even less common in children younger than 10 years of age. Conversion disorder can be triggered by extreme psychological stress, such as injury, death of a loved one, or enduring a dangerous situation. For example, in wartime, some soldiers who experience heavy bombardment but are not wounded are hospitalized because they cannot walk or speak after the combat experience. Conversion disorder under these circumstances has been called shell shock and battle fatigue. In this case and for those people facing other highly stressful situations, conversion disorder appears to occur as a way to help the individual avoid or escape from a life-threatening, tension-filled conditions.

What Causes Conversion Disorder?

An earlier term for conversion disorder is “hysteria.” Physicians in ancient Greece believed that hysteria only occurred in females and that it was caused by the uterus* wandering in the body (the Greek word for “uterus” is “hystera”). For centuries thereafter, people with hysteria were regarded as fakers or as imagining their symptoms. In the 17th century, some townspeople thought that people with hysteria were involved with witchcraft and burned them at the stake.

The term “conversion disorder” came into use only in the late 20th century. It is derived from the early work of the Austrian physician Sigmund Freud (1856–1939), the founder of psychoanalysis*. Freud believed that in times of extreme emotional stress, painful feelings or conflicts are repressed (kept from awareness or consciousness) and are converted into physical symptoms to relieve anxiety. Even in the 21st century, mental health experts do not all agree on the precise psychological mechanisms underlying conversion disorder. Many mental health professionals, however, see the benefits associated with the symptoms of

conversion disorder, such as sympathy, care, and the avoidance of stressful situations, as significant to the disorder.

What Are the Symptoms of Conversion Disorder?

Sometimes people with conversion disorder have tremors or symptoms that resemble fainting spells or seizures. An individual may also experience loss of feeling in various parts of the body or loss of the sense of smell and symptoms may occur together. For instance, following an automobile accident a person may be unable to move or feel sensation in an arm or leg, even though no injury to the limb is apparent. Other people may have difficulty swallowing or feel like they have a lump in their throat. Interestingly, some people with conversion disorder may seem quite comfortable with their symptoms, even though they may be greatly handicapped by them.

How Is Conversion Disorder Diagnosed and Treated?

To diagnose conversion disorder, a doctor must first rule out other possible physical causes of a patient's symptoms. To discount some of the physical disorders, the doctor may use special instruments that measure electrical activity in the muscles and the brain. In addition, experienced physicians using close observation can often discover important diagnostic clues. For example, without realizing it, a patient may momentarily use an arm or a leg that is supposed to be paralyzed. This clue would indicate that the symptom is psychological rather than physical and might indicate conversion disorder. To make sure that the patient is not just pretending to be ill, a mental health professional conducts a clinical interview to learn about the history of the individual and family, stressors that may be present, benefits the patient derives from the symptoms, and what factors may be sustaining the symptoms.

Conversion disorder is typically treated with psychotherapy*. The therapist attempts to help the patient understand whatever unconscious emotional conflicts, needs, or gains may have given rise to the symptoms. In some instances, symptoms of the disorder may last for years. With treatment, however, the symptoms of conversion disorder frequently last for only brief periods.

Corneal Abrasion

A corneal abrasion is an injury to the cornea of the eye.

What Is Corneal Abrasion?

Corneal abrasion is an injury to the cornea*. When the surface cells that cover the eyeball are injured, some of these cells are removed and damaged, which can be painful.

What Causes Corneal Abrasion?

Corneal abrasion usually occurs accidentally, when something scratches the eye. Poorly cleaned contact lenses, a finger poke to the eye, a grain of sand or other foreign body can all result in corneal abrasion.

Who Gets Corneal Abrasion?

Anyone can get a corneal abrasion, although children, active teenagers and adults, and older debilitated adults are most prone to this injury. Corneal abrasion is the most frequent diagnosis given to children who seek treatment in emergency departments for eye injury.

What Are the Symptoms of Corneal Abrasion?

Corneal abrasion usually causes intense tearing and discomfort. Light often hurts the eye, and individuals may notice the uncomfortable sensation of something gritty being in their eye. Pain may be worse when attempting to open or close the affected eye, and the eye may be red, somewhat bloodshot, and swollen in appearance.

How Is Corneal Abrasion Diagnosed?

Corneal abrasion is usually suspected from a history of likely injury and the characteristic symptoms of pain, light sensitivity, and tearing. The actual abrasion can be seen by an eye examiner. Eye drops containing a fluorescein dye are put into the affected eye, and a slit lamp is used to look at the eye in an otherwise darkened room. Other tests may be performed to make sure that there is no other, more serious injury to the eye, such as checking vision, evaluating the pressure within the eye (intraocular pressure), making sure there is no deeper cut to the cornea that would require surgical repair,

identifying foreign bodies that need removal, and verifying that no other serious disease of the eye is causing the symptoms.

How Is Corneal Abrasion Treated?

Luckily, the surface of the eyeball repairs itself very quickly (within 24 to 72 hours), and without significant medical intervention. Although corneal abrasions were traditionally treated by patching the affected eye to improve comfort during the period of time when the eye is particularly light sensitive, teary, and painful, this practice was later considered controversial. Some studies have suggested that patching (especially patching that is designed to apply pressure to the eye) can deprive the eye of necessary oxygen and slow healing or may increase the risk of infection. Anti-inflammatory eye drops may be soothing. Antibiotic eye drops may be prescribed if there is any possibility of infection.

Can Corneal Abrasion Be Prevented?

Prevention of corneal abrasion is not always possible, because it usually occurs due to a random accident. However, athletes and people whose occupations expose them to dirt, dust, cement and metal particles, or chemicals should be encouraged to wear appropriate protective eyewear to decrease their risk of this type of injury.

* **gastrointestinal** (gas-tro-in-TES-tih-nuhl) means having to do with the organs of the digestive system, the system that processes food. It includes the mouth, esophagus, stomach, intestines, colon, and rectum and other organs involved in digestion, including the liver and pancreas.

* **enterovirus** (en-tuh-ro-VY-rus) is a group of viruses that can infect the human gastrointestinal tract and spread through the body causing a number of symptoms.

* **poliomyelitis** (po-lee-o-my-uh-LYE-tis) is a condition caused by the polio virus that involves damage of nerve cells. It may lead to weakness and deterioration of the muscles and sometimes paralysis.

* **hepatitis** (neh-puh-TIE-tis) is an inflammation of the liver. Hepatitis can be caused by viruses, bacteria, and a number of other noninfectious medical conditions.

* **echoviruses** A group of viruses found in the intestinal tract. The word echo in the name is acronym for enteric cytopathic human orphan viruses. When these viruses were named, they were not associated with any disease, hence the use of the word orphan. However, later these viruses were associated with various diseases, including meningitis and encephalitis.

* **feces** (FEE-seez) is the excreted waste from the gastrointestinal tract.

Coxsackievirus and Other Enteroviruses

The enteroviruses (en-tuh-ro-VY-rus-sez) are a family of viruses that usually enter the body by infecting the gastrointestinal tract. They cause several types of infection, mostly in children. Coxsackieviruses (kok-SAH-kee-vy-ruh-sez) are some of the most well known enteroviruses.*

What Are Enteroviruses?

There are many different kinds of viruses in the enterovirus* family, which cause infections with different symptoms, mostly in children. These viruses make their home in the digestive tract and are related to the viruses that cause poliomyelitis* and hepatitis*. The largest subgroups of the enterovirus family are coxsackieviruses and echoviruses*. In most cases, coxsackievirus infection causes fever and sometimes a mild rash in children, but a variety of other symptoms can occur. Coxsackievirus is well known for its link to hand, foot, and mouth disease, which causes red bumps and blisters to appear inside the mouth and on the hands and feet.

Are Enteroviruses Contagious?

Everyone is at risk of contracting enteroviral infections, but they most commonly infect infants and children younger than five years of age and spread easily among children in group settings, such as day-care centers or schools. These viruses are most likely to cause infections during late summer and early fall and are very contagious. People with coxsackievirus are most contagious during the first week that they are sick.

How Are Enteroviruses Spread?

Enteroviruses are usually spread through contact with feces*, especially on unwashed hands and on surfaces that an infected person has touched, such as a countertop, phone, or toy. The viruses can stay alive for days on these surfaces, able to infect the next person who touches the contaminated area. Parents, babysitters, and day-care workers who change diapers typically have a higher risk of becoming infected with enteroviruses and passing them on to others, especially if they do not wash their hands often. Like many other viruses, enteroviruses also can spread through tiny droplets of fluid that are sprayed into the air when someone sneezes, coughs, or stands close to another person while talking. A person can become infected by breathing in these droplets or by touching something that the infected person has handled, sneezed at, or coughed on.

What Are the Signs and Symptoms?

Many people who become infected with enteroviruses have no symptoms or experience only mild symptoms that do not require medical attention. Some have a fever and a rash, whereas others may get a sore throat,

headache, mild abdominal* pain, or nausea. Fever can be as high as 104 degrees Fahrenheit and may come and go over the course of several days. Some enteroviruses can cause conditions characterized by groups of specific symptoms:

- Hand, foot, and mouth disease: red, painful blisters on the tongue and gums, inside the cheeks, on the palms of hands and the soles of feet, and sometimes on the buttocks.
- Herpangina (her-pan-JY-na): sore throat with blisters that appear on the tonsils and palate*.
- Pleurodynia (ploor-o-DIN-e-uh), also known as Bornholm disease: stabbing pain in the chest or upper abdomen.
- Hemorrhagic conjunctivitis (heh-muh-RAH-jik kon-jung-tih-VY-tis): sudden and severe eye pain with red and watery eyes, eye swelling, and sometimes blurred vision. Rarely, enteroviruses can cause myositis*, meningitis*, or encephalitis*. Myocarditis* or pericarditis* can also occur. In some cases, these infections can be serious or even lead to death.

How Do Doctors Diagnose and Treat Enteroviruses?

Usually a doctor diagnoses an enterovirus infection by getting a history of the patient's symptoms and performing a physical exam, paying particular attention to any rash or blisters. Sometimes doctors use cotton swabs to take a fluid sample from the back of the mouth or throat, which is tested to find out if an enterovirus is present. Samples of feces also might be tested. Like other viral infections, enteroviral infections do not respond to antibiotics, which treat only bacterial infections. Some antiviral medications can be used to treat some severe cases of enterovirus infection. Usually, treatment is aimed at relieving discomfort. Doctors recommend that people with these viruses get plenty of rest, drink cool fluids, and take over-the-counter, non-aspirin pain relievers such as acetaminophen* to ease fever, headache, muscle aches, and painful mouth blisters. Doctors may prescribe a medicated cream or gel to numb sores inside the mouth or on the gums or tongue. Rarely, hospitalization is necessary for infants and children who experience complications.

- * **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.
- * **palate** (PAL-it) is the structure at the roof of the mouth. Damage or poor functioning of the palate can affect swallowing, the voice, and breathing.
- * **myositis** (my-oh-SY-tis) is an inflammation of the muscles.
- * **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.
- * **encephalitis** (en-seh-fuh-LYE-tis) is an inflammation of the brain, usually caused by a viral infection.
- * **myocarditis** (my-oh-kar-DYE-tis) is an inflammation of the muscular walls of the heart.
- * **pericarditis** (per-ih-kar-DYE-tis) is an inflammation of the sac surrounding the heart.
- * **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

DID YOU KNOW?

Coxsackievirus got its name from the town of Coxsackie, New York, the site of the first recognized outbreak of the virus infection in 1948.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

How Long Do Enterovirus Symptoms Last and What Are the Complications?

Enteroviruses can cause illness that lasts from three days to two weeks, depending on the type of infection. Fevers usually last a few days, whereas rash and blisters take longer to disappear. Dehydration* can become a problem, especially in infants and young children, because mouth sores can make eating and drinking painful. In such cases, intravenous* fluids may be required. It is recommended that people with enterovirus infections seek medical attention if they start to experience pain in the chest or abdomen, a sore throat that does not improve, difficulty in breathing, severe headaches, neck stiffness, or vomiting.

How Are Enterovirus Infections Prevented?

There is no vaccine to prevent enterovirus infections. As with most contagious infections, washing hands with soap and water after going to the bathroom, changing diapers, shaking hands with other people, and touching surfaces, especially those in public places, may help prevent the spread of infection. It is a good idea to cover the mouth and nose when coughing and sneezing and to avoid contact with other people who are coughing and sneezing. It is recommended that toys shared by infants and toddlers, especially in day-care settings, be cleaned daily with a disinfectant because enteroviruses and other viruses can survive on them for days. Doctors usually advise that an infected child be kept out of day care or school for a few days to avoid spreading the virus to others.

Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob (KROYTZ-felt YAH-kub) disease is a fatal disorder of the brain.

What Is Creutzfeldt-Jakob Disease?

Described first in 1920 by German neurologist* Hans Gerhard Creutzfeldt (1885–1964) and Alfons Maria Jakob (1884–1931), Creutzfeldt-Jakob disease (CJD) is a very rare, slowly progressing and fatal disease of the brain. It is a form of transmissible* spongiform encephalopathy (SPUN-ji-form en-sef-a-LOP-a-thee), which means it causes the brain to become a sponge-like mass as it deteriorates. CJD damages the tissues of the brain, causing a rapid decline in mental function and muscle coordination, eventually leading to death. While most people who contract the disease die within several months, some people decline more slowly and may survive between one and two years after they are diagnosed. Creutzfeldt-Jakob disease usually affects people over 50 years of age, but a variant of the disease strikes younger people.

Because Creutzfeldt-Jakob disease affects the brain, its primary symptom is dementia* (dih-MEN-sha). Some signs of dementia are disorientation, neglect of personal hygiene and grooming, and irritability. Other symptoms are fatigue, insomnia*, and muscle twitching or sudden contractions. With no known cure as of 2009, medical treatment focused on palliative* care (intended to give comfort) designed to make people with CJD as comfortable as possible.

A tiny transmissible protein called a prion triggers CJD. The protease resistant protein (PRP) is found throughout the body in healthy people and in animals. However, it has two basic configurations, one diseased and one healthy. Its diseased configuration is believed to be the infection's agent. Essentially, the diseased protein is a misfolded protein, and it is thought that the misfolded protein is able to convert healthy protein molecules (simply by coming into contact with them) into the abnormal configuration. CJD is divided into three categories:

- Familial CJD, which accounts for up to about 10 percent of cases. In these instances, there exists a family history of the disease, and it has been theorized that in affected persons a mutation* has occurred in the gene that codes for PRP, suggesting that certain genes* shared by family members make them more susceptible to CJD.
- Sporadic CJD, in which afflicted people have no known risk factors for the disease and which make up about 85 percent of occurrences.
- Acquired or iatrogenic CJD, in which the defective protein is transmitted to an uninfected person due to exposure to infected brain or spinal tissue and which is the rarest form. Less than 5 percent of all cases result from exposure to infected brain or spinal tissue, occurring usually during a medical procedure.

CJD belongs to a family of diseases known as transmissible spongiform (SPUN-jih-form) encephalopathies (en-seh-fuh-LAH-puh-theez) (TSEs). Spongiform refers to the post-mortem appearance of brain tissue affected by the disease: The damaged tissue is riddled with holes, much like a

* **neurologist** (new-RHAL-eh-jist) a physician who specializes in diagnosing and treating diseases of the nervous system.

* **transmissible** (trans-MIH-sih-bul) means able to be transferred or spread.

* **dementia** (dih-MEN-sha) is a loss of mental abilities, including memory, understanding, and judgment.

* **insomnia** abnormal inability to get adequate sleep.

* **palliative** (PAL-ee-at-iv) means to ease or relieve without curing.

* **mutation** (myoo-TAY-shun) is a change in an organism's gene or genes.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

- * **kuru** (KUR-ew) is a progressive, fatal brain disease characterized by tremors and loss of muscle coordination that is caused by eating contaminated brain tissue from other humans who had the disease.
- * **scrapie** (SKRAY-pee) is a fatal brain disorder of sheep that is characterized by itching of the skin and difficulty walking.
- * **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.
- * **cornea** (KOR-nee-uh) is the transparent circular layer of cells over the central colored part of the eyeball (the iris) through which light enters the eye.
- * **dura mater** (DUR-uh MAY-ter) is the outermost of three membranes covering the brain and spinal cord.
- * **grafts** are tissue or organ transplants.
- * **pituitary** (pih-TOO-ih-tare-e) is a small oval-shaped gland at the base of the skull that produces several hormones—substances that affect various body functions, including growth.
- * **growth hormone** is a chemical substance produced by the pituitary gland that regulates growth and other body functions.
- * **cerebrospinal fluid** (seh-ree-bro-SPY-nuhl) is the fluid that surrounds the brain and spinal cord.

sponge. Other diseases in the CJD family are kuru*; bovine spongiform encephalopathy (BSE), which infects cattle and is known as mad cow disease; and scrapie*, which affects sheep, goats, and other animals. CJD generally affects people over the age of 50. However, in 1996 scientists identified a new form of CJD, called variant CJD or new variant CJD (vCJD), which typically affects people under the age of 30 and causes different symptoms. As of 2009, cases of vCJD had been limited mostly to the United Kingdom and France, and all the people in whom vCJD developed were exposed to areas where BSE had been found.

How Common Is Creutzfeldt-Jakob Disease?

CJD is rare. It occurs in one person per one million people worldwide. In the United States, about 200 cases are diagnosed annually. The age of onset for classical CJD is between 50 and 75 years, with the average age of onset about 60 years of age. About 90 percent of cases end in death within one year after symptoms begin, while the remaining 10 percent of people with CJD survive for one to two years.

Is Creutzfeldt-Jakob Disease Contagious?

Although CJD is transmissible, it does not appear to spread through usual types of direct person-to-person contact. CJD can be transmitted through contact with infected brain or central nervous system* tissue or fluid, contact that arises usually only during a medical procedure. For example, the disease has been reported to have occurred after cornea* transplants and dura mater* grafts*, following injection of human pituitary*-derived growth hormone*, and after contact with medical instruments that were used during brain surgery or other surgery on a person with the disease. Cerebrospinal fluid* can be responsible for the spread of CJD, but there is no evidence of transmission of the disease through other body fluids, including saliva, blood, or urine. Variant CJD has occurred only where cases of BSE also have been found, leading researchers to theorize that eating beef from cattle with BSE could spread the agent and lead to CJD in humans. Although this explanation was widely accepted, it had not been proved as of 2009.

What Are the Signs and Symptoms of Creutzfeldt-Jakob Disease?

The most characteristic symptom of CJD is quickly worsening dementia, including memory loss and impaired thinking. Patients often have problems with vision and muscle coordination. The inability to sleep, unusual sensations, and depression are also common. Many patients experience muscle jerking known as myoclonus (my-AH-kloh-nus), which consists of brief, rapid muscle contractions. If the disease was contracted from infected human tissue (such as from a transplanted cornea), symptoms may not appear for decades after exposure to the contaminated tissue. Variant CJD at first causes psychiatric (sy-kee-AH-trik) symptoms, such as depression, anxiety (ang-ZY-uh-tee), or personality changes; dementia and myoclonus typically occur later than in classic CJD.

How Is Creutzfeldt-Jakob Disease Diagnosed?

CJD can be diagnosed by a brain biopsy (BI-op-see), which requires removing a small piece of brain tissue during surgery to examine for signs of the disease, or at an autopsy*. Other, less invasive tests may point to a diagnosis of CJD or help to exclude other diagnoses, such as meningitis or encephalitis. During a physical examination, the doctor checks for muscle twitching and spasms. An eye exam may show areas of blindness that the patient may not have noticed, and a spinal tap* and blood tests may identify certain proteins associated with CJD. An electroencephalogram

MAD COW DISEASE AND THE HUMAN CONNECTION

In 1986, the brain disease called bovine spongiform encephalopathy (BSE) was discovered in cows. Termed “mad cow disease” because the infected cows stumbled and lost muscular coordination, the disease had been transmitted to the cows from feed made from ground sheep bones and parts. The sheep disease scrapie had been passed on to the cattle. (Scrapie is another form of spongiform encephalopathy found in sheep that causes them to lose coordination and exhibit behavior described as scraping up against the fences of their pastures.)

It was thought that the infectious agent of mad cow disease could not be passed on to people, but the British Ministry of Health discovered a variant form of CJD in people younger than the average age for CJD cases. BSE was subsequently linked to variant CJD. The practice of feeding cows sheep parts may have caused an epidemic* of BSE among cows in the United Kingdom, so in 1988 this feeding practice was banned. Countries all over Europe and other parts of the world began to ban the import of beef from Britain, and millions of cattle in Britain were killed in order to avoid spreading the disease. Many people turned to vegetarian diets, and many restaurants stopped serving beef. The number of new BSE cases dropped sharply, and then the ban on beef coming from the United Kingdom in the United States was lifted.

To further prevent the transmission of mad cow disease to humans, surveillance programs were put into effect to test cows for the disease before they are allowed to enter the food chain. The number of cows tested varies by country, as does the type of cow tested. Some countries test only cows that have been classified as “downer cows,” or cows that cannot walk, for BSE. Other countries test a selection of seemingly healthy cows as well as downer cows and test a greater number of cows than are tested in the United States. The U.S. government tests only a sample of cows from the population to screen for BSE. In 2007, the Department of Agriculture’s Food Safety and Inspection Service (FSIS) announced a permanent prohibition on the slaughter of downer cattle for food processing. The U.S. government only allows the animals with healthy appearance to be used as food, and it maintains meat removal practices that keep brain and spinal cord matter from getting into processed meat.

Variant Creutzfeldt-Jakob disease has occurred only where cases of bovine spongiform encephalopathy also have been found, leading researchers to theorize that eating beef from cattle with BSE could spread the agent. In France and England whole herds of cattle have been put to death in an effort to prevent the spread of disease. *AP Images.*

* **autopsy** (AW-top-see) is an examination of a body after death to look for the cause of death or the effects of a disease.

* **spinal tap** also called a lumbar puncture, is a medical procedure in which a needle is used to withdraw a sample of the fluid surrounding the spinal cord and brain. The fluid is then tested, usually to detect signs of infection, such as meningitis, or other diseases.

* **epidemic** (eh-pih-DEH-mik) is an outbreak of disease, especially infectious disease, in which the number of cases suddenly becomes far greater than usual. Usually epidemics are outbreaks of diseases in specific regions, whereas widespread epidemics are called pandemics.

Genetically Engineered Bacteria to the Rescue

Growth hormone once was obtained from the pituitary glands of cadavers (corpses), and patients who needed injections of growth hormone were at risk of getting CJD. Later growth hormone was produced in laboratories by inserting the genes controlling the production of growth hormone into bacteria, thus avoiding the need to extract the hormone from human tissue and eliminating the risk of transmitting CJD.

* **microorganism** is a tiny organism that can be seen only by using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

ARE PRIONS INFECTIOUS?

Like bacteria, viruses, and parasites, prions, which are abnormal versions of widely occurring protein particles, have been linked to certain transmissible diseases. Yet prions are different from other infectious agents. Whereas microorganisms* contain genetic material, prions do not, which means that prions are not alive. According to the prion theory, the protein (PRP) at first cannot cause or transmit disease. Instead, it undergoes a change that causes it to fold into a different shape, its “infectious” form. When one of these abnormal proteins enters a brain cell in the course of CJD, it binds to normal proteins, causing them to change shape. This sets off a chain reaction that leads to cell death and the release of more prions that will, in turn, enter and affect more cells. As cells die, holes form in brain tissue, giving it the characteristic sponge-like appearance. Prions can be acquired during a medical procedure or from some other exposure to brain tissue or fluids containing brain tissue. In the inherited form of CJD, it is believed that a gene mutation causes some normal protein to change into prions under certain conditions.

(EEG) test records electrical activity in the brain and may show a pattern of brain waves seen in many patients with CJD, although the typical EEG findings are not present in vCJD. Some people with CJD have negative test results, making a diagnosis difficult without a brain biopsy.

What Is the Treatment and Course of Creutzfeldt-Jakob Disease?

Because CJD cannot be cured, the goal of treatment is to make the patient as comfortable as possible. Medications can help control aggressive behavior, lessen pain, and ease muscle jerks. Dementia can progress to loss of speech, the inability to take care of oneself, blindness, and even coma*. As patients become bedridden, they are vulnerable to infections, such as pneumonia, and most eventually need to be hospitalized. Many patients die within a year after symptoms appear.

How Can Creutzfeldt-Jakob Disease Be Prevented?

No measures known as of 2009 could prevent the onset of CJD in a person whose brain tissue contains the prion. Because the ways by which the disease can be transmitted were still not fully understood, blood banks forbid people with confirmed or suspected CJD or those who may be at high risk, such as people with a family history of the disease, to donate blood, and doctors advise that they not be organ or tissue donors. Family members of a person with CJD may wish to have genetic counseling to learn more about any family risk. Special handling of surgical instruments can limit the chance of transmission during certain medical procedures, particularly those involving the brain.

Crohn's Disease

Crohn's disease is an inflammation of the alimentary canal. Inflammation from the disease can occur anywhere along the canal from the mouth the anus although it usually starts in the lower part of the small intestine, called the ileum, or in the colon. Its signs and symptoms vary widely among afflicted individuals.

What is Crohn's Disease?

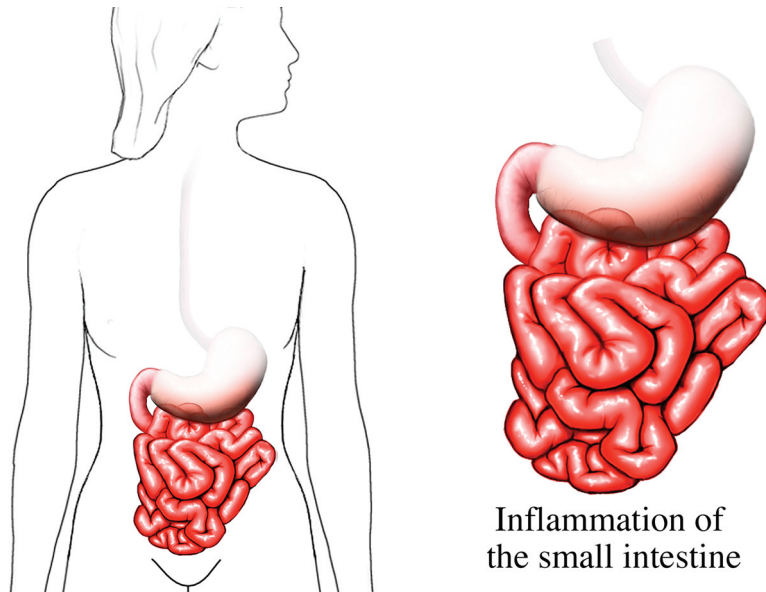

Crohn's disease is an inflammation of the alimentary canal for which the cause was unknown as of 2009 but the characteristics were well defined. The alimentary canal includes the mouth, esophagus, stomach, intestines, colon, and rectum. Inflammation from the disease can occur anywhere along the canal from the mouth the anus. It usually starts in the lower part of the small intestine, called the ileum, or in the colon.

The disease was named after American gastroenterologist Burrill Bernard Crohn (1884–1983), who described its symptoms in 1932 after observing various symptoms in patients all with an inflamed terminal ileum (the portion of the small intestine most distant from the digestive tract).

Classified as a type of inflammatory bowel disease (IBD), Crohn's disease can often be present simultaneously at various locations within the digestive tract. In fact, among its most characteristic features is the

Inflammation of the small intestine is a symptom of Crohn's Disease.

© Nucleus Medical Art, Inc./Alamy.

* **ulcers** are open sores on the skin or the lining of a hollow body organ, such as the stomach or intestine. They may or may not be painful.

presence of inflamed regions of intestine separated by apparently normal regions called skip areas. Another characteristic feature is that the inflammation goes through all layers of the intestinal wall from the innermost mucosal layer through the outermost serosal layer. The intense transmural nature of the inflammation explains the frequent stricture formation in the presence of holes, called fistulae, which pierced the intestinal wall. Because the inflammation can be at multiple sites, its signs and symptoms vary widely among afflicted individuals.

What Are the Signs and Symptoms of Crohn's Disease?

The visible signs and symptoms of Crohn's disease vary widely among individuals, and they may appear abruptly or take a long time to show up. However, overall, the primary signs and symptoms are:

- **Abdominal pain.** The bowel is likely to swell when inflammation occurs in its walls. Eventually, scar tissue may form, which can cause short areas of narrowing, called strictures, which obstruct the flow of intestinal contents and stretch the intestinal wall upstream to the stricture. This dilating, or stretching, of the intestine causes pain. Small ulcers (in minor cases) and large ulcers* (in more serious cases) that often penetrate into, or through, the tissues of the wall. These problems likely lead to reduced flow of digestive materials, which can lead to some discomfort at first with intensifying pain and cramping later on.
- **Bloody stool.** As food passes through the digestive tract, it can cause the inflamed, and sometimes ulcerated, tissues to bleed. The stool rarely appears as reddish in color as it often does in ulcerative colitis, another inflammatory bowel disease.

- **Diarrhea.** Inflammation of the digestive tract causes its tissues to secrete a saltwater-like solution. (Crohn's disease does not generally produce a secretory type of diarrhea. The diarrhea generally results from a combination of malabsorption and maldigestion along with intestinal motility disorder characterized by areas of partial structure and with brushes of intestinal content.) This buildup of liquids in the colon can produce loose stools—somewhat less firm than normal in minor cases, but much more liquid in severe cases. In these major cases, the patient can have multiple bowel movements each day.
- **Fistula or abscess.** Inflammation of the digestive tract can become so severe that the tract expands into other bodily organs. Such activity produces a fistula, or a physical connection between the other organs and the digestive tract. In other cases, an abscess* can be produced; that is, a pus-filled swollen sore.
- **Mouth ulcer.** Besides ulcers in the digestive tract, small sores, which look and feel like canker sores, may appear in the mouth.
- **Weight loss.** A reduced appetite and, consequently, weight loss usually result as inflammation in the digestive tract reduces a person's ability to digest and absorb nutrients throughout the body. Nausea and vomiting also contributes to weight loss.

When severe cases of Crohn's disease occur, other signs and symptoms can include arthritis, eye inflammation, fatigue, fever, inflammation of a bile duct* or the liver, and skin rashes. The signs and symptoms associated with the disease become more numerous and severe as the inflammation travels into more regions of the digestive tract. Crohn's disease is usually not a fatal condition. However, if left untreated, it can become a serious problem that can endanger the life of the patient.

How Is Crohn's Disease Diagnosed?

Especially when abdominal pain, bloody stool, bowel habit changes, diarrhea, and unexplained fever are present, a medical professional should be consulted. The professional, possibly a gastroenterologist (a person specializing in diseases of the digestive system), will likely use some of the following tests to identify the problem:

- **Upper gastrointestinal (GI) series:** Crohn's disease most frequently involves the upper GI tract, and upper GI series is generally done before a barium enema in suspected cases.
- **Barium enema:** Barium, a chalky solution that improves x-ray images. A barium enema is introduced into the lower gastrointestinal tract through a tube inserted into the anus before the observation of the large intestine.
- **Blood tests:** To analyze the blood for signs of inflammation and the presence of antibodies
- **Colonoscopy:** To observe the physical characteristics of the interior of the colon

* **abscess** (AB-ses) is a localized or walled off accumulation of pus caused by infection that can occur anywhere in the body.

* **bile duct** is a passageway that carries bile, a substance that aids the digestion of fat, from the liver to the gallbladder (a small pouch-like organ where the bile is temporarily stored) and from the gallbladder to the small intestine.

* **computerized tomography**

(kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **endoscopy** (en-DOS-ko-pee) is a type of diagnostic test in which a lighted tube-like instrument is inserted into a part of the body.

* **autoimmune diseases** (aw-toh-ih-MYOON) are diseases in which the body's immune system attacks some of the body's own normal tissues and cells.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **remission** is an easing of a disease or its symptoms for a prolonged period.

- Small bowel x-ray: To take pictures of the small bowel
- Computerized tomography* (CT) scans: To provide extra details that x-rays cannot convey
- Flexible sigmoidoscopy: To examine the sigmoid, which is the last segment of the colon
- Capsule endoscopy*: If all other tests result in a negative diagnosis, to have a video recording of the digestive tract by placing a minuscule camera inside a capsule, which is swallowed by the patient so it can record the entire length of the digestive tract

What Are the Causes of Crohn's Disease?

The exact physical cause of Crohn's disease was not known as of 2009. However, medical professionals think that genetic factors have something to do with causing the disease, as is the case with most autoimmune diseases*. About 20 percent of all patients have family members with the disease. Mutations (changes) in specific genes are believed to be the basis of this genetic problem.

Crohn's disease may also be caused by a problem with the person's immune system*. Bacteria or viruses may invade the human body and when the immune system tries to counter the germs, the digestive tract becomes inflamed. In another scenario, an abnormally functioning immune system may attack bacteria normally found in the intestines. Such action also causes the digestive tract to become inflamed. These theories were considered possible explanations as of 2009.

Some medical professions think that Crohn's disease is not caused by long-term anxiety and stress or any particular diet and eating habits. However, both emotional stress and diet are likely to complicate the condition.

How Is Crohn's Disease Treated?

A cure for Crohn's disease was not known as of 2009. Its treatment options aim to control the progression of the disease and the severity of the symptoms. If the disease goes into remission*, then such treatments help to minimize the chance that patients will relapse. When treatments are successful, most patients with Crohn's disease return to their normal daily lives.

Anti-inflammatory drugs are commonly the first step to treat Crohn's disease. Corticosteroids, mesalamine (Asacol, Rowasa), and sulfasalazine (Azulfidine) are among the anti-inflammatory drugs used.

Immune system suppressor drugs are used in some cases. Commonly used immune system suppressors are adalimumab (Humira), azathioprine (Imuran), infliximab (Remicade), and mercaptopurine (Purinetholand).

Antibiotic drugs are used to control abscesses and fistulas and to reduce intestinal bacteria—both problems that cause more severe symptoms among patients with Crohn's disease. Two frequently used antibiotics are ciprofloxacin (Cipro) and metronidazole (Flagyl).

WHAT CAN BE DONE IF TRADITIONAL TREATMENTS DO NOT WORK?

The National Center for Complementary and Alternative Medicine (NCCAM) was established by the National Institutes of Health (NIH) to provide resources and information for the non-traditional treatment of diseases such as Crohn's disease. Medical studies have shown that one out of two persons with Crohn's disease tries complementary or alternative therapies and medicines. However, medical science had not determined as of 2009 if these non-traditional treatments work. For the most part, the Food and Drug Administration does not regulate herbal and nutritional supplements used in such treatments. In addition, most Crohn's disease patients do not report non-traditional medicines to their family doctor, so their effectiveness has not been well documented. The web site of the NCCAM is <http://nccam.nih.gov>.

Other medicines used include anti-diarrheals, laxatives, pain relievers, along with supplements, including calcium, iron, vitamin B-12, and vitamin D. A special diet may also be prescribed to reduce the severity of symptoms.

As a last resort to relieve symptoms, surgery may be performed to remove one or more inflamed or severely damaged sections of the digestive tract. Surgery may also be recommended to eliminate fistulas or remove scar tissue. A surgical procedure is often used to widen a narrowed section of intestine. Many patients with Crohn's disease eventually have some type of surgery, and since the relief from surgery is temporary, many individuals have more than one surgery as their disease progresses.

Who Gets Crohn's Disease?

About 500,000 people in North America are afflicted with Crohn's disease. Men and women are equally at risk for getting the symptoms associated with the disease. People of all ages can develop the condition. However, teenagers and young adults in their 20s and 30s are most likely to get it, followed by people in their 50s to 70s.

Any ethnic group can acquire Crohn's disease. However, Caucasians have the highest risk. In fact, people of Jewish and European descent are four to five times more likely to get the disease than any other ethnic groups.

A person's immediate family is another important consideration when evaluating risk. If a person within an immediate family has Crohn's disease, then the other family members are at least thirty times more likely to get it than anybody else outside that family.

In addition, a person who uses tobacco is more likely to develop Crohn's disease than a non-smoker. The use of tobacco products during treatment also makes the disease much more difficult to treat successfully.

- * **trachea** (TRAY-kee-uh) is the windpipe—the firm, tubular structure that carries air from the throat to the lungs.
- * **larynx** (LAIR-inks) is the voice box (which contains the vocal cords) and is located between the base of the tongue and the top of the windpipe.
- * **stridor** (STRY-dor) is a high-pitched, squeaking noise that occurs while breathing in, present usually only if there is narrowing or blockage of the upper airway.

The physical environment in which people live is thought to be a contributing factor for developing Crohn's disease. Studies have found that people living in industrialized countries, especially those inside heavily polluted cities, are at higher risk for the disease than people living in non-industrialized countries and cities with clean air.

Croup

Croup (KROOP) is the name for a group of conditions, typically occurring in childhood, in which the trachea (windpipe) and larynx (voice box) become inflamed, and the upper airway narrows. As a result, croup can sometimes make breathing difficult. The characteristic symptom is a barking cough, which may be accompanied by a grunting or wheezing noise when the child inhales. Although the breathing difficulties frequently cause considerable alarm among parents, most children recover from croup without any complications.

What Is Croup?

Croup is an inflammation of the throat, and specifically the trachea* and the larynx*. The upper airway narrows, which may cause breathing difficulties. Typically occurring in childhood, the condition is characterized by a barking cough that often becomes especially evident when a child is crying. In more severe cases of croup, a high-pitched or squeaking noise called stridor* can be heard when the child takes a breath. The symptoms

can appear suddenly or develop over a few days. Common cold symptoms, such as a runny nose, usually precede the onset of the barking cough. An allergy or a bacterial infection can produce symptoms of croup, but the majority of cases, 75 percent or more, are caused by a virus, usually parainfluenza* virus. Influenza viruses, adenovirus*, respiratory syncytial virus*, and measles virus also can cause croup.

Who Gets Croup?

Croup tends to develop in infants and toddlers, because the windpipe is still small enough to be impeded by swelling. As a child grows older, the risk of croup drops. Adult cases of croup, although very rare, do occur. Croup is most common during the winter months and in the early spring. In the same way that an adult with a cold might have laryngitis*, a child with a cold might get croup. In fact, many of the viruses that cause croup in children can lead to laryngitis in adults. Some children are more prone to croup, for example, those who are born prematurely or who have narrowed upper airways. These children may get symptoms of croup every time they have a respiratory illness. Although the viruses that cause croup can pass easily between children through respiratory secretions, most children who come into contact with those viruses will not get croup.

What Are the Symptoms and Complications of Croup?

Croup is typically divided into two types: a spasmodic form and a viral form. Spasmodic croup results from an allergy or a mild respiratory infection and usually comes on suddenly. Viral croup arises from a viral infection and usually develops slowly over several days. A low fever is common in children with viral croup, but not among those with spasmodic croup. In both cases, children typically have a cough that resembles the sound of a barking seal. Crying can make the breathing symptoms worse. The symptoms also tend to worsen at night when children are tired, and a child with croup will often have trouble sleeping or even resting. In severe cases, when the airway becomes more swollen and narrowed, a child might experience difficulty breathing, which may include fast breathing and/or stridor. If oxygen intake drops too low, the lips, tongue, and skin around the mouth can start to appear bluish. In general, croup symptoms peak two to three days after they start, and the illness generally lasts less than a week. Children usually make a full recovery without complications, but in a small number of cases, they may experience an ear infection or pneumonia.

How Is Croup Diagnosed and Treated?

A barking cough is a telltale sign of croup. Other clues to the diagnosis are stridor, low fever (in cases of viral croup), common cold symptoms, previous bouts of croup, or a history of intubation* or other upper-airway problems. The degree of obstruction of the airways is the doctor's most important consideration in diagnosing and

* **parainfluenza** (pair-uh-in-floo-EN-zuh) is a family of viruses that cause respiratory infections.

* **adenovirus** (ah-deh-no-VY-rus) is a type of virus that can produce a variety of symptoms, including upper respiratory disease, when it infects humans.

* **respiratory syncytial virus** (RES-puh-ruh-toe sin-SIH-she-ul), or RSV, is a virus that infects the respiratory tract and typically causes minor symptoms in adults but can lead to more serious respiratory illnesses in children.

* **laryngitis** (lair-in-JY-tis) is an inflammation of the vocal cords that causes hoarseness or a temporary loss of voice.

* **intubation** (in-too-BAY-shun) is the insertion of a tube into the windpipe to allow air and gases to flow into and out of the lungs in a person who needs help breathing.

* **epiglottitis** (eh-pih-GLAH-tis) is a soft flap of tissue that covers the opening of the trachea (windpipe) when a person swallows to prevent food or fluid from entering the airway and lungs.

* **epinephrine** (eh-pih-NEH-frin) is a chemical substance produced by the body that can also be given as a medication to constrict, or narrow, small blood vessels, stimulate the heart, and cause other effects, such as helping to open narrowed airways in conditions like asthma and croup.

* **corticosteroid** (KOR-ti-ko-STER-oid) is one of several medications that are prescribed to reduce inflammation and sometimes to suppress the body's immune response.

treating croup. If the bronchi (breathing tubes), the lungs, or the epiglottis* become infected, a child may be unable to breathe or swallow adequately, and that is a true medical emergency. If the symptoms are severe, or if the child does not respond quickly to treatment, medical professionals may recommend a neck x-ray to check for specific causes of the breathing difficulty.

For most cases of croup, however, parents can treat their children at home. A common home treatment for mild cases of croup is moist air from a steam-filled bathroom or a cool-mist humidifier. The mist moistens the child's airway, helps open the air passage, and relieves coughing. Parents may also find that taking the child outdoors for a few minutes, even in the winter, can ease a coughing attack quickly, because the cool air can shrink the swollen tissues lining the airway. As with most illnesses, drinking fluids and getting plenty of rest help the body heal. Cigarette smoke near a child with croup or any other respiratory illness can make symptoms worse. Doctors advise prompt medical treatment for serious croup infections. Treatment may include inhaled medications, including epinephrine*, to minimize swelling in the upper airways. Doctors often will administer corticosteroid* medicines to ease airway swelling for a few days while the child recovers from the virus infection that causes croup. Although many hospitals place a child in a room with humidity levels of 100 percent, a study in a 2006 issue of the *Journal of the American Medical Association* showed no advantage in the high humidity compared with humidity levels of 40 percent.

As of the early 2000s, croup was not preventable, but frequently washing hands and avoiding contact with people who have respiratory infections was known to lessen the chance of spreading the viruses that cause croup.

Cryptosporidiosis See *Cyclosporiasis and Cryptosporidiosis*.

Cushing's Syndrome

Cushing's syndrome is a condition that occurs when the body is exposed to high levels of the hormone cortisol. Symptoms may include muscle weakness, weight gain, a round face (often referred to as a moon face), the growth of fat pads in specific places (along the collar bone and at the back of the neck), extra body fat, the growth of facial and body hair, and emotional problems.*

What Is Cushing's Syndrome?

Cushing's syndrome occurs when the body is exposed to high levels of the hormone cortisol for long periods. Cortisol is often called the “stress hormone” because its level in the body rises in response to stress. In the healthy individual cortisol helps to manage stress and to repair its ill effects. Cortisol helps regulate blood pressure and the metabolism, which is the sum total of all of the chemical reactions occurring in cells (including the conversion of food into energy and waste products). Cortisol also plays a role in immune system responses to stress. As with most hormones, the amount of cortisol in the body must be closely controlled, as either too much or too little cortisol has negative effects on the body.

In a healthy person, cortisol production is regulated by the interactions of three parts of the endocrine* system:

1. A part of the brain called the hypothalamus* (hy-po-THAL-uh-mus) secretes the corticotropin-releasing hormone (CRH).
2. CRH signals, the pituitary* gland located at the base of the brain and just below the hypothalamus to release adrenocorticotropic hormone (ACTH).
3. ACTH circulates in the bloodstream and stimulates the adrenal glands, paired organs located just above the kidneys in the abdominal cavity, to make cortisol and release it into the bloodstream. Cortisol then acts on various cells that help to regulate blood pressure and the use of fats, proteins, and carbohydrates in the body, particularly during times of stress. If something goes wrong with any of these glands or with the signaling system, the body may produce too much cortisol.

How Does Cushing's Syndrome Develop?

Use of glucocorticoid-based medications The most common cause of Cushing's syndrome is long-term treatment (daily doses for weeks or months) with drugs that are chemically related to cortisol

▲ The adrenal glands are a pair of organs located just above the kidneys in the abdominal cavity. In some people with Cushing's syndrome, the adrenal glands produce too much of the hormone cortisol. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **hormone** is a chemical substance that is produced by a gland and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

* **endocrine** (EN-do-krin) refers to a group of glands, such as the thyroid, adrenal, and pituitary glands, and the hormones they produce. The endocrine glands secrete their hormones into the bloodstream, and the hormones travel to the cells that have receptors for them. Certain hormones have effects on mood and sometimes cause emotional swings.

How Did Cushing's Syndrome Get Its Name?

Harvey Williams Cushing (1869–1939) was a leading American brain surgeon. Drawing on his observations of the pituitary gland, he made the connection between pituitary tumors and a collection of signs and symptoms that were shared by patients who had these tumors. He published his findings in 1932 and later the signs and symptoms he described became known as Cushing's syndrome.

* **hypothalamus** (hy-po-THAL-uh-mus) is a brain structure located deep within the brain that regulates automatic body functions such as heart rate, blood pressure, temperature, respiration, and the release of hormones.

* **pituitary** (pih-TOO-ih-tare-e) is a small oval-shaped gland at the base of the skull that produces several hormones—substances that affect various body functions, including growth.

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

* **asthma** (AZ-mah) is a condition in which the airways of the lungs repeatedly become narrowed and inflamed, causing breathing difficulty.

* **rheumatoid arthritis** (ROO-mah-toyd ar-THRY-tis) is a chronic disease characterized by painful swelling, stiffness, and deformity of the joints.

* **lupus** (LOO-pus) is a chronic, or long-lasting, disease that causes inflammation of connective tissue, the material that holds together the various structures of the body.

and can be converted into cortisol by the body. These drugs as a group are referred to as steroids, glucocorticoid-based drugs, or cortisone-like drugs. Prednisone is a common example. Glucocorticoid-based drugs are used to treat chronic inflammation* in disorders such as asthma*, rheumatoid arthritis*, lupus*, and other less common inflammatory diseases.

Tumors Some pituitary tumors can produce increased amounts of ACTH, which in turn causes the adrenal glands to produce excess cortisol. This form of the syndrome is known as Cushing's disease. Most of the ACTH-secreting tumors of the pituitary are not cancerous, and most affected people have only a single tumor. The tumors are five times more likely to occur in women than in men. Cushing's disease accounts for about 70 percent of all cases of Cushing's syndrome not caused by glucocorticoid-based therapies.

Tumors that arise elsewhere in the body, such as in the lungs, can also produce ACTH. Most ACTH-producing tumors located outside the pituitary gland are cancerous (malignant). In rare cases, tumors of the adrenal tissue itself cause excess cortisol production. Although most cases of Cushing's syndrome are not inherited, the tendency to develop tumors can be inherited.

What Are the Signs and Symptoms of Cushing's Syndrome?

The signs and symptoms of Cushing's syndrome are the same whether the syndrome is caused by drug therapy or tumor secretion. These include the following:

- Rounded face
- Increased fat in the region of the neck and upper body obesity
- Thin arms and legs
- Thin and fragile skin that bruises easily
- Purplish stretch marks* associated with fragile skin (the purplish color due to hemorrhages in the skin)
- Slow wound healing
- Slow recovery from surgery
- Weakened bones (osteoporosis)
- Fatigue and weak muscles
- Problems with sugar metabolism, which may lead to diabetes
- Menstrual irregularities
- Growth of excess facial and body hair
- High blood pressure
- Irritability and depression
- Increased susceptibility to bacterial infections

How Is Cushing's Syndrome Diagnosed and Treated?

Diagnosis A doctor who sees a patient with symptoms suggestive of Cushing's syndrome will ask questions about the person's medical history and medications being taken and perform a physical examination. Three specific laboratory tests that involve analysis of cortisol levels in the blood and urine are commonly used to measure cortisol levels. If cortisol levels are high, other tests are done to find out why. For example, imaging techniques for looking inside the body (such as CT scans* and MRIs*) can be used to look for tumors.

Treatment The treatment of tumors varies, depending on the tumor's location and whether it is cancerous. Noncancerous pituitary tumors are often successfully removed surgically. Cancerous tumors or pituitary tumors that cannot be operated on may be treated with radiation therapy or chemotherapy*, depending on the location of the tumor and the patient's general health. Additionally, Cushing's syndrome sometimes is treated with drugs that inhibit cortisol production.

If Cushing's syndrome occurs as a by-product of drug therapy, doctors will try to alter the drug dosage by reducing it, adjusting the patient's medication schedule so that there is less frequent dosing, or changing the medication to minimize the side effects of the drugs. Cortisol-inhibiting drugs may also be given.

Modifications of drug regimens (in the case of illness caused by drug therapies) and surgical removal of tumors can lead to a full recovery, although sometimes the tumors recur. When pituitary tumors are removed, the patient's level of ACTH may drop below normal. In such a case the patient must take doses of supplemental cortisol, until ACTH production returns to normal.

* **stretch marks** are stripes or lines on the skin (such as on the hips, abdomen, and breasts) from excessive stretching and rupture of elastic fibers, especially due to pregnancy or obesity.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **MRI** short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

* **parasites** (PAIR-uh-sites) are organisms such as protozoa (one-celled animals), worms, or insects that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. Parasites live at the expense of the host and may cause illness.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

Cyclosporiasis and Cryptosporidiosis

Cyclosporiasis (sy-klo-spor-I-a-sis) and cryptosporidiosis (krip-to-spo-ri-die-O-sis) are infections in the intestines that result from eating or drinking food or water contaminated by the parasites Cyclospora cayetanensis and Cryptosporidium parvum. These infections can result in diarrhea, stomach cramps, and nausea.

The Milwaukee Story

Thousands of people in Milwaukee, Wisconsin, started to get sick in early 1993 during the time that the Frozen Four, the college ice hockey finals were being played there. They had stomach pains, nausea, fever, and diarrhea, as if perhaps they had influenza. But authorities soon discovered that dangerous one-celled parasites* were in the city's water supply. When people drank the contaminated water, cryptosporidiosis developed.

In the end, more than 400,000 people came down with symptoms of cryptosporidiosis. More than 100 people died, including many who had other diseases such as AIDS*. The parasite had entered the water system from human waste in Lake Michigan, a water source for the city. Filters on the city's water plant had not removed the parasite. That problem was remedied.

How Do People Get Cyclosporiasis and Cryptosporidiosis?

Cryptosporidiosis and cyclosporiasis, a closely related illness, are common infections that result from contaminated water and food. They (and similar illnesses) affect millions of people worldwide and are especially dangerous to children, the elderly, and people with diseases that weaken the immune system, such as AIDS. The infections are common in developing nations, but they also are found increasingly in developed nations that import food, such as the United States. For example, a 1996 outbreak of cyclosporiasis in Houston, Texas, was linked with raspberries imported from Guatemala.

Cyclosporiasis and cryptosporidiosis result when humans eat food or drink water containing the cyst form of microscopic parasites from infected human or animal waste. The *Cyclospora cayetanensis* and *Cryptosporidium parvum* parasites can also enter the human body when people touch objects that have come in contact with infected fecal matter and then place fingers in their mouths. Fresh fruits and vegetables can become contaminated if they are irrigated with water that contains the parasites.

Additionally, as the ease and frequency of global travel have increased and as importation of food sources has increased, these infections gained the ability to spread from one part of the world to another in very short periods of time.

What Happens When People Get Cyclosporiasis and Cryptosporidiosis?

Symptoms Although caused by different parasites, cyclosporiasis and cryptosporidiosis may cause similar symptoms: watery diarrhea, stomach pain, nausea, fever, and vomiting. Weight loss, due to the diarrhea, and loss of appetite are also common. The first symptoms of cyclosporiasis often appear a week after the parasite enters the body, but the first symptoms of cryptosporidiosis may appear as soon as two days after infection or as long as ten days after. The illnesses can last for a few days to two weeks. Infections from cyclosporiasis sometimes last more than a month and return one or more times.

Diagnosis It can be hard to diagnose cyclosporiasis and cryptosporidiosis, because many illnesses can cause similar symptoms. If doctors suspect these infections, they may order tests to examine patients' stool for signs of the parasites.

Treatment The danger of intestinal infections such as cyclosporiasis and cryptosporidiosis is dehydration* from the loss of water through diarrhea. Doctors remind patients to drink plenty of fluids, such as water and sports drinks. Cyclosporiasis can also be treated with antibiotics*. Cryptosporidiosis, however, has no specific drug cure. Usually people completely recover from either illness in a week or two. People with AIDS and other diseases that weaken the immune system need extra medical attention, because they are at higher risk of more severe and more prolonged infections.

How Are These Infections Prevented?

Intestinal infections such as cyclosporiasis and cryptosporidiosis are among the most common illnesses in the world. Several preventive measures can lower the chances of getting these or similar intestinal illnesses:

- Washing hands frequently and thoroughly with hot water, especially after going to the bathroom, changing diapers, playing with animals or cleaning up after them, and gardening, because the soil can be contaminated by animal or human waste. It also is important to clean hands before eating.
- Washing fresh fruits and vegetables thoroughly before eating. Even fruit that can be peeled should be washed.
- Avoiding drinking unfiltered water from lakes, rivers, and other sources. Even a sparkling spring might be contaminated and should not be used for drinking water. It is also important to avoid swallowing water in lakes and rivers as well as in swimming pools and spas, because chlorine might not be enough to kill the parasites.

Water quality varies, even in industrialized nations such as the United States. Tap water led to the 1993 outbreak of cryptosporidiosis

Did You Know

Intestinal infections such as cyclosporiasis and cryptosporidiosis are among the most common illnesses in the world. Between 1.6 and 2.5 million people worldwide (mostly in low-income and developing countries) died from illnesses that cause severe diarrhea in 2000, a drop in diarrhea-associated deaths compared to statistics from 1982 through 2000. In 2006, about 137 cases of cyclosporiasis and 6,071 cases of cryptosporidiosis were reported to the U.S. Center for Disease Control and Prevention.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

in Milwaukee. Some people choose to drink only bottled water or use special filters for drinking water and ice. When overseas, especially when in developing nations, travelers should not drink tap water or use ice made from tap water. It also is recommended that fruits and vegetables be avoided by individuals who when they travel outside the United States, unless they can be cooked or peeled.

Cyst

A cyst is a small, balloon-like swelling anywhere in the body. A cyst may contain air, fluid, or solid content contained within a sac. Usually, cysts are harmless, but they may be removed surgically if they cause discomfort or distress.

Where Are Cysts Found in the Body?

Cysts may develop in many areas on the inside or outside of the body. They may be found in the mouth around a developing tooth, in the skin around a hair follicle or sweat gland, in other glands, in the spinal cord, in the liver, in bone tissue, in ovaries*, and in other parts of the body.

Cysts are cavities that are lined with epithelium. Epithelium is a common tissue in the body, which is part of the skin and also serves as a covering for organs and as a lining for vessels and other cavities throughout the body. Cysts form most often when fluid in a gland* becomes blocked in the ducts or tubes leading out of the gland. Sometimes cysts develop because the glands are overactive and produce more fluid than the tissues can absorb. Another cause of cyst formation is the presence of parasites in vital organs, such as the liver or brain.

What Are the Different Types of Cysts?

Cysts are classified mainly by their location in the body. Some of the most common are:

- Alveolodental (al-vee-o-lo-DEN-tal) cysts, which form around a developing tooth
- Baker's cysts, which form around the knee joint
- Chocolate cysts, which form in the ovary (named for their dark brown fluid)
- Corpus luteum (KOR-pus LOO-tee-um) cysts (plural form is corpora lutea), which are yellow bodies that form in the ovary when an egg is released during the normal reproductive cycle
- Ependymal (e-PEN-di-mal) cysts, which form in the central canal of the spinal cord
- Ganglion (GANG-lee-on) cysts, which usually develop around the tendons or joints
- Lacteal (LAK-tee-al) or milk cysts, which form in the breast
- Sebaceous (se-BAY-shus) cysts, which form under the skin from plugged oil glands
- Solitary bone cysts, which form in long bones of children and adults
- Wens, which are sebaceous cysts that form on the scalp.

Cysts are also associated with polycystic kidney disease and bilateral cystic mastitis. In the first, numerous fluid-filled cysts form in the kidneys, a condition that can sometimes lead to kidney failure. The second is a much more common disease. In cystic mastitis (also known as Von Schimmelbusch's disease), cysts form in the breast and may be tender especially just before a woman has her menstrual period, but they are not dangerous to her health. Sometimes they can, however, be a health hazard because they may make it more difficult for the woman or her doctor to check the breasts for other unusual growths.

* **ovaries** (O-vuh-reez) are the sexual glands from which ova, or eggs, are released in women.

* **gland** is an organ that produces substances such as hormones and chemicals that regulate body functions.

“Bible Bumps”

Ganglion cysts of the wrist used to be called “Bible bumps.” The home remedy for ganglion cysts once was to rupture them by hitting them with a big book. Many people had only the *Farmers’ Almanac* and the Bible in the home, and because the Bible was the bigger book, it was used to break the cyst.

* **abscess** (AB-ses) is a localized or walled off accumulation of pus caused by infection that can occur anywhere in the body.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

How Are Cysts Treated?

Most cysts do not need treatment. Those that may require treatment are cysts that have become painful, have formed on visible parts of the body such as the hand or around the ears, or have become infected. An infected cyst may contain pus, in which case it is technically known as an abscess*. A doctor can remove a cyst by drawing out the fluid with a needle and syringe (aspiration) or by surgically removing it. Surgery is more effective. When the fluid is removed with a needle, the cyst has a tendency to return. Sometimes cysts disappear without any treatment.

Cystic Fibrosis

Cystic fibrosis is an inherited condition in which glands produce excessively sticky mucus. The sticky material clogs the lungs, liver, pancreas, and intestines and makes it difficult to breathe and to digest food properly.

Rachel’s Story

Rachel’s parents were worried. They believed they provided all the proper care Rachel needed, just as they had for their older daughter when she was a baby, but Rachel failed to gain as much weight as other children her age, even though she seemed to have the appetite of a normal infant. Rachel also seemed to have more colds than other children had and a lot more colds than her older sister ever had. She coughed often and breathed with a wheezing sound. Then, around the time of her second birthday, Rachel developed pneumonia*.

Rachel’s failure to gain weight and her frequent respiratory infections led her doctor to suspect that Rachel had cystic fibrosis (SIS-tik fy-BRO-sis), which is usually known by its initials, CF. Tests confirmed the diagnosis.

CF is a hereditary disease that affects about 30,000 children and adults in the United States. It is one of the most common hereditary conditions. Especially affecting people of European ancestry, CF occurs in one of every 3,000 live births. Nearly 1,000 new cases of CF are diagnosed each year in the United States, usually by the time children reach their third birthday.

are blocked by mucus

Lungs with cystic fibrosis

What Is Cystic Fibrosis?

Cystic fibrosis is a chronic, hereditary disease that affects many of the body's organ systems. In CF, some of the thin, easy-flowing mucus* in the body's respiratory and digestive systems becomes thicker. Glands* produce mucus to do various tasks, such as lubricate the lungs, trap dust and bacteria that is inhaled through the nose, and protect the lining of the intestines from the acidic fluids that help digest food.

The glands in people with CF, however, produce sticky mucus that clogs the passageways in the lungs, which makes breathing difficult and leads to infections. The sticky mucus also blocks the easy flow of digestive acids and enzymes from the pancreas* and liver* to the intestines. Without adequate amounts of these digestive fluids in the intestines, people with CF cannot break down their food into the substances the body needs for nourishment.

What Causes Cystic Fibrosis?

CF is caused by a mutation in a gene* on chromosome 7. Chromosome 7 is one of 23 pairs of chromosomes that are part of each person's genetic makeup. The CF gene causes the production of a protein that lacks an

- * **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.
- * **glands** are organs that produce substances such as hormones and chemicals that regulate body functions.
- * **pancreas** (PAN-kree-us) is a gland located behind the stomach that produces enzymes and hormones necessary for digestion and metabolism.
- * **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.
- * **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

Lung infections are common in cystic fibrosis. Seen under a light microscope are tissue samples from a healthy lung (left) and from a lung affected by cystic fibrosis (right). *Custom Medical Stock Photo, Inc. Reproduced by permission.*

Turning on the CF Gene

In 1989, scientists discovered the location of the CF gene. If they could replace the defective gene with a normal gene, then they would be able to cure the cells that produce the defective CF protein, in which case the mucus in the respiratory and digestive systems would be thin and easy flowing as opposed to thick and sticky.

In 1990, two teams of researchers were able to correct CF cells in lab dishes by adding normal copies of the gene. In the spring of 1993 a person with CF got the first experimental dose. In October 1993, scientists determined that gene treatment had repaired a damaged gene in a human patient. Numerous studies followed. Some have had very encouraging results, but no cure had been found as of the early 2000s.

Gene therapy is a complicated experimental process, and a particular hurdle has been finding a way to deliver the gene to the parts of the body where it can do its work. Perhaps, gene therapy will never be able fix all of the defective genes, but it might cause enough of them to work properly to improve the quality of life for people with CF.

important building block, or amino acids*. The missing amino acid is called phenylalanine (fen-il-AL-a-neen). Without that amino acid, the protein hinders the ability of mucus to obtain the proper amounts of water and salt from the body, and the mucus is unable to maintain its thin and easy-flowing texture. As a result, the mucus becomes dense and sticky and clogs the respiratory and digestive systems.

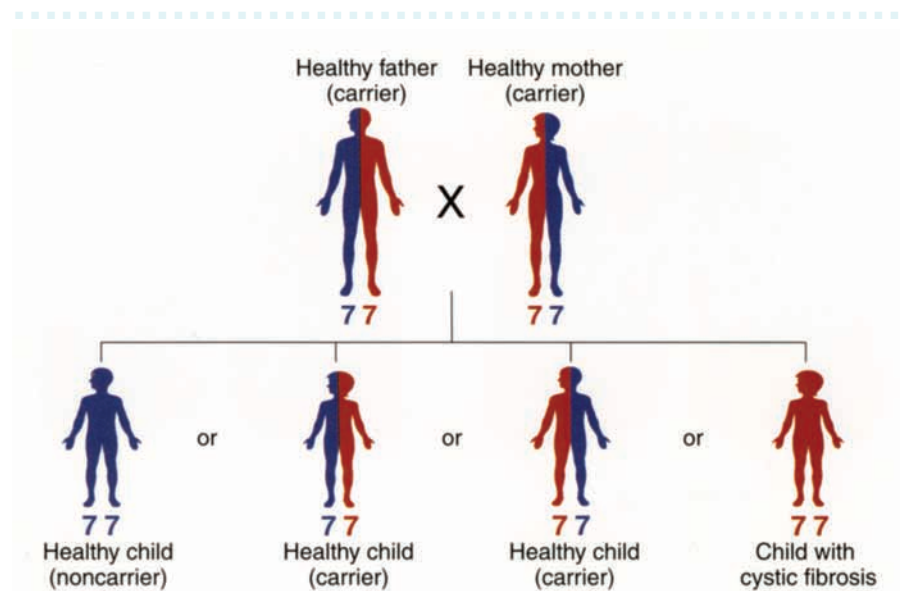

The obstructions in the lungs make breathing difficult and can increase the risk of infections. The problems in the digestive system prevent the body from getting all the nutrients it needs from food. It also means people with CF often have thicker, foul-smelling bowel movements, because fat in food cannot be broken down by digestive fluids and absorbed.

A person may carry the CF gene on one of the two copies of chromosome 7 and not have any signs of CF. This person is called a carrier*. Parents can pass the CF gene to many generations of offspring. If a person inherits the CF gene on both copies of chromosome 7, then that person develops CF. When parents are both carriers, such as Rachel's parents, their children have a one in four chance of having CF. Estimates are that 10 million Americans, or about one out of 30, carry the CF gene.

How Do Doctors Know Someone Has Cystic Fibrosis?

Descriptions of children with symptoms of cystic fibrosis appear as far back as the 1600s, but not until 1938 was CF recognized as a separate disease. Even in the early 2000s, the symptoms of CF can sometimes be confused with pneumonia or asthma.

Symptoms Cystic fibrosis affects each person differently. Many people with CF do not appear to be severely ill. In general, people with CF have some or all of the following symptoms:

Cystic fibrosis is a chronic disease caused by a mutation in a gene located on chromosome 7. If both parents carry the CF gene, there is a 50 percent chance that their child may carry the gene too, and a 25 percent chance that their child may have CF. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

- Salty-tasting skin and sweat
- Persistent cough or wheezing
- Many respiratory infections
- Bulky, smelly stools or bowel movements
- Nasal polyps (small growths in the nose)
- Enlargement of the fingertips and toes (clubbing)

Also, people with CF may eat large amounts of food but still be hungry, because mucus blocks the ability of digestive enzymes* and acids to break down food and absorb nutrients. So these individuals do not properly digest their food. Large portions of the poorly digested food pass out of the body during bowel movements. Some individuals may lose weight.

Later, the pancreas may clog and fail to secrete the enzymes essential to normal digestion. The liver becomes clogged, which may lead to cirrhosis (si-RO-sis), a condition in which the liver becomes hardened and fails. Diabetes also develops frequently in people with CF as they get older.

Diagnosis Doctors may begin to suspect CF soon after a baby is born when the infant becomes ill with repeated respiratory infections, fails to gain weight despite a healthy appetite, and shows other symptoms of CF. In addition, about 10 percent of infants with CF have intestinal blockage due to thick mucus that is apparent at birth. Many of the symptoms of CF are common in people who do not have the disease, but tests are available to confirm that a person has CF.

A sweat test is a preferred method for diagnosing cystic fibrosis because it is relatively easy to perform and is accurate. The test determines the salt content of perspiration. Although sweat can seem salty in people who do not have CF, the level of salt in the perspiration of people with CF is higher. Besides the sweat test, medical professionals may use a more complicated test to look for the CF gene on both copies of chromosome 7.

A Morning Ritual for Rachel

After her doctor determined that Rachel had cystic fibrosis, her parents worried she would not be able to engage in the same activities her older sister or other children enjoy. As she grew, however, Rachel went to school, participated in sports, and performed many other everyday activities.

Most people with CF get treatment that involves helping them breathe more easily and digest food better, which makes day-to-day activities less difficult. Although their symptoms can range from mild to severe, many people with CF get treatments similar to those that Rachel receives. One of those treatments is chest physical therapy. Each morning, her parents vigorously thump her back and chest to help loosen the thick mucus in her lungs so she can cough it out. They learned the technique, called daily percussion therapy, from a physical therapist after

* **amino acids** (a-MEE-no acids) are the chief building blocks of proteins. In humans, certain amino acids are required to sustain life.

* **carrier** is a person who has in his body a bacterium or virus or gene for a disease that he can transmit to other people without getting sick himself.

* **enzymes** (EN-zimes) are proteins that help speed up a chemical reaction in a cell or organism.

Boomer Fights Back

When two-year-old Gunnar Esiason was diagnosed with cystic fibrosis in 1993, his father, Norman Julius “Boomer” Esiason, decided to fight back. Boomer, who played quarterback for the National Football League’s Cincinnati Bengals, New York Jets, and Arizona Cardinals and later became a television sports reporter, had been a fierce competitor for many years. Now, his greatest battle became the fight against CF.

The NFL star started the Boomer Esiason Foundation with the main goal of finding a cure for CF. The foundation supports basic research and clinical trials for new CF treatments.

Rachel was diagnosed with CF. Depending on the patient’s condition, such therapy can sometimes take up to an hour. Sometimes, thumping is not enough, and the mucus must be extracted by suction.

Coughing is one of the main ways that people with CF can clear the mucus from their lungs, so Rachel coughs often at school. Because her teachers and the other students know Rachel has CF, they do not make a big deal about her coughing. Rachel keeps her own box of tissues on her desk, so she can cough the mucus into tissue and toss it into a nearby wastebasket.

Rachel also participates in physical education classes. Exercise is another way that people with CF loosen the mucus in their lungs. Sometimes Rachel gets tired more quickly than the other children, because she cannot breathe as easily, but she joins in many of the exercises and games on most days.

At lunch and other times that she eats a meal or snacks, Rachel takes pills. The pills contain enzymes to help her digest food. Without them, the mucus in her digestive system prevents her from getting the nutrients she needs from food. Even with the enzyme pills, Rachel and others with CF often need to take vitamin supplements and eat a diet rich in nutrients to assure they get the proper nourishment.

Rachel and others with CF also take antibiotics to prevent or treat lung infections. Sometimes, the antibiotics are taken as pills or inhaled into the lungs using a device called a nebulizer. People with CF also sometimes take prescription medications that thin the mucus and help reduce lung inflammation, which makes breathing easier and helps reduce the number of lung infections.

DNase, which is short for recombinant human dextroxyribonuclease, is one medication often used to treat CF. It does its job as a follow-up to the body’s normal response to invading bacteria, a problem that people with CF are constantly battling. The body fights bacterial infections with an army of white blood cells that destroy the bacteria. The blood cells die after they do their job. In people with CF, these dead white blood cells and bacteria serve to make the mucus thicker, basically turning its consistency from a fluid gel into a semi-solid custard. DNase helps break down these dead white blood cells and bacteria, which allows the mucus to thin out again.

Living with Cystic Fibrosis

Once CF almost always caused death in childhood, but treatments in the last decades of the twentieth century allowed many people with CF to live into adulthood. As for children with CF, the symptoms for an adult can range from mild to severe, but eventually the recurring infections in the lungs begin to damage the lungs’ ability to function. This complication is fatal for many people with CF. In the 1990s and early 2000s, however, lung transplantation has been performed on some patients who developed severe lung disease. The Cystic Fibrosis Foundation reports that

about 120 to 150 people annually receive lung transplants in the United States. Of them, up to 90 percent are alive a year later, and 50 percent are alive after five years.

According to the Cystic Fibrosis Foundation, the average life expectancy of people with CF was about 36.5 years in 2008, an increase from 32 years as of 2000. With treatment, people with CF are able to perform many activities that other people do.

Cytomegalovirus (CMV) Infection

Cytomegalovirus (sye-tuh-MEH-guh-lo-vy-rus), or CMV infection, is very common and usually causes no symptoms. It poses little risk for healthy people, but it can lead to serious illness in people with weak immune systems.

Once inside the human body, the cytomegalovirus can invade many organs and systems including the salivary glands, brain, lungs, kidneys, and liver. *PHOTOTAKE Inc./Alamy.*

- * **herpes** (HER-pee-z) is a viral infection that can produce painful, recurring skin blisters around the mouth or the genitals, and sometimes symptoms of infection elsewhere in the body.
- * **mononucleosis** (mah-no-nu-klee-O-sis) is an infectious illness caused by a virus with symptoms that typically include fever, sore throat, swollen glands, and tiredness.
- * **bone marrow** is the soft tissue inside bones where blood cells are made.
- * **semen** (SEE-men) is the sperm-containing whitish fluid produced by the male reproductive tract.
- * **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.
- * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.
- * **jaundice** (JON-dis) is a yellowing of the skin, and sometimes the whites of the eyes, caused by a buildup in the body of bilirubin, a chemical produced in and released by the liver. An increase in bilirubin may indicate disease of the liver or certain blood disorders.
- * **microcephaly** (my-kro-SEH-fah-lee) is the condition of having an abnormally small head, which typically results from having an underdeveloped or malformed brain.
- * **retinitis** (reh-tin-EYE-tis) is an inflammation of the retina, the nerve-rich membrane at the back of the eye on which visual images form.

What Is CMV?

CMV is part of the herpesvirus (her-pee-z-VY-rus) family, which also includes the viruses that cause herpes*, chicken pox, and mononucleosis*. As with other members of the herpesvirus family, once CMV enters a person's body, it remains there for the person's whole life. CMV infection can cause flu-like symptoms when a person is first infected, but many people have no symptoms at all. The virus usually becomes dormant after it enters the body, meaning that it remains hidden and does not cause symptoms of illness. The virus can emerge at a later time, however, and produce illness in people with weakened immune systems, such as people who have cancer or AIDS or those who have received organ or bone marrow* transplants. CMV is a risk for pregnant women because of the danger that it can be transmitted to their babies. The disease is the leading cause of mental retardation and hearing defects in newborns in the United States as a result of congenital (kon-JEH-nih-tul) infection, that is, infection that is present at birth.

How Is CMV Spread?

CMV is contagious and can spread through bodily fluids, including blood, saliva, semen*, breast milk, tears, and urine*. The virus can be transmitted by sexual contact, by close person-to-person contact, or from mother to baby during pregnancy, birth, or breast-feeding. It often spreads among children in day care or preschool or among family members. In the United States, as many as three of every five adults have been infected with CMV by the time they reach age 40. CMV infects people all over the world and is even more widespread in developing countries and among those with poor living conditions.

What Are the Symptoms of CMV?

Most people who have been infected with CMV never show symptoms. In some people, the virus causes mild symptoms that mimic the flu or infectious mononucleosis, such as fever, chills, body aches, headache, swollen lymph nodes*, sore throat, and fatigue. Newborns who contract CMV infection in the womb may be born with jaundice*, microcephaly*, signs of brain damage, and a serious inflammation of the eyes known as retinitis*. Others seem healthy when they are born but later have growth problems and signs of hearing loss or mental retardation.

How Are CMV Infections Diagnosed and Treated?

Most cases of CMV infection are never diagnosed because they produce few or no symptoms. When doctors do suspect CMV, they often base the diagnosis on symptoms, physical examination, and blood tests for antibodies* to the virus. They will also rule out other diseases that cause similar symptoms, such as infectious mononucleosis caused by the Epstein-Barr virus*. Sometimes blood tests show evidence of past infection with CMV but do not indicate active infection. A test known as the polymerase

(pah-LIM-er-ace) chain reaction, or PCR, can test specifically for active CMV infection by finding traces of DNA* from the virus in body fluids. People with healthy immune systems who contract CMV infection usually do not require medical treatment. When people with weakened immune systems develop CMV infection, doctors often prescribe medication made to fight viruses. These antiviral medicines may need to be given by injection, and patients sometimes have to take them for months or even years. Symptoms of initial CMV infection usually last two to three weeks in healthy people. After that, the virus remains in the body for life. Flare-ups of illness from CMV in healthy people are rare and typically occur when the immune system has been stressed by fighting another illness.

What Are the Complications of CMV Infection?

CMV infection can cause more severe illness in people with weakened immune systems, such as pneumonia* and retinitis. If it is untreated, retinitis can lead to blindness. CMV also can cause severe inflammation of the esophagus and colon, leading to difficulty in swallowing, long-lasting diarrhea, and weight loss. It also can affect the brain or nerves. Infants born with CMV infection may have jaundice, poor growth, problems with vision and hearing, and other disabilities, including slow development and mental retardation.

How Is CMV Infection Prevented?

The best way to help prevent the spread of CMV is to wash the hands regularly, especially after changing diapers or touching bodily fluids. Doctors advise women who are pregnant and people who work in child care to be particularly careful. Patients scheduled to have organ or bone marrow transplants typically receive medication before the operation to prevent CMV disease from developing, as the transplant process weakens their immune systems.

Deafness and Hearing Loss

Deafness is complete loss of hearing, whereas hearing loss may be partial or complete. Deafness may be present from birth, as a result of many possible causes, or it may begin later in life as a result of age-related changes in the ear, disease, injury, or excessive exposure to noise.

Loud Music and Hearing Loss

Kathy Peck was a guitarist in the 1970s and 1980s in a rock band known as the Contractions. The band played a mix of punk and new wave music in San Francisco and toured across the United States. The band gained some critical and popular success, playing shows with such groups as Duran Duran. In the mid-1980s, Peck realized she was losing some of her hearing. All those years of playing loud music and attending concerts had damaged her ears, as had happened to musician Pete Townshend of the Who. When Kathy Peck and a physician named F. Gordon attended an especially loud concert in 1988, they decided to make a difference. They started H.E.A.R. (Hearing Education and Awareness for Rockers), a group that aims to prevent hearing loss among musicians and their fans. H.E.A.R. promotes wearing earplugs to reduce loud music to a level that does not damage the ear.

Rock music is not the only cause of noise-related ear damage. Excessive exposure to power tools and other forms of machinery is one of the most common causes of deafness and hearing loss in the United States. Overall, more than 28 million Americans have some form of hearing loss.

What Is Hearing?

Hearing is the ability to perceive sounds. It depends on the ability of sound waves to travel through the various parts of the ear. As sound waves travel through the ear, they are converted into electrochemical impulses or messages that are sent along more than 30,000 nerve connections to the brain. The brain then interprets these messages as words and other sounds.

Anatomy of the Ear

The ear is comprised of the following parts:

- **Pinna** (PIN-na) is the medical term for the outer ear: the part of the ear that protrudes from the head and is used to hold up eyeglasses and to wear earrings.
- **Tympanic membrane** (eardrum) is the thin, flexible layer of semi-transparent tissue that forms the dividing wall between the outer ear and the middle ear.
- **Ossicles** (OSS-i-kulz) are the three smallest, most delicate bones in the body: the malleus (MAL-ee-uss) looks like a hammer; the incus (ING-kuss) looks like an anvil; and the stapes (STAY-pee-z) looks like a stirrup.
- **Cochlea** (KOKE-lee-a) is the organ of hearing that resembles the shell of a snail.
- **Cilia** (SILL-ee-a) are the delicate hairs in the inner ear.

Anatomy of the ear. As sound waves travel through the ear, they are converted into electrochemical messages that are sent along more than 30,000 nerve connections to the brain. The brain then interprets these messages as words and other sounds. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **earwax** also known as cerumen (se-ROO-men), is the wax-like substance in the ear that traps dust and other particles to prevent them from damaging the inner ear.

How sounds are heard Sounds actually are waves of energy that move through the air. Sometimes it is even possible to feel them, as when a hand is placed for a few moments next to a loudspeaker.

The pinna is the fleshy, visible part of the outer ear that captures the sound waves. It directs sound waves down a short tunnel, called the ear canal. The canal ends at the eardrum, which vibrates when sound waves reach it.

The vibrating eardrum causes the ossicles that are connected to it to begin vibrating as well. The ossicles are three tiny bones in the air-filled middle ear. As the bones move, the sound waves are transferred through another thin layer of tissue into the inner ear.

The most complex action in the ear occurs in the inner ear, deep within the skull. The sound waves first enter the cochlea, which contains liquid and is lined with cilia (tiny strands of hair). The liquid in the cochlea begins to vibrate and causes the microscopic hairs to move, too. The movement of the hairs stimulates nerves that are connected to the brain, which interprets the signal as a particular word or sound.

How some people cannot hear sounds People with deafness can hear no sounds at all. Others have partial hearing loss, which means they may have trouble hearing certain sounds unless someone is speaking close to them. Hearing loss can be unilateral (affecting only one ear) or bilateral (involving both ears). Some people slowly start to lose their ability to hear, and the problem gets worse as time passes. Hearing loss may be temporary, such as when earwax* builds up. If the wax is removed properly by a health professional, hearing is restored. But some forms of total or partial hearing loss are permanent.

What Causes Hearing Loss?

There are basically three types of hearing loss: conductive, sensorineural (sen-sor-i-NOOR-al), and a mixed form that combines conductive and sensorineural hearing loss.

Conductive hearing loss Conductive hearing loss happens when sound waves are not transferred (conducted) completely from the outer and middle ear to the inner ear. If sound is imagined as waves of water, then conductive hearing loss occurs when something is creating a “dam” that blocks the sound waves. This dam can result from the buildup of earwax in the ear, water in the ear canal that comes from swimming, or an infection that causes part of the ear to malfunction. Other causes include:

- **Damaged eardrums:** Sometimes the eardrum gets a tear or hole in it, which causes it to lose some or all of its ability to vibrate properly. Such damage may occur if a cotton swab or other object is placed too far inside the ear; if an explosion or gunshot or other extremely loud sound occurs too close to the ear; or as a result of an ear infection, a head injury, or a sudden or extreme change in air pressure.
- **Abnormal bone growth:** The ossicles are the tiny bones in the middle ear that work together in a very small space to conduct sound from the ear drum to the inner ear. If they grow too much or too little or are damaged, they cannot do their jobs well. This problem may be present from birth or it may occur as children grow.

Sensorineural hearing loss Sensorineural hearing loss occurs when there is a problem with some part of the inner ear or with the nerves that send messages from the inner ear to the brain. This type of hearing loss is more common than conductive hearing loss and more difficult to treat. Some estimates suggest that about 90 percent of hearing loss results from sensorineural problems. The most common cause of sensorineural hearing loss is change in the inner ear as people age. Not all older people experience sensorineural hearing loss, but many do. Common forms include:

- **Presbycusis** (press-bi-KOO-sis), the most common form, starts gradually for many people when they are in their 40s or 50s. More than 50 percent of people age 75 and older have some form of presbycusis.
- **Damage to the cilia** (SILL-ee-a), the delicate hairs in the inner ear. Loud noises can damage the cilia, as can poor blood supply to the inner ear resulting from high blood pressure, heart disease, smoking, or poor nutrition. Infections, tumors, and some medications also may damage the cilia and nearby parts of the inner ear or nerves to the brain.

Watching the Volume Control

Loud music can be enjoyable, but it can damage the hair in the inner ear and lead to permanent hearing loss. It can be a special problem for those who listen to music through earphones.

Even listening to two hours of loud music can damage the ear. Doctors advise those who listen to music to keep the volume at a level where other sounds and conversation still can be heard. If other people can hear the music from earphones, then it is too loud to be safe. At concerts, ear plugs can lower damaging sound levels.

The same advice about protecting the ears applies to those who work regularly with loud machines, including power tools, lawn mowers, chain saws, and leaf blowers. It also applies to many recreational or leisure activities such as snowmobiling.

* **vertigo** (VER-ti-go) is the feeling that either the environment or one's own body is revolving or spinning, even though they are not.

LUDWIG VAN BEETHOVEN'S HEARING LOSS

Composer Ludwig van Beethoven (1770–1827) created some of the most important symphonies even though he spent most of his life struggling with hearing loss and deafness. He began to experience mild episodes of hearing loss when he was about 28 years old. His hearing progressively worsened until he was left completely deaf at the age of 44.

Nonetheless Beethoven continued to compose great works. Contemporaries reported that he placed his ear to the piano while he played in order to sense the vibrations of the different notes. Medical historians are uncertain as to how Beethoven became deaf, although they believe nerve damage and otosclerosis (o-to-skler-O-sis), which damages the bones in the ears, are the likeliest causes.

- Genetic disorders may cause deafness from birth by interfering with the proper development of the inner ear or nerves to the brain.
- Injuries to the ear or head, such as a skull fracture, may cause sensorineural hearing loss.
- Ménière's (men-YERZ) disease affects more than 3 million people in the United States, many of them between the ages of 30 and 60. It can cause sensorineural hearing loss, vertigo* and dizziness, and a ringing in the ears called tinnitus (ti-NY-tis).

Mixed hearing loss Mixed hearing loss involves any combination of conductive hearing loss and sensorineural hearing loss. For example, loud noise can damage the ear drum, which causes conductive hearing loss. But loud noise also can damage the hairs in the inner ear, which is sensorineural hearing loss. If both occur, people are said to have mixed hearing loss.

When Sounds Begin to Fade

Hearing loss or deafness that is present from birth usually is first discovered by parents. They might begin to notice that loud sounds do not startle the baby or cause the baby to turn toward them. By school age, all children should have had their hearing tested, either by the family doctor or in school.

Hearing loss at later ages often is not recognized at first. People may find they can hear almost as well by increasing the volume on the television set or by moving closer to someone who is speaking, but they may not realize they are adapting this way. Other signs of hearing loss include needing people to repeat what they have said; complaining

that other people are mumbling; misunderstanding what people have said; and not hearing the phone, doorbell, or voices calling from other rooms. Often, the voices of women and children cause earlier problems, because the hair cells that recognize their higher-pitched voices are the first to fail.

Diagnosis Doctors use several tests to diagnose hearing loss. One requires patients to listen with earphones for a variety of tones and signal when they are heard and when they disappear. A related test involves a special device that is placed behind the ear and transmits tones directly to the inner ear through a portion of the skull called the mastoid. If these tones are recognized better than those from the earphone test, the hearing problem is in the middle ear. Another test involves understanding various words as they are spoken through earphones.

How Is Hearing Loss Treated?

Treatment for earwax buildup or infections can reverse some forms of hearing loss. Surgery to repair damaged ear drums or the bones of the middle ear is also possible.

Hearing aids The most common device used to amplify sound is the hearing aid. Aids come in various forms that fit in or behind the ear and can help make sounds louder and clearer. They cannot completely restore lost hearing, but they can make it easier for many people to hear sounds. Audiologists are trained specialists who help select, fit, and monitor the use of hearing aids for both children and adults.

Cochlear implants A cochlear (KOKE-lee-ar) implant is a complex device that replaces the work of the delicate hair cells (cilia) of the inner ear. A receiver worn behind the ear captures sound waves and transmits them to a receiver that is surgically placed inside the skull. This receiver then stimulates the nerves that the brain uses to interpret sounds. The surgery can be expensive, and it does not work for everyone, but for some it can be an effective way to partially restore hearing.

Living with Deafness and Hearing Loss

People with deafness and hearing loss usually learn to read lips and to use sign language for conversation. Other ways to improve activities of daily living include:

- Closed caption televisions that display words as people speak
- Lights that flash when the phone or doorbell rings
- Enhanced telephone services and telephones
- Dogs trained to alert their human companions to sounds, such as the phone ringing, a baby crying, or the person's name being called

Many people with deafness and hearing loss take pride in the many ways that deafness education and deaf culture enrich the lives of people who can hear.

Death and Dying

Death and dying present the most difficult of human experiences. Situations caused by or surrounding the dying process and death evoke intense and complicated feelings. Moreover, adults and children process death and express grief differently.

Life's Two Great Mysteries

Everyone shares two experiences: birth and death. Someone dies about every 20 seconds. Most people know someone who has died. But people tend to resist thinking about death or talking about it. People tend to avoid acknowledging that everyone dies. Worldwide and through the centuries, people have considered birth and death as the two great mysteries. They have witnessed death and dying and viewed it with fear.

How Do People Understand Death?

The grief people feel in the face of death tends to be affected by the facts pertaining to the event of death they witness. The age of the person and the cause of death affect the way the death is understood by the living. The most easily accepted, perhaps, are deaths of people in old age, when the body has worn out and the elderly individuals are ready to die. Death at the end of a long life is understandable and fitting. But when the young die or when death comes accidentally and without warning in the prime of life, death is unacceptable, and grief can be more intense. Illness, injuries, natural catastrophes, and violence can all cause early death.

Sometimes death results from terminal disease. Individuals of all ages with these diseases have to face their own deaths and their families and friends must witness the dying process of their loved one. Psychologists* and physicians who have worked with people in this situation assert the importance of honesty and love. People with terminal illness and those who love them need to understand the effects of the terminal illness and find ways to express their feelings about it. It helps to talk about it, enjoy time together, and help with caregiving.

What Is Grief?

Grief is the wide range of feelings that accompany a death, such as shock, anger, sadness, and confusion. Knowing ahead of time that someone is going to die does not necessarily soften the impact of the person's death. It still may be difficult to believe that the death has occurred and hard to imagine life without the person who has died. When the death is sudden and unexpected, the shock of the news makes the reality all the more difficult to accept. Such shock can take time to fade. Most people need comfort and support while they grieve, from their relatives and friends, perhaps from members of the clergy, from therapists, or members of a support group.

* **psychologists** (sy-KOL-o-jists) are mental health professionals who treat mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth. Psychologists also study the brain, behavior, emotions, and learning.

STAGES OF GRIEF, TWO VIEWS

Elisabeth Kübler-Ross, in her 1969 book *On Death and Dying*, identified five emotional stages that people move through as they face their own dying process and death:

1. Denial: This is not happening.
2. Anger: Why is this happening to me?
3. Bargaining: I will make a deal in order to escape dying.
4. Depression: I do not care any more.
5. Acceptance: I am ready to die.

Roberta Temes, in her 1977 work *Living with an Empty Chair: A Guide through Grief*, identified three behavioral stages people move through as they cope with the loss of a loved one:

1. Numbness, which includes mechanical functioning and social isolation
2. Disorganization with painful feelings of loss
3. Reorganization with a return to a more normal social life

How Do Children Cope with the Death of a Parent or Sibling?

When a parent or sibling dies, everyone in the family suffers. Very young children may not fully understand what has happened and that the death is permanent. Children feel many of the same feelings that adults do when someone dies: shock, sadness, or confusion. But children seem to process those feelings differently. They may wonder what effects the death will have on their lives. While they may not be able to express grief as adults do, they may find themselves wondering about the changes this loss may have on them and on their future. They may have fears about their widowed parent remarrying or their having to move from their family home.

Sometimes it is hard for young people to understand their own feelings and reactions to death. Young people may also have trouble understanding the grief of adults around them. Grief can cause people to lose interest in activities that they normally enjoy, and it may cause people to avoid situations that used to involve the person who died. People express grief in different ways and at different tempos. Family members may find it impossible to talk about what they are experiencing. Sometimes children get ignored as adults become preoccupied with their own feelings. Finding someone to talk with (a family member, friend, or trusted adult) may help young people understand their feelings and the feelings of those around them.

How Do Adults Cope with the Death of a Child?

The death of a child disrupts the natural order in which members of the older generation die before members of the younger one do. Adults assume that they will be outlived by their children. Parents assume their children will outlive them. The death of an offspring is sometimes said to be the hardest loss. Regardless of the facts concerning such a death, parents often feel guilt for having failed to keep their child safe. Sometimes, after losing a child, parents become overly protective of their surviving children. Some parents want to move or change their lives to avoid being reminded of the child who died. Different adults choose different paths in the process of coming to terms with their grief and continuing to live their lives.

How Do Rituals Help People Cope with Death?

Funerals, memorial services, and burials are generally held a short time after a death and sometimes on the anniversary of a death. These ceremonies bring out painful feelings and are often difficult to attend. But they offer a way for people to express their feelings, take comfort with others who are grieving, and pay tribute to a person's life. Funerals or other rituals—such as planting a memorial garden, writing memories or a tribute, enjoying the person's interests—help people stay connected to the person even after the death.

What Happens after Death?

People have different beliefs about what happens after death. Some religions assert that the souls of dead people go to heaven. Some religions assert that the soul takes on another form and lives on earth again, a belief called reincarnation. Some people believe that the body as matter decomposes, and this matter becomes part of the life cycle in plant growth, which is consumed by living organisms. Many people with religious faith or without it take comfort in the cycle of life and death observable in nature and the seasons. Many people are comforted by their memories of those who have died.

MUMMIES OF ANCIENT EGYPT

In ancient Egypt, elaborate methods were used to preserve the body of royalty after death. These methods were used because the Egyptians believed they assured the dead person a good life in the afterworld.

The first step was embalming, which involved removal of major body organs, drying the body, and wrapping it in linens and spices. The higher the individual's status in society, the more elaborate the ritual. The coffin was painted with a portrait of the person and filled with valuables, such as gems and prized possessions of the deceased, to be used in the afterlife. Cats, which were thought to be sacred, were sometimes mummified and buried with their owners.

▲ Mummy of an Egyptian priestess dating from about 1000 B.C.E. showing the outer decoration of the coffin and wrapped body inside. *British Museum, London, UK/Bridgeman Art Library.*

* **neurotransmitters** (nuro-trans-MIH-terz) are chemical substances that transmit nerve impulses, or messages, throughout the brain and nervous system and are involved in the control of thought, movement, and other body functions.

Delirium

Delirium is a sudden onset of widespread generalized confusion. It is a serious condition that can lead to death if not treated urgently. The cause is presumed to be interference in the neurotransmitters in the brain. The neurotransmitters act as messengers throughout the nervous system. When a situation prevents the neurotransmitters from sending out the vital instructions from the brain to the rest of the body, there is no way to make*

sense of the information coming from the senses. Therefore, general confusion sets in. In this condition, an individual cannot even recognize or accurately perceive familiar objects and situations.

* **psychoactive** (sy-ko-AK-tiv) affecting a person's mood, behavior, perceptions, or consciousness.

Joey's Story

Joey was hurrying down the hall of his high school, heading to Algebra class. He noticed a man standing in the hall watching the students go past. The man seemed very interesting. His face looked like someone from Joey's history book, but his clothes were modern. Joey was so fascinated with the man that he went up to him and asked, "Who are you?"

"Where are you supposed to be going?" The man asked sternly.

Joey felt that the man did not want to be bothered, but as he turned away from the man, he realized that he did not know where he was going. "I guess I'm going to lunch," Joey muttered.

"Lunch was hours ago," the man exclaimed.

"What am I doing in school? How did I get here?" Joey asked.

"Joey, are you all right? Tell me that you know me. I am Principal Fletcher," the man said. "Joey, come on. Tell me that you are joking." Principal Fletcher thought Joey was acting like students he had seen who used psychoactive* drugs, but Joey was not the type. What kind of drug could he be on? Then Principal Fletcher remembered signing Joey into school late this morning because Joey had been to the doctor's office. If the doctor had prescribed a new drug, Joey could be suffering from delirium.

What Is Delirium?

Delirium is a symptom of some disease or medical disorder. Its onset is sudden with severely impaired thinking. The person with delirium has trouble with simple reasoning and speaking. Delirium characteristically involves rapid and frequent change between mental states. The individual may start off agitated and then become extremely calm only to go right back to being agitated. The doctors who most often have to deal with delirium work with emergency room and cancer patients.

Medical conditions that bring on delirium include extreme pain and trauma. Many cases are caused by the patient misusing a drug or the patient's doctor prescribing the wrong drug. Delirium is considered a medical emergency. It can lead to long term mental and physical difficulties or even death. Proper and rapid treatment of underlying condition is essential.

How Common Is Delirium?

Delirium can affect people of all ages. However, it is most common among elderly people. There are more cases of delirium in males than in females. Delirium is the problem in about 20 percent of all people admitted to the hospital, but the proportion of patients admitted to Intensive Care

- * **psychological** (SI-ko-LOJ-i-kal) refers to mental processes, including thoughts, feelings, and emotions.
- * **serotonin** (ser-o-TO-nin) is a neurotransmitter, a substance that helps transmit information from one nerve cell to another in the brain. It is associated with feelings of well-being.
- * **dopamine** (DOE-puh-meem) is a neurotransmitter in the brain that is involved in the brain structures that control motor activity (movement).
- * **dementia** (dih-MEN-sha) is a loss of mental abilities, including memory, understanding, and judgment.

Units is estimated at 40 percent. Moreover, delirium goes unreported in as many as two-thirds of all patients. Most of these unreported cases are for patients whose main delirium symptom is abnormal calmness.

Where Causes Delirium?

There are many causes of delirium, but the psychological* explanation for the symptoms is dysfunction in critical areas of the brain and the interference of essential neurotransmitters. The two main areas of the brain that influence the onset of delirium symptoms are the prefrontal cortex (responsible for decision making) and the parietal areas (responsible for perception). The main neurotransmitters that are disrupted leading to delirium are acetylcholine, serotonin*, and dopamine*. Acetylcholine is important for learning and memory. Serotonin affects moods and arousal. Dopamine contributes to attention and emotion.

How Is Delirium Diagnosed and Treated?

The key symptom of delirium is sudden acute confusion. Detailed signs of delirium can be deduced by reviewing the brain functions that are disturbed at the time of the onset. Because the prefrontal cortex is not working correctly, the person will not be able to make even the smallest decisions. Hallucinations are common because the individual's perception has ceased operating. With acetylcholine dispersed or blocked, even the most common and essential thoughts and memories are unavailable. The inaction of serotonin brings on wide mood swings as well as sleep disorders. Emotion is inappropriate and attention is weak due to the problems with the dopamine levels in the brain. The person affected may be inappropriately agitated or inappropriately unaroused.

Diagnosis As with most medical conditions, delirium is diagnosed through an admissions interview regarding the existence of essential symptoms. With other medical problems, the doctor can interview the patient directly, but with delirium the patient is confused and has problems communicating. Any answers given by the patient in such a state of mind cannot be trusted. Preferably a family member or someone who knows the patient can be interviewed regarding the patient's medical situation. Of course, this is not always possible. The family member might not know enough about the patient's condition or the patient may have been brought to the hospital by a stranger. In such a situation, without a medical history, the doctor might not be able to determine if the patient has long-term dementia* or acute, sudden delirium.

Another problem with diagnosis stems from the fact that delirium may arise from a condition for which the patient is already hospitalized. Many unreported cases of delirium occur among patients already hospitalized. Nurses tend not to report with necessary urgency any confusion they observe in a patient. Also, delirium usually is recognized by inappropriate agitation, it can also occur with inappropriate tranquility, which can be missed as a sign of delirium.

The diagnosis of delirium cannot be achieved without a detailed history of the person and the current onset of delirious symptoms. Nurses, who have more interaction with the hospitalized patient than doctors do, need to know what to look for and how to report their observations. Furthermore, critically ill patients should be monitored regularly for delirium.

Treatment Treatment for delirium is focused on addressing the underlying cause. Doctors concentrate on finding the cause of the delirious episode. After the underlying cause is identified and treated, efforts are made to relieve the delirium.

Drugs are not the first choice in treating delirium. However, some drugs can help if the patient is hurting himself or others or is not responding well to non-medicinal treatments. An antipsychotic drug may be prescribed. Antipsychotic drugs* are mainly used for their calming effects. The use of drugs for delirium can have adverse or even paradoxical effects which lead the patient to be even more agitated and delusional.

Non-medicinal treatments include making the patient's environment as familiar and calming as possible. The patient's family should bring some personal objects from home to make the hospital room familiar. The hospital staff interacting with the patient should be limited in number so that the patient does not get confused with too many new faces. Also, whenever possible the patient should have a private room. The patient should regularly be informed about his condition and provided with mentally challenging activities.

Complications Delirium is often confused with dementia. The two disorders share symptoms but one of the key components of delirium is the struggle to understand one's surroundings that is not necessarily present in dementia. Dementia is characterized by memory impairment that interferes with processing information. Sufferers of both delirium and dementia have a hard time understanding what is being told to them. However, delirium involves a general confusion, while dementia involves a confusion specific to the processing of new information and memory tasks. Delirium is a symptom of a serious underlying disorder. Dementia is a disorder with a collection of symptoms, one of which may be delirium. Delirium is expected to be short-term and reversible, whereas dementia involves a slow steady decline in mental functioning.

Can Delirium Be Prevented?

Delirium has a sudden onset; therefore, by definition, it cannot be prevented. However, applying what is known about delirium can offer some preventive measures in some cases. For instance, research has identified some of the characteristics of people at risk and also some of the conditions that lead to higher occurrence of delirium. Doctors should be particularly aware when dealing with someone at risk to respond quickly when such a person has a condition that threatens delirium. Certain prescribed drugs may induce delirium. A doctor should be especially

* **antipsychotic drugs** are medications that counteract or reduce the symptoms of a severe mental disorder such as schizophrenia.

cautious in prescribing these drugs to an elderly person or someone with a preexisting psychological disorder. Of course, the recreational use of psychoactive drugs is a preventable risk factor, but the warnings are often ignored by users. If more information is made available to the public, people can be more aware in taking care of themselves and others.

Delusions, Delusional Disorders, and Paranoia

Delusions (dee-LOO-zhunz) are one or more false beliefs that a person holds despite either lack of evidence that the belief is true or clear evidence that the belief is not true.

What Is a Delusion?

Imagine being completely convinced that someone is following you, to the point where you even call the police several times. Or imagine believing that your friend is spreading horrible rumors behind your back, even though there is no reason to think she is. Or imagine thinking that you are about to release a new hit record or that there is something physically wrong with you when your doctor has found otherwise.

These thoughts may sound ridiculous, but they help to illustrate what it means to be “delusional.” It is normal for people to have occasional thoughts that, for example, a boss, teacher, or friend is “out to get them.” Delusions are different, however. A person with delusions holds on to unfounded beliefs for a long time (more than a month) and is certain that they are true in spite of evidence to the contrary.

Delusions often are classified into the following subtypes:

- **Erotomaniac** (air-ROT-oh-MAN-ik). People with erotomaniac delusions falsely believe that someone is in love with them and make repeated attempts to establish contact through phone calls or letters or by stalking.
- **Grandiose** (gran-dee-OSE). People with grandiose delusions falsely believe that they have a great talent or have made an important discovery. These so-called delusions of grandeur involve wild exaggerations of the person's own importance, wealth, power, or talents.
- **Persecution**. People with delusions of persecution may falsely believe that someone is plotting against them, spying on them, lying about them, or harassing them. They may repeatedly call the police or try to get justice through appeals to the court system and other government agencies.
- **Jealousy**. People with this type of delusion incorrectly believe that a spouse or significant other is cheating on them, despite a lack of supporting evidence. People with jealous delusions sometimes resort to violence.
- **Somatic** (so-MAT-tik). This type of delusion relates to a bodily function. For example, people with somatic delusions may falsely believe that they have a physical deformity, an unusual odor, or some kind of germ in their bodies. As a result, they may make repeated trips to doctors, even after the doctors tell them they are fine.

* **hallucinations** (ha-LOO-sin-AY-shuns) occur when a person sees or hears things that are not really there. Hallucinations can result from nervous system abnormalities, mental disorders, or the use of certain drugs.

What Is the Difference between Delusional Disorder and Schizophrenia?

Delusions often are a symptom of serious psychotic (sy-KOT-ik) disorders, the most common being schizophrenia (skitz-oh-FREN-ee-uh). Besides delusions, other symptoms of schizophrenia include hallucinations*, disorganized thoughts and speech, and bizarre and inappropriate behavior. Schizophrenia typically first affects people in late adolescence or early adulthood.

If a person has delusions but none of the other symptoms of schizophrenia, the doctor may diagnose a delusional disorder. In delusional disorder, the delusions are not bizarre as they often are in schizophrenia. A delusion is bizarre if it is clearly impossible and not derived from ordinary experiences, such as believing a stranger has replaced your internal organs with someone else's organs without leaving any scar. Delusions that involve situations that could actually occur in real life, such as being followed or poisoned or having a serious illness, are not considered bizarre. Unlike schizophrenia, delusional disorder usually begins when people are in middle age (ages 35 to 55) or later adult life. Also, it generally does not lead to severe problems with everyday functioning and thinking. Many people with delusional disorder can keep their jobs, and, on the whole, their personalities do not change. However, once delusions occur, the false beliefs

often prove to be a long-term problem. Some people with delusions can become dangerous or violent, threatening harm to themselves or others.

How Is Delusional Disorder Treated?

Treatment for delusions usually involves regular meetings with a doctor who specializes in treating mental disorders. People with delusions tend to resist treatment at first and deny that there is any problem. The doctor needs to establish a cooperative relationship with the person, listening to his or her thoughts, easing any fears, and suggesting ways of coping. Some medications, particularly those used to treat depression and psychotic disorders, may help as well. Hospitalization may be necessary if the person shows signs of dangerous behavior or suicidal tendencies as a reaction to the delusional beliefs.

John's Experience

One day John came across a group of his friends huddled together on the soccer field. As he approached, they were all talking, laughing, and enjoying themselves. When he reached the group, however, his friends suddenly became quiet. John could not help feeling that his friends had been talking about him and that was why they had all stopped talking when he approached. He found himself thinking about it the rest of the day. He even began to suspect that his friends had been plotting against him.

The next morning, John saw the same group of guys huddled around his locker. This time when he approached, they shouted “surprise” and presented him with a new CD for his birthday. With embarrassment he realized that they had probably been discussing his birthday surprise the day before on the soccer field. He wondered what had caused him to doubt himself and his friends. Was it paranoia or a simple misunderstanding?

What Is Paranoia?

Paranoia is not a particular disorder so much as a way of experiencing (or incorrectly experiencing) reality. For example, John experienced paranoia when he wrongly believed that his friends were out to get him. A person whose phone was once tapped and was thereafter cautious about stating confidential information over the telephone might be considered reasonably concerned rather than paranoid. In contrast, a person who unrealistically feared that his or her phone was tapped even though it never had been before and who continued to think the phone was tapped even when presented with compelling evidence that it was not true, would be considered paranoid. The key issue is not the behavior itself so much as its basis in reality.

Common characteristics of people who tend to be paranoid include the following:

- Poor self-image
- Social isolation
- Expectation that others are trying to take advantage of them
- Inability to relax

- Inability to work with others
- Deep mistrust of others
- Inability to let go of insults or to forgive others
- Poor sense of humor

Like many personality traits, paranoia is something that can occur in different degrees of severity. In its milder forms, paranoia may be what a person feels only occasionally or only in certain situations. John, for example, experienced paranoia one day, but he did not usually feel this way. In its more severe forms, however, paranoia can seriously limit an individual's activities. People with significant levels of paranoia may consistently misinterpret reality and experience delusions.

Even people with severe paranoia may function normally much of the time if, for instance, they have a paranoid delusion that affects only a part of their life. For example, an individual might become obsessed with the idea that a particular chain of restaurants is conspiring to poison unsuspecting customers. He or she might stop eating in those restaurants and even go so far as to call the health authorities to investigate. Despite this delusion, the individual still may function normally in other respects.

What Causes Paranoia?

Medical and scientific experts do not fully understand the cause or causes of paranoia. Many healthy people experience paranoid feelings at some point in their lives, just as John did, and certain situations may increase the likelihood that someone will experience paranoid feelings. For example, evidence suggests that immigrants are more prone to suspiciousness and paranoia as a result of the language and other cultural barriers they face. People in the majority culture may misunderstand the immigrants' suspiciousness and react with hostility, which creates even more mistrust and misunderstanding.

Paranoia can accompany a number of illnesses. It is associated with certain neurological conditions such as temporal lobe epilepsy* and some forms of dementia* associated with aging, such as Alzheimer's (ALTS-hy-merz) disease*. People who repeatedly use drugs such as cocaine* or amphetamines* can also experience paranoia. In addition, paranoia is associated with mental disorders such as schizophrenia (skit-so-FREE-nee-a) and paranoid personality disorder.

Paranoid schizophrenia Schizophrenia is a serious mental disorder that causes people to experience hallucinations, delusions, and other confusing thoughts and behaviors that distort their view of reality. Doctors have come to understand that schizophrenia likely is the result of brain differences or chemical imbalances within the brain. However, schizophrenia is a complex and disabling disorder, and scientists and medical professionals do not fully understand it. Schizophrenia is also a disorder that can assume many different forms, or subtypes. Paranoid schizophrenia is

* **temporal lobe epilepsy** (EP-i-lep-see), also called complex partial epilepsy, is a form of epilepsy that affects the part of the brain that is located underneath the sides of the head, near the ears. Epilepsy is a condition of the nervous system characterized by recurrent seizures that temporarily affect a person's awareness, movements, or sensations. Seizures occur when powerful, rapid bursts of electrical energy interrupt the normal electrical patterns of the brain.

* **dementia** (dih-MEN-sha) is a loss of mental abilities, including memory, understanding, and judgment.

* **Alzheimer's (ALTS-hy-merz) disease** is a condition that leads to gradually worsening loss of mental abilities, including memory, judgment, and abstract thinking, as well as changes in personality.

* **cocaine** (ko-KAYN) is a stimulant, a drug that produces a temporary feeling of alertness, energy, and euphoria.

* **amphetamines** (am-FET-a-meenz) are stimulants, drugs that produce a temporary feeling of alertness, energy, and euphoria.

one of the subtypes. (The others are catatonic, disorganized, undifferentiated, and residual.)

Paranoid schizophrenia is characterized by the presence of one or more prominent delusions or auditory hallucinations—hearing threatening voices that are not there—in a person who seems to have otherwise relatively normal thinking ability and emotions. The delusions are usually organized around a consistent theme relating either to the idea that the person is being persecuted (he is being targeted) or that he or she has special powers; the hallucinations, when they are present, are typically related to the delusional theme. People with paranoid schizophrenia often act anxious, aloof, angry, and argumentative, and they may also exhibit either a stiff, formal attitude or be quite intense in their interactions with others.

None of the other major characteristics associated with schizophrenia, such as disorganized speech, inappropriate behavior, or inappropriate emotional reactions, is present in people with paranoid schizophrenia, and the age at which this disorder begins tends to be later than it is for the other forms of schizophrenia. People with paranoid schizophrenia are more likely to succeed in holding a job and at living independently when compared to people with other subtypes of schizophrenia.

Paranoid personality disorder Paranoid personality disorder is one of several different types of personality disorders (others include narcissistic, dependent, avoidant, and antisocial). All of the personality disorders cause individuals to behave inappropriately in many different situations. These disorders typically lead to problems in social, school, and work settings, and cause the affected person significant internal distress. The personality patterns that later develop into personality disorders usually begin during childhood or adolescence. The persistent nature of these conditions makes them particularly difficult to treat.

The key characteristic of paranoid personality disorder is a pattern of deep distrust of others. Unlike people who have paranoid schizophrenia and whose ideas may be totally bizarre or out of touch with reality, people with a paranoid personality disorder are not completely out of touch with reality, but they are out of step with it. Their belief that other people are untrustworthy colors all aspects of their lives, and as a result, they have difficulty forming close relationships.

Some common characteristics of people with paranoid personality disorder are as follows:

- Suspecting, without justification, that others are trying to harm or trick them
- Doubting the loyalty of friends
- Avoiding talking about themselves for fear that the information will be used against them
- Interpreting casual remarks or events as threats or insults
- Carrying grudges and seeking revenge

- Overreacting with anger to minor slights
- Being overly jealous and suspicious about others (e.g., girlfriend, boyfriend, or spouse) without justification

One complication about paranoid personality disorder is that it is often self-fulfilling. A paranoid person's suspicious and combative nature may provoke hostile responses from others. These responses, in turn, confirm the paranoid person's fears that others are hostile and not to be trusted. The paranoid person, then, does not see his or her own role in creating the situation, but instead erroneously concludes that his or her suspicions are justified.

Some possible signs of paranoid personality disorder may appear in childhood or adolescence. These include difficulties making friends and relating to others, the tendency to be a loner in social situations, and poor performance in school. Paranoid personality disorder is more common in males than in females. Overall, it affects between 0.5 percent and 2.5 percent of the population. Frequently, an individual who has schizophrenia also has relatives with paranoid personality disorder, and this link suggests that the two conditions may have a genetic* component.

Dementia

Dementia (dee-MEN-shuh) is a decline in mental ability that usually progresses slowly, causing problems with thinking, memory, and judgment. It is most often seen in the elderly and is caused by deterioration in parts of the brain. A person with dementia eventually has difficulty with the activities of everyday living, such as balancing a checkbook, reading, and working.

Why Doesn't Grandpa Recognize Me?

As Jacob sat in the hospital waiting room, he reminisced about this same day last year; Grandpa had taken him to the Baltimore Orioles' home opener to celebrate his eleventh birthday. Since then, his grandfather had experienced a few small strokes, or blockages in the blood vessels that supply oxygen and nutrients to his brain. The resulting loss of oxygen caused damage to parts of Grandpa's brain, and now he could barely talk or make any decisions for himself. Grandpa was 70 years old, but he almost seemed like a little kid.

During today's visit, Grandpa did not seem to know that it was Jacob's twelfth birthday. In fact, Grandpa did not even seem to know who Jacob was. Seeing his grandfather in this state made Jacob very sad and a little bit angry. He did not understand why his grandfather did not recognize him. Grandpa's doctor saw Jacob sitting in the waiting room and knew he was upset. She sat beside him and explained that Grandpa did not recognize people because he had a condition called dementia, which was a result of the brain damage caused by the strokes. (This kind of dementia is called multiple infarct dementia or vascular dementia.) She said that only time would tell if Grandpa's condition would improve, but in the meantime Jacob should keep visiting him, talking to him, and including him in special occasions. She told Jacob that even though Grandpa might act differently in many ways, there was still a part of the old Grandpa inside and that Jacob's presence could still bring enjoyment to him.

What Are the Common Forms of Dementia?

Dementia is a term that refers to several different physiological brain diseases, all of which affect the way brain neuron cells function, and the symptoms of which can overlap. In the healthy brain, neuron cells produce electrical and chemical impulses or signals, and the process of relaying these signals helps people think. In a person suffering from some form of dementia, this neuron relay process does not work correctly and thinking processes are impaired. Dementia has four common forms:

- Alzheimer's disease: Degeneration of healthy brain tissue occurs as clumps of plaques and knots called tangles form in cell neurons. Several genes have been identified that are associated with Alzheimer's disease, and many researchers theorize that the predisposition for this disease may be inherited. This disease is progressive and fatal.

- **Vascular dementia:** With gradual or sudden onset of symptoms, arteries that normally deliver blood to the brain become narrow or are obstructed altogether. When the blood flow to the brain is cut off, a person may experience a stroke. The resulting brain damage may cause symptoms of dementia. Sometimes underlying causes, such as high blood pressure, can be treated, in which case the progression of the disease can be slowed or eliminated. Sometimes brain damage is irreversible, but not necessarily fatal.
- **Lewy body dementia:** Clumps of protein in the brain, called Lewy bodies, cause this form of dementia, and are also found in the brains of people with Alzheimer's disease and Parkinson's disease*. People with Lewy body dementia may be treated effectively with some medicines used to treat Alzheimer's and Parkinson's. However, brain impairment can be serious and is permanent.
- **Frontotemporal dementia:** In this condition, cells located in the frontal area of the brain are specifically affected, and people with this disease develop socially inappropriate behavior. With onset as early as age 40, this disease is inherited.

In addition, people who have Huntington's disease, Parkinson's disease, and Creutzfeldt-Jakob disease may develop dementia in the later stages of their disease.

What Are the Symptoms of Dementia and Who Is Affected?

People who develop dementia typically experience changes in personality, frequent confusion, and reduced energy. Thinking, reasoning, memory, and judgment are often affected, and a person with dementia might also have trouble with language and motor (movement) skills.

Dementia is mostly a disease of the elderly. It is estimated to affect more than 15 percent of people (about 1 in 7) over age 65 but as many as 40 percent of people (2 out of 5) over age 80. It is one of the most common reasons for nursing home admissions in the United States. In the early 2000s, more than 5 million people in the United States were estimated to be living with Alzheimer's disease, which is a common form of dementia. When dementia affects young people, it is usually the result of an injury or some other condition that causes brain damage.

What Causes Dementia?

Dementia can result from any physical damage that interferes with the normal functioning of the brain. This damage may be permanent or temporary, and it can have a variety of causes that are usually classified into three categories:

- **Structural:** a problem with the structure of the brain that affects its ability to function.

* **Parkinson's disease** is a disorder of the nervous system that causes shaking, rigid muscles, slow movements, and poor balance.

* **metabolic** (meh-tuh-BALL-ik) pertains to the process in the body (metabolism) that converts food into energy and waste products.

* **high blood pressure** also called hypertension, is a condition in which the pressure of the blood in the arteries is above normal.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **degenerative** (dee-JEN-er-uh-tiv) means progressively worsening or becoming more impaired.

* **Acquired Immunodeficiency Syndrome** or AIDS, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

Infectious (in-FEK-shus): a bacterium or virus causes an infection that interferes with brain function.

metabolic* or toxic: a problem with the substances in the blood that are needed to nourish the brain.

Structural causes of dementia The most common form of dementia is Alzheimer's (ALZ-hy-mers) disease, a condition in which abnormal structures (called plaques and tangles) accumulate in the brain's neuron cells and increasingly interfere with nerve cell function. Alzheimer's disease leads to a gradual loss of mental abilities, including memory, judgment, and abstract thinking, as well as to changes in personality. This disease usually affects people over age 65.

Successive strokes are the second most common cause of dementia. Strokes, which are caused by blockages in arteries that feed the brain, gradually destroy brain tissue. People who develop this condition often have a history of high blood pressure* and/or diabetes*.

Other structural causes of dementia include:

- A brain tumor, which is a mass of abnormal cells growing in the brain. As the tumor grows, it presses on certain areas of the brain and causes personality change and problems with thinking, movement, and other functions. Severe or repeated milder head injuries can lead to dementia, also.
- Parkinson's disease is a slowly progressing, degenerative* disorder of the nervous system that leads to shaking, difficulties with movement, and muscle stiffness. About 15 to 20 percent of people who have it also develop dementia.
- Huntington's disease is a rare inherited disease in which people in midlife begin having occasional jerks or spasms that are caused by a gradual loss of brain cells. People with Huntington's disease eventually develop uncontrolled movements and mental deterioration.

Dementia caused by infectious diseases People who have Acquired Immunodeficiency Syndrome* (AIDS) sometimes experience dementia because the virus that causes AIDS can infect the brain. Another dementia-causing condition is Creutzfeldt-Jakob Disease (CJD), a very rare, rapidly progressing disease that affects the brain. Researchers are not sure what causes CJD, although in some cases it appears to have been passed from human to human by contaminated surgical instruments. One form of the disease has been found in humans who have eaten beef from a cow that has mad cow disease. Yet another cause of dementia is viral encephalitis (en-sef-uh-LIGHT-us), an inflammation of the brain that can be caused by certain viruses, particularly those transmitted to humans by the bite of a mosquito.

Metabolic and toxic causes of dementia Having too much or too little of certain substances in the body can damage the brain enough to cause dementia. The excessive or insufficient substances affect the metabolism. For example, anoxia (too little oxygen reaching the brain),

vitamin B12 deficiency, and hypoglycemia (hy-po-gly-SEE-mee-uh; a lower than normal amount of sugar in the bloodstream) are conditions that can lead to dementia if left untreated. Toxic reactions can occur in people who take in excessive amounts of alcohol or some other drugs, and these toxic amounts can cause dementia. People with severe alcoholism can develop Wernicke-Korsakoff syndrome, which occurs when a person's body has too little of the vitamin called thiamine. Thiamine plays a key role in helping the brain process sugar for energy; over time, a thiamine deficiency can cause mental confusion and memory loss. People who are malnourished or do not get enough of certain other nutrients from their diet have also been known to develop Wernicke-Korsakoff syndrome.

How Is Dementia Diagnosed and Is It Treatable?

The process of diagnosing dementia usually begins when the person and/or family members begin to notice that the person is experiencing increasing forgetfulness, lapses in memory, or problems with

GET TO KNOW THE SCIENTISTS

Many dementia-causing conditions are named after the physicians or scientists who discovered them:

Alois Alzheimer (1864–1915) was the German physician who published an article on a “new disease of the cortex” (the outermost or “reasoning” portion of the brain) in 1907. The disease is now called Alzheimer's disease.

James Parkinson (1755–1824) was the English physician who published “Essay on the Shaking Palsy” in 1817, one of the first articles on the disease later named for him.

George Huntington (1850–1916) was an American doctor from Ohio whose 1872 paper on hereditary chorea (kor-EE-uh; a condition of uncontrolled, rapid movements) made him famous because of its accurate and complete descriptions of this disease. The condition later became known as Huntington's chorea or Huntington's disease.

Hans Gerhard Creutzfeldt (1885–1964) and Alfons Jakob (1884–1931) were German physicians who, in the 1920s, first described the brain disease later known by their last names hyphenated.

Carl Wernicke (1848–1905) was a German physician whose 1881 *Textbook of Brain Disorders* first described a nervous system condition caused by insufficient amounts of a vitamin known as thiamine.

Sergei Korsakov (1853–1900) was a Russian psychiatrist who studied and described the connections among alcoholism, nerve inflammation, and mental symptoms.

everyday tasks. The doctor may give the patient a mental status test by asking questions that require memory of everyday events or by asking the patient to perform simple tasks such as counting backwards. The doctor will also try to determine whether there is some underlying cause of the person's symptoms. Blood tests and scans of the brain can help the doctor see whether there is an imbalance of certain substances in the body or a structural problem in the brain. The doctor will also ask for a complete description of the person's symptoms, his or her family medical history, current medications, and about the presence of any other medical conditions (such as high blood pressure or diabetes).

In most cases, dementia cannot be cured; rather, it is likely to worsen over time, especially when a progressive disease such as Alzheimer's disease or Parkinson's disease is the cause. However, in some cases the worsening of dementia can be slowed and sometimes the symptoms can actually improve if the underlying cause can be addressed. For example, controlling blood pressure and quitting smoking can slow or stop progressive dementia associated with blockages in blood vessels within the brain. Stopping excessive alcohol intake or correcting a vitamin deficiency can also help, if either of these is causing the problem.

When a Loved One Has Dementia

Dementia is especially hard on family members and loved ones who remember the person as he or she once was. The loss of memory, increased helplessness, and personality changes can be especially difficult to witness and accept. However, family and friends can play an important role in helping the person deal with dementia. Familiar faces, regular exercise, and having a cheerful, familiar environment have all been shown to help people with dementia. Caregivers can also help the person establish a routine, take part in low-stress activities, and get good nutrition and regular exercise. Large calendars and clocks can help the person keep track of the day and time. Reminders from family, friends, or other caregivers about what is going on, who they are, and where the person is can also be helpful.

Dengue Fever

Dengue (DENG-gay) fever is a serious illness commonly occurring in tropical and subtropical regions of the world. It is caused by a virus that passes from person to person through the bite of a mosquito, and it causes high fever and pain in the muscles, joints, and bones.

What Is Dengue Fever?

Dengue fever, which was originally known as breakbone fever, is characterized by a sudden high fever and severe pain in the muscles, joints, and bones. The disease is more likely to cause serious illness in children, and some cases are fatal. Dengue fever is caused by four different strains

Aedes Aegypti, the Dengue host transmitter. Image copyright Vinicius Tupinamba, 2008. Used under license from Shutterstock.com.

of flavivirus (each of the four is known as “dengue virus”), which are within the arbovirus family of viruses, spread by blood-sucking insects. The genus of mosquitoes known as *Aedes* is responsible for most dengue transmission. This genus of mosquito is distinct from the type that transmits malaria, which is most active at night. *Aedes* mosquitoes are day feeders, as they are most active during the day as opposed to night biters. Each of the four strains, or serotypes, can cause illness, and being infected by one type of dengue virus does not make a person immune to the other three. Infection with one strain of dengue virus increases the chances that an individual will develop more severe complications if infected with a second strain.

Who Gets Dengue Fever and How?

The World Health Organization (WHO) reported in 2008 that worldwide dengue fever was increasing sharply. Whereas before 1970 only 9 countries had reported epidemics, as of 2008, more than 100 countries had. Dengue fever is widespread in Southeast Asia, Africa, the Americas, Eastern Mediterranean, and western Pacific. WHO estimated that as of 2008, 2.5 billion people were at risk of infection with 50 million infections reported worldwide. The fever occurs most frequently in highly populated areas such as cities with poor control of stagnant water and mosquito populations. Dengue fever is one of the leading causes of death in children in many countries of Southeast Asia. Transmission may be increased under El Niño conditions. Although the number of places where dengue fever is found continues to grow in the early 2000s, the disease remained rare in the United States, with most cases appearing in travelers arriving from other countries.

The virus does not spread directly from person to person. The bite of a mosquito, usually the female *Aedes* mosquito, is required to transmit the disease. The insect takes in the virus with its meal of blood when it

WHAT'S IN A NAME?

The history of medicine is replete with fanciful names derived from the symptoms or causes of various medical conditions, such as “breakbone fever.” The following are examples:

- **Alice in Wonderland syndrome:** a neurologic condition in which a person has delusions or hallucinations
- **Cri-du-chat, or cat-cry, syndrome:** a genetic disease with many signs and symptoms, including mental retardation and a high-pitched, catlike mewing cry
- **Cauliflower ear:** thickening of the outer ear with distortion of the contours, also known as boxer’s ear
- **Happy puppet syndrome:** a genetic disorder marked by a jutting out of the jaw, seizures, and prolonged spasms of laughter
- **Jumping disease:** an exaggerated response to being startled, causing a person to jump, fling the arms around, and yell; sometimes called jumping Frenchmen of Maine disease after the French loggers it was first found to affect
- **Kissing disease:** infectious mononucleosis, an acute viral illness that can be spread through saliva
- **Mitten hand:** a birth defect involving the fusion of several fingers, with a single fingernail
- **Vagabond’s disease:** discoloration of the skin in people who are exposed to lice bites over a long period of time.

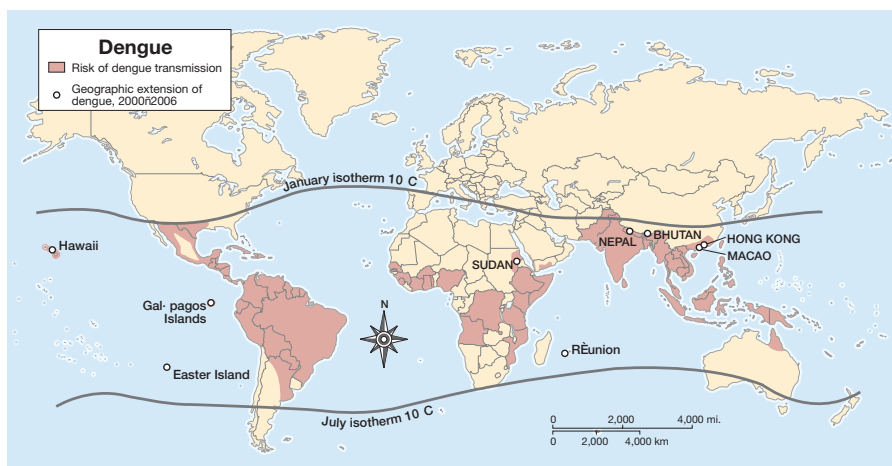

bites an infected person. Because the virus remains in the mosquito for the rest of its life, the mosquito can pass the infection to many people. In areas with large populations of mosquitoes, dengue fever epidemics can occur.

What Are the Symptoms of Dengue Fever?

A sudden high fever, sometimes reaching 104 or 105 degrees Fahrenheit, often is the first sign. The affected individual also usually has a flushed (reddish) face. Muscle, joint, or bone pain develop, especially in the knees and shoulders; nausea and vomiting occur with a severe headache and pain behind the eyes. There are also small hemorrhages, for example, bleeding gums, petechiae (pin-point red dots under the skin), or a nosebleed. Fever typically begins on the third day after infection and lasts five to seven days. In some children a pattern known as saddleback fever may occur in which the fever fades for a day and then returns. Once the fever goes away, the other signs and symptoms usually fade as well, with recovery usually complete by seven to ten days. Some symptoms may linger for a few weeks.

Dengue Fever

The areas of the world at risk of dengue transmission in 2006. Dengue fever has a close relationship to the regions where the *Aedes* mosquito lives. The disease is widespread close to the equator, in the tropical areas of Asia, Africa, South America, and Central America, the mosquito's preferred habitat. © World Health Organization (WHO). Reproduced by permission.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

What Are the Complications of Dengue Fever?

The most serious form of the disease is called dengue hemorrhagic fever, which usually occurs between the third and seventh day. Dengue hemorrhagic fever is characterized by high fever; serious hemorrhage (often with bleeding from the nose, mouth, and gums); pneumonia; and sometimes owing to blood vessel collapse, failure of the circulatory system (heart failure) or shock. People who develop dengue hemorrhagic fever usually require hospitalization, and in the hospital they receive fluids. It is possible to die from this form of the disease, although most people recover. Dengue hemorrhagic fever and dengue hemorrhagic shock are more likely to develop if an individual has previously been infected with another strain of dengue, and most people who experience this complication have had prior infection with one or more other strains. One theory to explain this phenomenon is that some of the immune responses formed by the body in defense against the first strain may predispose some of the body's cells for further viral entry and replication. Other complications from dengue fever may include brain damage from prolonged shock, inflammation of the heart tissue, and liver failure, but these are rare.

How Is Dengue Fever Diagnosed and Treated?

Doctors typically diagnose dengue fever from a patient's history of symptoms and risk factors, including whether that person has been in locations where dengue fever is found. The doctor looks for high fever, pain, and rash, known as the dengue triad. To help confirm the diagnosis, doctors may order blood tests or tests on spinal fluid to look for antibodies to the virus.

The disease usually clears up on its own. Supportive care such as fever reducers and pain killers may be used. Dengue fever often involves excessive loss of body fluids, through sweating, vomiting, or diarrhea, requiring the patient to drink plenty of fluids to avoid dehydration*. Over-the-counter medicine, such as acetaminophen*, can relieve pain and fever

while the disease runs its course. Patients suspected to be developing dengue hemorrhagic fever are closely monitored and have frequent blood work to check for signs of hemorrhagic conditions.

How Is Dengue Fever Prevented?

In the early 2000s, scientists were working on a vaccine for dengue fever, but one was not yet available. The only way to control the spread of the disease is to reduce mosquito populations. Using pesticides, stocking lakes and ponds with special fish that eat mosquito larvae, and covering or eliminating small pools of standing water in which the insects breed can help keep mosquito levels in check. People can protect themselves from bites by using insect repellent, wearing clothing that covers much of the body, and avoiding outdoor activity. Mosquito repellent containing DEET* is most effective.

Depressive Disorders

Major or clinical depression (dee-PRESH-un) is a mental disorder that causes people to feel long-lasting sadness and to lose interest in activities that normally give them pleasure. It is also referred to as unipolar depression because the people have only one type of feeling, that of sadness. People with depression have continuing negative and pessimistic thoughts and may experience changes in eating and sleeping patterns and in their ability to concentrate and make decisions.

▲ Computer-generated positron emission tomography (PET) scan (top) shows the brain of a healthy person in contrast to the brain of a person with untreated depression (bottom). Doctors and researchers use PET scans to study how the brain functions. *ASAP/Photo Researchers, NIH/Science Source, Photo Researchers, Inc.*

* **DEET** (abbreviation for N,N-Diethyl-meta-toluamide) is the active ingredient in many insect repellants.

▲ In his autobiographical book *Darkness Visible*, William Styron, seen here in a 2000 photo, explores the possible sources of his debilitating depression, his recovery, and the history of this illness which has affected many other artists and writers. Sean Gallup/Getty Images.

Jodie's Story

The sun is shining brightly, but 15-year-old Jodie feels darkness all around her. She used to sleep so soundly that her father said he needed a cannon blast to wake her. In recent weeks, however, she rises unexpectedly in the gray light before dawn. She lies awake, staring at lights caused by headlights of passing cars and crying as the shapes slowly cross her ceiling.

Why would Jodie cry over a thing like that? Lately, so many odd things bring tears to her eyes. She is tired constantly. She cannot concentrate. Sometimes when she tries to solve a simple math problem in class or decide what to have for lunch, it seems as if her brain will not work. Jodie used to love to go with her friends to get a soda after school. Now all she wants to do is get home to her room and be alone. Nothing is enjoyable, not her favorite books or television shows or even foods. Sometimes Jodie is annoyed at things and people, but she cannot explain why. For weeks, Jodie's friends have told her to snap out of it. She thinks to herself, "I want to, but what would the point be? I wish I knew what was wrong!"

What is Depression?

Jodie has major or unipolar depression, a disorder that affects more than 17 million people in the United States. Although people often say that they are depressed when they feel down, this is not the same thing as the mental disorder called depression. The condition often leads to constant negative thinking and sometimes substance abuse or self-harm. Extreme depression can lead to the sufferer attempting or committing suicide.

Everyone feels sad at times. Perhaps a relative has died or the home team has lost an important game. However, in a short time, that unhappy mood passes, and person is excited about a day at the beach or a good grade on a test. However, people with depression have long periods when nothing seems to make their mood better. It affects their whole body and mind: how they feel, think, and behave. The good news is that, if they get professional help, more than 80 percent of people with depression can feel better, often within a few weeks.

Award-winning author William Styron, who wrote the book *Sophie's Choice*, suffered from depression. In *Darkness Visible*, a book about his own depression, Styron calls the disorder a "veritable howling tempest in the brain." He compares depression to a storm that blows away all of a person's usual feelings and abilities to cope with life.

How Does Major Depression Differ from Other Forms?

Depression comes in many forms. The *Diagnostic and Statistical Manual of Mental Disorders IV* established guidelines for determining what kind of depression a person may have. According to the manual, major depression or clinical depression involves excessive sadness and/or loss of interest that lasts for at least two weeks. Episodes of feelings of sadness may be a single occurrence or recurrent as certain events happen over the lifespan.

In some cases, the down period lasts for many weeks or months. At times, a person with major depression may feel as if the disease has gone away on its own. Normal feelings return, like the ones the individuals used to experience. But like a tide that moves in and out at the beach, the suffering usually comes back if the person does not get treatment. About 8 percent of people experience this type of depression at some point in their lives.

Chronic depression, also known as dysthymia (dis-THI-mee-ah), is a form of depression that lasts for two years or more. People with chronic depression do not experience the severe down feelings of someone with major depression. Instead, they suffer from a nagging feeling of emptiness that never seems to go away. They often are said to have a negative view of life or to feel “down in the dumps.” About 15 to 20 percent of people who get a depressive disorder have chronic depression. Chronic depression and major depression are referred to as unipolar because the person experiences one type of feeling, that of sadness.

Bipolar disorder (sometimes called manic depression) is a very different type of depressive disorder. People with bipolar disorder have periods of almost unlimited energy, wild happiness, and hyperactivity that are followed by periods of depression. The mood extremes may be mild or severe, and the mood changes may occur slowly or quickly. Because this type of depression involves two different feelings, it is called bipolar depression, to distinguish it from unipolar depression. Only about 1 percent of people with a depressive disorder have bipolar disorder.

How Do People Know They Have a Unipolar Disorder?

Major depression and chronic depression involve a variety of symptoms. Some people experience only a few symptoms, while others feel most of them. Possible symptoms include the following:

- Ongoing feelings of sadness, hopelessness, or emptiness. In children, the mood can appear more as irritability than as sadness.
- Loss of interest in family, friends, favorite hobbies, and other activities that usually make the person happy.
- Crying easily or frequently.
- Change in sleeping habits. Some people have trouble sleeping. Others find themselves sleeping too much.
- Change in eating habits. Some people lose their appetite or lose weight without dieting. Others overeat or gain weight.
- Extreme fatigue or a feeling of slowness.
- Inability to concentrate or make decisions.
- Increased interest in death or thoughts of suicide.

These symptoms must last for at least two weeks and be present every day for most of the day before depression is diagnosed. If the person has recently experienced a major loss, the symptoms must last for two months

Did You Know?

- Clinical depression affects about 7 to 18 percent of the population before the age of 40 on at least one occasion in their lives.
- According to the Center for Mental Health Services, a U.S. government agency, as many as 1 in 33 children may have depression.
- For teenagers, the rate of depression may be as high as 1 in 12.
- About twice as many females as males report or receive treatment for clinical depression, although the gap is narrowing in recent history.
- According to the World Health Organization, by the year 2020 depression was anticipated to be the second leading cause of disability worldwide (after heart disease).
- The majority of people who commit suicide have a depressive disorder.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **identical twins** are twins produced when a single egg from the mother is fertilized and divides to form two separate embryos of the same sex with nearly identical DNA.

* **neurotransmitters** (nu-ro-trans-MIH-terz) are chemical substances that transmit nerve impulses, or messages, throughout the brain and nervous system and are involved in the control of thought, movement, and other body functions.

or longer before it is considered depression, and then it might be called reactive depression, meaning the person is adjusting to (or reacting to) a serious loss. For people with major depression, the symptoms might occur once, or they might return over and over. For those with chronic depression, the symptoms linger for a long time.

What Causes Depression?

Experts are not exactly sure what causes depression. Depression is not the result of laziness, weakness, or a flaw in character. The person simply cannot drive out the feelings of emptiness and sadness. Many different factors about a person's biological makeup and life experience can trigger depression. A combination of factors often must exist together, both within a person's body and during day-to-day activities, for depression to occur. Unlike a cold, this illness cannot be caught from another person. Components that appear to be involved are genetics, physiology, mental thoughts, and environmental happenings.

Genetic predisposition Some studies show that depression can occur in several members of the same family. Certain genes* that are passed from parent to child might increase the chance of getting the disorder. The strongest evidence of heredity comes from twin studies. Researchers have found that identical twins*, who have the same genes, are twice as likely to both experience major depression as fraternal twins, who do not have identical genes. Twin studies show that about 50% of the possible cause of depression is genetic and the other 50% is related to other factors. Someone who has a parent or sibling with major depression has a two to three times greater risk of developing depression compared with the average person. Specific single genes do cause some diseases such as cystic fibrosis, but combinations of many genes probably predispose some people to depression.

Mental components Some researchers observe that certain people seem more vulnerable to depression because of how they think about themselves and their lives. For example, people with low self-esteem might be more likely to develop depression. They might think that they are ugly, stupid, or always saying the wrong things, even if family and friends tell them differently. Also, people who tend to be pessimistic can become overwhelmed by depressed feelings. Such people see the negative in many situations and have feelings of being helpless and of having no choices. Perfectionists, who often set unrealistic goals for themselves, are prone to depression.

Physiological components Some researchers who study depression and the brain have found links between depression and an imbalance in certain chemicals in the nervous system, known as neurotransmitters*. These chemicals let brain cells communicate with each other and, therefore, allow the brain to function normally. In people with depression, the nervous system may have either too much or too little of these chemicals,

especially, serotonin* and norepinephrine*. Some research has suggested a link between depression and the hippocampus, a horseshoe-shaped structure that is a center for both mood and memory. Several other physical conditions may relate to depression:

Some illnesses such as heart disease, hepatitis, hypothyroidism, and brain damage caused by Alzheimer's disease or a head trauma may cause depression.

Some medications, such as birth control pills and steroids, may contribute to depression.

Depression may be caused by certain dietary deficiencies, such as reduced levels of omega-3 fatty acids and lower magnesium levels.

Poor sleep quality may occur with major depression. Depression leads to alterations in the function of the hypothalamus and pituitary and causes excessive release of chemicals that cause poor sleep.

Seasonal affective disorder (SAD) is a type of depressive disorder that occurs among some people living in areas in which winter months are especially dark. The reduction in sunlight may lead the body to produce higher levels of melatonin, a major player in SAD.

After childbirth some women may experience a disabling depression called postpartum depression. The incidence rate is 10 percent to 15 percent and usually sets in within three months of delivery and can last for about three months.

Environmental components Certain situations or events can cause depression or make it worse. The causes may arise from psychological factors, early experiences, or current circumstances. One of the toughest experiences for anyone is loss of a loved one, such as a grandparent who dies or a parent who moves away because of a divorce. It is natural to feel sadness on such occasions. For some people, however, the sadness does not go away; rather, it develops into depression. Other situations are linked with depression. Children and young adults can experience depression caused by school-related problems, difficulties with friends or family, or physical or sexual abuse. Adults may become depressed while dealing with the loss of a job, money problems, or separation or divorce.

Any one of these factors might lead to depression. Often, however, depression occurs for a combination of reasons. For example, it is normal for a teenager who loses a parent to feel sad. However, if the teenager already thinks that the world is a terrible place and nothing good ever happens, the stress of the loss might be worse for this teenager than for another. If the teenager also inherited a gene linked to depression, it might be difficult for the individual to bounce back from the loss without treatment.

How Are Depressive Disorders Diagnosed?

Depression is not always easy to diagnose. When a person cannot move one arm after a fall, the doctor can order an x-ray to check for a broken bone. However, the symptoms of depression may not be so obvious.

▲ Positron emission tomography (PET) records electrical activity inside the brain. With red and yellow showing brain activity, the brain of a depressed person at the top shows a decrease in activity compared to the brain of a person who has been treated for depression at the bottom. Treatment can improve metabolic activity and blood flow in the brain. *Photo Researchers, Inc.*

* **serotonin** (ser-o-TO-nin) is a neurotransmitter, a substance that helps transmit information from one nerve cell to another in the brain. It is associated with feelings of well-being.

* **norepinephrine** (NOR-e-pi-ne-frin) is a body chemical that can increase the arousal response, heart rate, and blood pressure.

* **psychiatrist** (sy-KY-uh-trist) is a medical doctor who has completed specialized training in the diagnosis and treatment of mental illness. Psychiatrists can diagnose mental illnesses, provide mental health counseling, and prescribe medications.

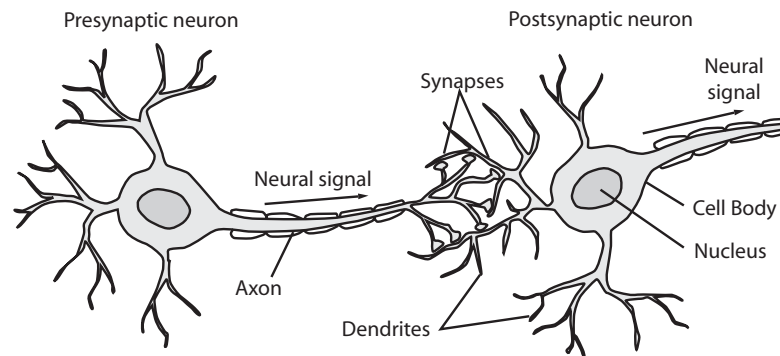

* **clinical psychologist** refers to a mental health professional who has earned a non-medical doctoral degree. Clinical psychologists can do psychological evaluation and provide mental health counseling and therapy.

DEPRESSION IN HISTORY

Ancient Egyptians and Greeks described 4,000 years ago a disorder that sounds like depression.

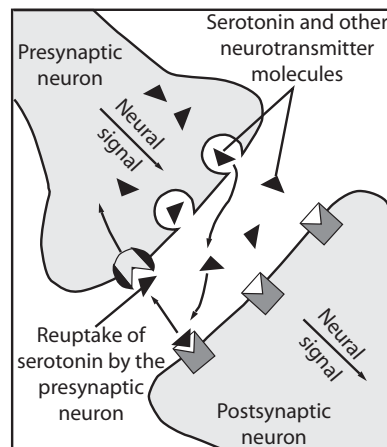

In past centuries, people tried treatments that seem cruel in the 21st century, such as removing parts of the brain or dropping depressed people into freezing water to shock them.

Often, people with depression do not realize that they have the disorder. They might sense that things are wrong, but often it is a family member, friend, coworker, family doctor, or teacher who notices the problem. That is when a professional who specializes in mental health, such as a psychiatrist* or clinical psychologist*, should be consulted. Such professionals are trained to observe how a person acts and talks. They look for symptoms of depression and decide what to do based on what they see and hear from the person and the person's family.

Nerve cells (neurons) use chemicals called neurotransmitters to send messages. The message (neural signal) travels in a specific direction from one cell to the next across a connecting synapse (SIN-aps), often transmitted from the axon terminal of one cell (the presynaptic neuron) across the synapse to the dendrites of the next (the postsynaptic neuron). Some antidepressant medications work by targeting levels of serotonin and other neurotransmitters in the synapses.

How Are Depressive Disorders Treated?

Almost all people who get depression can be helped. Statistics show that about 8 of every 10 people who get help find that their symptoms improve. Two primary kinds of treatment are used: psychotherapy and medication.

Psychotherapy Psychotherapy or counseling assists individuals in understanding and resolving habits or problems that may be contributing to or cause depression. Depressed people may benefit from talking with a psychiatrist, clinical psychologist, clinical social workers, or other mental health counselors. Mental health professionals can help depressed individuals learn how to cope better with stressful situations, such as moving to a new town or experiencing problems at home. Family members sometimes also take part in counseling.

Medication There are several antidepressant medications* that psychiatrists and other physicians can prescribe to affect the way that neurotransmitters work in the brain. These medications correct the imbalance that causes the symptoms of depression and allow a person to feel better. Examples of medications that are prescribed for depression are as follows:

- **Selective serotonin reuptake inhibitors (SSRIs)** are a family of antidepressants that are considered to be the standard treatment. Many scientists believe that one cause of depression is an inadequate amount of neurotransmitter serotonin. Proloft, Paxil, and Zoloft are SSRIs.
- **Serotonin-norepinephrine reuptake inhibitors (SNRIs)** are antidepressants that act on both norepinephrine and serotonin. Examples are Effexor and Cymbalta.
- **Tricyclic antidepressants (TCAs)** are older drugs for use in depression and include such medication as amitriptyline and desipramine.
- **Augmentor drugs** are used in combination with other drugs. Such drugs include a variety of tranquilizers and sedatives and tryptophan.

If one medication does not work in a matter of weeks or has side effects, another can be tried. Medications work best for individuals who are also getting counseling. However, medications and mental health counseling do not work for everyone. About 20 percent of people with the worst symptoms of depression do not respond well to these treatments, either used alone or in combination.

Some severe cases of depression require the person to spend time in a hospital for more intensive observation and treatment. In addition, psychiatrists sometimes treat such severe cases with electroconvulsive therapy*. This procedure involves passing a small amount of electricity through the brain after the person has been put to sleep with a drug. Although this is a controversial procedure, many who receive the treatment report feeling better.

* **antidepressant medications** are used for the treatment and prevention of depression.

* **electroconvulsive therapy** popularly known as shock therapy, involves sending small, carefully controlled pulses of electric current to the brain, which leads to brief seizures. It is a fast treatment for severe depression.

About two-thirds of the people with symptoms of depression do not seek or get the proper help. The disorder often makes it hard for them to recognize what is wrong. Some people try to mask depression by using alcohol or illicit drugs, but such self-medication usually just makes the depression worse. Other people might believe that their mood problem can be overcome without outside help, so they endure the symptoms without seeking help. Such people need to understand that depression is an illness, not a character flaw. Just as something can go wrong with the heart or lungs, people can have something go wrong in their brain.

For long periods of sadness or other symptoms of depression, people need to seek help. A young person should talk with parents, relatives, teachers, school counselors, or a close adult friend about these feelings, especially if they include thoughts of suicide. In most cases, people with depressive disorders can be helped with proper treatment.

Diabetes

Diabetes mellitus is a condition that results when the pancreas produces little or no insulin* or when the cells of the body cannot use the insulin produced effectively. When insulin is absent or ineffective, the cells of the body cannot absorb glucose (sugar) from blood to provide the body with energy.*

Melinda's Story

Melinda had just turned 12 and felt hungry all the time. Her stomach growled in class and her after-school snack no longer held her until dinner. No matter how many trips she made to the school water fountain, she was always thirsty. Even worse, she needed to go to the bathroom very frequently. One of her teachers, after signing Melinda's seventh bathroom pass for the day, suggested that Melinda ask her parents to take her to the doctor. She thought that Melinda might have diabetes, and she was right.

What Is Diabetes?

The term "diabetes" refers to a group of related diseases characterized by elevated levels of glucose (sugar) in the blood. It is caused by the failure of the pancreas to produce sufficient insulin or any insulin at all. It can also be caused by the failure of the body's cells to make proper use of the insulin that is produced.

The pancreas, the site of insulin production, is a large gland near the stomach. It contains groups of cells that function like tiny factories, producing different hormones* at exactly the right time and in the right amount. These groups (or "islands") of cells are called islet (EYE-let) cells.

One type of islet cells, the beta (BAY-ta) cells, are responsible for producing the hormone insulin. The human body needs insulin to function, because insulin helps the body turn food into energy.

When people eat, their bodies break down food and convert it into sugars and other fuels. The main fuel is a sugar called glucose (GLOO-kose). When it is in the blood, it is called "blood glucose" or sometimes "blood sugar." Glucose provides the energy people need to carry out almost every task, from pumping blood to walking to reading a book. But glucose cannot get too far on its own: Insulin must be there to allow it to pass into the body's cells.

Insulin works like a key, "unlocking" the door to cells. When insulin production stops or slows down in the beta cell factory, the body's cells cannot take in the glucose they need for energy. People with diabetes get

▲ The pancreas is one of the most important organs in the body. It has several functions as part of the endocrine (hormone-producing) system and the digestive system including the production of insulin. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **pancreas** (PAN-kree-us) is a gland located behind the stomach that produces enzymes and hormones necessary for digestion and metabolism.

* **insulin** is a kind of hormone, or chemical produced in the body, that is crucial in controlling the level of glucose (sugar) in the blood and in helping the body use glucose to produce energy. When the body cannot produce or use insulin properly, a person must take insulin or other medications.

* **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

Greek Origin for Words: A Diabetes Dictionary

Many English words come from Greek, including many of the words used to describe diabetes, as well as the word “diabetes” itself:

Diabetes: Greek for “passing through,” because Greek doctors noticed how much liquid people with diabetes drank and how often they needed to urinate

Mellitus: Greek for “honey-like” or “sweet,” because it was noticed that the urine of people with diabetes tasted sweet, due to its high sugar content

Insulin: Greek for “island.” The groups of islet cells in the pancreas that are responsible for making insulin and other hormones look like tiny islands under a microscope.

Hypo: Greek for “below,” and thus “too little”

Hyper: Greek for “above,” and thus “too much”

Glyk: Greek for “sugar”

Emia: Greek for “blood”

The hormone insulin is the key that unlocks the cell’s glucose channel, allowing glucose (“blood sugar”) to enter the cell and refuel it. Without the insulin key, glucose is locked out of the cell and must remain in the bloodstream. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

glucose from their food, but no matter how much they eat, if the insulin “key” is absent or not working properly, their glucose fuel is “locked out” of the body’s cells.

What Are the Different Types of Diabetes?

As of 2007, 23.6 million people (7.8% of the U.S. population) had diabetes. Experts estimated that 17.9 million people had been diagnosed with diabetes, whereas 5.7 million people remained undiagnosed. According to data provided by the National Diabetes Information Clearinghouse, 15,000 young people in the United States are newly diagnosed each year with Type 1 diabetes, and about 3,700 young people are newly diagnosed with Type 2 diabetes. Melinda has Type 1 diabetes. It is also called immune-mediated diabetes or insulin-dependent diabetes mellitus (IDDM).

Type 1 diabetes is usually diagnosed before a person turns 19 and is, therefore, also referred to as “juvenile” diabetes. People with Type 1 diabetes make little or no insulin of their own, so they depend on injections of insulin to stay healthy. They also need to make lifestyle changes, regarding when and what they eat.

About 186,300 people younger than 20 years have Type 1 or Type 2 diabetes, which represents 0.2 percent of all people in this age group in the United States. But these numbers do not include all youth who have Type 2 diabetes because some individuals are undiagnosed. However, among all people 20 years of age or older, 23.5 million, or 10.7 percent, have diabetes.

The other 16 percent of Americans with diabetes have what is called Type 2 diabetes. Two other names for Type 2 diabetes are “non-insulin-dependent” diabetes mellitus and “adult-onset” diabetes. Type 2 diabetes occurs when the cells of the body do not respond to insulin the way they

should. This type of diabetes typically, but not always, affects people who are over 40 years old. Extra body fat often contributes to this condition, and in many cases, weight loss can help remedy it. A person with Type 2 diabetes is not necessarily dependent on insulin injections the way a person with Type 1 diabetes is. Type 2 diabetes can be treated with pills in addition to a change in diet.

What Causes the Different Types of Diabetes?

Type 1 diabetes Type 1 diabetes is not contagious like a cold or chickenpox: People cannot catch it from one another. Nor do people get Type 1 diabetes suddenly. It usually takes months or years to develop. Despite what many people think, Type 1 diabetes is not caused by eating too many sweets.

Although causes for Type 1 diabetes were not fully understood as of 2009, some evidence suggested at least two reasons why one person develops it when another does not: genes and environmental triggers.

- **Genes***. People with Type 1 diabetes are born with certain genes for the illness, just as they are born with genes that determine eye color. Genes are inherited from biological parents. In some families, the genes for Type 1 diabetes are passed from parents to more than one child; a sibling of someone with Type 1 diabetes has about a 5 percent chance of also developing it.
- **Environmental triggers**. In some people, Type 1 diabetes is caused by an environmental trigger, such as a virus*. The trigger makes the person's immune system attack and destroy the beta cells, with the result that insulin can no longer be produced. However, for an environmental trigger to have this effect, people probably have to have a genetic predisposition to disease. Most people do not just suddenly develop diabetes because they get a viral infection such as the flu.

Type 2 diabetes People with Type 2 diabetes are not contagious. Two major factors seem to play a role in why people develop Type 2 diabetes: genes and obesity*.

- **Genes**. Just as certain genes determine that a person may be more likely to develop Type 1 diabetes, other genes play an important part in the development of Type 2 diabetes.
- **Obesity**. Many people who have Type 2 diabetes are obese. The extra weight may impair the body's ability to use insulin effectively.

How Do People Know If They Have Diabetes?

Symptoms When the body does not have adequate amounts of insulin, symptoms like Melinda's result. Frequent urination is common in a person with Type 1 diabetes. This symptom occurs because glucose cannot get into the body's cells, and it builds up in the blood instead. Normally,

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **virus** (VY-rus) is a tiny infectious agent that can cause infectious diseases. A virus can only reproduce within the cells it infects.

* **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

the kidneys do not allow glucose to get into the urine. But in the case of diabetes, the high level of blood glucose spills into the urine, pulling extra water out of the body along with it.

Feeling thirsty is also common because the body needs to make up for all the liquid lost through urination. Feeling hungry and eating a lot are also common symptoms; the body is looking for a way to get the energy that it is missing. But even with all the extra eating, people with undiagnosed diabetes may lose weight, because their bodies start to use fat for energy instead of sugar. In the case of growing children and teenagers, the fact that they are not gaining weight at a time in their lives when they should be may be a sign of diabetes.

These symptoms are common to both Type 1 and Type 2 diabetes, although usually less severe in the latter. Type 2 diabetes may sometimes have other symptoms, such as repeated or hard-to-heal infections; blurred vision; and dry, itchy skin. But often these symptoms are quite mild, and sufficient attention is not paid to them.

Diagnosis When doctors suspect that a patient has diabetes, usually they first perform a urine test. A strip of paper that has been treated with a chemical to detect glucose is placed in a small sample of the patient's urine. If the immersed strip shows that glucose is present, the doctor will want to confirm the test by checking the patient's blood sugar with a blood test. If the doctor feels sure that there is too much glucose in the patient's blood, further evaluation and testing will be done. (Diabetes is defined by the American Diabetes Association (ADA) as a fasting blood sugar in excess of 126 mg per deciliter.) Treatment will be started if the diagnosis of diabetes is confirmed.

Because people with Type 2 diabetes continue to make insulin that is functioning to a certain extent, they may develop symptoms over a

TWO MILLENNIA OF MEDICINE

The ancient Greek physician Aretaeus (ar-e-TE-us) of Cappadocia (c. 81–c. 138 C.E.) described diabetes as a “melting down of the flesh and limbs into urine.” Throughout history, many people with the disease died at an early age by wasting away, although the disease was probably not as prevalent in ancient times as it is in modern times.

Treatments frequently involved dietary changes. Aretaeus recommended milks, cereals, and starches. In 1797, John Rollo recommended a meat diet high in proteins. These diets were not cures for diabetes, but they did allow people with diabetes to live longer than if they had remained on regular diets.

The first truly successful treatment for diabetes was finally made available in the 1920s when Frederick Banting, Charles Best, and John James Macleod first isolated insulin for use through therapeutic injections.

period of months or years without facing immediate danger. They may feel tired, worn out, or thirsty much of the time, without thinking that it could be diabetes. In many cases, Type 2 diabetes is actually discovered by accident, during a routine physical exam or screening blood or urine test.

How Is Type 1 Diabetes Treated?

A person who has been diagnosed with Type 1 diabetes needs to take several steps in order to function well. These include taking insulin, following a diabetic diet, exercising, monitoring blood glucose levels, and taking urine tests. All of these measures contribute toward achieving the major goal: keeping the amount of glucose in the blood as close to normal as possible, so the person with diabetes can stay healthy and feel good.

Insulin People with Type 1 diabetes must get the correct amount of insulin into their blood. If not, usually within a matter of days they develop the severe emergency condition diabetic ketoacidosis, which is fatal unless treated with insulin. Different sources of insulin have been used to treat diabetes. Pork insulin is extracted from the pancreata of pigs, and bovine insulin comes from the pancreata of cows. These animal insulins work well in humans but the structure of the insulin proteins differs slightly in their amino acid sequence, and they produce mild immunologic reactions. These animal insulins were used as treatment for diabetes for many decades and were still available in the early 2000s. As of 2009, synthetic human insulin, which has the same amino acid sequence as the native human insulin, was preferred.

Insulin comes in liquid form (dissolved in water) in a bottle and must be injected into the body. Unlike a lot of medications, insulin cannot be swallowed in pill form because the hormone insulin is a protein. Like other proteins, it would be digested and broken apart in the stomach, just like the protein contained in food.

Most people take insulin by using a needle to inject it into the layer of fat beneath the skin. The most common places where people inject insulin are in the arms, legs, stomach, and hips, all places where people have some fat. The injection does not hurt much, since the needle is very thin. Usually, a person needs to inject insulin this way two or more times a day, on a set schedule, coordinated with meals.

Some people with Type 1 diabetes use an insulin pump, which is about the same size as a beeper, with a small container filled with insulin. The insulin gets automatically pumped into the person's body through a small tube attached to a needle inserted into the skin. The insulin is pumped in at a slow rate all the time, with an extra "boost" pumped in before meals to prepare the body for the incoming sugar.

However people with Type 1 diabetes take insulin, one factor stays constant: They must take insulin every single day to allow the body's cells to take in and use glucose properly. They cannot take a break or decide to stop taking it, or they will become ill.

Sports Stars with Type 1 Diabetes

These outstanding athletes were all diagnosed with Type 1 diabetes at an early age:

Jackie Robinson. Robinson was the baseball player who broke the color barrier in 1947. In his 10-year career with the Brooklyn Dodgers, Robinson was a batting champion, the League Most Valuable Player (MVP), and a member of six championship teams. He was baseball's first Rookie of the Year. Robinson was elected to the Hall of Fame in 1962, his first year of eligibility.

Bobby Clarke. The tenacious leader of hockey's Philadelphia Flyers for 15 seasons, Clarke was first diagnosed with diabetes at the age of 15. Undeterred, he went on to win three Hart trophies as league MVP.

Wade Wilson. An National Football League (NFL) quarterback for more than 16 years. Beginning in 1981, Wilson led the Minnesota Vikings to three playoffs and the 1987 NFC championship game.

* **ketones** (KEE-tones) are the chemicals produced when the body breaks down fat for energy.

Food Proper nutrition is a very important part of staying healthy—for everyone—especially for a person with Type 1 diabetes. Because food affects how much glucose is in the blood, people with Type 1 diabetes must pay careful attention to the food they eat, how much they eat, and when they eat it. In particular, because carbohydrates are the body's main source of glucose, many people with diabetes estimate the amount of carbohydrates in each meal to determine if they are getting the right amount of sugar.

All that does not mean that the eating habits of someone with diabetes are so very different from other people. The food itself can be the same as that eaten by most people. But in most cases, their meal plans must be on some sort of schedule, include snacks, and limit sweets because of the large amount of sugar they contain.

Exercise Just like healthy eating, exercise is something that is important for everyone especially for people with Type 1 diabetes. In the 20th century some doctors thought people with Type 1 diabetes should not exercise, but that opinion changed. Exercise helps insulin work better to control the level of glucose in the blood. Exercise also helps keep people with diabetes at the right weight, and it helps maintain a healthy heart and blood vessels. In addition, exercise helps people feel good about themselves.

When people with Type 1 diabetes exercise, they use glucose at a faster-than-normal rate, so they must pay special attention to ensure that their blood glucose level does not drop too low. To assure the proper level, they may need less insulin, more food before exercise, or snacks during and after exercise.

Blood glucose and urine testing People who have Type 1 diabetes usually test their blood glucose three or more times per day. This process involves pricking the finger with a tiny, sharp device to get a drop of blood. The blood drop is put on a chemical strip and inserted into a testing meter that reads the amount of sugar in the blood. The person then records the blood glucose numbers in a diary. This monitoring helps to determine if the level of glucose in the blood is where it should be and guides adjustment in the treatment plan.

Urine testing is another helpful form of monitoring. It is especially important when a person with Type 1 diabetes is sick (with the flu, for example). Any kind of physical stress, such as an infection, tends to interfere with the absorption and proper use of glucose. When this interference occurs, the cells begin to break down fat for energy. A potentially harmful byproduct of this process is the production of ketones*. Urine testing is an effective means of determining if ketones are building up in the blood.

Hypoglycemia, Hyperglycemia, and Ketoacidosis

Sometimes, even with insulin, proper nutrition, and exercise, it can be difficult to control diabetes completely. Blood glucose levels can become either too high or too low in some cases, and blood levels of ketones can rise to toxic levels.

Hypoglycemia Hypoglycemia (hy-po-gly-SEE-mee-a) occurs when the level of glucose in the blood is too low, which can result when someone takes too much insulin, misses a meal or snack, or exercises too hard without taking special precautions. In its beginning stages, hypoglycemia can make someone weak, shaky, dizzy, and sweaty. A person with diabetes learns to be aware of these warning signs and almost always takes action immediately to treat them, by drinking some juice or taking glucose tablets. If left untreated, a person may become disoriented, sleepy, or have a hard time talking. Eventually, the person may become very confused and uncoordinated and, in extreme cases, go into a coma*. The treatment for an extreme case of hypoglycemia is to give the person sugar as soon as possible, by intravenous* injection if necessary.

Hyperglycemia Hyperglycemia (hy-per-gly-SEE-mee-a) occurs when too much glucose is in the blood, which happens if the person has taken too little insulin, has eaten too much high-sugar food, or is ill with an infection or stressed for other reasons. Symptoms include very frequent urination, extreme thirst, weakness, and tiredness.

Ketoacidosis Ketoacidosis (ke-to-a-si-DO-sis) occurs in uncontrolled diabetes when the blood becomes too acidic due to high levels of ketones. People in ketoacidosis may be nauseated or vomiting and breathing deeply. If they do not get treated, they will become dehydrated and go into a coma. Emergency treatment involves insulin and lots of intravenous fluids. Fortunately, ketoacidosis is almost always preventable in people whose diabetes had been diagnosed early and in those who had managed to take care of their diabetes properly.

How Is Type 2 Diabetes Treated?

People who have Type 2 diabetes are often able to manage their diabetes with dietary changes and a weight-control program, if needed, which consists of balancing a healthy combination of foods and exercise.

In some cases, people with Type 2 diabetes are given pills to help the body make more insulin or respond to insulin more normally. In some cases, a person with Type 2 diabetes needs to take insulin injections, like a person with Type 1 diabetes.

There are many similarities in the treatments for Type 1 and Type 2 diabetes, but the main difference is the role of insulin. If individuals with Type 2 diabetes forget to take their insulin, they will not go into ketoacidosis. And while a doctor might say it is all right for a person with Type 2 diabetes to stop taking insulin completely and just take pills, this would not be possible for a person with Type 1 diabetes.

Living with Type 1 or Type 2 Diabetes

Between taking insulin, following a meal plan, testing blood sugar levels, and the rest, living with Type 1 diabetes can sound like a big job—and it can be—especially in the beginning. Luckily, many people who have been

Diabetes Research

Clinical trials are research projects undertaken by scientists, pharmaceutical companies, and government researchers to determine whether medications and treatment plans are safe and effective.

To evaluate the effectiveness of careful self-management in reducing the long-term complications of diabetes, in 1983 the U.S. National Institute of Diabetes and Digestive and Kidney Diseases undertook a ten-year study, called the Diabetes Control and Complications Trial (DCCT).

People with diabetes took part in the DCCT and followed instructions for testing their blood glucose three or four times a day, taking more frequent insulin injections or using an insulin pump, and following a diabetic diet. The test results showed that the people who maintained near-normal blood glucose levels had fewer long-term complications, such as problems with their hearts, eyes, or kidneys. It proved that for a person with diabetes, paying close attention to small symptoms on a daily basis has a big payoff later on.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

The United States and the World

Globally, there were approximately 180 million adults with diabetes in 2008. By the year 2030, that number was expected to rise to 360 million. The World Health Organization (WHO) provides the following data:

- In 2005 an estimated 1.1 million people died from diabetes.
- Almost 80 percent of diabetes deaths occur in low and middle-income countries.
- Almost half of diabetes deaths occur in people under the age of 70 years; 55 percent of diabetes deaths are in women.
- WHO projected that deaths from diabetes would increase by more than 50 percent between 2006 and 2016 without urgent action. Most notably, diabetes deaths were projected to increase by more than 80 percent in upper-middle income countries between 2006 and 2015.
- WHO estimated that between 2006 and 2015, China would lose \$558 billion in national income due to heart disease, stroke, and diabetes alone.

* **retina** (RET-i-na) is the tissue that forms the inner surface of the back of the eyeballs; it receives the light that enters the eye and transmits it through the optic nerves to the brain to produce visual images.

ANIMAL RESEARCH AND DIABETES

In 1880 Oskar Minkowski (1858–1931) and Josef, Freiherr von Mering (1849–1931) were among early researchers to discover that removing the pancreas of dogs rendered them diabetic. Shortly thereafter Edward Sharpey-Schafer (1850–1935) discovered the active principle in the islets of Langerhans, and he named it “insuline.”

Canadian surgeon Frederick Banting (1891–1941) and physician Charles Best (1899–1978), using the laboratory of John James Macleod (1876–1935) at the University of Toronto, conducted research also on dogs that led to better understanding of the medical uses for insulin.

In 1923, Banting and Macleod were awarded the Nobel Prize for medicine and physiology for the discovery of insulin. Banting shared his half of the prize money with Best.

diagnosed with Type 1 diabetes have an entire diabetes treatment team to help them. This team usually includes a doctor, a diabetes nurse, a dietitian, a psychologist, and a social worker. Ideally, the entire team works to become partners with the patient and the patient’s family, so that they can maintain as normal a life as possible.

People with diabetes can do almost everything that people without diabetes can. They can:

- Go to school
- Play sports
- Spend time with friends
- Eat food at parties
- Do almost every kind of job
- Go to college
- Get married and have children

A person with diabetes may have to eat an extra snack before competing in a track meet or duck out of a party for a minute to take insulin or have only a small bit of ice cream when everyone else is going for the Super Sundae. But people who control their diabetes lead normal lives. And women with diabetes who want to have babies can usually do so, with the support of their diabetes treatment team.

How Can Diabetes Affect a Person’s Future?

Both Type 1 and Type 2 diabetes can have negative long-term effects on a person’s health. These effects tend to develop very slowly. Because a person with diabetes may not process fat properly, there tends to be damage to the blood vessels in the body, which increases the chances for high blood pressure, heart attacks, and strokes. Diabetes can also have long-term effects on the eyes, because tiny blood vessels in the retina* become

weakened. If these blood vessels burst, they can cause bleeding and scarring in the eye, or even blindness. The chance of nerve damage and of developing kidney disease is also increased in a person with diabetes. Finally, foot health can become an issue for people with diabetes. Because the condition can affect circulation to the feet, small cuts or wounds can turn into serious infections without proper care. When such infections occur, they may lead to death of cells and tissue. When this happens, the affected foot may be amputated (surgically removed) to prevent further spread of infection or tissue death.

People with diabetes can help prevent or lessen the effects of these long-term problems. Blood sugar control is a key factor. It is very important for people with diabetes to have regular physical checkups, when a doctor can monitor blood pressure and foot health, check fat levels in the blood, and look for problems with the kidneys. Annual trips to the eye doctor are crucial for people with diabetes. If the ophthalmologist* discovers problems with the blood vessels in the retina, vision problems often can be prevented or lessened with laser surgery.

While people with diabetes must depend on doctors and other medical professionals to help them, they can also do quite a bit to help themselves. Continued education about proper diabetes management is important for helping people with diabetes stay healthy.

Will There Ever Be a Cure?

Diabetes research is an active field in the early 2000s. Much of the scientific work is concerned with insulin: how to get it into the body or how to get the body to produce it on its own. Because insulin cannot be swallowed, researchers have investigated other ways to get it into the bloodstream without an injection, such as eye drops, nasal sprays, and inhalers. As of 2009, clinical trials of inhaled and oral spray forms of insulin were being conducted. Scientists have also experimented with pancreas transplantation, as well as transplantation of the islet cells that make insulin. Until there is a cure for diabetes, however, people must live with it and control it by using the information and equipment available to them.

Medic Alert Tags

People with diabetes often wear metal tags or bracelets imprinted or inscribed with important medical information. In the event of an accident or diabetic coma, the information on the tag can alert medical personnel about the patient's condition.

Some companies offer medical alert tags that have an identification number that is unique to the individual so that a doctor who does not know the person can retrieve the patient's medical history in the event of emergency.

Diagnostic Tests

Diagnostic tests are used to help medical professionals diagnose illnesses.

What Are Medical Diagnostic Tests?

Before doctors can treat someone with an illness, they have to identify or diagnose the illness. By talking with the patient (“taking the history”), examining the patient, and, when necessary, ordering laboratory tests and/or other kinds of medical tests (such as imaging tests), doctors are able to make a diagnosis. Laboratory tests are analyses of samples of blood, urine, or tissue. Imaging tests provide images of the body’s interior. Often, doctors are able to make a diagnosis without needing to order any medical tests. Thousands of possible medical tests exist, ranging from simple, inexpensive tests, such as the use of a sphygmomanometer (a blood pressure

gauge that includes an inflatable cuff, usually placed around the upper left arm) to measure blood pressure to much more complicated and expensive tests, such as magnetic resonance imaging (MRI), which produces cross-sectional images of the body. Through training and experience, doctors learn when to use medical tests, which ones to use, and how to interpret the results.

Medical tests often help to identify the cause of a person's illness. Sometimes a test reveals the presence of a specific microorganism* or other cause of illness, and the diagnosis is made relatively easily. For example, a person with a high fever, painful sore throat, and white patches or white coating on the throat and tonsils* may have strep throat, an infection by streptococcus bacteria that can lead to more serious illness. The doctor will perform a laboratory test known as a throat culture*, in which the doctor swabs the patient's throat and attempts to grow any microorganisms that have been collected in a laboratory dish. Thus the lab test may confirm the diagnosis of strep throat.

Sometimes a test result suggests only a general area of focus or a range of possible causes of an illness, and making the diagnosis requires medical insight as well as further medical testing. For example, an elderly person who feels short of breath is probably going to receive a chest x-ray. The x-ray may show an enlarged heart, which is a sign that the heart is overworked, but that result is not a diagnosis. To make a diagnosis, further medical tests are needed.

A lab test can also rule out a suspected cause of illness, thereby shortening the list of diagnoses that are considered. For example, a person with anemia* is likely to undergo iron tests, a group of tests that measure iron levels in blood and blood serum and the amounts of iron stored in the body. Tests that show adequate amounts of iron in serum would help to eliminate the diagnosis of anemia and help to guide the evaluation toward other possibilities.

How Did Laboratory Testing Develop?

The existence of microorganisms has been known since 1674 when Dutch scientist Antonie van Leeuwenhoek (1632–1723) first described “little animals” in a drop of rain water. But it was the German physician Robert Koch (1843–1910), the “father of modern bacteriology” (the study of bacteria), who proved that a specific microorganism was the cause of a specific disease. That disease was anthrax (AN-thraks), an infectious disease that occurs in humans and animals; the microorganism was the bacterium *Bacillus anthracis*. That bacterium had already been discovered, but Koch was able to prove that it caused the disease. Koch also observed that anthrax bacteria, under conditions unfavorable to its growth, would produce spores* that were able to resist adverse conditions and that when favorable conditions were restored would develop into new bacteria. In 1881 Louis Pasteur took it one step further and was able to develop an effective vaccine for sheep and cattle against anthrax.

* **microorganism** is a tiny organism that can be seen only by using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

* **tonsils** are paired clusters of lymphatic tissue in the throat that help protect the body from bacteria and viruses that enter through a person's nose or mouth.

* **culture** (KUL-chur) is a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

* **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.

* **spores** are a temporarily inactive form of a germ enclosed in a protective shell.

- * **fungi** (FUNG-eye) are microorganisms that can grow in or on the body, causing infections of internal organs or of the skin, hair, and nails.
- * **viruses** (VY-rus-sez) are tiny infectious agents that can cause infectious diseases. A virus can only reproduce within the cells it infects.
- * **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

Following his work with the anthrax bacterium, Koch set out to find a better way of growing and isolating microorganisms. Previously, he had used liquid media for growing it, but these were easily contaminated with other microorganisms, and he was obliged to use live animals as reservoirs for the bacteria he was studying. Encouraged by his observations of colonies of bacteria (groups visible to the naked eye) growing on slices of potato, he set out to develop a solid substance nutrient medium on which he would be able to grow bacteria. With the help of his assistant Julius Petri, who is credited for having developed the Petri dish, a shallow glass dish used by biologists to grow cells, Koch developed methods for isolating colonies of microorganisms. Koch also developed new methods of staining bacteria, which made them more visible and easier to identify.

The methods for culturing bacteria that Koch developed well over a century ago became the commonly accepted standard for use by labs in the 20th century. After Koch's work, culture methods improved. Laboratories in the 21st century also culture yeast, fungi*, and viruses*.

How microorganisms are cultured First, a sample of tissue or fluid is taken from the infected region of a person's body. When the throat is cultured, sterile cotton is used to swab the throat. The sample obtained is then plated (wiped onto plates). The plates contain growth media that enable microorganisms (usually bacteria) to grow. An agar plate is a sterile Petri dish that contains a growth medium (agar plus bacterial nutrients). Agar is a gelatinous substance derived from seaweed. Individual microorganisms placed on the plate will grow into individual colonies. The bacteria that are grown are then identified. Small samples of blood, urine, pus drawn from a site of infection, and sputum (material that is expelled from the respiratory tract, usually by coughing) are also used to grow bacteria in medical laboratories, for eventual identification.

Identifying bacteria When a large enough population of bacteria has grown on the plate in the form of a "lawn," laboratory technicians must perform two operations: identification of the bacteria and sensitivity testing (determining the sensitivity of bacterial populations to a range of antibiotics*). Identification of bacteria uses a range of techniques: examination of lawn characteristics with the naked eye, staining, observation of which nutrients or combinations of nutrients (in nutrient media) are needed for bacterial growth, and microscopic examination.

Staining and sensitivity Staining is the use of a dye to make cells or cell structures more visible and easier to study. Gram staining is the use of a particular dye (the Gram stain) to differentiate bacteria into two major groups: Gram-positive bacteria and Gram-negative bacteria. Bacteria absorb the dye and turn color according to the properties of their cell walls. Gram-positive bacteria have thick cell walls, retain more dye, and stain dark blue or purple. Gram-negative bacteria have relatively thin cell walls, retain the dye less well, and stain red or pink.

Sensitivity testing is accomplished by placing small amounts of specific antibiotic substances (sometimes small paper disks that have been saturated with the antibiotic) directly onto the bacterial lawn and then allowing the bacteria to incubate for 24 hours or more. The plate is then examined, to see whether bacterial growth has been inhibited (or not) by the antibiotic. A clear area or “halo” around the antibiotic disk indicates an absence of bacteria and strongly suggests that the antibiotic will be effective against that species of bacteria in the patient. Sensitivity testing is increasingly important in medicine because bacteria that were once sensitive to (killed by) a given antibiotic may have become resistant to it.

It usually takes 48 to 72 hours to get results for routine bacterial cultures. Other cultures may take much longer to produce results. Fungal and viral cultures can take weeks. Doctors may prescribe antibiotics while waiting for culture results and later stop the antibiotic therapy if the culture results are negative or if the sensitivity tests show that the growth of the microorganisms has not been inhibited by the antibiotic.

Types of Laboratory Tests

Urinalysis A urinalysis is an array of tests that are performed on urine*. It is one of the most common laboratory tests and is performed routinely during physical examination. A typical urinalysis includes visual inspection of the urine sample (a visual check of the urine’s color and clarity), urine dipstick chemical analysis, and microscopic examination of the urine. Dipsticks are strips of paper coated with chemical compounds that are dipped in urine and change color when they come into contact with substances that may be present in urine. Dipsticks are used to measure the urine’s pH (a measure of how acidic or basic the urine is) and the urine’s “specific gravity” (urine has solutes, or dissolved matter, and specific gravity is a measure of how concentrated the urine is). Dipsticks are used to test for the presence of several substances that are usually absent in urine: protein (its presence may be an indicator of kidney* disease); glucose (its presence may be an indicator of diabetes*); ketone bodies (substances produced by the body when it must use fatty acids and other fat molecules for energy; their presence in urine may also point to diabetes); and hemoglobin (the main constituent of red blood cells; its presence in urine may indicate urinary tract* infection, kidney disease, or the presence of a kidney stone). Dipsticks are a quick screen for urinary tract infections, diabetes, and a range of kidney diseases.

For microscopic analysis, the urine is centrifuged (rotated rapidly) in a test tube until sediment appears at the bottom of the test tube. The sediment is examined under a microscope for the presence of casts (aggregations of particulate matter), including red blood cell casts, white blood cell casts, and bacterial casts, all of which are indicative of disease.

Stool tests Stool tests are diagnostic tests in which fecal matter that has been collected from a patient is sent to a laboratory for chemical and

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

* **kidney** is one of the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body’s pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **urinary tract** (YOOR-ih-nair-e TRAKT) is the system of organs and channels that makes urine and removes it from the body. It consists of the urethra, bladder, ureters, and kidneys.

- * **parasites** (PAIR-uh-sites) organisms such as a protozoan (one-celled animals), worm, or insect that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. A parasite lives at the expense of the host and may cause illness.
- * **gastrointestinal** (gas-tro-in-TES-tih-nuhl) means having to do with the organs of the digestive system, the system that processes food. It includes the mouth, esophagus, stomach, intestines, colon, and rectum and other organs involved in digestion, including the liver and pancreas.
- * **platelets** (PLATE-lets) are tiny disk-shaped particles within the blood that play an important role in clotting.
- * **hemoglobin** (HE-muh-glo-bin) is the oxygen-carrying pigment of the red blood cells.
- * **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.
- * **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.
- * **gall bladder** is a small pear-shaped organ on the right side of the abdomen that stores bile, a liquid that helps the body digest fat.
- * **bile duct** is a passageway that carries bile, a substance that aids the digestion of fat, from the liver to the gallbladder (a small pouch-like organ where the bile is temporarily stored) and from the gallbladder to the small intestine.

microbiologic tests. The stool is tested for the presence of illness-causing bacteria, protozoa, and parasites* such as pinworms. The fat content of the stool sample is often measured, as a check for the malabsorption of fat. Stool samples are tested for the presence of blood, which is very often evidence of abnormal bleeding in the gastrointestinal* tract. The color of the stool may give evidence in support of specific diagnoses. For example, stools light in color could suggest hepatitis.

Blood tests The most common test is the complete blood count (CBC), which supplies information about the cells in a patient's blood. A CBC generally provides the following information: the number of red blood cells (per volume of blood); the number of white blood cells (per volume of blood); the number of platelets* (per volume of blood) and information about their sizes; the amount of hemoglobin* (per volume of blood); the red blood cell indices, which include the average size of red blood cells and the average amount of hemoglobin per individual red cell; and the white blood cell differential count, a determination of the number of each type of white blood cell (e.g., lymphocytes, monocytes, neutrophils) expressed as an absolute number (per volume of blood) and as a percentage. During a bacterial infection, the numbers of white cells are almost always elevated because these cells are the responders to infection.

A doctor may request blood coagulation tests to determine if a patient has bleeding or clotting problems. Prothrombin time (PT) and partial thromboplastin time (PTT) are tests that measure the blood's clotting ability. In either test, the test result is the time it takes a small sample of blood to clot after substances that promote clotting have been added to the sample.

The erythrocyte sedimentation rate (ESR) is the rate at which red blood cells settle in a test tube of blood under standardized conditions. The ESR becomes elevated as a result of virtually any kind of inflammation* in the body. When inflammation is present, there are changes in blood cells and in blood serum that cause the red cells to settle more slowly. ESR is a non-specific measure of inflammation.

Liver* function tests (LFTs) are an array of blood tests that indicate how well the liver, gall bladder*, and bile ducts* are working. They measure the circulating blood levels of liver enzymes* (the liver is a biochemical factory and employs a large number of enzymes to catalyze its biochemical reactions), clotting factor proteins, and chemical substances such as bilirubin (a pigment molecule, formed when red blood cells break down, which is the cause of jaundice).

The lipid profile is a group of blood tests that help to determine a patient's risk of coronary heart disease* and stroke*. The typical lipid profile includes measures of the circulating blood levels of total cholesterol*, low-density lipoproteins (LDLs, often called "bad cholesterol"), high-density lipoproteins (HDLs, often called "good cholesterol"), and triglycerides (a common dietary fat).

Lumbar puncture (spinal tap) A lumbar puncture, also known as a spinal tap, is a diagnostic procedure that is administered to collect a sample of cerebrospinal fluid (CSF), the clear fluid that surrounds the brain and spinal cord and protects them from physical impact. It is used most often to collect cerebrospinal fluid in cases of suspected meningitis*. Meningitis is an inflammation of the meninges, the thin membranes that envelop the brain and spinal cord. It is often extremely serious and even life-threatening and needs to be diagnosed and treated in its early stages. A neurologist* inserts a spinal needle between two adjacent vertebrae, the bony segments of the spinal column, in the lumbar or lower back area and then withdraws a small amount of cerebrospinal fluid from the spinal canal. The fluid is then tested for the presence of microorganisms.

Biopsy Samples of tissue that must undergo microscopic or chemical analysis are removed by biopsy. The tissue specimens may be obtained by needle biopsy or by minor surgical techniques. Some examples of biopsy specimens are tissue samples obtained from the liver, lung, breast, and bone marrow*. Bone marrow specimens are often needed to determine the cause of a person's unexplained anemia*. A pathologist, a doctor who studies cells and tissues under a microscope, examines tumor cells to determine if a tumor is malignant (cancerous, the cells of which are likely to spread) or benign (not cancerous and localized).

Antibody and antigen tests Many antibodies* can be detected (and their levels measured) in blood samples. Tests that can identify specific antibodies in blood serum are commonly used to diagnose many infectious diseases. These tests measure the body's response to an infectious disease. Antibodies are produced by specialized cells of the immune system* in the presence of antigens* found on the surface of the invading organism. It takes some time for the body to mount an effective antibody response to a new infectious agent and for levels of antibody to rise to detectable levels, so this kind of test may not be useful when an infectious process is starting. For this reason antibody tests (also known as serology tests) are often repeated several weeks after the initial testing. Once an individual has recovered from an infectious illness, some of the immune cells that produced the antibodies become "memory" cells and are stored in lymph nodes*. These memory cells will recognize the same antigen in the event it is reintroduced to the body and will be able to mount a rapid response to the disease-causing agent. This process often gives a person immunity (protection from) to future infection. Many infectious diseases are diagnosed using antibody testing, including hepatitis*, Lyme disease*, and HIV* infection. Antibody tests are helpful in the diagnosis of some autoimmune diseases (in which the body is likely to produce antibodies to some of its own antigens).

Unlike antibody tests (which detect the presence of the disease-causing agent indirectly), antigen tests detect the presence of the disease-causing agent directly, by identifying the specific proteins that the infectious

- * **enzymes** (EN-zimes) are proteins that help speed up a chemical reaction in a cell or organism.
- * **heart disease** is a broad term that covers many conditions that prevent the heart from working properly to pump blood throughout the body.
- * **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.
- * **cholesterol** (ko-LES-ter-ol) is a fatlike substance found in the blood and body tissues.
- * **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.
- * **neurologist** (new-RHAL-eh-jist) a physician who specializes in diagnosing and treating diseases of the nervous system.
- * **bone marrow** is the soft tissue inside bones where blood cells are made.
- * **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

- * **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.
- * **antigens** (AN-tih-jens) are substances that are recognized as a threat by the body's immune system, which triggers the formation of specific antibodies against the substance.
- * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.
- * **hepatitis** (heh-puh-TIE-tis) is an inflammation of the liver. Hepatitis can be caused by viruses, bacteria, and a number of other noninfectious medical conditions.
- * **Lyme disease** (LIME) is a bacterial infection that is spread to humans by the bite of an infected tick. It begins with a distinctive rash and/or flu-like symptoms and, in some cases, can progress to a more serious disease with complications affecting other body organs.
- * **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).
- * **chlamydia** (kla-MIH-dee-uh) are microorganisms that can infect the urinary tract, genitals, eye, and respiratory tract, including the lungs.
- * **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

organism has on its surface. Unlike antibody test results, which might indicate that there had been an infection in the past, the presence of a specific antigen probably means that the infection is present at that moment. Examples of antigen testing include rapid strep tests, chlamydia* tests, and some HIV testing.

Nucleic acid tests Nucleic acid tests (NATs) are highly sensitive tests that can detect the presence of exceedingly small amounts of nucleic acid (DNA* or RNA*) in a blood or tissue sample. They use a nucleic acid amplification technique that multiplies (makes many copies of) the existing DNA/RNA so that it rises to detectable levels. Polymerase chain reaction (PCR) is the most frequently used technique to accomplish this amplification. Polymerase enzymes are used to catalyze (increase the rate) the formation of new DNA or RNA. Nucleic acid tests can detect viruses that are at extremely low concentration in the blood by multiplying a small segment of that virus's DNA or RNA to create a larger sample that can then be detected. They are a new and valuable tool in the identification of many infectious agents, particularly those that are difficult to culture. NATs are used in the diagnosis of hepatitis C and HIV infection. They are useful in making the diagnosis of HIV infection in infants because antibody testing in such young people is not reliable. NATs have also been used in the diagnosis of *Helicobacter pylori** infection, and research work in the early 2000s sought to develop tests of this kind for the rapid diagnosis of many serious infectious diseases. The use of these molecular technologies is not restricted to detection and identification of microbial pathogens but also can be used for genotyping, allowing one to determine antibiotic resistance or to perform microbial fingerprinting.

Imaging tests Imaging tests, using a range of technologies, provide doctors with images, including cross-sectional images, of the body's interior.

RADIOGRAPHY Radiography is the use of x-radiation, or x-rays, to view the body's interior. X-rays are a form of electromagnetic radiation. The term "x-ray" originally referred only to the electromagnetic radiation itself (waves of oscillating energy), but over time the term came to refer to the x-ray image or radiogram (the radiographic image that is produced) as well. X-ray images help physicians to see aspects of the body that are usually unseen. X-radiation is energetic enough to pass through the body. In general, a controlled amount of x-radiation is emitted by an x-ray tube and allowed to strike a specific area of the body. An x-ray image is generated when the x-rays that pass through the body are recorded on a photographic plate that has been positioned on the side of the body opposite to the source of the x-rays. Photographic plates are sensitive to x-rays. The resulting image has light and dark areas because differing amounts of x-radiation are absorbed by different tissues and organs, and differing amounts of x-radiation reach different regions of the plate. If the part of

the body through which the x-radiation has passed is relatively dense (such as bone) or has a high water content (for example, lung tissue in a person who has pneumonia*), relatively greater amounts of the radiant energy are absorbed, relatively smaller amounts reach the photographic plate, and the corresponding regions on the radiogram will appear whiter. In digital radiography, digital x-ray sensors replace the photographic plate. Doctors sometimes use a medical contrast medium, a substance that enhances and improves the contrast between light and dark in medical images. Contrast media are often used to enhance the visibility of structures, such as blood vessels or the gastrointestinal tract. They are usually swallowed or injected intravenously*.

NUCLEAR MEDICINE IMAGING Nuclear medicine imaging, also called radionuclide scanning, is an imaging technique in which very small amounts of radioactive materials (radionuclides or radiotracers) are introduced into the body, either orally or by intravenous injection, and the small amounts of radiation that are emitted by these materials are used to create an image. The radionuclides travel to locations in the body via the bloodstream and are absorbed by tissues and organs in the body. The radionuclides that have found their way to these tissues and organs emit extremely small amounts of gamma radiation. Gamma rays, emitted by the nuclei of radioactive atoms, are a type of electromagnetic radiation. The gamma ray signals are detected by a gamma camera (similar to a Geiger counter). The signals that are detected by the camera are converted to digital signals that are processed by computer software to produce an image, or scan. The places in organs where the radionuclides have accumulated in greater amounts are called “hot spots.” The hot spots show up on the scan. Hot spots usually indicate increased circulation to an area and may indicate a disease process. Some of the more common nuclear medicine diagnostic imaging tests are bone scans, liver scans, renal (of or relating to the kidneys) scans, brain scans, and breast scans. Positron emission tomography, or PET, is a nuclear medicine imaging technique. It is a computer-based technique that generates three-dimensional images, including three-dimensional images of the brain that show areas of increased radioactive signaling, which correspond to areas of increased brain activity.

COMPUTERIZED TOMOGRAPHY Computerized tomography (kom-PYOO-ter-ized toe-MAH-gruh-fee), or CT, is a diagnostic imaging technique that uses x-rays in which the source of the x-rays (and the x-ray detectors) rotate around the body. Computer software processes the vast amount of data that is collected by the x-ray detectors and assembles it into images, or scans, of the body, including cross-sectional images.

MAGNETIC RESONANCE IMAGING Magnetic resonance imaging (MRI) uses strong magnetic fields that generate slight changes in the “magnetic resonance” of individual protons in the body. A change in magnetic resonance produces a small signal. These signals are detected by a scanner,

* **RNA** or ribonucleic acid (ry-bo-nyoo-KLAY-ik AH-sid), is the chemical substance through which DNA sends genetic information to build new cells.

* **Helicobacter pylori** (HEEL-ih-ko-bak-ter pie-LOR-eye) is a bacterium that causes inflammation and ulcers, or sores, in the lining of the stomach and the upper part of the small intestine, also known as peptic ulcer disease.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

* **intravenously** (in-tra-VEE-nus-lee) means given or injected directly through a vein.

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

* **thyroid gland** (THY-roid GLAND) is located in the lower part of the front of the neck. The thyroid produces hormones that regulate the body's metabolism (me-TAB-o-LIZ-um), the processes the body uses to produce energy, to grow, and to maintain body tissues.

which converts the signals into digital information. Computer software processes the information and generates an image.

ULTRASOUND IMAGING Ultrasound imaging, also known as sonography and ultrasonography, is a diagnostic imaging technique that uses ultrasound (sound waves with frequencies that are beyond the upper limit of human hearing). Ultrasound imaging is used to visualize the body's internal structures and to visualize the developing fetus* as part of routine prenatal care. Sound waves travel through liquids and solids as well as air. When sound waves encounter solid materials, they are likely to travel through, be absorbed by, and be reflected by those materials. With ultrasound imaging, a probe that emits high-frequency sound waves is placed near the surface of the body. Some of the sound waves penetrate to tissues and organs inside the body and are reflected back to the probe. (The reflected sound waves are echo waves.) The echo waves are relayed to an electronic calculating device. This device, using time measurements of the echo's return and pre-existing data on the speed of sound in tissues, calculates the distances the echo waves have traveled and is then able to put together an image. Ultrasound imaging is widely used in medical diagnosis. Ultrasound is good at imaging a range of soft tissue organs, including the heart, the liver or kidneys, and the thyroid gland*. Ultrasound imaging can be used to detect the presence of tumors or cell masses of abnormal size or density. It can be used to distinguish between solid and cystic (hollow) masses. Ultrasound imaging can generate single images, somewhat like photographs, and real-time moving images, somewhat like videos. Some ultrasound imaging systems allow for three-dimensional real-time imaging.

ECHOCARDIOGRAPHY An echocardiogram (eh-ko-KAR-dee-uh-gram) is an ultrasonogram of the heart. Echocardiography can be used to visualize the size of the heart's valves and chambers, the movements of the heart walls, the heart's pumping capacity, and patterns of blood flow through the heart. It is especially useful in the diagnosis of diseases of the heart's valves.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

Diarrhea

Diarrhea is a condition in which bowel movements are abnormally frequent and stools are abnormally fluid. It is not itself a disease but is usually a symptom of some underlying disorder. Diarrhea may be a result of food poisoning, infection, diseases such as dysentery or cholera, emotional upsets, or many other conditions.

What Is Diarrhea?

Diarrhea is very common, a condition with which almost everyone is familiar. Usually, it is little more than an unpleasant nuisance that briefly interferes with work or play. Sometimes, however, severe attacks can seriously endanger a person's health by causing dehydration*. Diarrhea can last different lengths of time: It may be either acute (sudden onset and short term) or chronic (recurrent and long-lasting).

Diarrhea develops in the small or large intestines. The intestines may become irritated and inflamed by an infection or by certain foods. The inflamed intestine does not reabsorb as much water from the stool (bowel contents) as it normally would. In some infections, the intestines actually add more water to the stool. This extra water makes the stools very loose.

What Are the Symptoms of Diarrhea?

Although diarrhea may occur by itself, often it is accompanied by abdominal pain, gurgling bowel sounds, nausea, vomiting, and general weakness. The stools, or bowel movements, are loose or watery and may contain blood, pus, mucus, or droplets of fat. Sometimes attacks of diarrhea alternate with periods of constipation.

* **microorganisms** are tiny organisms that can only be seen using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

What Causes Diarrhea?

Bouts of diarrhea that range from mild to severe can be caused by several types of infectious microorganisms* (my-kro-OR-gan-iz-ims) in contaminated food or water. Diarrhea can also result from the body having trouble digesting dairy products or other foods. Mild cases of diarrhea can be caused by eating spicy food or by anxiety about some stressful event, like having to give a speech in front of a lot of people.

Food poisoning Everyone has heard of a party at which a lot of people got sick after eating the same food. Foods that are not cooked thoroughly or kept refrigerated until just before serving can cause food poisoning. It is important to make sure that raw meat or poultry does not come in contact with cooked foods, that the hands are washed thoroughly before handling any foods, and that all dishes and utensils are thoroughly washed after they have been in contact with raw meat or poultry. These measures help prevent food poisoning.

Bacteria such as staphylococcus (staf-i-lo-KOK-us) can cause digestive upsets of this kind. Certain strains of a common intestinal bacterium known as *E. coli* (EE KO-ly) can cause very serious illness with symptoms that include diarrhea. A group of bacteria called salmonella (sal-mo-NEL-la) can also lead to food poisoning. Salmonella causes gastroenteritis (gas-tro-en-ter-I-tis), or inflammation of the gastrointestinal tract. Salmonella infection can cause diarrhea for a week or longer.

Causes of diarrhea

Causes	Examples
Viral infections	Rotavirus, Norwalk virus
Bacterial infections	<i>E. coli</i> , <i>Vibrio cholerae</i> , <i>Campylobacter</i> , <i>Shigella</i>
Parasites	<i>Giardia</i> , <i>Entamoeba</i>
Helminths (intestinal worms)	<i>Strongyloides</i>
Allergic	Lactose intolerance, celiac sprue, medication side effects
Autoimmune	Ulcerative colitis, Crohn's disease
Malabsorptive	Pancreatic deficiency, biliary disease
Nutritional	Zinc deficiency, vitamin A deficiency, enteral feedings consisting of liquid nutritional formulas delivered straight to the bowels
Functional	Irritable bowel syndrome, short bowel syndrome, cancer

Dysentery Dysentery is an intestinal infection that causes severe diarrhea, often with blood, pus, and mucus in the stools. It is especially common in poor countries with inadequate sanitation facilities, causing the food and water supply to be contaminated. The most common causes of dysentery are bacteria and amebas*. Amebic dysentery can cause chronic diarrhea.

Cholera Outbreaks of cholera often accompany natural disasters such as earthquakes and great storms that disrupt sanitation and cause food and water to be contaminated. It also is widespread in refugee camps and other wartime situations in which people live in severely overcrowded conditions. Food and water contaminated by the cholera bacteria cause a watery form of diarrhea that can rapidly lead to death from severe dehydration.

Giardiasis A mainly tropical disease that can give rise to severe diarrhea is giardiasis (jee-ar-DY-a-sis). Caused by a parasite*, it usually enters the body in contaminated drinking water. Travelers to tropical countries can develop this form of diarrhea, but it can also be contracted in more temperate areas.

In the 1990s and early 2000s, giardiasis became increasingly prevalent in developed countries such as the United States, especially among preschool children. In settings such as households and day-care centers, where children are in close contact, giardiasis can be caught by touching stool-contaminated objects or from hand-to-hand contact.

Traveler's Diarrhea Traveling to foreign countries and drinking water or eating foods washed in the local water supply can cause digestive upsets that include diarrhea; these are sometimes called traveler's diarrhea.

Often, the exact cause of traveler's diarrhea cannot be determined. Likely suspects are certain viruses and strains of bacteria such as *E. coli* that are present in the local water supply. Sometimes parasites such as *Giardia lamblia* and amebas such as *Entamoeba histolytica* may cause traveler's diarrhea. Diarrhea caused by such parasites usually lasts longer than traveler's diarrhea caused by other substances. Other causes of traveler's diarrhea may include changes in diet, excessive alcohol intake, and salmonella or shigella bacteria.

Traveler's diarrhea usually occurs about one week after a person enters the foreign country. People who travel to Latin America, Africa, and Southeastern Asia have a high risk for developing traveler's diarrhea.

Lactose Intolerance Sometimes people get diarrhea from eating dairy products such as milk, cheese, and ice cream. This condition occurs because there is a sugar in milk and milk products called lactose (LAK-tos), which some people cannot digest. To be able to digest this sugar, there must be an enzyme* in the body called lactase (LAK-tays). Some people do not make enough of this enzyme, and when they eat milk or milk products they get diarrhea.

* **amebas** (a-MEE-buz) are small, one-celled animals that live in fresh and salt water. Amebas can be seen only with a microscope.

* **parasite** (PAIR-uh-site) is an organism such as a protozoan (one-celled animals), worm, or insect that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. A parasite lives at the expense of the host and may cause illness.

* **enzyme** (EN-zime) is a protein that helps speed up a chemical reaction in cells or organisms.

Malabsorption and Maldigestion Many diseases can interfere with the intestine's ability to digest (break down) foods or absorb (soak up) digested foods. Problems breaking down foods are called maldigestion (mal-di-JES-shun). Failure to absorb digested foods is called malabsorption (mal-ab-SORP-shun). If foods are not properly digested and absorbed, diarrhea may occur. Problems with the pancreas, Crohn's disease, and lactose intolerance are some of the medical conditions that cause digestion or absorption problems.

Antibiotic-Induced Diarrhea Antibiotics are medicines that kill bacteria. Diarrhea is a common side effect of antibiotics. This condition occurs because antibiotics kill both the bad bacteria that make people sick and the good bacteria that live in the large intestine. Good bacteria help keep unhealthy, disease-causing bacteria from growing too much. An overgrowth of certain unhealthy bacteria, such as *Clostridium difficile*, can cause diarrhea. Good bacteria also add thickness, or bulk, to the stools, which makes them less watery.

What If Diarrhea Lasts a Long Time?

Diarrhea caused by parasites, such as in amebic dysentery and giardiasis, can become chronic. Infestation with worms also can produce lasting diarrhea.

More often, the cause of chronic diarrhea is not an infection. Instead, it may be the result of inflammatory bowel diseases, which include ulcerative colitis (ko-LY-tis) and Crohn's disease. A disorder known as diverticulitis (di-ver-tik-yoo-LY-tis), in which abnormal pouches in the walls of the intestines become inflamed, can also cause chronic diarrhea. Other causes include cancer of the intestine, irritable bowel syndrome, and the inability to digest certain foods.

Diarrhea in Infants

Infants and young children commonly get diarrhea from viral infection or giardiasis. When a baby has diarrhea, usually the condition is more serious than in adults or older children. An infant with these symptoms can lose body fluids so rapidly that it is life threatening, especially if vomiting also occurs. Signs of dehydration in infants, such as a dry mouth, lack of urine production, or unresponsiveness, require immediate medical attention. Bacterial intestinal infections such as cholera cause many infant deaths in developing countries.

How Is Diarrhea Treated?

Most cases of diarrhea are mild and do not require medical attention. For bouts that last more than a few days, that recur, or that show blood in the stool, a doctor should be consulted. For infants, medical advice should be sought if the diarrhea lasts more than 48 hours. Medical tests used in diagnosis may include examination and culture of stool samples (for bacteria, viruses, or parasites), x-rays, or use of a colonoscope (ko-LON-o-skope),

an instrument for viewing the lining of the colon. Changes in the diet may be recommended in order to find out if diarrhea is due to a food allergy or problems digesting or absorbing foods. For example, diarrhea symptoms may get better if a person with lactose intolerance avoids milk products.

Treatment of diarrhea consists mainly of drinking liquids to replace lost fluids and prevent dehydration. The World Health Organization's salt, sugar, and water formula is commonly used to hydrate (add water to) children with severe diarrhea. It is easy-to-use and inexpensive and has helped save the lives of millions of people around the world.

In some cases, doctors may prescribe medications that ease mild diarrhea symptoms. Treatment of severe diarrhea depends largely on the cause. For example, antibiotics may be prescribed for dysentery or certain kinds of food poisoning.

Milk products, greasy foods, and sweets can make diarrhea worse. Such foods and drinks should be avoided until after the diarrhea stops. Some doctors recommend that children who are recovering from diarrhea eat bananas, plain rice, applesauce, and toast. Adults may add other soft, non-spicy foods to their diet as symptoms lessen. Such foods include boiled potatoes and baked, skinless chicken.

Can Diarrhea Be Avoided?

Washing one's hands thoroughly after using the toilet is always important, but especially so where contagious forms of diarrhea such as giardiasis can be spread. Also people should wash hands thoroughly before and after handling foods, especially raw meats. Travelers in foreign countries should use bottled (not tap) water, even for brushing teeth, and avoid eating raw meats, fish, fruits, and vegetables. Medicines may be given to prevent traveler's diarrhea in persons at high-risk for the condition or who have certain medical conditions that can be made worse by diarrhea or dehydration.

People should be cautious about eating foods that are left out of the refrigerator for a long time. Bacteria thrive in warm temperatures. Leftovers should be refrigerated quickly. All food preparation surfaces, including cutting boards and countertops, should be washed before and after food preparation.

Janowitz, Henry D. *Your Gut Feelings*. New York: Oxford University Press, 1994.

Did You Know?

More people died from unsanitary conditions during the American Civil War than from bullets. Of the estimated 600,000 fatalities during the war, the majority were due to epidemics of diarrhea-inducing diseases such as dysentery and typhoid fever. These diseases were caused by contaminated food and water in the encampments. A voluntary organization called the U.S. Sanitary Commission was founded to combat the conditions and provide medical assistance, and they held sanitary fairs to raise money.

Dietary Deficiencies

Dietary deficiencies are disorders that occur due to a lack of essential nutrients in the diet or because the body cannot absorb and process those nutrients once they are eaten. Most dietary deficiency diseases are caused by a lack of protein, vitamins, or minerals.*

What Are Dietary Deficiencies?

The human diet is divided into five nutritional groups: proteins, carbohydrates, fats, vitamins, and minerals. These five groups include about 50 nutritional items that are necessary for good health and growth. Each of these items plays a vital role in the functioning of the human body. The amount of nutrients needed for good health varies from individual to individual. Age, gender, and overall health condition affect how much of these nutrients a person needs for good health.

Whenever individuals do not get enough of an essential nutrient, they are at risk for a dietary deficiency disease. Most dietary deficiency diseases result from a lack of protein, vitamins, or minerals. Protein deficiency diseases occur when a person does not eat enough protein; these diseases are prevalent in developing countries where people are too poor to buy protein-rich foods or where such foods are hard to find. Generally speaking, vitamin and mineral deficiencies result from diets that lack some of the nutrients found in fresh vegetables and fruit, as well as milk, cheese, or eggs. In some cases, genetic* disorders, metabolic* disorders, or illnesses that prevent the body from digesting or absorbing particular nutrients cause the deficiencies.

The Supplement Habit

Use of vitamin and mineral supplements grew in the United States during the 1990s and early 2000s. Estimates suggest that from 30 to 40 million people in the United States alone use nutritional supplements on a daily basis. The potency of small amounts of vitamins to cure deficiency diseases may have led to the unrealistic expectation that vitamins and minerals can ensure good health when taken in large amounts as supplements. Despite this widespread habit, few scientific studies exist to prove these supplements can make a difference.

It is important to check with a doctor before adding nutritional supplements to the diet and to keep in mind the following facts:

- Most vitamins are water-soluble. The body can absorb only so much of a vitamin, and the rest is excreted in the urine throughout the day.
- Large doses of some vitamins, such as A and D, can be harmful. Vitamins A and D are fat-soluble vitamins and can accumulate in the liver to the point of becoming toxic.
- Too much of certain trace elements, such as zinc, copper, fluoride, and selenium, can be toxic.
- Most nutritionists recommend eating a well-balanced diet as the most effective and least expensive way of getting the nutrients needed to stay healthy.
- Vitamin supplements are warranted for certain people, such as pregnant women, newborns, and people on special diets.
- The health-food and vitamin industries that market supplements claim that the minimum daily amounts recommended by the Food and Drug Administration (FDA) are too low. The American Dietetic Association (ADA) recommends that doctors or licensed dietitians be the source of supplement prescriptions.

Protein Deficiencies

Proteins are the essential components of all organs and chemical activities. Proteins make up muscles, connective tissue, skin, and other tissues, as well as hormones and various components of blood. In addition, some proteins are enzymes, chemicals that cause reactions to occur that allow the body to function. For example, some enzymes digest food or convert sugar into energy. Proteins are composed of strings of building blocks called amino acids. When a person eats and digests proteins, these proteins break down into amino acids that are then distributed throughout the body where they form new proteins and enzymes. When protein is missing from the diet, the body cannot function properly. Milk, meat, and legumes are important sources of dietary protein.

Protein-energy malnutrition (PEM) The term protein-energy malnutrition (PEM) is used to describe the range of conditions related to calorie

* **weaning** means accustoming a child to take food other than by breastfeeding.

* **edema** (e-DEE-ma) means swelling in the body's tissues caused by excess fluids.

* **retina** (RET-i-na) is the tissue that forms the inner surface of the back of the eyeballs; it receives the light that enters the eye and transmits it through the optic nerves to the brain to produce visual images.

(energy) and protein deficiency disorders. These diseases are prevalent in developing countries where people lack sufficient food. In this category of malnutrition are the diseases kwashiorkor (kwash-e-OR-kor) and marasmus (ma-RAZ-mus). These diseases affect mainly children, with as many as half of the children in starvation-prone countries not surviving to five years of age. Adults rarely suffer from protein deficiency diseases unless they experience a problem in the intestines that prevents absorption of amino acids.

Kwashiorkor The disease kwashiorkor is caused specifically by a lack of protein in the diet. The term originates from an African word that describes the situation of an infant being weaned* from breast milk to make room for the next baby. When weaning occurs and protein-rich food (such as milk, meat, or legumes) is not available, the baby experiences tiredness, muscular wasting, and edema*. The hair and skin lose color, the skin becomes scaly, and the child may experience diarrhea and anemia.

Marasmus Marasmus is a wasting away of body tissue from a lack of both calories and protein in the diet. A child with marasmus is cranky and irritable and is skinny rather than swollen with edema.

Vitamin Deficiencies

While animals, including humans, can construct all the proteins they need from the building blocks called amino acids, they cannot make most vitamins. Vitamins are chemicals, and almost all of them must be obtained from foods. Thirteen vitamins are essential for healthy growth, development, cell function, and metabolism: vitamins A, C, D, E, K, and eight B vitamins (together they are called the B-complex vitamins). All vitamins must be taken into the body from outside food sources, except for vitamins D and K, which can be made under specific circumstances by the body.

Vitamin A, night blindness, and xerophthalmia Vitamin A is necessary to protect the retina*, and for the normal growth and health of skin and membrane cells. A deficiency of vitamin A can cause night blindness, a condition in which the eyes fail to adjust to the dark due to problems with the retina. The deficiency also may cause glare blindness, or problems seeing when the eye is exposed to too much light or to a sudden change in the amount of light when entering a darkened room.

Vitamin A deficiency can also cause the disease xerophthalmia (zeer-off-THAL-mee-a). The symptoms of this disease are eye dryness and thickening of the surface of parts of the eye. If left untreated, xerophthalmia may lead to blindness.

Vitamin A can be obtained directly from foods such as milk, eggs, and liver, as well as from carotene, a chemical that is found in green and yellow fruits, and vegetables such as apricots, cantaloupe, oranges, peaches, collards, broccoli, turnip greens, kale, carrots, sweet potatoes, and squash. Carotene is converted to vitamin A in the body.

Vitamin B1 and beriberi Beriberi (BER-ee-BER-ee) is a disease that affects the heart, digestive system, and nervous system. It results from a lack of vitamin B1 (also called thiamin) in the diet. Thiamin is used to help the body make energy. Food sources for this vitamin are meats, wheat germ, whole grain and enriched bread, legumes, nuts, peanuts, and peanut butter. The early stages of beriberi are characterized by fatigue; loss of appetite; and a numb or tingling feeling in the legs.

Beriberi has three forms:

- **Infantile beriberi:** Although a nursing mother may not have the disease herself, her infant gets sick from not getting enough thiamin in the breast milk. The child may die in infancy, or the child may develop wet or dry beriberi.
- **Wet beriberi:** This disease affects the cardiovascular system and can lead to such symptoms as an enlarged heart and increased heart rate, in addition to congestion in the lungs, shortness of breath, and swelling in the lower legs.
- **Dry beriberi:** This disease affects the central nervous system, which encompasses the brain and spinal cord. Its symptoms include pain, loss of feeling in the hands and feet, vomiting, confusion, difficulties in speaking, and muscle damage. Some people with dry beriberi experience paralysis of the lower legs or coma*. People with dry beriberi often require the aid of a cane in order to walk, and they may become bedridden and susceptible to infectious diseases. Dry beriberi is sometimes known as Wernicke-Korsakoff syndrome. The syndrome involves damage to the central nervous system as well as the nerves elsewhere in the body. People who are heavy drinkers of alcohol may be diagnosed with this syndrome, because alcohol use interferes with the body's ability to break down and absorb thiamine. Even if individuals get enough of this vitamin in their diet, the body cannot access it.

Beriberi is found in Japan, Indonesia, China, Malaysia, India, Burma, the Philippines, Brazil, Thailand, and Vietnam. In the United States and other developed nations, it usually occurs in a milder form, often accompanying malnutrition and alcoholism. Beriberi may also affect pregnant women who have a poor diet, and people in institutions in which there is poor nutritional planning, such as some prisons, geriatric hospitals, or institutions for the mentally ill.

Vitamin B3 and pellagra A deficiency of vitamin B3 (also known as niacin) leads to the disease pellagra (pe-LAG-ra). Good sources of niacin include liver, lean meat, whole wheat products, fish, eggs, roasted peanuts, the white meat of poultry, avocados, dates, figs, prunes, kidney, wheat germ, and brewer's yeast.

Pellagra affects the skin, nervous system, and digestion, and can cause the "four Ds": diarrhea*, dermatitis*, dementia*, and death. A person who is developing pellagra may feel weak and tired, may have trouble

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

* **diarrhea** (di-ah-RE-a) refers to frequent, watery stools (bowel movements).

* **dermatitis** is a skin condition characterized by a red, itchy rash. It may occur when the skin comes in contact with something to which it is sensitive.

* **dementia** (dih-MEN-sha) is a loss of mental abilities, including memory, understanding, and judgment.

JOSEPH GOLDBERGER'S DISCOVERY

Joseph Goldberger (1881–1929) was a member of the U.S. Public Health Service. In 1914 he joined a commission to study the high number of pellagra cases in the southern United States. Goldberger determined that pellagra was not an infectious disease and that a pellagra-preventing factor in certain foods could prevent its occurrence. In 1928 niacin (vitamin B3) was accepted as the factor that prevents pellagra.

Niacin is also known as nicotinic acid. The active form of niacin used by the body is called niacinamide.

sleeping, and may lose weight. The skin that is exposed to the sun may become scaly, rough, and reddened, and painful sores may develop in the mouth. Loss of appetite is accompanied by indigestion and diarrhea. A person with pellagra might also experience headaches, dizziness, and muscular tremors. Sometimes mental disorders (or dementia) appear.

Pellagra is common around the world, although the “fortification” of processed wheat with vitamin B in the United States keeps the numbers low. Pellagra is seen in people who eat mostly corn rather than wheat and in people whose diets lack enough protein. People with gastrointestinal diseases that prevent their bodies from using B vitamins properly may also develop pellagra.

Other B complex vitamins Cobalamin (B12) deficiency can result from a lack of the substance called gastric intrinsic factor in the stomach that is necessary to absorb the vitamin. People who are on a vegan diet can also get too little of this vitamin. Vitamin B12 deficiency can lead to megaloblastic anemia, which is characterized by enlarged blood corpuscles and in some cases to severe damage to the nervous system, including degeneration of the spinal cord and paraplegia.

Vitamin B6 can protect against anemia, skin problems, and irritability.

Vitamin C and scurvy Vitamin C affects blood vessels, skin, gums, connective tissue, red blood cells, wound healing, and the absorption of iron. A vitamin C deficiency leads to scurvy. The main symptom of scurvy is hemorrhaging, or bleeding under the skin, which results in many bruises. A person with scurvy may also have swollen and infected gums. Wounds heal slowly, and bleeding in or around vital organs can be fatal.

Scurvy is one of the oldest deficiency diseases recorded and the first one to be cured by adding a vitamin to the diet. It was a common malady of sailors during the fifteenth century, the age of exploration of the New World. In modern times, people whose diets lack vitamin C-rich foods,

such as citrus fruits, are still at risk of developing scurvy. Those most at risk are infants, the elderly, and people on fad diets.

Vitamin D, rickets, and osteomalacia Vitamin D is essential for proper bone formation because it helps regulate the amounts of certain bone-forming minerals (calcium and phosphate) in the bloodstream. Vitamin D is added to milk and infant formula* and is found in other foods, such as sardines, salmon, and tuna. Vitamin D is also made by the skin in response to exposure to sunlight.

Without enough vitamin D, a person can develop the disease rickets, which is characterized by bone deformities. Rickets affects mainly children, because bone growth occurs during childhood. Rickets can cause the legs to become bowed by the weight of the body, and it can cause the wrists and ankles to become thickened. Teeth are badly affected and take a longer than usual to come in. All the bones are affected by not having sufficient calcium and phosphorous for their growth and development. Childhood rickets was once a common disease of infants and children, but it is rarely seen in the early 2000s because milk and infant formulas have vitamin D added to them.

Osteomalacia (os-tee-o-ma-LAY-sha) is an adult version of rickets caused by a deficiency of Vitamin D, calcium, and phosphorous. The bones become soft, deformed, and painful. This disease is seen more often in the Middle East and Asia than in Western countries.

Vitamins E and K Vitamin E helps prevent reproductive problems and promotes good skin health. Vitamin K promotes normal blood clotting by aiding in the manufacture of fibrinogen (fy-BRIN-o-jen) and other proteins needed for clotting. Vitamin E deficiencies are not very common, and vitamin K deficiencies are rare except in newborns. To prevent newborn bleeding, newborns receive a shot of vitamin K.

Folate and birth defects A deficiency in folate (also known as folic acid or folacin) in pregnant women can result in some central nervous system birth defects in their babies. To help prevent these birth defects, pregnant women should supplement their diets with folate very early in their pregnancies. Excellent food sources for folate include deep-green and leafy vegetables, carrots, liver, egg yolk, cantaloupe, apricot, pumpkin, avocado, beans, and whole wheat and dark rye flours.

Mineral Deficiencies

Minerals are formed as a result of geological processes, are normally crystalline, and usually appear in the form of simple salts. The human body contains about 25 minerals. Those minerals that appear in large amounts are called macrominerals, whereas those that are in small or trace amounts are called microminerals. Minerals known to be essential to a healthy body include calcium, phosphorous, cobalt, copper, fluorine, iodine, iron, and sodium. The result of a mineral deficiency depends on the which mineral is missing from the diet.

* **formula** is a prepared, nutritious drink or a dry drink mix designed specifically for infants.

- * **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.
- * **hemoglobin** (HE-muh-glo-bin) is the oxygen-carrying pigment of the red blood cells.
- * **prostate** (PRAH-state) is a male reproductive gland located near where the bladder joins the urethra. The prostate produces the fluid part of semen.

Iodine, goiter, and hypothyroidism Iodine is necessary for the proper functioning of the thyroid, a gland that controls the body's metabolic rate and produces essential hormones*. Without sufficient iodine in the diet, the thyroid begins to enlarge its cells in an effort to produce its hormones, and this activity may produce a goiter, which causes a swelling in the front of the neck. In countries with high standards of living, most goiters result from diseases of the thyroid rather than from a dietary deficiency of iodine.

Some geographic regions lack iodine in the soil, which can lead to hypothyroidism (underactive thyroid), and to arrested physical and mental development in infants. One common source of iodine is iodized salt, which is produced and distributed in developed parts of the world. Another excellent source of iodine is kelp, a sea vegetable.

Iron and anemia Iron is necessary for the formation of certain proteins and enzymes. Hemoglobin (HE-mo-glo-bin), which is the oxygen-carrying protein in the blood, is one such iron-dependent protein. Iron deficiency can lead to anemia, which is characterized by low levels of either healthy red blood cells or hemoglobin*, which in turn can lead to fatigue and other complications. Good food sources of iron are liver, lean meats, legumes, dried fruits, and green leafy vegetables.

Other minerals A zinc deficiency can bring about prostate* and skin disorders, whereas a copper deficiency can lead to metabolic disorders. Deficiencies of calcium and phosphorus lead to softening of the bones or to hypercalcemia (hy-per-kal-SEE-mee-a), a condition in which too much calcium leads to a surplus formation of bone.

Zinc and copper are trace elements found in a variety of foods. Deficiencies of these minerals are rare. Dairy products, red meat, sunflower seeds, cooked dried beans, walnuts, sardines, and whole grains are good sources of zinc. Copper is found in many foods, including fish, poultry, organ meat, whole grains, nuts, and seeds.

How Are Dietary Deficiency Diseases Treated and Prevented?

In most cases, dietary deficiency diseases are treated by giving affected individuals foods that are rich in the missing nutrient and/or by giving them supplements. The recovery (none, partial, or full) depends on the particular disease, at what age the disease developed, and whether the effects are reversible once they have occurred.

Most dietary deficiency diseases can be prevented by people eating a well-balanced diet comprising many types of foods. Ongoing medical care can help prevent dietary deficiency diseases caused by genetic problems and by metabolic problems that prevent the body from absorbing or utilizing nutrients properly.

In countries where food and money are scarce, however, dietary deficiency diseases remain all too common.

Diphtheria

Diphtheria (dif-THEER-e-uh) is an infection of the lining of the upper respiratory tract (the nose and throat). It is a serious disease that can cause breathing difficulty and other complications, and it can be fatal. Routine vaccination against diphtheria has made it rare in the United States.*

What Is Diphtheria?

Diphtheria is an infection caused by a bacterium called *Corynebacterium diphtheriae* (kor-ih-nee-bak-TEER-e-um dif-THEER-e-eye) that infects the upper respiratory tract. As the bacteria infect the nose, throat, or larynx (LAIR-inks, the voice box), a distinctive thick membrane forms over the site of infection. The membrane can become large enough to interfere with a person's ability to breathe and swallow. Some strains of *Corynebacterium diphtheriae* also produce an exotoxin* that can cause arthritis and damage

▲ *Corynebacterium diphtheriae* which causes diphtheria in humans magnified 19,500 times. Kwangshin Kim/Photo Researchers, Inc.

* **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.

* **exotoxin** (ek-so-TOK-sin) is a substance produced by bacteria that has harmful effects on the infected person.

Canine Heroes

In the winter of 1925, a diphtheria epidemic swept through Nome, Alaska. Antitoxin was located almost 1,000 miles away in the city of Anchorage. The only way to transport the medicine was by dog sled. A relay of sled-dog teams, with the last leg led by a dog named Balto, successfully carried the medicine through frigid temperatures in time to save many lives.

In honor of that achievement, a statue of Balto was erected in Central Park in New York City.

* **shock** is a serious condition in which blood pressure is very low and not enough blood flows to the body's organs and tissues. Untreated, shock may result in death.

* **epidemic** (eh-pih-DEH-mik) is an outbreak of disease, especially infectious disease, in which the number of cases suddenly becomes far greater than usual. Usually epidemics are outbreaks of diseases in specific regions, whereas widespread epidemics are called pandemics.

* **carrier** is a person who has in his body a bacterium or virus or gene for a disease that he can transmit to other people without getting sick himself.

to the nerves and heart. Sepsis, a potentially serious spreading of infection (usually bacterial) through the bloodstream and body, can result from diphtheria, causing shock*, heart failure, and even death.

How Common Is Diphtheria?

Diphtheria occurs throughout the world and is common in developing regions of Africa, Asia, and South America where children often do not receive the diphtheria vaccine. Cases usually occur in winter and the cooler months of autumn and spring.

Diphtheria infection is extremely rare in the United States due to the widespread use of diphtheria vaccination during childhood. From 1992 through 2008, 41 cases of diphtheria were reported in the United States with only one death. However, a diphtheria epidemic* has affected the countries that made up the former Soviet Union. Since 1990 more than 150,000 cases have been reported in these countries.

Is Diphtheria Contagious?

Diphtheria is highly contagious. An untreated person who has diphtheria can spread the infection for up to a month. Within 48 hours of receiving antibiotics, however, people infected with diphtheria are usually no longer contagious.

The bacteria that cause diphtheria are spread through the air in drops of moisture from the respiratory tract, often from coughing or sneezing. Sharing drinking glasses or eating utensils or handling soiled tissues or handkerchiefs that have been used by a person with the disease can also transmit the bacteria. A person can get diphtheria from someone who has symptoms of the disease or from someone who is just a carrier* of the bacteria.

What Are the Signs and Symptoms of Diphtheria?

Within five days after becoming infected, a person typically begins to have symptoms of diphtheria. Early symptoms often include a severe sore throat, runny nose, mild fever, and swollen glands in the neck. People infected with diphtheria in the nose, throat, or larynx usually develop a thick membrane at the site of the infection. Membranes in the nose are often white, whereas those at the back of the throat are gray-green.

As diphtheria progresses, respiratory symptoms can become more severe and include difficulty breathing or swallowing and a bark-like cough. Sometimes inflammation and swelling in the throat and the diphtheria membrane itself can cause blockage of the upper airways, making emergency treatment necessary.

How Is Diphtheria Diagnosed and Treated?

Diphtheria is diagnosed when the membrane that signals the disease is seen in the nose or throat during an examination of someone with symptoms of the disease. The diagnosis is confirmed by taking a swab of the coating from underneath the membrane and performing a laboratory test that identifies diphtheria bacteria.

Hospitalized people who are known to have diphtheria are isolated to prevent the disease from spreading to others. Patients are treated in the hospital with antibiotics and diphtheria antitoxin*. The antitoxin, which is produced in horses, is given intravenously (directly into a vein).

In severe cases of diphtheria, patients may need a ventilator (VEN-tuh-lay-ter) to help with breathing or medication to treat complications of the disease, such as septic shock*, heart inflammation, or heart failure. After they leave the hospital, bed rest at home for several weeks is generally recommended. Members of the same household are usually given a diphtheria booster vaccine to protect against possible infection. Recovery from diphtheria often takes four to six weeks or more.

Complications of diphtheria include abnormal heart rhythms, arthritis, and neuritis*. Diphtheria is most dangerous for children under five and adults over 40. Death occurs in up to 10 percent of people with diphtheria who receive medical treatment; death rates are higher in some parts of the world where treatment is not readily available.

Can Diphtheria Be Prevented?

In the United States, immunization programs have been very effective in preventing diphtheria. The diphtheria vaccine is given in combination with vaccines for tetanus* and pertussis* (this is called the DTaP vaccine) as part of a child's routine immunizations. Four doses of the vaccine are given before the child is two years of age. A first booster dose is given at four to six years of age when a child enters school. Additional booster doses are recommended every 10 years, in combination with a tetanus booster.

Sometimes people have mild reactions to the vaccine, including a low-grade fever, tenderness at the injection site, and irritability. Very rarely, stronger reactions such as seizures* or allergic reactions can occur.

Disability

Disability is a potentially limiting reduction in the normal functioning of the human body. Disabilities can influence both the physical and mental well-being of a person, and they can have serious impact on self-esteem and social adjustment.

What Is Disability?

Disability is a deviation from the normal range of functioning that places a limit on what a person can do or that imposes special conditions or needs. These conditions or needs must be met to allow individuals to function in the normal range or up to their full capacity. Disabilities can be mental, physical, psychological, or a combination of all three. The disability may be obvious to the casual observer, such as the loss of a leg, or invisible, such as a back injury. Some people prefer to refer to anyone whose range of function falls outside the norm as “differently abled,” as a way to stress that the condition is a difference rather than a lack of completeness. Many people with disabilities do quite well meeting the same challenges people without disabilities meet.

Sean Halsted (left) turns a corner past Jacqueline Tyler (right) during the handcycle event in the 26th National Veteran Wheelchair Games in Anchorage, Alaska, July 4, 2006. Halsted won the men's Class 4, 5, open division in the 10K handcycle race. *AP Images.*

What Are Various Types of Disability?

Disability may be physical, mental, or psychological. Examples of physical disability include those resulting from blindness or due to amputation of a limb. Examples of mental disability are mental retardation and disability due to exposure to toxic substances such as lead or other hazardous chemicals. Examples of psychological disability are severe depression or chronic anxiety. Some types of disability can result from a combination of mental and physiological limitations, such as certain learning disabilities.

What Are Some Physical Disabilities?

People can be born with a physical disability. When they are, the problem is called a congenital* (kon-JEH-nih-tul) disability. In many cases, the cause of a congenital disability is unknown. Some congenital disabilities with known causes are:

- **Inherited disabilities:** Some disabilities are the result of genetic* disorders, for example, cystic fibrosis*.
- **Exposure of the mother to disease, alcohol, drugs, harmful medications, pollutants, or chemicals during pregnancy:** For example, a mother who has rubella* early in pregnancy may have a child who is deaf or who has other birth defects.

Physical disability also can arise at any time after birth. These types of disabilities commonly occur from accidents, illness, working conditions that expose a person to an unhealthy environment (such as coal miners who breathe in coal dust), or repetitive physical stresses (such as repeated heavy lifting).

What Are Some Mental Disabilities?

Individuals experiencing mental disability may appear slow in speech, movement, and interaction with others. In addition, they may learn and comprehend information at a different rate than those without mental disability. Behavioral problems and learning difficulties can coincide with this type of disability. Often times these individuals benefit from specialized teaching methods and one-to-one interaction. Individuals may have mental disability due to complications during birth such as low oxygen supply leading to brain damage and mental retardation. Others may experience mental disability later in life due to exposure to certain drugs or other hazardous chemicals, leading to changes in brain function. Those with mental disability may have varied levels of intellect due to different degrees of mental retardation.

What Are Some Psychological Disabilities?

Severe depression or chronic anxiety are forms of psychological disability. Bipolar disease and schizophrenia* are also types of psychological disability. Those with psychological disability generally have biochemical characteristics in their brains that are different from individuals without

- * **congenital** (kon-JEH-nih-tul) means present at birth.
- * **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.
- * **cystic fibrosis** (SIS-tik fy-BRO-sis) is a disease that causes the body to produce thick mucus that clogs passages in many of the body's organs, including the lungs.
- * **rubella** (roo-BEH-luh) is a viral infection that usually causes a rash and mild fever.
- * **schizophrenia** (skit-so-FREE-nee-ah) is a serious mental disorder that causes people to experience hallucinations, delusions, and other confusing thoughts and behaviors, which distort their view of reality.

- * **psychologist** (sy-KOL-uh-jist) is a mental health professional who can do psychological testing and provide mental health counseling.
- * **psychiatrist** (sy-KY-uh-trist) is a medical doctor who has completed specialized training in the diagnosis and treatment of mental illness. Psychiatrists can diagnose mental illnesses, provide mental health counseling, and prescribe medications.
- * **chronic** (KRAH-nik) lasting a long time or recurring frequently.

psychological disability, and this difference in the brain chemicals causes them to think and act in a different way from people who do not experience psychological disability. They may experience periods of balance and imbalance depending on the severity and duration of the disability. These individuals often benefit from medication and therapy from a trained professional such as a psychologist* or psychiatrist*. Psychological disability may affect children as well as adult populations and may be short term; however, many psychological disabilities are chronic* in nature.

What Is the Connection between Disability and Self-Image?

Self-image is the mental picture people have of themselves, including their external appearance, intellectual abilities, strengths, and weaknesses. This mental picture begins to develop in infancy and continues to grow and change throughout life. People develop their mental pictures through their interactions with other people and the world around them. When individuals with disabilities confront negative reactions, they may internalize that negative judgment and develop a poor self-image. Self-esteem is strongly linked to self-image. Self-esteem is the value that people put on the mental image that they have of themselves.

What Impact Does the Onset of Disability Have?

Disability may occur at different stages in one's life, including at birth, as an unexpected incident after birth, or later on in life.

Disability noted at birth is called a congenital disability. Because congenitally disabled people may have never lived in a non-disabled body, they often feel complete, intact, and okay with the disability, even though the outside world may view them as different. Children whose parents accept them, support them, show pride in them and their abilities, and communicate factually and directly about the disability are more likely to develop good self-image and self-esteem.

Disability may also arise the result of an unexpected, sudden incident later in life, such as with a car accident or a machinery accident in the workplace. This type of disability may be called an acquired disability. People who acquire disabilities later in life have a different experience from those who are born with a disability. These people have lost some aspect of self that played a part in their development of their self-image, whether it is the loss of an arm or leg or the loss of an ability to perform a particular activity. People with acquired disabilities tend to feel an array of emotions such as grief, denial, anger, and depression as they learn to adapt and work out a new way to live. Many individuals obtain artificial limbs or specialized machinery, such as electric wheelchairs, to assist them with activities of daily living. Over time they adapt to varying degrees to their acquired disability.

Disability sometimes progresses over a longer period. For example, disability can develop as people age or as a complication from medical conditions such as diabetes or high blood pressure. Progressive chronic

illnesses, such as muscular dystrophy* or Alzheimer's (ALTS-hy-merz) disease*, may lead to mental or physical disability over time.

What Are the Connections between Disability and Health?

Many physicians and mental health practitioners agree that there is a connection between mental health and physical wellbeing. In general, the better a person's self-image and self-esteem, the more able a person is to cope with various changes and challenges and the better a person feels both mentally and physically.

Many studies have found that people with disabilities experience psychological problems (especially depression and anxiety) and behavior problems at about twice the rate of the non-disabled individuals. Family members of people with disabilities are also more likely to experience emotional problems brought on by the extra responsibilities, financial burdens, and limitations of caring for someone with a disability. Although chronic illness and disability include the risk of psychological problems, many individuals and families learn to cope with these conditions.

In 1996 the American Academy of Pediatrics reviewed many studies of people with disabilities and concluded that certain risk factors increase the chance that people with disabilities will experience psychological problems. Other protective factors appear to decrease the chance that a person with a disability will have psychological problems.

Risk factors that increase the likelihood of psychological problems include:

- Chronic illnesses that are painful, unpredictable (such as seizures), or embarrassing
- Invisible disabilities (because people may feel stressed by wondering if they should tell others about their limitations)
- Disabilities that require a schedule of time-sensitive special treatments
- Poor social skills and a rigid personality
- Failure of loved ones and professionals to talk honestly with the person about the disability
- Failure of parents to address sexuality in teens with disabilities
- Allowing the disability to become the focus of family life
- Fighting between the parents or break-up of the parents' marriage
- Overprotectiveness on the part of parents or caregivers

Factors that decrease the likelihood of psychological problems include:

- Family acceptance of the disability
- Strong bonds within the family that help the family work together
- Open and direct communication about the nature of the disability and what to expect

* **muscular dystrophy** (DIS-tro-fee) is a group of inherited disorders that causes muscle weakening that worsens over time.

* **Alzheimer's (ALTS-hy-merz) disease** is a condition that leads to gradually worsening loss of mental abilities, including memory, judgment, and abstract thinking, as well as changes in personality.

- Balancing of family needs with the needs of the disabled person
- Good social skills and plenty of social interaction
- Appropriate expectations of accomplishments
- Strong support network in the community

What Are Some Myths about People with Disabilities?

Non-disabled people are often uninformed about the actual nature of a disabled person's life. False beliefs people with disabilities frequently encounter include the following:

Myth: Disabled people are usually mentally retarded.

Reality: Most disabilities do not affect intelligence.

Myth: Disabled people are sick.

Reality: Illness is not the same as disability. Some people are disabled with chronic illness, whereas others are healthy.

Myth: People with disabilities can never have a good quality of life.

Reality: Quality of life is mainly determined by the disabled person's character and by the degree of social acceptance that person experiences rather than on the disability itself.

Myth: People with disabilities need continuous supervision and cannot lead independent lives.

Reality: The degree of independence a person achieves depends on the nature of the disability, the person's education and training, and the accommodations that are available to make independent living physically possible.

▶ In the middle of his career, artist Chuck Close became partially paralyzed due to a blood clot in his spinal column. To continue painting, he developed a technique that allowed him to work with his weakened hands from his wheelchair. He is still able to create the large, multicolored portraits for which he is known. *AP Images.*

Myth: People with disabilities are especially noble, brave, and courageous for coping with their handicaps.

Reality: There are all kinds of people with disabilities. Most disabled people carry on with their lives just as non-disabled people do.

What Role Does the Community Play?

The Americans with Disabilities Act is the federal law that is intended to integrate people with disabilities into mainstream life as much as possible. It requires that disabled people be provided with access to public and private spaces and with workplace accommodations and, whenever possible, that they be included in mainstream public education. Although physical accommodations, such as wheelchair-accessible restrooms or Braille instructions for the blind on automatic teller machines, are common in new buildings, many older facilities and private spaces have not been renovated to accommodate people with physical disabilities.

Employers are increasingly willing to make workplace accommodations for people with physical disabilities, but they are still fearful of making such arrangements for people with mental or psychological disabilities. The unemployment rate among disabled people, especially disabled women, is very high, and many people with disabilities are employed at jobs below their skill levels. Service industries hire more people with disabilities than any other type of employer.

People with disabilities face some common challenges. At the same time, disabled people are individuals with differing personalities and needs. People who are born with a disability may have self-image issues that are different than people who acquire a disability later in life. Someone who is confined to a bed with a chronic, long-term illness faces challenges that are different from someone who is healthy but who has a disability such as blindness or mental retardation.

Although researchers can draw a group picture of people who are disabled, this picture does not represent an individual with a disability any more accurately than a general picture of the average American represents a non-disabled person. The challenge is to see people with disabilities as individuals, each with his or her own strengths, weaknesses, hopes, and dreams, regardless of each person's type of disability.

Dissociative Identity Disorder

Dissociative identity (di-SO-see-a-tiv i-DEN-ti-tee) disorder (DID) is a mental disorder in which a person displays two or more distinct identities—sometimes called alters—that take control of behavior in turn. It was formerly called multiple personality disorder (MPD).

The Real-Life Sybil

Sybil Dorsett was a 22-year-old college student who had amnesia*. She also had terrible headaches and sometimes could not see, almost as if she were blind. Upon turning for help to the psychiatrist* Cornelia Wilbur in New York, Sybil soon started to show other personalities. It was as if there were more than one person inside Sybil's body. One personality, who called herself Vicky, said she was from Paris. Another personality, called Peggy Lou, was a tough woman who showed no fear. As time passed, Sybil displayed more personalities: a writer, a flirt, a pianist, a mother, and even an infant and two men.

Wilbur noticed that each personality acted and sounded different from the Sybil Dorsett she had first met. Each personality even described his or her physical features in different ways. One said that she had blue eyes, while another said that his eyes were brown. Almost everything, from details about hair color to gestures, changed as Sybil switched from one personality to another. In all, Sybil displayed 16 different identities.

Sybil's case became one of the most famous examples of dissociative identity disorder after a book about her experiences appeared in 1973.

A movie starring Sally Field as Sybil was made in 1976. Sybil's story offers a revealing glimpse of an often-misunderstood mental disorder.

What Is Dissociative Identity Disorder?

Dissociative identity disorder (DID) is a severe psychiatric condition in which a person has two or more distinct sub-personalities that periodically take control of his or her behavior. The sub-personalities are thought to be caused by repeated episodes of an extreme form of dissociation. Dissociation is a condition in which a person's thoughts, emotions, sensations, or memories become compartmentalized, usually as a result of a severe emotional trauma* or series of traumas. The symptoms of dissociation may include amnesia, depersonalization*, and derealization*. It is possible for survivors of natural disasters, plane crashes, criminal assaults, or military combat to develop dissociative symptoms without developing DID.

In contrast to dissociative symptoms that may develop in traumatized adults, dissociative identity disorder is thought to begin early in life when a child is subjected to repeated incidents of physical or sexual abuse in his or her family. The child splits off, or dissociates, memories of the abuse in order to survive. The memories later surface and are experienced in the form of a separate personality. This process can be repeated at different points in the child's development to form new alter personalities. The patient may eventually have as many as 100 alter personalities, although most patients display between 10 and 15 different personalities. Each alter takes control over the patient's behavior for a period of time, usually adopting a unique name, voice, dress style, and life history.

Descriptions of dissociative identity disorder can be found in ancient myths and many documents written through the centuries. However, until the early 1900s it was not regarded as a treatable mental disorder, when Morton Prince (1854–1929), a Boston psychiatrist, treated a patient he called Sally Beauchamp, who had four alter personalities. Prince used the term “dissociation” to describe his patient's symptoms. He published a book about Beauchamp in 1906 titled *The Dissociation of a Personality*. Much of what was learned about DID, however, was discovered during the last quarter of the twentieth century.

Dissociative identity disorder should not be confused with schizophrenia*. Schizophrenia usually occurs in people in their late teens or early adult years. Its name comes from the Greek for “split mind.” Unlike dissociative identity disorder, which is characterized by multiple personalities, schizophrenia causes a split between reality as others experience it and the delusional perceptions of the schizophrenic. These distinct mental disorders have quite different symptoms, causes, and treatments.

How Common Is Dissociative Identity Disorder?

Dissociative identity disorder is a controversial diagnosis; that is, some doctors believe it does not exist at all and others maintain that it is a subtype of post-traumatic stress disorder*. The number of reported cases of

* **trauma** refers to a wound or injury, whether psychological or physical. Psychological trauma refers to an emotional shock that leads to lasting psychological damage.

* **depersonalization** (de-per-son-al-i-ZAY-shun) is a mental condition in which people feel that they are living in a dream or are removed from their body and are watching themselves live.

* **derealization** (de-reel-i-ZAY-shun) is a mental condition in which people feel that the external world is strange or unreal.

* **schizophrenia** (skit-so-FREE-nee-ah) is a serious mental disorder that causes people to experience hallucinations, delusions, and other confusing thoughts and behaviors, which distort their view of reality.

* **post-traumatic stress disorder** (post-traw-MAT-ik STRES dis-OR-der) is a mental disorder that interferes with everyday living and occurs in people who survive a terrifying event, such as school violence, military combat, or a natural disaster.

- * **incidence** means rate of occurrence.
- * **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.
- * **addiction** (a-DIK-shun) is a strong physical or psychological dependence on a physical substance.
- * **personality disorders** are a group of mental disorders characterized by long-term patterns of behavior that differ from those expected by society. People with personality disorders have patterns of emotional response, impulse control, and perception that differ from those of most people.
- * **flashbacks** are intensely vivid, recurring mental images of a past traumatic event. People may feel or act as if they were reliving the experience.

DID in the United States rose sharply between the 1970s and 1990s but declined thereafter. Some researchers asserted that the increase occurred because doctors were increasingly aware of the disorder's symptoms. Others, however, speculated that the disorder was being diagnosed in some people because they were open to suggestion about memories of childhood trauma. Still other researchers noted that most cases of DID after the 1970s were reported in the United States and other English-speaking countries, which led to the possibility that dissociative identity disorder is a by-product of certain cultures or periods of history rather than a universal and fixed psychiatric condition.

Estimates for incidence* in the United States range from 0.01 percent to 1 percent of the general population, or between 30,000 and 300,000 people. These estimates vary widely because the disorder is difficult to diagnose; in addition, people with DID frequently suffer from such other disorders as depression*, alcoholism or drug addiction*, or personality disorders*. As a result, the doctor may think that the patient's dissociative symptoms are caused by these other disorders and not consider DID as a possible diagnosis. Consequently, a diagnosis of dissociative identity disorder typically takes at least six to seven years to be made.

How Do People Know They Have Dissociative Identity Disorder?

The first symptom of DID is amnesia. Like Sybil, people with the disorder often start to realize that there are abnormally long periods of time that they cannot remember. They might "wake up" in a different place or wearing different clothes and recall nothing that explains the changes. In some cases they find items in their closet that they do not remember purchasing. There have even been cases of DID patients meeting people at a party or on the street who call them by the name of one of their alters. Such episodes of amnesia can lead them to suspect that something is seriously wrong.

Patients often are skilled at hiding their alter personalities from family and friends. A person might be Sam, a shy clerk, at work. However, at night, he might lead life as Jack, an outgoing man who spends time in bars far from his neighborhood.

The patient's primary identity usually uses the name that the patient was given at birth. This identity often feels depressed, behaves passively, and displays guilt feelings that cannot be explained easily. This primary identity usually is not aware at first of the other identities, but the other identities may talk about the primary identity. For example, one of Sybil's identities Vicky often commented to Dr. Wilbur about Sybil's life and the lives of the other identities.

Other symptoms of DID include attempted suicide and self-inflicted injuries, such as cuts or burns. Many people with dissociative identity disorder also show signs of post-traumatic stress disorder. They may startle easily or have nightmares or flashbacks*.

A FOOTBALL HERO TELLS HIS STORY

Herschel Walker, a former professional football player, was a high school superstar. In 1980 college recruiters made him the most sought-after young athlete in the United States. Walker chose the University of Georgia and helped that school to win the national collegiate football title. In 1982 he was awarded the Heisman Trophy, given each year to the most outstanding college football player. In 1983 Walker left college to become a professional athlete, playing with such teams as the Dallas Cowboys and Minnesota Vikings.

After retiring from professional sports, however, Walker began to notice that he had memory problems. He could not remember the season he won the Heisman Trophy or even the dinner when the award was presented to him. His alter personalities emerged as bitter, angry people who threatened his wife with physical violence. On one occasion, Walker held a gun to his own head but could not remember the incident afterward. He then realized that he had some kind of mental disorder and sought help. Diagnosed with DID in 2000, Walker wrote a book about his psychological problems, *Breaking Free: My Life with Dissociative Identity Disorder* (2008). He told his story in order to help other people with DID know that the condition is treatable and that they are not alone.

How Do Doctors Diagnose and Treat Dissociative Identity Disorder?

DID is usually diagnosed by psychiatrists or other mental health professionals rather than primary care doctors. The first step in diagnosis is to exclude any physical disease or condition that might be causing the patient's symptoms, such as head injuries, brain tumors, alcohol or drug abuse, or seizures*.

In order for a psychiatrist to diagnose individuals as having dissociative identity disorder after possible physical causes have been ruled out, the doctor must observe two or more distinct identities in the patient. For example, patients may come to the doctor's office dressed very differently from their first visit or talk in a different tone of voice. Each identity must also become the dominant personality for a time. In some cases, doctors may talk to patients for long periods or ask them to keep a journal between visits, in hopes of learning more about the different personalities. Psychiatrists sometimes use hypnosis* to bring out different identities.

The psychiatrist may also use questionnaires or diagnostic interviews that are designed to help identify patients with DID. One brief screener is the Dissociative Experiences Scale (DES), which patients can fill out in the doctor's office in a few minutes. If individuals score high on the DES, they can be given one or two longer interviews in which the doctor

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **hypnosis** refers to a trance-like state, usually induced by another person. The person under hypnosis may recall forgotten or suppressed memories and be unusually responsive to suggestions.

asks them to describe their experiences in detail. These interviews take between 45 and 90 minutes to complete.

The goal of treatment is to bring the separate identities together into one primary identity. Therapy attempts to help patients recall past trauma and deal with emotions without the primary identity being split into parts. The doctor may also prescribe medications to help patients cope with the anxiety and depression that often accompany DID. Success in treatment is possible, but treatment can take many years; it took about 11 years for Sybil's 16 personalities to blend into one. Patients with DID who are still emotionally attached to their abusers, however, do not usually respond well to therapy.

Can Dissociative Identity Disorder Be Prevented?

DID can be prevented by healthy parenting and caregiving. Parents who are afraid that they might abuse their children should contact a doctor or member of the clergy and ask for help in locating a parents' support group or a family therapist. Some churches, synagogues, and community centers offer parenting classes. Parents with children who have suffered a criminal attack or other traumatic event should also consult a doctor or mental health professional to help their children cope with their memories and feelings.

Diverticulitis/Diverticulosis

Diverticulosis is the presence of diverticula (dy-ver-TIK-yoo-la) in the colon (large intestine). Diverticula are small sacs or pouches that bulge outward from the inside surface of intestinal wall. If diverticula become inflamed or infected, the resulting disease is called diverticulitis.

What Causes Diverticulitis and Diverticulosis?

Diverticulosis is caused by not enough roughage (fiber) in the diet. Roughage is coarse, bulky food that is rich in plant fiber. Observations show that people in developing countries whose diets include large amounts of plant materials (fruits and vegetables) almost never have diverticulosis. Diverticulosis is common in the United States and in other developed countries, where refined foods often lack significant amounts of fiber.

Young people rarely have diverticulosis, but it becomes more common as people age. By the time individuals in the United States reach the age of 60, they have about a 50 percent chance of having diverticulosis.

What Do Diverticula Look Like?

Diverticula are pouches that occur most commonly in the sigmoid colon, which is the S-shaped part of the large intestine closest to the rectum. Many diverticula are usually present, and they may range from pea-sized or smaller to about one inch in diameter. The pouches form due to transmural (across-the-wall) pressure in the lower intestine that often occurs during constipation. A high-fiber diet that keeps wastes moving smoothly through the bowel and distributes pressure more evenly is thought to reduce the likelihood of developing diverticulosis or the related condition called diverticulitis, which is described below.

How Do Doctors Diagnose and Treat Diverticula?

Symptoms People with diverticulosis may not know they have it because it does not always cause symptoms. Sometimes, however, the diverticula may become plugged with waste and infected, causing diverticulitis. The symptoms of diverticulitis may include abdominal* pain, fever, and tenderness when external pressure is applied over the abdomen. At other times the small artery feeding the diverticulum may rupture and cause severe bleeding from the rectum. Both of these conditions require immediate attention.

Diagnosis A doctor may discover that a person has diverticula by x-ray examination or by looking inside the colon through a viewing instrument such as a sigmoidoscope (sig-MOI-do-skope) or a colonoscope (ko-LON-o-skope). Doctors often discover diverticula that have not caused symptoms during routine medical procedures.

▲ Inflamed, perforated, and hemorrhaging diverticula in the descending (or sigmoid) colon. Diverticulosis is almost always located in the descending colon. © 1999. Reprinted with permission of Delmar Learning, a division of Cengage Learning.

* **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.

* **intravenous fluids** (in-tra-VEE-nus) are fluids injected directly into a vein.

If the patient has symptoms of infection, such as fever or abdominal pain and tenderness, the doctor generally does not use a sigmoidoscope or colonoscope because these instruments may perforate the colon. The doctor may use another method such as a CAT scan in order to search for pus-filled diverticula. Often the symptoms alone are enough to allow the doctor to be confident of the diagnosis of diverticulosis/diverticulitis, and treatment may begin without any other diagnostic tests being performed.

Treatment Diverticulosis usually requires no special treatment, although doctors may recommend increased roughage in the diet. In mild cases of diverticulitis, treatment may include drinking more fluids, bed rest, and antibiotics to control infection. Sometimes doctors recommend intravenous fluids* containing antibiotics.

Occasionally, diverticulitis may be accompanied by serious complications. If diverticula rupture (RUP-chur, break open), intestinal contents may leak or spill out and cause an infection in the surrounding abdomen. Sometimes the intestine may become blocked or narrowed, in which case a patient may need surgery. Another situation that may call for surgery is a bleeding diverticulum. Often, bleeding diverticula can be corrected with medical treatments, but when that fails and a diverticulum continues to bleed, it may require surgical removal.

How Are Diverticula Prevented?

Medical professionals typically recommend adequate amounts of vegetable fiber in the diet as a way to avoid diverticulosis and diverticulitis. Bran, cabbage, beans, and whole-grain breads are examples of foods high in dietary fiber. Physicians may also suggest fiber supplements, especially for older adults, to maintain regular bowel habits and to reduce the risk of diverticulitis.

Down Syndrome

Down syndrome is a genetic condition that occurs when a person has three copies of chromosome 21 rather than the usual two. People with Down syndrome usually have a characteristic physical appearance, significantly lowered intellectual abilities, and sometimes a number of physical problems, such as heart defects.*

Jason's Sister Anna: A Look at Someone with Down Syndrome

First and foremost, Jason's sister Anna is a happy, active, five-year-old girl. She also is a girl with Down syndrome, and Jason feels more protective of his sister than do most big brothers. When they are out at the mall, everyone remarks about how adorable Anna is, but they also stare at her. Anna has many of the characteristic features of people with Down syndrome, and some of them are quite noticeable. These features may include:

- a flattened face
- up-slanted eyes
- low-set ears
- a protruding tongue
- a short neck
- a single, straight crease across the palm
- distinctive patterns on the ridges of the skin on her fingers, palms, and soles
- short arms and legs
- poor muscle tone
- mental retardation

All of these characteristics vary among affected people, and some people with Down syndrome have fewer of these features than others do. Anna is somewhere in the middle of the range. She is also moderately mentally retarded.

Jason did some research on Down syndrome for a school report and now worries about Anna's health. Many people with Down syndrome have health problems such as heart defects, increased susceptibility* to infection, respiratory problems, and digestive problems. Childhood leukemia occurs slightly more frequently in children with Down syndrome than in other children, and adults with the syndrome are at increased risk for Alzheimer's (ALTS-hy-merz) disease*.

What Is Down Syndrome?

All people have chromosomes in their cells. Chromosomes provide the genetic information needed for the cells of the body to work properly. Normally, most of a person's cells contain 23 pairs of chromosomes, for a

Chart showing the twenty-two chromosome pairs, in this case with three chromosomes instead of two in pair twenty-one, an abnormality producing Down Syndrome (Trisomy 21).

Dr. Dennis Kunkel/PHOTOTAKE Inc./Alamy.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **susceptibility** (su-sep-ti-BIL-i-tee) means having less resistance to and higher risk for infection or disease.

* **Alzheimer's (ALTS-hy-merz) disease** is a condition that leads to gradually worsening loss of mental abilities, including memory, judgment, and abstract thinking, as well as changes in personality.

total of 46. The exceptions are eggs and sperm cells, which have only one set of 23 chromosomes. People who have Down syndrome, by contrast, have an extra copy of a certain chromosome, the one called chromosome 21, or extra chromosome 21 parts. Down syndrome can occur in three ways.

Nondisjunction About 95 percent of people with Down syndrome have three copies of chromosome 21, a condition called trisomy 21 (*tri* means three). This condition occurs due to an error in the way that cells divide. This error is known as nondisjunction.

The error starts in the reproductive cells: the egg or the sperm cell. These cells, each of which has 23 chromosomes, make identical copies of themselves in a process called meiosis (my-O-sis). In this process, a normal cell first duplicates its chromosomes and then divides in half, with each newly created cell getting a complete set of 23 chromosomes. If the two copies of chromosome 21 do not separate, however, the result is an

A BRIEF HISTORY OF DOWN SYNDROME RESEARCH

1866: An English physician, John Langdon Haydon Down (1828–1896), published the first description in the medical literature of a person with Down syndrome.

1959: Jérôme Lejeune (1927–1994), a French physician, found the extra chromosome 21.

2000: Scientists unraveled the genetic code of chromosome 21. Chromosome 21 is the smallest of all human chromosomes, and scientists believe it has 200–400 genes, each of which has a specific job to do. Some of these genes produce proteins, one of which regulates the auto-immune system, whereas other genes produce enzymes, one of which affects the amino acids that are the building blocks of proteins. When a cell has an extra chromosome, and therefore extra genes, the genes can make too much of their protein, and the extra proteins can cause an abnormality.

2006: Researchers found that a gene on chromosome 21 seems to be responsible for mental retardation among people who have Down syndrome. They did their study on mice instead of humans but believe it may work the same way in humans. They found that mice with three copies of the gene made too much of a certain protein, the extra protein caused certain nerve cells to be especially large, and this, in turn, caused retardation. The researchers later tried to figure out if they could find a way to “turn down” the gene so it makes less of its protein. If they were successful, they envisioned eventually using this knowledge to help treat people with the syndrome. In the meantime, scientists elsewhere were carefully studying other genes on chromosome 21 to learn the particular function of each and possibly find ways to treat or prevent Down syndrome.

egg or a sperm cell with two copies of the chromosome instead of the usual one. At least 95 percent of the time, trisomy 21 occurs when a normal sperm with one set of chromosomes fertilizes an egg with two copies of chromosome 21. The fertilized egg, therefore, has two pairs of all of the other chromosomes, but three copies of chromosome 21. As the embryo grows, its cells replicate* and continue to make new cells with the extra copy of chromosome 21—for a total of 47 chromosomes rather than the normal 46—throughout its body.

Translocation Some patients with Down syndrome have the normal number of 46 chromosomes in their cells. This infrequent condition occurs because they still have some extra parts of chromosome 21 in their cells. The extra chromosome 21 results when a piece of it breaks off while a cell is making a copy of itself, and that extra piece attaches to another chromosome. This abnormal process is called translocation. In this case, the incorrectly attached genetic material from chromosome 21 causes the features of Down syndrome. Translocation only accounts for 3 to 4 percent of all Down syndrome cases.

Mosaicism The third type of Down syndrome, mosaicism (mo-ZAY-i-siz-im), occurs when nondisjunction of chromosome 21 takes place after the initial fertilization of an egg with a sperm but still very early in the fertilized egg's development. In this case, cells can either replicate from originals (so-called parent cells) that have 46 chromosomes or from those with 47 chromosomes. As a result, some of the cells in the embryo's body may have 46 chromosomes, and others may have 47. Mosaicism is very rare, occurring in only 1 to 2 percent of people with Down syndrome.

What Causes Down Syndrome?

No one knows what causes the chromosomal abnormality that results in Down syndrome, a condition that affects one in 800 to 1,000 babies in the United States. Any woman can have a baby with Down syndrome. It is not associated with a person's culture, race, geographic location, or relative wealth.

A mother's age, however, does seem to be correlated* with her risk of having a child with Down syndrome. About 91 percent of women have babies before they reach 35 years of age, but they give birth to only 75 percent of children with Down syndrome. The remaining 25 percent are born to women who are older than 35. In other words, older women have a greater chance of giving birth to a baby with Down syndrome, and the risks increase with every passing year. Researchers estimate the chance of having a baby with Down syndrome to be as follows:

- less than 1 in 1,000 for a woman below age 30
- approximately 1 in 400 for a 35-year-old woman
- approximately 1 in 105 for a 40-year-old woman
- approximately 1 in 20 for a 46-year-old woman

* **replicate** (REP-li-kate) means to create an identical copy.

* **correlated** means linked in a way that can be measured and predicted.

- * **alpha-fetoprotein** (AL-fah-FEE-toe-PRO-teen) a substance produced by a fetus and present in maternal blood and amniotic fluid, measured to determine likelihood of neural tube defects.
- * **amniocentesis** (am-nee-o-sen-TEE-sis) is a test in which a long, thin needle is inserted in the mother's uterus to obtain a sample of the amniotic fluid from the sac that surrounds the fetus. The fetal cells in the fluid are then examined for genetic defects.
- * **umbilical cord** (um-BIH-lih-kul) is the flexible cord that connects a baby to the placenta, the organ that unites the unborn child to the mother's uterus, the organ in which the baby develops.

Can a Pregnant Woman Learn If Her Baby Has Down Syndrome?

Down syndrome is the most common chromosomal abnormality in humans, and medical professionals have several ways to test for it, but that does not mean all pregnant women decide to have the tests. Some women prefer not to know; many women do want to know. The reasons for getting tested may include early preparation for the child's medical care, making sure that funding or insurance to pay for the child's special needs is available, or, for women who decide for any number of reasons not to have a child with Down syndrome, ending the pregnancy.

Screening tests Medical professionals commonly use the triple screen test or the alpha-fetoprotein (AFP)* test to predict whether a woman is carrying a baby with Down syndrome. They are called screening tests because they do not give a definite answer. Instead, they measure the amounts of certain substances in the mother's blood that can indicate a problem. If one of these tests is positive, it does not necessarily mean that the fetus (the developing baby) has Down syndrome, but it does indicate that the woman should have more tests done. Sometimes the test results are false-negatives, meaning that the test did not indicate Down syndrome even though the fetus has it. Low levels of AFP in the mother's blood are correlated with Down syndrome in the fetus, but the test detects only about 35 percent of cases. The triple test, which measures levels of three substances, is correct about 60 percent of the time.

Another screening is called nuchal (NOO-kul) translucency screening. In this test, medical professionals perform an ultrasound, which uses sound waves, to examine the skin at the back of the fetus's neck. They look at the size of the clear space in the neck tissue. Babies with Down syndrome have extra fluids in this part of the neck, which makes the clear space look larger. This test is able to detect about 80 percent of Down syndrome cases.

Diagnostic tests Medical professionals recommend several different diagnostic tests for pregnant women older than 35, and for women with positive results on screening tests. A common diagnostic test is amniocentesis* (am-nee-o-sen-TEE-sis). In this test, medical professionals examine chromosomes from the fetus's cells. This diagnostic test gives a definite answer, which means they are correct 98 to 99 percent of the time. In this test, medical professionals extract fetal cell samples, which can be taken from the fluid surrounding the fetus or from the umbilical cord*. On rare occasions, these procedures cause the mother to have a miscarriage (lose the baby before birth). Women who plan to have diagnostic tests performed should receive information and have emotional support available to help them understand the procedures and cope with the possibility of miscarriage and also with the possibility of results indicating Down syndrome.

What Does Life Hold for Anna and Her Family?

In 1910, most children with Down syndrome did not live past the age of nine, often due to infections. When antibiotics were developed in the 1940s, the average child with Down syndrome survived to age 19 or 20. In the early 2000s, the average life expectancy is nearly 50 years. Because this is an average, some individuals live longer and some do not live this long.

Anna's family learned all they could about Down syndrome as soon as Anna was born. They knew Anna would learn to sit, walk, and talk somewhat later than her peers. Anna's family is providing her with a stimulating home environment, good medical care, and good educational programs. They are teaching her to be a happy productive member of the community. Whether she will be able to go to school or to work or live independently depends on the level of her mental development. However, Anna's family knows that the Americans with Disabilities Act of 1991 (ADA) helps to protect Anna's right to live her life free of unnecessary limitations or discrimination due to her disabilities.

Dyslexia

Dyslexia (dis-LEX-ee-a) is a learning disability that affects a person's ability to interpret written words and read, write, and spell properly. Dyslexia, which is not a form of intellectual disability, affects people of all levels of intelligence.

What Is Dyslexia?

Dyslexia is a language processing disorder that makes a person unable to recognize written words and numbers properly. It comes from the combination of two Greek words: “dys,” which means “impaired,” and “lexis,” which means “words.” Most people with dyslexia also have trouble with writing and spelling. In addition, some have difficulty with numbers. Dyslexia is sometimes referred to as specific reading disability.

When people with dyslexia look at or hear words, their eyes and ears work properly, but a part of their brain misinterprets the words and delivers a faulty message back to them. In many cases, dyslexia may be genetic*, because people with the disorder often have a family history of learning disabilities.

Dyslexia affects more than 5 percent of school-age children. About four out of every five children with dyslexia are boys. The disorder affects all races equally and is the most common type of learning disability.

What Causes Dyslexia?

There are three forms of dyslexia. Primary dyslexia is caused by a genetic malfunction in the left side of the brain (cerebral cortex*), which is the part of the brain that recognizes and interprets words. Primary dyslexia is usually hereditary, and patients often struggle with this type of dyslexia throughout their lives. Secondary dyslexia occurs during fetal development. This type of dyslexia often diminishes as a child ages. Traumatic dyslexia occurs after an injury that affects the part of a person's brain that reads and interprets words. This type of dyslexia is uncommon in school-age children.

Students with dyslexia often have trouble with writing and spelling as well as reading. *Will and Deni McIntyre/Photo Researchers, Inc.*

People with dyslexia are not unintelligent or lazy. In fact, most people with dyslexia have average or above-average intelligence and work very hard at learning how to read well. They simply have a part of their brain that does not correctly translate messages about written words.

How Do People Know They Have Dyslexia?

Dyslexia usually is not diagnosed very early in a child's life, because children are not expected to learn to read until about six years of age. However, once children with dyslexia start school, they may have a hard time keeping up with their classmates. Words and letters appear much differently to a person with dyslexia than to a person without it. Sometimes words look all jammed together, while other times there seem to be spaces between words where they do not belong.

The biggest problem for people with dyslexia is that they do not recognize that words are made up of small units of sound, known as phonemes*. As a result, people with dyslexia struggle to connect the sounds that make up words. They may see p's where there are b's; for example, "pall" instead of "ball."

Because the skill of reading goes along with the skill of writing, children with dyslexia often have a difficult time learning to write, spell, and even speak correctly. They may flip letters or write letters upside down. Letters that look similar may confuse such children when they try to write; for example, "doll" may become "boll." Because the letters are shaped incorrectly, the children's handwriting may be very hard to read. The ability to spell properly also is affected by dyslexia. Letters may not appear in the right order; for example, "purple" may become "pruple." Some letters may be left out entirely, making the word "puple."

* **phonemes** (FO-neemz) are the smallest units of spoken language, such as the puh' sound at the start of the word pat.

* **neurologic exam** refers to systematic tests of how well various parts of the nervous system are functioning.

* **intelligence quotient test** also known as an IQ test, refers to a test designed to estimate a person's intellectual potential.

When children have this kind of difficulty with reading, writing, and spelling, they may quickly fall behind in school and feel frustrated, even though they may be intelligent. Not surprisingly, many adults with dyslexia say that they hated reading when they were young. Fortunately, most teachers as of the early 2000s are trained to recognize dyslexia and take action to help children who have this problem.

How Is Dyslexia Diagnosed?

Sometimes, children who are having difficulty with reading or writing will feel embarrassed or ashamed and try to hide it from their parents, teachers, and friends. Dyslexia may be suspected when a child shows difficulty with reading, keeping up in school, or following directions.

Once a parent or teacher recognizes that there is a problem, such children should be referred to their doctor for a thorough physical exam. The physician can run various tests, including vision and hearing tests, to rule out other problems. The physician also can do a neurologic exam* to measure how well the different parts of the nervous system are working.

If dyslexia is suspected, the physician may enlist the help of a specialist in learning disabilities. The specialist can administer tests to figure out how the children's brains process information. The children may take an intelligence quotient test* as well as academic achievement tests that assess reading and writing skills. Sometimes the children also take tests that assess abilities in other areas, such as math, logic, and creative thinking.

Once testing is completed, the specialist can determine whether the children have dyslexia by comparing their intelligence test against the reading and writing tests. Average or high scores on an intelligence test

READING DISABILITY

When Tommy opened his history book, this is the story he saw:

*Wenthe Pilgrims la n bed ta Plymouththey wer ein a mostbre carioussitua
tion. T heye ar saw lateandther e wasmuc h sicknes s a mon g the sett l ers.*

When Jason opened his book to the same page, this is what he saw:

*When the Pilgrims landed at Plymouth they were in a most precarious
situation. The year was late, and there was much sickness among the
settlers.*

For Jason and most of his classmates, reading about the first American settlers is easy and interesting. For Tommy and any other students in the class with dyslexia, reading is difficult and frustrating, because they do not see the words correctly.

and low scores on reading and writing tests are typical of people with dyslexia.

What Can Be Done about Dyslexia?

The earlier children are diagnosed with dyslexia and the earlier their families and teachers are made aware of the diagnosis, the better the outcome. Children with dyslexia must learn to read in a different way from those who do not have the disorder. Many children who do not have their dyslexia diagnosed until later do poorly in school year after year, as they try to learn to read the same way everyone else does. Eventually, after their dyslexia is diagnosed, they must go back and relearn how to read.

Whether it is a younger child with dyslexia who is first learning to read or an older child who is relearning, a special approach must be taken. In many cases, an individualized reading program is the first step. A reading specialist creates a plan that is designed just for the child. The plan is based on many factors, such as how severe the child's dyslexia is and what the child's strengths are in other areas in school.

Many times, the reading plan for a student with dyslexia includes a multisensory approach, which means that instead of just using the sense of sight, the student also uses other senses, such as touch or hearing. In some cases, a student might feel clay or wooden models of letters while saying the letters aloud. In other cases, the student might learn letter sounds while looking at pictures or listen to letter sounds on a tape while looking at the letters. The use of computers is also beneficial to children with dyslexia. The student can also work with the reading specialist on phonemes. Eventually, the student learns to create combinations of phonemes to form words and from there to recognize and read words.

Students with dyslexia can be taught in different settings. Some are placed in special classrooms with other students who have reading disabilities, while others work one-on-one with a reading specialist at certain points during the school day.

Living with Dyslexia

Children with dyslexia face a special challenge: not only must they learn to read, but they also must learn to read in a special way. People with dyslexia usually learn to read slowly, and it can take lots of practice. Emotional support is important. Many children with dyslexia feel inadequate because they cannot read as easily as most of their classmates. With enough help and support, however, children with dyslexia can learn to read and write well. The reading and writing level that a person with dyslexia can achieve depends a lot on the severity of the disorder. For example, someone with a mild form of dyslexia may learn to read and write well, whereas a person with severe dyslexia may always find reading and writing difficult.

Children with dyslexia usually grow into healthy adults with normal lives. Many people with dyslexia go to college and excel in their classes, sometimes by using special methods such as tape recording their lectures

Dyslexia Hall of Fame

Many people with dyslexia go far beyond merely living up to their potential. The following list identifies some of the famous people who achieved their career dreams despite dyslexia or other learning disabilities:

Albert Einstein
 Hans Christian Andersen
 Cher
 Winston Churchill
 Tom Cruise
 Leonardo da Vinci
 Thomas Edison
 Danny Glover
 Whoopi Goldberg
 Bruce Jenner
 Greg Louganis
 Walt Disney
 Michelangelo
 Auguste Rodin
 Woodrow Wilson
 William Butler Yeats
 Orlando Bloom

or taking oral exams instead of written ones. Adults with dyslexia can do well in many different kinds of jobs.

Can Dyslexia Be Cured?

As of 2009 there was no cure for dyslexia. There was no drug that people with dyslexia could take to correct the problem. Scientists have studied the various parts of the brain to learn why information is interpreted incorrectly in some people. However, the brain is complex, and there remain many mysteries about what causes dyslexia and other learning disabilities.

Dyspepsia See *Heartburn (Dyspepsia)*.

Dysrhythmia

Dysrhythmia (dis-RITH-mee-a), or arrhythmia (a-RITH-mee-a), is a change in the regular beat of the heart. The heart may seem to skip a beat, beat irregularly, or beat very rapidly or very slowly.

The sinoatrial node is the heart's pacemaker. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

Annie's Story

Annie, who had just turned 15, was running for student council treasurer. On the morning she had to give her campaign speech before the entire student assembly, her heart began to race. Stepping behind the podium in the auditorium, she felt a little dizzy and out of breath. During the first few minutes of her speech, she worried that she might faint, but as she kept speaking and gained confidence, the sensations vanished and her heartbeat slowed down. By the time she reached her last sentence, she felt completely normal.

What Is Dysrhythmia?

Dysrhythmia is any variation in the regular beat of the heart. Some of these changes are normal—like Annie's palpitation*—whereas others are more serious. People's hearts naturally speed up with emotion or exercise, and slow down during sleep. Other dysrhythmias are associated with heart disease and can be life-threatening.

The human heart is a muscular pump divided into four chambers: two atria located on the top and two ventricles located on the bottom. But it is more than a pump; it is also an amazing piece of electrical machinery that, when healthy, keeps these chambers beating in an organized manner.

Normally, the heartbeat begins in the right atrium when the sinoatrial (SA) node, a special group of cells, transmits an electrical signal across the

* **palpitation** is the sensation of a rapid or irregular heartbeat.

* **stimulants** (STIM-yoo-lunt) a drug that produces a temporary feeling of alertness, energy, and euphoria.

* **autonomic nervous system** is a branch of the peripheral nervous system that controls various involuntary body activities, such as body temperature, metabolism, heart rate, blood pressure, breathing, and digestion. The autonomic nervous system has two parts—the sympathetic and parasympathetic branches.

heart. This signal spreads throughout the atria and to the atrioventricular (AV) node. The AV node connects to a group of fibers in the ventricles that conducts the electrical signal and sends the impulse to all parts of the ventricles. This exact route is necessary to ensure that the heart pumps properly.

As the electrical impulse crosses through the heart, the heart contracts. This contraction normally occurs about 60 to 100 times per minute, with each contraction equaling a single heartbeat. The atria contract about one-fifth of a second before the ventricles, allowing them to empty their blood into the ventricles before the ventricles contract.

Under some conditions, almost all heart tissue is capable of starting a heartbeat, or becoming the pacemaker. A dysrhythmia occurs in the following circumstances:

- The heart's natural pacemaker (SA node) becomes defective
- The normal conduction pathway to the AV node and the ventricles is interrupted
- Another part of the heart takes over as pacemaker

What Causes Dysrhythmia?

External and internal forces can cause dysrhythmia. External factors include exhaustion, overexertion, emotional stress (such as Annie's delivering her campaign speech), cigarette smoking, alcohol consumption, and ingesting stimulants*, such as caffeine, decongestants, and cocaine. Internal factors include heart defects present at birth, thyroid problems, inflammatory diseases, and problems in the autonomic nervous system*, which carries nerve impulses from the brain and spinal cord to the heart. The most important factor that contributes to serious dysrhythmias, however, is heart disease, including coronary artery disease, abnormal heart valves, and congenital heart disease.

What Are Different Types of Dysrhythmia?

The more common dysrhythmias are as follows:

- **Bradycardia** (bray-dee-KAR-dee-a), a heart rate of fewer than 60 beats per minute in an adult
- **Tachycardia** (tak-i-KAR-dee-a), a heart rate of more than 100 beats a minute in an adult
- **Sick sinus syndrome**, in which the heart rate slows down or varies between slow and fast rates
- **Atrial flutter**, in which the atrial rate reaches 240 to 350 beats per minute (the ventricular rate in this condition rarely goes above 180 due to a protective effect of the AV node)
- **Atrial fibrillation** (AY-tree-al fib-ri-LAY-shun), in which the atria quiver instead of beating effectively. This is a major cause of stroke.

- **Ventricular fibrillation** (ven-TRIK-yoo-lar fib-ri-LAY-shun), in which the ventricles quiver instead of beating, and the heart cannot pump any blood. Without emergency treatment, the person will die within minutes.
- **Ventricular tachycardia**, rapid heartbeat (> 150 beats per minute) that can lead to ventricular fibrillation. This rhythm is abnormal because it originates in the ventricles themselves and, therefore, has the potential to deteriorate into ventricular fibrillation.
- **Premature ventricular contractions**, extra heartbeats that are often felt as “missed beats” or “flipflops” in the chest

* **electrocardiogram** (e-lek-tro-KAR-dee-o-gram), also known as an EKG, is a test that records and displays the electrical activity of the heart.

How Are Dysrhythmias Diagnosed?

Symptoms of dysrhythmias can vary. Some people have no symptoms, whereas others experience fatigue, lightheadedness, dizziness, palpitations, fainting, shortness of breath, and in some cases, sudden collapse and death. Although many dysrhythmias are harmless, a doctor should check them because they can signal heart disease or other conditions that need treatment.

Like fingerprints found at a crime scene, electrocardiogram* (ECG or EKG) tracings are important pieces of physical evidence that track irregularities in the heartbeat. Sometimes, however, an abnormal heartbeat does not show up during a visit to the doctor. In that case, the patient can wear a 24-hour Holter ECG monitor to track the heartbeat. A stress test, in which the patient walks on a treadmill while being monitored, can help a physician see the effect of exercise on the heart.

How Are Dysrhythmias Treated?

Normally, people’s heart rates vary a bit—even from one beat to the next. Many dysrhythmias—such as Annie’s—require no treatment at all.

Some abnormal rhythms may need to be controlled with medication or, on occasion, electric shock. Dysrhythmia can also be treated with the implantation of a battery-powered pacemaker that sends small electrical charges through an electrode placed next to the wall of the heart. A cardioverter/defibrillator, a sophisticated device that actually senses an abnormal rhythm and delivers one or more lifesaving jolts of energy to shock the heart back to normal rhythm, can replace a defective natural pacemaker or a blocked pathway. Catheter ablation is a surgical technique that uses a tiny device at the end of a catheter (a flexible tube) inserted into the heart to burn away the part of the heart causing the abnormal rhythm.

If heart disease is not the culprit, the doctor may suggest that the patient not drink coffee, tea, and colas (which all contain the stimulant caffeine), or alcoholic beverages. Over the long term, it is important to eat a balanced, low-fat diet and exercise regularly to keep the heart healthy.

Eating Disorders: Overview

Eating disorders are habits or patterns of eating that are out of balance and may involve major health and emotional problems.

What Are Eating Disorders?

Eating disorders are not merely unhealthy eating habits; they involve patterns of eating too little or too much, and they may cause a variety of physical and emotional problems. Eating disorders usually develop during adolescence and usually affect girls, although boys can also be affected. Eating disorders include anorexia (an-o-REK-see-a), bulimia (bull-EE-me-a), binge eating disorder, and obesity (o-BEE-si-tee).

Anorexia Anorexia (also called *anorexia nervosa*) is an eating disorder that involves the fear of becoming or being fat, intensive dieting or exercise, and a distorted body image*. People with anorexia see themselves as fat even though they may be dangerously underweight. They severely restrict their food intake and/or exercise to extremes in order to lose weight. People may be diagnosed with anorexia if they refuse to eat enough food to maintain a healthy weight and have lost more than 15 to 20 percent of their healthy weight. For example, a girl with anorexia whose healthy weight is 125 pounds might weigh 105 pounds. She might eat as little as 500 calories per day (most healthy teenagers eat 2,000 or more calories per day).

Bulimia Sometimes referred to as the binge-purge disorder, bulimia (or bulimia nervosa) involves repeated episodes of binge eating (consuming large quantities of food while feeling little control over the behavior) followed by purging (trying to rid the body of the food by vomiting or by using laxatives or enemas*). Some people with bulimia also exercise

▲ Eating disorders have multiple causes, which may include social and cultural pressures, emotional issues, and family stressors. Chemical imbalances in the brain, shown here in cross-section, may also cause eating disorders. These imbalances affect the hypothalamus, which is believed to control appetite. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **body image** is a person's impressions, thoughts, feelings, and opinions about his or her body.

* **enemas** (EH-nuh-muhz) are procedures in which liquid is injected through the anus into the intestine, usually to flush out the intestines.

AT A GLANCE

According to Walden Behavioral Care, more than 1,000 women and girls die of anorexia each year. More than 90 percent of people with anorexia are adolescent and young women, but it can affect boys too, especially boys who are active in sports that overly praise body image. The factors increasing the risk of an eating disorder are complex and may include the following:

- **Gender.** Teenage girls and young women are more likely to develop eating disorders than teenage boys and young men.
- **Age.** Eating disorders are much more common in teenagers and young adults in their early 20s.
- **Family issues.** Teenagers who feel less secure in their families, whose parents and siblings are overly critical, or who are teased or ridiculed about their appearance are at higher risk of developing eating disorders.
- **Negative body image.** People with negative body image are at high risk of developing an eating disorder and are more likely to suffer from obsessions with weight loss.
- **Other psychological factors.** Low self-esteem, feelings of inadequacy or lack of control in life, loneliness, and troubled personal relationships have all been shown to contribute to eating disorders.
- **Emotional disorders.** Depression, anxiety disorders, and obsessive-compulsive disorder are often associated with an eating disorder. People with anorexia often have perfectionist traits, whereas some with bulimia have been shown to be overly impulsive.
- **Excessive exercise.** People who pursue highly competitive athletic activities are at greater risk of developing an eating disorder.
- **Genetic contribution.** Eating disorders may be more common in people who have close family members with eating disorders.
- **Biological causes.** Some research focuses on potential biochemical or biological causes of eating disorders. In some patients, certain chemicals in the brain that control hunger, appetite, and digestion have been found to be imbalanced.

excessively. In bulimia, self-image is overly tied to body shape and weight, and people with this disorder are dissatisfied with these aspects of their body. However, unlike those with anorexia, people with bulimia usually stay at a fairly healthy weight.

Binge eating disorder Binge eating disorder involves out-of-control overeating but lacks the purging that is seen with bulimia. Binge eaters often are obese or constantly dieting, and they often feel guilty after a binge. Painful emotions or stress may trigger binges.

Obesity Obesity is an excess of body fat. People are considered overweight if extra body fat causes them to weigh 20 percent more than the healthy weight for their height and obese if they weigh more than 30 percent above what is healthy for their height.

Who Develops Eating Disorders?

Most teenagers are concerned about how they look. After all, their appearance changes very quickly. Girls develop breasts and their hips become round and fuller. Boys' voices deepen and body hair increases. Most teenagers have an ideal image of what they should look like, and images

Symptoms of eating disorders

Anorexia nervosa

Resistance to maintaining body weight at or above a minimally normal weight for age and height

Intense fear of gaining weight or becoming fat, even though underweight

Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight

Infrequent or absent menstrual periods (in females who have reached puberty)

Bulimia nervosa

Recurrent episodes of binge eating, characterized by eating an excessive amount of food within a discrete period of time and by a sense of lack of control over eating during the episode

Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting or misuse of laxatives, diuretics, enemas, or other medications (purging); fasting; or excessive exercise

The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months

Self-evaluation is unduly influenced by body shape and weight

Binge-eating disorder

Recurrent episodes of binge eating, characterized by eating an excessive amount of food within a discrete period of time and by a sense of lack of control over eating during the episode

The binge-eating episodes are associated with at least 3 of the following: eating much more rapidly than normal; eating until feeling uncomfortably full; eating large amounts of food when not feeling physically hungry; eating alone because of being embarrassed by how much one is eating; feeling disgusted with oneself, depressed, or very guilty after overeating

Marked distress about the binge-eating behavior

The binge eating occurs, on average, at least 2 days a week for 6 months

The binge eating is not associated with the regular use of inappropriate compensatory behaviors (e.g., purging, fasting, excessive exercise)

SOURCE: National Institute of Mental Health, National Institutes of Health, U.S. Department of Health and Human Services

of film stars on television and in the movies reinforce the goal of thinness as perfection.

Many young people, particularly girls, go on diets to control their body weight. Dieting has been reported to start as early as elementary school. Dieting without guidance by a medical doctor can cause problems with growth and development for children and teens. Sometimes an earnest but misguided effort to control weight can evolve into an eating disorder.

Diane, a 13-year-old seventh grader, began dieting. She thought she was 10 to 15 pounds overweight and switched her lunch from a sandwich and cookies to a salad. She lost a few pounds. She liked feeling thinner and got a lot of compliments. Soon she reduced the salad at lunch to a carrot and a piece of cheese. Diane trimmed her dinner as well, telling her parents that she had eaten a big lunch and was not hungry. Before long, Diane had lost 20 pounds. But Diane was surprised that she did not feel happy; instead, she was obsessed with food and her weight (she still felt fat) and was embarrassed whenever anyone commented on her body. Diane continued dieting and also began to exercise two times per day to try to lose more weight.

Diane is not alone. Experts say that more than five million American women and girls and one million men and boys suffer from eating disorders. About 1 in 100 girls between 12 and 18 years old has an eating disorder. As many as 1 in 10 college females has anorexia or bulimia. More than 1,000 young women die each year from the serious medical problems that develop due to eating disorders.

*Illustration by GGS Information Services.
Reproduced by permission of Gale, a part
of Cengage Learning.*

- * **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.
- * **menstruate** (MEN-stroo-ate) means to discharge the blood-enriched lining of the uterus. Menstruation occurs normally in females who are physically mature enough to bear children. Because it usually occurs at four-week intervals, it is often called the monthly period. Most girls have their first period between the age of 9 and 16.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.
- * **heart disease** is a broad term that covers many conditions that prevent the heart from working properly to pump blood throughout the body.
- * **high blood pressure** also called hypertension, is a condition in which the pressure of the blood in the arteries is above normal.
- * **osteoarthritis** (os-tee-o-ar-THRY-tis) is a common disease that involves inflammation and pain in the joints (places where bones meet), especially those in the knees, hips, and lower back of older people.

Young people who participate in sports that prize thinness are at particularly high risk of developing eating disorders. Female dancers, ice skaters, and gymnasts are three times more likely to develop an eating disorder than girls not involved in such activities. Boys who participate in similar sports or in wrestling are also at higher risk. Girls who enter puberty* early and girls who are overweight may also be more likely to develop eating disorders.

What Causes Eating Disorders?

There is no clear-cut, single cause for any eating disorder. Many factors seem to contribute, including social influences (such as the glorification of thinness by the mass media), emotional issues (such as a teenager's striving for perfection, exposure to intensely stressful situations, and fears of maturity, puberty, or sexuality), family factors (such as overly controlling parents, serious emotional conflicts, or problems expressing feelings), or poor childhood feeding and eating patterns. People who have an eating disorder usually do not set out deliberately to have this problem. Generally, eating disorders develop slowly, as do the signs and symptoms.

What Medical Complications Are Caused By Eating Disorders?

Eating disorders are serious problems and can cause a variety of medical complications. In anorexia, rapid weight loss can lead to blood chemical imbalances, failure to menstruate*, slow pulse, low blood pressure, and heart problems. In some cases, damage to vital organs is so serious that it can result in death. The frequent vomiting associated with bulimia can cause throat tears or sores, damaged tooth enamel, broken blood vessels in the eyes, and puffy cheeks from swollen salivary glands. With both anorexia and bulimia, bowel and intestinal problems can occur and serious vitamin and mineral deficiencies can cause serious and long-lasting problems. Binge eating often results in obesity, which in turn can lead to other health problems. People who are obese are at greater risk of developing diabetes*, heart disease*, high blood pressure*, osteoarthritis*, and other ailments.

How Do Doctors Diagnose Eating Disorders?

Teenagers with anorexia, bulimia, and binge eating disorder often try to hide the problem, so formal diagnosis can be delayed or difficult. Even when caring friends or family members ask about the weight loss or other symptoms, most teenagers with eating disorders are ashamed or embarrassed, especially by the purging that accompanies bulimia. Because of distorted body image, those with anorexia may not be able to recognize the seriousness of their extreme weight loss. Unbearable fear of being fat may cause people with anorexia to resist attempts to help them gain weight. A concerned health professional might ask questions about eating, body image, and exercise. Blood or other laboratory tests

can help determine if a person's nutrition is adequate and if general body chemistry is balanced. A careful interview and health history may reveal concerns about body image or distorted opinions about body appearance.

A doctor can generally determine if adults are obese by measuring their body weight and height. Obesity in children can be similarly determined but these measurements should be considered more carefully because the child is still growing. Through the late 1990s and early 2000s, there was a significant rise in obesity in children in the United States, in part a result of people eating more frequently in fast food restaurants, watching a lot of television, working or playing games on computers, and engaging in other activities that promote overeating and a sedentary (sitting too much with little exercise) lifestyle.

How Are Eating Disorders Treated?

Overcoming eating disorders may take a long time and lots of commitment and hard work. Most teenagers with eating disorders need the assistance of mental health and other healthcare professionals to manage the problem. Anorexia, bulimia, and binge eating disorder are treated most successfully with a combination of therapies. Behavior change programs, monitoring of diet and eating patterns, individual or group psychotherapy*, support groups, nutritional counseling, family counseling, and sometimes medication may all be part of treatment.

People with obesity can be helped by doctor-recommended weight-loss programs that teach healthy habits. To lose weight, people must take in fewer calories* than they use, and the best way to control weight is through exercising and eating a balanced diet. In some cases, doctors may also treat severe obesity by prescribing very low-calorie diets or medications. In rare cases, doctors may advise a surgical procedure that either limits the amount of food the stomach can hold or causes food to bypass the stomach or part of the intestines.

Ebola Hemorrhagic Fever

Ebola hemorrhagic (e-BO-luh heb-muh-RAH-jik) fever is a rare viral disease that may cause severe internal and external bleeding and that results in death in 50 to 90 percent of those who have been infected. Its contagiousness, high lethality, and short incubation period (seven days is the average), have raised fears of its use as a potential agent of bioterrorism.*

A Fast-Moving Epidemic

Ebola hemorrhagic fever appeared without warning in late 2000 in the northern district of Gulu, in Uganda, Africa. Health workers responded quickly, caring for people infected with the disease and isolating them so that they would not spread the devastating virus to others. Despite

the workers' efforts, more than 40 people died in the first wave of the epidemic*, and the disease spread throughout the district and beyond.

By February 2001, the epidemic had killed 224 people. Then, suddenly, it was over. The Ebola virus seemed to disappear back into the jungle.

What Is Ebola Hemorrhagic Fever?

Although much remains unknown about Ebola virus and Ebola hemorrhagic fever, scientists have begun to piece together some of the puzzle. Ebola hemorrhagic fever was first identified in 1976 in the Democratic Republic of Congo (formerly Zaire) and named for a river that flows through that African nation. Part of the filovirus family, Ebola virus had as of 2008 four known subtypes, each named for the location in which it was discovered: Ebola-Zaire, Ebola-Sudan, Ebola-Ivory Coast, and Ebola-Reston. The Ebola-Reston virus, first detected in the United States in 1989, was discovered in sick monkeys imported from the Philippines to a research laboratory in Reston, Virginia. Although a few laboratory workers later showed signs of the virus in their blood, none of them became ill. The Reston strain was assumed to be harmless to humans.

The geographic locale of the virus is probably the rain forests of Africa and Asia. Scientists think that the Ebola virus is animal-borne (or zoonotic) and that it is passed to primates (monkeys and apes) and humans by another animal. Decades after its identification, researchers continued to search for the natural reservoir, or long-term animal host, of the Ebola virus.

How Common Is Ebola Hemorrhagic Fever?

Although outbreaks of Ebola hemorrhagic fever have been widely publicized because of the scary symptoms that became manifest in most outbreaks of the disease and the suddenness with which infected individuals die, the disease is actually quite rare. Between the late 1980s and early 2000s, about 1,850 cases of Ebola virus infection were reported in humans, and approximately 1,200 of those infected died.

Is Ebola Hemorrhagic Fever Contagious?

Ebola virus is extremely contagious*, but scientists do not know exactly how it spreads. They do know that it can spread through direct contact with infected blood, especially from contaminated needles, and possibly through contact with the nasal or respiratory secretions of someone who is infected. Healthcare workers and family members tending to the people who have the virus are at high risk of becoming infected and dying of Ebola virus infection. The needles used to take blood samples from patients are an extreme biohazard*, because accidental needle pricks expose healthcare workers to the virus and are therefore potentially life-threatening. Traditions in some African cultures may contribute to the spread of Ebola virus. For example, some funeral rites require a ritual cleansing of the corpse, which can bring the person performing the rite

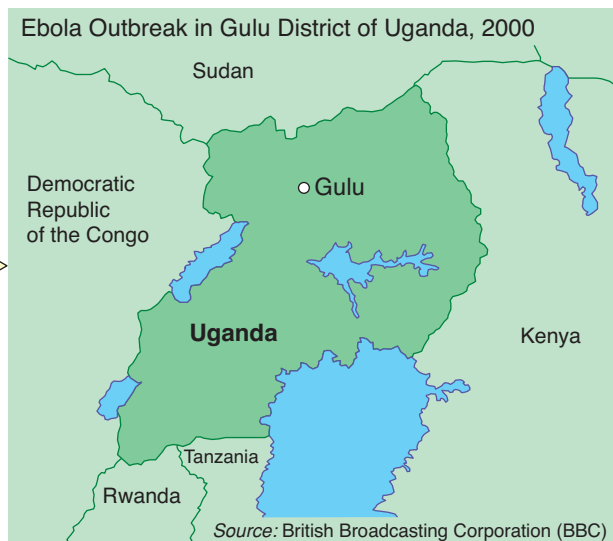

* **epidemic** (eh-pih-DEH-mik) is an outbreak of disease, especially infectious disease, in which the number of cases suddenly becomes far greater than usual. Usually epidemics are outbreaks of diseases in specific regions, whereas widespread epidemics are called pandemics.

* **contagious** (kon-TAY-jus) means transmittable from one person to another, usually referring to an infection.

* **biohazard** is a biological agent or condition that causes a threat to humans.

Ebola Hemorrhagic Fever

In October 2000 an epidemic of Ebola broke out in Gulu, Uganda, and in 4 months it killed 224 people. Some doctors believe that eating ape meat contaminated with the virus may be one source of infection. It is hoped that research to determine the natural source of the virus and the ways in which it is transmitted to primates and humans will provide information about how to prevent future outbreaks. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

- * **shock** is a serious condition in which blood pressure is very low and not enough blood flows to the body's organs and tissues. Untreated, shock may result in death.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.
- * **hemorrhage** (HEH-muh-rij) is uncontrolled or abnormal bleeding.
- * **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.
- * **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

into contact with the blood or other body fluids of the deceased. Ebola virus infects nonhuman primates, such as monkeys and apes. Ape meat is considered a delicacy in parts of Africa; however, some scientists recommend that people who live in these regions not eat it because it may contain the Ebola virus, which can infect nonhuman primates such as monkeys and chimpanzees.

What Are the Signs and Symptoms of Ebola Hemorrhagic Fever?

In the first few days after individuals are infected with Ebola virus, symptoms are variable. They often resemble those of many other diseases: fever, severe sore throat, headache, and muscle aches. The symptoms of Ebola hemorrhagic fever will often rapidly progress to more serious symptoms such as rash, chest pain, severe bloody vomiting and diarrhea, uncontrolled internal bleeding, kidney and liver failure, and shock*.

Doctors can diagnose Ebola hemorrhagic fever on the basis of the signs and symptoms that become manifest in patients as they quickly become ill during outbreaks. Blood tests can sometimes identify the virus directly, or antibodies* to Ebola virus produced by the body during infection can be detected in the blood. Doctors have to be careful when performing tests because simply injecting a needle into a patient who is prone to hemorrhage* can trigger uncontrolled bleeding.

How Is Ebola Hemorrhagic Fever Treated?

There is no medication to treat or cure Ebola virus infection. Patients with Ebola hemorrhagic fever are hospitalized and receive supportive care to treat symptoms. They may receive intravenous* (IV) fluids to protect against dehydration*; monitoring of blood pressure, heart rate,

STRANGER THAN FICTION

The tale reads like something from a Stephen King novel. Ebola virus infected and killed monkeys in a laboratory in Reston, Virginia. A biohazard SWAT team descended on the Reston Primate Quarantine Unit and, working in secret just miles from the nation's capital, struggled to decontaminate the monkey house.

In his suspenseful book, *The Hot Zone*, Richard Preston recounts in detail how the U.S. Veterinary Corps at Frederick, Maryland, detected Ebola virus in the primate population at Reston in 1989 and recruited the secret SWAT team to contain the deadly virus.

Scientists later named the virus subtype Ebola-Reston and determined that, although it is deadly to monkeys, it does not cause Ebola hemorrhagic fever in humans. The following year the same virus was found in monkeys in labs in Texas and Pennsylvania.

Researchers were able to trace the infected monkeys to a single exporter in the Philippines. In the United States, several of the monkeys died and four people were infected with the virus, although none of them became ill.

and breathing; and treatment for bleeding or other infections that may develop during the illness. During past outbreaks, 50 to 90 percent of people who developed symptoms of the disease died. Those who survive usually recover in several weeks.

Researchers discovered a protein on the surface of the Ebola virus that attaches to and damages specific cells of blood vessels, and this finding may help to explain the massive bleeding that leads to most Ebola virus deaths. Researchers have attempted to develop new drugs or a vaccine directed against this protein that might prevent the disease or at least reduce the severity of the symptoms and the number of deaths caused by the virus.

Can Ebola Hemorrhagic Fever Be Prevented?

Because there is no vaccine to prevent Ebola virus infection and no medication to halt it, the first line of defense for health officials is to isolate infected patients in a hospital. Healthcare workers use gloves and masks when coming into contact with patients to try to prevent the virus from spreading. However, the epidemic in Gulu, Uganda, demonstrated that even those precautions sometimes fail.

Research efforts to determine the natural source of the virus and how it is carried to nonhuman primates and humans was anticipated to provide information that could help in the prevention of future outbreaks.

Ehrlichiosis

Ehrlichiosis (air-lik-e-O-sis) is an infectious disease caused by various strains of Ehrlichia (air-LIH-kee-uh) bacteria, transmitted to humans by ticks.

What Causes Ehrlichiosis?

Caused by an organism once thought to infect only dogs, sheep, cattle, goats, and horses, ehrlichiosis was first discovered in humans in 1953 when researchers in Japan found that Sennetsu fever, an illness that resembles mononucleosis*, was caused by *Ehrlichia sennetsu* bacteria. Between the 1980s and early 2000s, scientists identified three additional strains* of *Ehrlichia* bacteria that cause forms of human ehrlichiosis in the United States: *E. chaffeensis*, which causes human monocytic ehrlichiosis (HME); bacteria similar or identical to *E. phagocytophila* or *E. equi* (known to cause ehrlichiosis in animals), which cause human granulocytic ehrlichiosis (HGE), which later was called anaplasmosis; and *E. ewingii*, which has only been seen in a few patients in the midwestern United States and Tennessee.

What Is Ehrlichiosis?

Ehrlichiosis can be a very severe disease. It interferes with the body's immune system* by attacking white blood cells, a vital part of the body's defense against invading bacteria, viruses, and other microorganisms* or harmful substances. Untreated, the disease can leave people vulnerable to other infections. About 50 percent of all cases require hospitalization.

Ehrlichiosis does not spread from person to person. The *Ehrlichia* bacteria that cause the disease are spread through tick bites. The species that most commonly spread the disease are the lone star tick, the black-legged tick, and the western black-legged tick.

The number of cases of ehrlichiosis reported to the Centers for Disease Control and Prevention (CDC) climbed steadily between 1999 and 2006. Most occurred along the Atlantic Coast and in southern and central states, although cases were reported in almost every region of the country. The number of cases peaks during tick season, which runs from April to October.

What Happens When People Get Ehrlichiosis?

Most cases of ehrlichiosis are associated with mild flu-like symptoms, such as fever, chills, headaches, muscle or joint pain, nausea and vomiting, cough, stomach pain, and sore throat. Other cases may have diarrhea (frequent, soft or watery bowel movements), skin rashes, or confusion (trouble thinking). Some people with the infection show no symptoms at all. Symptoms usually start within two weeks after a tick bite but can take up to a month to appear.

Because ehrlichiosis shares many symptoms with Lyme disease* and other infections transmitted by ticks, diagnosis based on symptoms alone can be difficult. Blood tests are done to look for evidence of *Ehrlichia* infection, such as antibodies* to the bacteria or the presence of the germ itself in the blood.

If treated early, ehrlichiosis responds very well to certain antibiotics. As a result, doctors often treat this disease presumptively, meaning that patients who have had tick exposure and who have fevers, low white blood cell count, and decreased platelets* are often treated with appropriate antibiotics even before the diagnosis has been definitively confirmed in the laboratory. Over-the-counter medicine such as acetaminophen* can help lower fever and relieve pain. Usually, people recover from mild cases of ehrlichiosis soon after finishing a week of antibiotic treatment. About one-half of all patients need treatment in the hospital, in part due to a lack of diagnosis of ehrlichiosis and in part due to increased severity of illness.

Although many cases of ehrlichiosis are mild, the infection can become serious if it is not diagnosed and treated early. Some people who get ehrlichiosis develop anemia* and inflammation of the liver and kidneys. Breathing problems, internal bleeding, encephalitis (en-seh-fuh-LYE-tis; brain inflammation), and seizures* can also develop. People with weakened immune systems, such as those with HIV* infection, certain

How to Remove a Tick

- Using thin-tipped tweezers, grasp the tick as close to the person's skin as possible.
- Pull straight upward firmly and steadily until the tick lets go (do not squeeze or twist the tick body).
- Clean the skin with soap and warm water, alcohol, or other antiseptic.
- Save the tick for identification.
- Petroleum jelly, lit matches, nail polish or other products do not help in tick removal and should not be used.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **microorganisms** are tiny organisms that can only be seen using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

* **Lyme disease** (LIME) is a bacterial infection that is spread to humans by the bite of an infected tick. It begins with a distinctive rash and/or flulike symptoms and, in some cases, can progress to a more serious disease with complications affecting other body organs.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **platelets** (PLATE-lets) are tiny disk-shaped particles within the blood that play an important role in clotting.

- * **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.
- * **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.
- * **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.
- * **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-nodih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).

types of cancer, or the elderly, tend to develop more severe symptoms and complications. For these people, ehrlichiosis can be fatal.

Can Ehrlichiosis Be Prevented?

Avoiding direct contact with ticks is the best way to prevent ehrlichiosis. Experts recommend that people use tick repellent and wear light-colored, long-sleeved shirts (to help find ticks more easily) and long pants tucked into socks when entering potentially tick-infested areas such as woods or campgrounds. After visiting such areas, it is wise to carefully check the body, clothes, and hair for ticks. Pets need to be checked as well.

Electrolyte Disorders See *Fluid and Electrolyte Disorders*.

Elephantiasis

Elephantiasis (el-e-fan-TY-a-sis), the medical name of which is lymphatic filariasis, is the result of a tropical worm infection called filariasis (fil-a-RY-a-sis). When injected mosquitoes transmit the parasitic worm Wuchereria bancrofti to people, the worm blocks the lymphatic system. The blockage causes swelling in the legs or other parts of the body, making these body parts appear large and puffy, or elephant-like. Elephantiasis is not elephant man disease, which is an inherited condition with completely different causes and symptoms.

An Ancient, Widespread Disease

Elephantiasis was known to the early Greeks and Romans. It is a tropical or subtropical disease, occurring where many kinds of disease-carrying mosquitoes are found: South America, Cuba, Puerto Rico, West Indies, Africa, Spain, Turkey, Asia, Australia, and many South Pacific Islands. About 100 million people worldwide are affected.

The Mosquito Carrier

Insects that carry diseases are known as vectors*, and several species of mosquito are vectors of *Wuchereria bancrofti*, the nematode worm that causes elephantiasis. When a *Culex* (KYU-lex), *Anopheles* (a-NOF-e-LEEZ), *Aedes* (ay-EE-deez), or *Mansonia* (man-SO-ne-a) mosquito carrying the *Wuchereria bancrofti* organism bites a human, the mosquito may inject worm larvae* into the body. The tiny larvae then may make their way into the lymph glands and the lymphatic system.

Lymphedema The lymphatic system is a complicated network of very fine tubes, about the diameter of a needle, which crisscross body tissues to collect a fluid called lymph. Lymph is a milk-like substance (containing white blood cells, proteins, and fats) that plays an important role in absorbing fats from the intestine, in fighting infections, and in the proper functioning of the immune system. Lymph is returned to the bloodstream via many vessels known as lymphatics. At various points, the lymphatics drain into masses of tissue known as lymph nodes or glands. If a blockage occurs, fluid may collect in the tissues, causing a type of swelling known as lymphedema (limf-e-DEE-ma). In the lymph system draining the legs, for example, few connections exist, and the legs often are a site of swelling when lymphedema occurs.

Lymphatic filariasis Worm larvae that make their way into lymph vessels can mature into adult worms. Male worms are long and slender, about 4 to 5 centimeters long, and 0.1 millimeter in diameter. Female worms are much larger, 6 to 10 centimeters long, and about three times wider than the males. The adults make their home mostly near the lymph glands in the lower part of the body. The adult female releases eggs enclosed within an egg membrane (microfilariae), and the microfilariae (mi-kro-fi-LAR-ee-i) develop into larvae to continue the life cycle.

In most parts of the world, microfilariae are at their peak in the blood during the night. The worms restrict the normal flow of lymph, resulting in swelling, thickening of the skin, and discoloration. This action can cause the appearance of an elephant's leg. However, the swelling of elephantiasis usually does not occur until a person has been bitten by the disease-carrying mosquitoes many times and has had years of exposure to infected mosquitoes.

What Happens to People with Elephantiasis?

Symptoms In addition to the characteristic swelling, people with this disorder sometimes have bouts of fever and headache. Sometimes their

▲ Parasitic worms transferred to people by infected mosquitoes can block the lymphatic system, causing the puffiness and swelling of lymphatic filariasis (elephantiasis). *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **vectors** (VEK-tors) are animals or insects that carry diseases and transfer them from one host to another.

* **larvae** (LAR-vee) are the immature forms of an insect or worm that hatches from an egg.

THE ELEPHANT MAN

Joseph “John” Cary Merrick (1862–1890) was known as the Elephant Man, but he did not have elephantiasis.

Born in 1862 in Leicester, England, Merrick became a human attraction in circus side shows. His appearance was normal at birth, but when he was about five years old, he developed extensive growths of skin that affected his face, head, torso, arms, and legs. He was reported to have had a 12-inch wrist and a fin-like hand.

For many years, researchers believed that Merrick had neurofibromatosis (neur-o-fib-ro-ma-TO-sis), a genetic condition that causes large growths on the skin and in tissues. Later research using x-ray studies, however, suggested that Merrick in fact had Proteus syndrome, a condition so rare that only 100 cases in history have been reported.

swollen limbs become infected. Elephantiasis commonly causes marked swelling of the scrotum in males.

Diagnosis Microfilariae sometimes can be seen in blood under a microscope. Often the doctor diagnoses the disorder based on the symptoms and a medical history, after ruling out other disorders with similar symptoms.

Treatment Medications are not very effective against adult worms. New microfilariae produced by the adult worms often continue to show up months after treatment. For this reason multiple treatments with diethylcarbamazine (DEC) are often necessary.

Prevention Because elephantiasis is found mainly in poorer countries, money for research into the cure and prevention of the disease has been limited. Effective treatment and preventive efforts would include:

- spraying to kill mosquitoes
- giving antibiotics to prevent infection
- giving medications (DEC) to kill microfilariae circulating in the blood
- applying pressure bandages to reduce swelling
- surgically removing infected tissue.

Embolism

An embolism (EM-bo-liz-um) is a blockage in the bloodstream, caused by a blood clot, air bubble, fatty tissue, or other substance that plugs a blood vessel.*

What Is an Embolism?

The body's circulatory system* is like a huge network of small roads and large interstate highways. It is important that blood continuously flow through the body to carry nutrients, oxygen, and other substances to cells and organs. But like a road, sometimes a part of the circulatory system can become blocked by an accident.

An embolism is a blockage that plugs up a blood vessel and slows or even stops blood flow to the area of the body supplied by the artery*. Many substances can cause blockages. Usually, the embolus (EM-bo-lus) is something small that has broken free from another part of the body and travels through the bloodstream until it gets jammed in a blood vessel that is too narrow for it to pass freely.

Emboli (EM-bo-ly; plural of embolus) may be life threatening. They may cause death if they block a major artery, such as the large pulmonary artery that runs through the lungs. They may also cause death of body tissue if they prevent blood flow to a given area.

How Do Emboli Happen?

The most common type of embolism results from the clotting* of blood. When blood clots form inside blood vessels, which is a process called thrombosis*, they may break free and travel to the pulmonary artery. The pulmonary artery carries blood from the right side of the heart into the lungs. In the lungs, blood disposes of carbon dioxide and picks up more oxygen. When blood clots get stuck in the pulmonary artery, they can prevent blood from picking up oxygen. This condition is a medical emergency that causes symptoms similar to a heart attack.

Thrombophlebitis (throm-bo-fluh-BI-tis) can occur when a blood clot causes inflammation inside a vein (usually in the legs). If the clot forms in a vein found in the muscle, it causes what is known as a deep vein thrombosis (DVT). A DVT may break free, becoming an embolus that travels inside the blood vessel to the lungs and eventually causes blockage of the pulmonary artery inside the heart. When this occurs, it is called a pulmonary embolism.

The following are substances, although less common, that may cause embolism:

- Bubbles. Sometimes bubbles occur in the blood vessels of underwater divers as they ascend; as compressed nitrogen bubbles out of solution, divers develop joint pain, called the bends, from decompression sickness. Bubbles can also occur during injections of fluids

▲ An embolism in an artery. An embolism blocking blood flow through an artery may be a serious problem. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

- * **blood clot** is a thickening of the blood into a jelly-like substance that helps stop bleeding. Clotting of the blood within a blood vessel can lead to blockage of blood flow.
- * **circulatory system** (SIR-kyoo-luh-tor-e) is the system composed of the heart and blood vessels that moves blood throughout the body.
- * **artery** An artery is a vessel that carries blood from the heart to tissues in the body.
- * **clotting** is a process in which blood changes into a jellylike mass that stops the flow of blood.
- * **thrombosis** is the formation or development of a blood clot or thrombus.

* **tumors** (TOO-morz) usually refer to abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

into veins or arteries, which is one reason why doctors and nurses squeeze the air out of needles before using them on patients.

- **Tumors***. These growths may block blood flow or a piece of a tumor may break off into the bloodstream and get caught in another part of the body.
- **Fat**. An embolism may occur when fat breaks off in place and travels through the blood vessel. For example, when a serious injury occurs to an organ such as the liver, fat may break off and travel through the bloodstream.
- **Bone fragments**. A bone chip from a broken arm or leg may become lodged in a blood vessel.

An embolism may occur in any artery. However, it often occurs in the pulmonary arteries because all the blood returning to the heart from the body is pumped through the pulmonary arterial system first.

What Are the Signs and Symptoms of Embolism?

Symptoms of a pulmonary embolism may include chest pain that can feel worse when breathing deeply, shortness of breath, coughing or coughing up blood, dizziness, sweating, rapid breathing, and rapid heartbeat. These symptoms are similar to those of a heart attack. However, sometimes embolism does not cause any symptoms at all.

How Do Doctors Diagnose and Treat Embolism?

Doctors may use blood tests, an x-ray, a CT scans*, or a lung scan to check for the embolism. Sometimes dye is injected to make it easier to see the embolism on the x-ray or scan. Doctors may suspect an embolism (especially a pulmonary embolism) if a patient has had recent surgery, been immobile for an extended period, or had a fracture of a large bone such the thigh (femur) or hip (pelvis) bone. Doctors may extend the use of drug therapy or consider surgery to insert a filter to catch clots, for individuals having multiple chronic pulmonary emboli.

Pulmonary emboli develop in as many as 500,000 Americans each year, and up to 10 percent die within the first hour. With immediate treatment, many are saved and lead normal lives. Doctors may use drugs that dissolve the embolism and prevent others from forming. Exercise, weight loss if needed, and a proper diet can help prevent emboli from forming.

Encephalitis

Encephalitis is an inflammation of the brain and can range from mild to extremely serious. Often the inflammation also affects the meninges (the lining around the brain and spinal cord). Such cases are called meningoencephalitis. The usual cause of encephalitis is a viral infection.

What Is Encephalitis?

Encephalitis is an inflammation* of the brain that can result from many causes. One of the most common causes is infection with one of several different types of viruses. Depending on the type of virus or other cause, the condition may be mild to severe. Most cases of encephalitis are so

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.

Causes of Encephalitis	How Spread	
Enteroviruses	Contact with body fluids	
Herpes simplex virus	Person to person contact	
HIV (human immunodeficiency virus)	When an infected person's blood or body fluids are introduced into the bloodstream of a healthy person	
Arboviruses	Bites from mosquitoes that pick up the virus from infected birds, chipmunks, squirrels, or other animals	
Animal-borne illnesses	Bites from infected animals such as cats, dogs, and bats	

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

mild that people do not realize they have it. A person, often a child, may have fever, headache, nausea, or sleepiness—symptoms much like the flu—that go away on their own. In more severe cases, however, the viral infection destroys so many neurons (nerve cells) in the brain that it can lead to seizures, breathing problems, personality changes, and coma*. When white blood cells arrive to fight the virus, they may cause brain tissues to swell, which also can destroy neurons or lead to bleeding within the brain. Permanent brain damage, or even death, can result.

Medical professionals report several thousand cases of encephalitis every year in the United States, but health officials believe that many

THE UNITED STATES AND THE WORLD

Some kinds of encephalitis are caused by arboviruses (ar-buh-VY-ruh-sez), which are viruses that are spread from animals to humans when blood-sucking insects, such as ticks and mosquitoes, bite infected birds, rodents, and other small animals, and then bite humans. In the United States these include the following:

- St. Louis encephalitis, a virus found in birds. The most common form of encephalitis, with 200 to 300 cases reported in the United States in a typical year, mostly in Midwestern and eastern states. Occasionally, outbreaks occur. Of cases severe enough to diagnose, about 5 to 15 percent are fatal, with the elderly at greatest risk.
- LaCrosse encephalitis, found in chipmunks and squirrels. An average of 100 cases are reported annually, mostly in Midwestern states and in children younger than age 16. It is rarely fatal.
- Eastern equine encephalitis, found in horses and birds, especially birds that live near the water. The most severe type, it can kill as many as half of those who experience symptoms, but usually fewer than a dozen cases occur each year in the United States, mainly in the eastern states.
- Western equine encephalitis, also found in horses and birds. It rarely affects humans and when it does, it is hardly ever fatal, but it sometimes causes permanent brain damage in babies.

In Asia, by contrast, Japanese encephalitis virus is common, with 30,000 to 50,000 cases reported each year in the region, usually in rural and agricultural areas. According to the World Health Organization, the fatality rate among those patients who experience symptoms ranges up to 60 percent. In addition, 30 percent of those who survive may have lasting effects. A vaccine to prevent this disease is available in Japan, China, India, Korea, and Thailand, but its high cost sometimes makes it unavailable to people of limited financial means. The Japanese encephalitis virus is related to the St. Louis form, and it infects mostly pigs, ducks, and wading birds.

more cases—mainly mild ones—probably occur. Serious encephalitis is particularly common in people with weakened immune systems*, such as those with AIDS*.

What Causes Encephalitis?

Many viruses and a few other microbes can cause encephalitis. One of the most common—and most dangerous—causes is infection with the herpes simplex virus* (HSV). It rarely infects the brain, but when it does, it can be life-threatening.

Encephalitis may also develop in a person who has meningitis (meh-nin-JY-tis), an inflammation of the membranes surrounding the brain and spinal cord, called the meninges (meh-NIN-jeez). It also can be a complication of other infectious diseases, such as rabies, cytomegalovirus* infection, listeriosis*, syphilis*, or Lyme disease. In people with a weakened immune system, for instance, those with HIV/AIDS, infection by parasites can lead to encephalitis, especially the parasite that causes toxoplasmosis*.

In addition, several arboviruses (meaning viruses spread by insects) cause encephalitis in horses or other animals and may spread to humans by mosquitoes. In the United States, this route of contagion was once rare, with a few hundred cases in an average year. In the late 1990s, however, the spread of West Nile virus (WNV) led to an increase in mosquito-borne encephalitis in humans. In 1999, for instance, the Centers for Disease Control counted 62 cases of WNV infections, all of which were located in and around New York. By 2006, that number had grown to 4,269 cases, which were spread to nearly every state in the nation. Of those 4,269, nearly two-thirds only experienced a fever, but more than one-third developed encephalitis or meningitis, and 177 individuals died.

In some cases, encephalitis develops after a person has a viral illness like measles, chickenpox, mononucleosis, mumps, or rubella (German measles). This condition is called post-infectious or parainfectious encephalitis.

Often, however, medical professionals cannot pinpoint exactly why a particular person has encephalitis.

How Does Encephalitis Spread?

Because several different germs can cause encephalitis, spread of the infection may take different paths. For example, mosquitoes transmit viruses that cause West Nile encephalitis, St. Louis encephalitis, and western equine encephalitis. Other viruses, such as herpes simplex virus or the varicella-zoster (var-uh-SEH-luh ZOS-ter) virus that causes chicken pox, spread between individuals through fluids from the mouth, throat, or nose. For example, tiny drops of these fluids, such as saliva and nasal mucus*, may disperse into the air when an infected person coughs or sneezes. Ticks spread Lyme disease, and humans can contract rabies from the bite of infected animals, such as raccoons and bats.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **herpes simplex (HER-peeZ-SIM-plex) virus** is a virus that can cause infections of the skin, mouth, genitals, and other parts of the body.

* **cytomegalovirus** (sy-tuh-MEH-guh-lo-vy-rus), or CMV, infection is very common and usually causes no symptoms. It poses little risk for healthy people, but it can lead to serious illness in people with weak immune systems.

* **listeriosis** (lis-teere-O-sis) is a bacterial infection that can cause a form of meningitis in infants and other symptoms in children and adults.

* **syphilis** (SIH-fih-lis) is a sexually transmitted disease that, if untreated, can lead to serious lifelong problems throughout the body, including blindness and paralysis.

* **toxoplasmosis** (tox-o-plaz-MO-sis) is a parasitic infection that usually causes no symptoms in healthy people, but it can cause serious problems in unborn babies and people with weak immune systems.

* **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.

- * **double vision** is a vision problem in which a person sees two images of a single object.
- * **hallucinations** (ha-LOO-sin-AY-shuns) occur when a person sees or hears things that are not really there. Hallucinations can result from nervous system abnormalities, mental disorders, or the use of certain drugs.
- * **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.
- * **rabies** (RAY-beez) is a viral infection of the central nervous system that usually is transmitted to humans by the bite of an infected animal.
- * **toxoplasmosis** (tox-o-plaz-MO-sis) is a parasitic infection that usually causes no symptoms in healthy people, but it can cause serious problems in unborn babies and people with weak immune systems.
- * **Lyme disease** (LIME) is a bacterial infection that is spread to humans by the bite of an infected tick. It begins with a distinctive rash and/or flulike symptoms and, in some cases, can progress to a more serious disease with complications affecting other body organs.

What Happens When People Get Encephalitis?

Symptoms Symptoms range from mild to severe. Symptoms may appear suddenly and include sudden fever, headaches, sensitivity to light, loss of appetite, and muscle pain. If the meninges (me-NIN-jez) are involved, the neck and back often are stiff. In more serious cases, an individual may experience high fever, nausea (NAW-zee-uh), vomiting, confusion, double vision*, personality changes, problems with hearing and speech, hallucinations*, sleepiness, clumsiness, muscle weakness, loss of sensation, and irritability. In the most severe cases, seizures* and loss of consciousness may occur. Encephalitis can be particularly dangerous in elderly people and in babies, who are more likely to suffer permanent brain damage than adults. Any serious to severe symptoms require immediate medical attention.

Diagnosis To diagnose encephalitis, a doctor may use a number of techniques, including the followings:

- Various blood tests to look for encephalitis-related microorganisms in the blood or to tell whether the person's body is producing antibodies* in response to a specific virus or bacterium. For instance,

CAUSES OF ENCEPHALITIS

Encephalitis may result from a variety of viruses, bacteria, and other organisms. These agents include the following:

- Measles, chicken pox, rubella (German measles), mumps, polio, and other viral illness, which generally lead to a mild form of encephalitis known as postinfectious or para-infectious encephalitis.
- Enteroviruses (en-tuh-ro-VY-ruh-sez), viruses that typically infect the intestines and then may spread to other parts of the body, including the brain.
- Herpes simplex virus, a virus that can infect the mouth, skin, and other parts of the body.
- Animal-borne illnesses, such as rabies*, toxoplasmosis*, cat scratch disease, and Lyme disease*, that are transmitted to humans by contact with an infected animal's saliva (through a bite or lick, for example), contact with an infected animal's feces (FEE-seez, or bowel movements), or an insect that bites an infected animal and then bites a person.
- HIV (human immunodeficiency virus), the virus that causes AIDS (acquired immunodeficiency syndrome). This virus moves from one individual to another when an infected person's blood or body fluids are introduced into the bloodstream of a healthy person.

a blood test for Lyme disease checks for antibodies to that particular encephalitis-causing microbe, which is a bacterium.

- A spinal tap, also called a lumbar puncture, a procedure in which a sample of cerebrospinal fluid is taken from around the spinal cord to examine under a microscope for signs of infection.
- One or more imaging tests, such as computerized tomography* scans or magnetic resonance imaging*, to look for signs of bleeding or swelling in the brain.
- Sampling with cotton swabs of fluids from the nose, throat, and rectum* to test for certain viruses.
- A brain biopsy*, in which a small piece of brain is removed with a needle so it can be examined under a microscope.

These tests often cannot positively diagnose encephalitis, but they can help the doctor rule out other possible causes for the symptoms. In many cases, however, the doctor may never be able to identify the microbe causing the encephalitis.

Treatment Encephalitis can range from mild forms that can be treated at home to more severe forms that require hospitalization. Frequently, a doctor recommends over-the-counter medicines, such as acetaminophen*, to treat minor symptoms such as fever and headache. A doctor may also prescribe antiviral medications that sometimes can help prevent the spread of the virus and are very important in the treatment of encephalitis caused by herpes simplex virus. Other medications may include anticonvulsants* to help control seizures, and corticosteroids (anti-inflammatory medications) to lessen swelling in the brain, which can lead to a dangerous increase in the pressure within the skull.

If a patient is admitted to a hospital, medical professionals take special care to monitor body fluids. This information can help them prevent or control swelling of the brain. They may also take various supportive measures, such as providing machines to help with breathing, if needed, and caring for comatose patients to prevent bedsores* or other infections.

How Long Does the Illness Last?

The acute phase of the disease, the time when symptoms are most severe, usually lasts up to a week. Lingering symptoms can continue for weeks to months.

Most people recover from encephalitis completely, but some experience swelling of the brain that leads to permanent brain damage. These patients may face long-term complications, such as learning disabilities, seizures, speech problems, memory loss, lack of muscle control, paralysis*, or coma. In rare cases in which brain damage is severe, death can result. Infants younger than one year of age and adults older than 55 have the greatest risk of permanent brain damage and death from encephalitis.

Regional Forms of Encephalitis

Other regional forms of encephalitis include the following:

- Venezuelan equine encephalitis, a usually mild form that causes occasional epidemics in Central and South America.
- Russian spring-summer encephalitis, which is spread by ticks. This disease has death rates as high as 25 percent in some outbreaks, but a vaccine is available in Russia and Europe.
- West Nile encephalitis. Related to Japanese and St. Louis encephalitis, this disease was once only seen in Africa, Asia, and Europe. In 1999, however, medical professionals detected it in New York City, and it later spread through much of North America. It is sometimes fatal.
- Murray Valley encephalitis. Found in parts of Australia and New Guinea, this disease is also related to St. Louis and Japanese encephalitis. It is rarely fatal.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

- * **rectum** is the final portion of the large intestine, connecting the colon to the outside opening of the anus.
- * **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.
- * **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.
- * **anticonvulsants** (an-tie-kon-VUL-sents) are medications that affect the electrical activity in the brain and are given to prevent or stop seizures.
- * **bedsores** also called pressure sores, are skin sores caused by prolonged pressure on the skin and typically are seen in people who are confined by illness or paralysis to beds or wheelchairs.
- * **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.

How Is Encephalitis Prevented?

Childhood vaccines are available to prevent measles, mumps, chicken pox, and some of the other viral infections that cause encephalitis. To prevent encephalitis caused by West Nile virus or other viruses transmitted by mosquitoes, health officials urge people to avoid being outside at dawn and dusk when mosquitoes are most active. They also recommend that people wear light-colored, long-sleeved shirts and long pants; use insect repellent when they are outdoors in mosquito habitat; and empty any sources of standing water, such as birdbaths and flower pots, where the mosquitoes may breed. Individuals can help prevent rabies by vaccinating pets and by avoiding contact with wild mammals; and they can help prevent Lyme disease encephalitis by avoiding ticks. A partially effective Lyme vaccine is also available. In addition, individuals can prevent HIV infection and, therefore, eliminate many cases of encephalitis, by avoiding sexual contact and by never sharing needles.

Endocarditis, Infectious

Infectious endocarditis (in-FEK-shus en-do-kar-DYE-tis) is an inflammation of the valves and internal lining of the chambers of the heart, known as the endocardium (en-doh-KAR-dee-um), that is initiated by an infection.

A technician takes an echocardiogram (EKG) of a patient's heart. *Susan Leavines/Photo Researchers, Inc.*

What Is Endocarditis?

The heart has four chambers and four valves that regulate the flow of blood through the heart. Each valve is made up of two or three smaller parts, known as leaflets, that swing open and shut. As the heart beats, it pumps blood through the chambers and out of the heart to the lungs and the rest of the body. The valves open to allow blood to pass through and out of the heart and then close to keep the blood from flowing backward.

In a normal heart, the swift, smooth movement of blood sweeps foreign material such as bacteria away from the heart. However, some people have defects in their heart valves, the endocardium, or other parts of the heart that disrupt the flow of blood. This disruption can allow bacteria or other germs that reach the heart through the bloodstream to lodge there and multiply, which results in an infection that inflames the heart valves, muscles, and endocardium, producing endocarditis. The inflammation (in-flah-MAY-shun), which is the body's response to injury or infection, can be significant, in which case it may inflict damage on or even destroy the heart valves.

What Causes Infectious Endocarditis?

Viruses, fungi, or other microscopic organisms can all cause infectious endocarditis, but the disease usually arises from a bacterial infection. A common bacterium abundant in the oral cavity, *Streptococcus viridans* (strep-tuh-KAH-kus VEER-ih-danz), is responsible for up to half of all cases of bacterial endocarditis. Other bacterial culprits include bacteria from the staphylococcus, streptococcus, and enterococcus families and, less commonly, other types.

- * **intestines** are the smooth muscle tubes that food passes through during digestion after it exits the stomach.
- * **urinary tract** (YOOR-ih-nair-e TRAKT) is the system of organs and channels that makes urine and removes it from the body. It consists of the urethra, bladder, ureters, and kidneys.
- * **platelets** (PLATE-lets) are tiny disk-shaped particles within the blood that play an important role in clotting.
- * **clot** is the process by which the body forms a thickened mass of blood cells and protein to stop bleeding.
- * **catheter** (KAH-thuh-ter) is a small plastic tube placed through a body opening into an organ (such as the bladder) or through the skin directly into a blood vessel. It is used to give fluids to or drain fluids from a person.
- * **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube that has penetrated the skin's surface and has been inserted directly into a vein.
- * **rheumatic fever** (roo-MAH-tik) is a disease associated with fever, joint pain, and inflammation of many body tissues, including parts of the heart. It occurs following infection with certain types of strep bacteria.
- * **heart murmur** is an abnormal heart sound that can be heard with a stethoscope and is usually related to abnormal flow of blood through the heart. Some murmurs indicate a problem with a heart valve or other part of the heart's structures, but many heart murmurs are benign (do not indicate any problem).

In most cases of infectious endocarditis, bacteria that normally live harmlessly on the body, such as in the mouth, on the skin, in the intestines*, or in the urinary tract* (YOOR-ih-nair-e TRAKT), enter the blood (a condition known as bacteremia, bak-tuh-REE-me-uh). The bacteria can enter tissues through a cut or a tear that has resulted from a dental or medical procedure, or they may enter the blood because of a site of an infection somewhere else in the body. Additionally, intravenous drug users are at high risk for infectious endocarditis, as staphylococcus bacteria in skin have many opportunities to enter the bloodstream through broken skin. Once in the bloodstream, the bacteria travel to the heart and may stick to the endocardium or heart valves. As they grow and multiply, the bacteria may become entangled in vegetations, which are composed of clumps of platelets*; bacteria; red and white blood cells; and fibrin, a protein that helps blood clot*.

Who Gets Infectious Endocarditis?

Infectious endocarditis is not contagious, so there is no reason to avoid contact with individuals who have it. The disease is not common among people with normal hearts, but people with a heart abnormality are more susceptible to it. Because bacteria can easily attach to a malformed or damaged part of the heart, people with an artificial or damaged heart valve or a heart defect are more likely to get endocarditis. Anyone who has had infectious endocarditis or who has an indwelling catheter* has a greater chance of becoming infected. Although many people with heart defects are born with them, other people acquire the defects during their lifetime, for example, as a consequence of intravenous* drug use or rheumatic fever*, which puts them at increased risk for endocarditis as well. In the United States between 1 and 4 cases of infectious endocarditis occur annually per 100,000 people.

What Are the Signs and Symptoms of Infectious Endocarditis?

Flulike symptoms, such as fever and chills and weakness, are the most common symptoms of infectious endocarditis. Some people experience weight loss, weakness, headache, tiredness, shortness of breath, joint and muscle pain, and excessive sweating at night (night sweats). A heart murmur* usually develops in the course of the illness, and individuals may look pale, have red spots on their skin, and see blood in their urine. An enlarged spleen*; small hemorrhages* in the nail beds and on the whites of the eyes; and swelling of the feet, legs, and abdomen also can occur with infectious endocarditis.

How Do Doctors Diagnose and Treat Infectious Endocarditis?

Doctors may suspect infectious endocarditis if someone with a known heart abnormality develops an unexplained long-lasting fever, an abnormal heart sound (a murmur), or symptoms of heart failure such as shortness of breath or swelling of the legs.

Certain tests can help doctors to diagnose infectious endocarditis, including blood cultures that can establish the presence of bacteria in

the bloodstream, a complete blood count, and laboratory tests that look for evidence of inflammation. For example, checking a patient's erythrocyte sedimentation rate (ESR) reveals how quickly the person's red blood cells, or erythrocytes (eh-RITH-ruh-sites), settle to the bottom of a test tube, which is a measure of inflammation in the body. Another blood test identifies levels of C-reactive protein, which are increased in the blood when there is significant inflammation in the body. Doctors may also use an echocardiogram to look for signs of infection on the heart valves or in the heart. An echocardiogram (eh-ko-KAR-dee-uh-gram) is a diagnostic test that uses inaudible sound waves to produce images of the heart's chambers and valves and enables visualization of blood flow through the heart.

Doctors treat infectious endocarditis with antibiotics. The medication is given intravenously in the hospital at first, but sometimes patients complete the treatment at home. Several weeks of antibiotic treatment may be necessary to eliminate the infection. In more serious cases, patients may need oxygen and medications to support heart function while hospitalized, and some people require surgery to repair damage sustained by the heart due to the inflammation.

Do People Recover from Infectious Endocarditis?

Infectious endocarditis can start suddenly or develop gradually over weeks or months. Left untreated, infectious endocarditis is often fatal. However, when treated successfully with antibiotics and when there has been little damage to the heart valves, patients usually begin to feel better and to recover within a few days. If the infection does not improve with antibiotics, or if there is evidence that a heart valve has been damaged significantly, surgery to repair or replace the valve may be required to clear the infection from the body and restore heart function.

Infectious endocarditis can cause other complications. In some people with the disease, small pieces of vegetations in the heart may break off and travel through the bloodstream to other organs. If one of these pieces travels to the brain and blocks a blood vessel there, for example, the affected person may develop a stroke*. If the pieces lodge in other organs, they may cause serious infections there. Infectious endocarditis that is allowed to progress can also engender an irregular heartbeat, congestive heart failure, jaundice*, kidney failure, and heart failure.

How Is Infectious Endocarditis Prevented?

Doctors give antibiotics to people as a protective measure, prior to their undergoing dental or medical procedures that could introduce bacteria into the bloodstream. For example, simple dental work, removal of the tonsils, or medical procedures in which parts of the upper respiratory tract* (such as the mouth and throat), urinary tract (specifically the urethra*), or lower gastrointestinal* tract are involved can all provide an avenue for bacteria to enter the bloodstream and travel to the heart.

* **spleen** is an organ in the upper left part of the abdomen that stores and filters blood. As part of the immune system, the spleen also plays a role in fighting infection.

* **hemorrhages** (HEH-muh-rih-jes) are areas of uncontrolled or abnormal bleeding.

* **stroke** is a brain-damaging event usually caused by interference with blood flow to and within the brain. A stroke may occur when a blood vessel supplying a region of the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific functions they support, stop working.

* **jaundice** (JON-dis) is a yellowing of the skin, and sometimes the whites of the eyes, caused by a buildup in the body of bilirubin, a chemical produced in and released by the liver. An increase in bilirubin may indicate disease of the liver or certain blood disorders.

* **respiratory tract** includes the nose, mouth, throat, and lungs. It is the pathway through which air (and primarily oxygen) makes its way down into the lungs, and through which carbon dioxide leaves the lungs and the body.

* **urethra** (yoo-REE-thra) is the tube through which urine passes from the bladder to the outside of the body.

* **gastrointestinal** (gas-tro-in-TES-tih-nuhl) means having to do with the organs of the digestive system, the system that processes food. It includes the mouth, esophagus, stomach, intestines, colon, and rectum and other organs involved in digestion, including the liver and pancreas.

- * **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.
- * **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.
- * **menstrual cycle** (MEN-stroo-al SYkul) culminates in menstruation (men-stroo-AY-shun), the discharging through the vagina of blood, secretions, and tissue debris from the uterus that recurs at approximately monthly intervals in females of reproductive age.
- * **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

Endometriosis

Endometriosis (en-do-me-tree-O-sis) is a chronic (ongoing) condition in which pieces of the lining of the uterus (YOO-ter-us) become embedded in tissues outside the uterus.*

What Is Endometriosis?

The endometrium (en-do-ME-tree-um) is the lining of the uterus, which is the muscular organ where a fetus* develops during pregnancy. Endometriosis is a condition in which endometrial tissue implants and grows outside the uterus. During the monthly menstrual cycle*, chemicals called hormones* cause the endometrium to grow thick in preparation for receiving a fertilized egg at the beginning of pregnancy. If the egg is not fertilized, there is no pregnancy and the endometrium is shed as blood and tissue in the monthly menstrual period.

The endometrium is the lining of the uterus. In women with endometriosis, fragments of endometrial tissue become attached to other organs outside the uterus. The symptoms of endometriosis may include heavy bleeding, abdominal pain, lower back pain, and tenderness and pain in the pelvic area. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

In a woman with endometriosis, fragments of endometrial tissue develop outside the uterus. The cause of endometriosis is not fully understood. There are several theories. Some scientists think that some of the endometrial tissue that should leave the body during menstruation does not. Instead, these stray fragments find their way into other parts of the pelvic cavity. Here the stray pieces of tissue attach to other organs such as the ovaries* or intestines*, stick organs together, or form scar tissue. Scientists theorize that there may be a genetic predisposition* (inherited tendency) toward developing endometriosis. Research ongoing as of 2009 sought to determine if stray tissues develop in some women because their immune systems*, which normally destroy any unexpected material such as stray endometrium, do not function efficiently. In addition, some scientists were exploring whether exposure to human-made chemicals found in the environment may trigger endometriosis in some women. Estimates as of 2007 suggested that between 2 and 10 percent of women or 5.5 million women in North America have endometriosis.

What Are the Symptoms and Effects of Endometriosis?

Endometrial implants or clumps of tissue outside the uterus respond to hormones in the same way as endometrial tissue inside the uterus: They grow, break down, and bleed. When endometrial tissue breaks down outside the uterus, it releases chemicals that irritate internal tissues and cause

* **ovaries** (O-vuh-reez) are the sexual glands from which ova, or eggs, are released in women.

* **intestines** are the muscular tubes that food passes through during digestion after it exits the stomach.

* **genetic predisposition** is a tendency to get a certain disease that is inherited from a person's parents.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

Hormones and Endometriosis

Changing levels of hormones regulate the menstrual cycle. Estrogens, progesterone, and prostaglandins control the buildup and the shedding of the endometrial lining of the uterus. Altering these hormone levels, either during pregnancy or by taking oral contraceptives (birth control pills), may help to relieve symptoms of endometriosis.

Many women with endometriosis are able to have children, and many are free of symptoms when they are pregnant. During pregnancy, the hormone balance that usually causes the monthly menstrual cycle changes. Instead of causing the endometrium to grow and then break down, different hormones work to make the lining of the uterus hospitable to the developing fetus. Therefore, the implants may be free of the hormonal effects that cause the symptoms of endometriosis.

Oral contraceptives are mixtures of reproductive hormones that, when taken every day, act to change the hormone balance in the body to prevent pregnancy. Side effects of oral contraceptives include less cramping and lighter menstrual periods. By altering the body's hormonal balance, they also may be effective in reducing the symptoms of endometriosis.

* **rectum** is the final portion of the large intestine, connecting the colon to the outside opening of the anus.

* **fallopian tubes** (fa-LO-pee-an tubes) are the two slender tubes that connect the ovaries and the uterus in females. They carry the ova, or eggs, from the ovaries to the uterus.

pain. Although some women with endometriosis do not have any symptoms, for others the symptoms of endometriosis include heavy bleeding during menstruation, abdominal and lower back pain, tenderness and pain in the pelvic area, diarrhea, constipation, and bleeding from the rectum*.

Endometriosis can develop in any woman who is menstruating, but it most often affects women who are between the ages of 25 and 40. Endometriosis is one of the three major causes of female infertility (the inability to conceive a child) and accounts for 10 to 15 percent of all instances of female infertility. Endometriosis can keep women from becoming pregnant if stray endometrial tissue attaches to the ovaries and forms scar tissue that prevents the egg from leaving the ovary. Alternately, stray endometrial tissue can block the fallopian tubes* that carry the egg from the ovaries to the uterus. Between 30 and 40 percent of women who have endometriosis have difficulty becoming pregnant.

How Is Endometriosis Diagnosed?

A doctor may suspect that a woman has endometriosis based on her history of symptoms. Initially the doctor may perform an ultrasound* or a magnetic resonance imaging* (MRI) test. These noninvasive tests use energy waves to produce a picture of the internal organs. However, to definitively diagnose endometriosis, the doctor uses a procedure called laparoscopy (lap-a-ROS-ko-pee), in which a laparoscope (viewing instrument) is inserted into the abdomen or pelvic cavity through a small incision. This procedure allows the doctor to examine the abdominal or pelvic cavity for pieces of endometrium that may have become implanted on surfaces of the intestines, ovaries, and other places where they are likely to be found.

How Is Endometriosis Treated?

Endometriosis is treatable, but there is no cure for the condition. In mild cases, treatment may not be necessary. When treatment does become necessary, it can be complicated. The age of the woman, her general health, the severity of her condition, and whether she wants to have children must all be considered.

Hormone medications can suppress the development of endometrial tissue or cause the fragments to wither away, which may take as long as six months. Other medications may be prescribed to relieve pain. Sometimes surgery is needed to remove some of the abnormal tissue. Older women not planning to have more children may consider having a hysterectomy (his-ter-EK-to-mee) to help solve the problem. This surgery removes the uterus and sometimes other reproductive organs. Women who wish to have children and are having difficulty becoming pregnant should consult a doctor who is a fertility expert.

Environmental Diseases

Environmental diseases are illnesses and conditions that result from human-made environmental problems.

Silent Spring

Rachel Carson's 1962 book *Silent Spring* described an environment ravaged by pesticides:

Over increasingly large areas of the United States, spring now comes unheralded by the return of birds, and early mornings are strangely silent where once they were filled with the beauty of bird song.

Carson questioned the use of pesticides, particularly DDT (dichloro-diphenyl-trichloroethane), and described how people were slowly destroying the world around them. Carson and her ideas received attacks from many sides, and one chemical company tried unsuccessfully to stop the book from being published.

Silent Spring marked the beginning of the environmental movement. Slowly the public began to listen to Carson, and ultimately, the government listened, too. In 1972 the United States banned the use of DDT because it had been linked to cancer in laboratory studies with mice.

What Are Environmental Diseases?

Illnesses and conditions caused by factors in the environment are collectively called environmental diseases. Pesticides, chemicals, radiation, air pollution, and water pollution are some of the human-made factors that contribute to human illnesses. Potential illness-causing agents are everywhere: at home, at work, and at play. The likelihood of individuals developing

WHAT HAPPENED AT LOVE CANAL?

From 1942 to 1953, the Hooker Chemicals and Plastics Corporation used the Love Canal in Niagara Falls, New York, as a dumpsite for its chemical wastes. When the site was full, the corporation covered the site with soil and later sold it to the Niagara Falls School Board with a warning about the chemical wastes buried beneath the land.

The land that once had been a hazardous waste site became a neighborhood called Love Canal, complete with a school and hundreds of homes. Homeowners, however, did not get the warning about the hazardous wastes buried under their houses.

From the 1950s to the 1970s, residents of Love Canal smelled unusual odors and discovered strange substances in their yards. Some people developed unexplained health problems. At various times, the city investigated complaints, but the government took no action to remedy the problems until 1978.

In April of that year, the New York State Department of Health Commissioner declared a public health emergency at Love Canal, and by August ordered the school closed and the evacuation of many residents from the neighborhood. Ultimately, President Jimmy Carter declared the Love Canal neighborhood a disaster area, which allowed federal funds to be used to relocate the 239 families living closest to the dump site.

Love Canal became a symbol for citizens, scientists, activists, and politicians who became more aware of their environment. It resulted in the passage of federal laws designed to force the clean up of landfill sites.

a specific disease depends on the hazards present in their particular environment and on their individual genetic makeup, which makes them susceptible to a specific hazard. For example, x-ray technicians are at risk for radiation-induced illnesses, whereas coal miners are prone to lung diseases caused by inhalation of dust. Proper use of safeguards can help to prevent these and other environmental diseases.

What Are Some Common Environmental Diseases?

Lung diseases Any substance other than air that is breathed into the lungs has the potential to cause damage to these organs. For example, air pollution, including smoke from other people's cigarettes (secondhand smoke*) and workplace chemicals can lead to lung diseases. Examples of lung diseases include the following:

- Asthma (AZ-ma), a condition in which breathing is difficult, affects millions of Americans. Environmental triggers for asthma include naturally occurring substances such as animal dander, plant pollen, dust, and mold, and human-made substances such as chemicals. Not everyone is sensitive to these triggers, but many people are sensitive to some of them.
- Black lung disease is an illness among coal miners, whose lungs become coated with coal dust, causing a chronic condition in which breathing becomes difficult and painful.
- Bronchitis (brong-KY-tis), an inflammation of the airways of the lungs, can result from breathing in certain chemicals or smoke. Welders and firefighters among others are at risk for this condition. Smokers are also at increased risk for developing bronchitis and lung cancer.
- Silicosis (sil-i-KO-sis) is a lung disease caused by exposure to the silica dust in clay. Pottery workers are at risk of developing this disease.

Asbestos Breathing asbestos (a natural mineral fiber) can lead to asbestosis (as-bes-TO-sis), a severe lung disorder, and lung cancer. Schools, homes, and businesses that have asbestos in them as a fire retardant put people at risk when the asbestos dust begins to leak into the air during repairs and renovations. These buildings used asbestos in the walls and ceilings as insulation before laws were passed to ban their use.

Cancers Besides asbestos, scientists have linked chromium and coal tar to lung cancer. Construction workers, welders, and steelworkers may be repeatedly exposed to these compounds. People working in plastics manufacturing are at risk for liver or bladder cancer. People who work with radioactive substances are at increased risk for cancer caused by radiation. Fortunately, legal restrictions and careful oversight of hazardous materials can reduce risks.

▲ Open sewers can pollute the water creating conditions that can lead to environmental diseases. *Image copyright Vankina, 2008. Used under license from Shutterstock.com.*

* **secondhand smoke**, also called environmental tobacco smoke or passive smoke, is smoke that is inhaled passively or involuntarily by someone who is not smoking. It is a mixture of gases and particles from a burning cigarette, cigar, or pipe and the smoke exhaled by smokers.

Gulf War Syndrome

Many U.S. veterans complained about disabling symptoms that they attributed to their participation in the 1991 Persian Gulf War. Gulf War syndrome encompasses symptoms such as chronic fatigue syndrome, aching muscles and joints, skin rashes, memory loss, miscarriages, and giving birth to babies who have birth defects.

Gulf War syndrome is a mysterious condition. While veterans experienced very real medical problems, physicians and scientists could not agree on the source of these problems. Some believed that the syndrome actually consisted of multiple illnesses for which symptoms overlap. Veterans could be reacting to chemical weapons, biological weapons, pesticides, vaccines, oil fires, or infectious diseases to which they were exposed during the Gulf War. A presidential commission set up to study the controversy surrounding the Gulf War syndrome proposed that psychological stress was the major cause. A 2004 report from the Department of Veterans Affairs suggested that chemical exposure, and not stress, was a more likely cause. A 2008 report from the Department of Veterans Affairs concluded that nearly one-third of Gulf War veterans, about 200,000 people, suffered a Gulf War syndrome caused by exposure to organophosphate nerve gas, nerve gas remedies, and insecticides, from which only a few veterans had recovered.

* **infertility** (in-fer-TIH-lee-tee) is the inability of females to become pregnant or of males to cause pregnancy.

* **nervous system** is a network of specialized tissue made of nerve cells, or neurons, that processes messages to and from different parts of the human body.

In addition, scientists have tied various pesticides, herbicides, and radioactive substances to cancer and suspect that almost 2,000 other chemicals may also cause cancer. Although the U.S. government restricts the use of some of them, it does not restrict them all as of 2009.

Birth Defects Infertility*, miscarriage, stillbirth (the baby is born dead), childhood cancer, and birth defects may be linked to various environmental toxins. When a pregnant woman is exposed to lead, her child has a higher than usual risk of being born with behavioral and nervous system* problems. Exposure to radiation, chemical wastes, pesticides, solvents, paints, lead, and methyl mercury all can cause problems in a developing fetus*.

Chemical poisonings Lead is a serious environmental hazard to children in many parts of the world, including the United States. It affects children's mental and physical development, and high doses can cause paralysis and death. Lead paint, leaded gasoline, lead water pipes, and certain ceramics can all expose people to lead. Although most of these products in the United States no longer contain lead, lead paint and pipes can still be found in older homes and in some imported products.

As of 2009, many people who worked at the site of the World Trade Centers following the 2001 attacks have reported respiratory illnesses that they believe resulted from exposure to debris and dust related to the buildings's destruction. Some workers have even died from respiratory illnesses that their families attribute to their work at the disaster site. Researchers have been studying data and following other workers to determine whether working conditions at the site are linked to the illnesses. In 2006 a large study by doctors at Mount Sinai Health Center reported that workers who experienced a variety of respiratory problems while working at the site continued to have the symptoms, and in some cases their symptoms became worse.

The metals mercury and cadmium can cause nerve damage, cancer, and liver and skin diseases. Many industrial processes have used mercury since the beginning of the 1900s. In earlier times, people who worked with mercury were often unknowingly poisoned. Mercury can accumulate in the food chain and present a health risk. For example, some fish in the Great Lakes are contaminated with mercury they acquired through eating plants and other fish. Eating a lot of these contaminated fish can transfer unhealthy levels of mercury to a person, and some states post dietary restrictions. The effects are cumulative (build up) because the body cannot rid itself of mercury. Mercury can occur in fluorescent lights, latex paint, batteries, dental fillings, and mercury thermometers.

Other sources of environmental poisoning can arise from the manufacture of refrigerants, plastics, and other industrial products and from the manufacture and misuse of pesticides.

Can Environmental Diseases Be Prevented?

Regulations protecting people from environmental hazards vary widely from country to country. The U.S. Congress has enacted laws to protect workers from intentional and accidental exposure to environmental hazards. The following resulted from these laws:

- The National Institute of Occupational Safety and Health (NIOSH) was established in 1971 to set standards for health and safety in the workplace.
- The Occupational Safety and Health Administration (OSHA) was also established in 1971 to enforce rules and regulations based on NIOSH's findings.
- In 1983 OSHA required industries to make full disclosure to their workers about the dangerous chemicals used in their facilities and to teach workers how to protect themselves from these hazardous substances.
- In 1987 the 1983 standards were extended to include more workers. Later a regulation was added to set standards to prevent occupational exposure to infectious diseases such as AIDS* and hepatitis* B and C.

Sick Building Syndrome

Sick building syndrome describes an elusive health problem in which people attribute a variety of symptoms to the buildings in which they work. Common complaints include headaches, dizziness, nausea, tiredness, concentration problems, sensitivity to odors, dry itchy skin, a dry cough, and irritated eyes, nose, and throat. Typically, as soon as affected people leave the building, their symptoms vanish and they feel well again.

As of 2009 scientists had not identified one specific illness or one common cause for sick building syndrome. In fact, no specific set of symptoms is common to all people complaining of the syndrome. Many factors may contribute to sick building syndrome, including humidity, inadequate ventilation, and poor temperature control. Pollution from outdoor sources (for example, car exhaust, pollen, or smoke) or chemicals from inside a building (cleaning supplies, glues, upholstery, or copy machine chemicals) may affect people who are sensitive to them. Bacteria, viruses, and molds also can invade buildings and make people sick.

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **hepatitis** (heh-puh-TIE-tis) is an inflammation of the liver. Hepatitis can be caused by viruses, bacteria, and a number of other noninfectious medical conditions.

Normal airways allow the free flow of air through the nose and mouth past the epiglottis and then into the lungs. Bacterial infection may cause inflammation and swelling of the epiglottis, which can quickly bring about narrowing or even closing of the airway and severe breathing problems. *Illustration by Molly A. Moore Blessington. Reproduced by permission of Gale, a part of Cengage Learning.*

* **epiglottis** (eh-pih-GLAH-tis) is a soft flap of tissue that covers the opening of the trachea (windpipe) when a person swallows to prevent food or fluid from entering the airway and lungs.

Epiglottitis

Epiglottitis (eh-pih-glah-TIE-tis) is a condition involving life-threatening swelling of the epiglottis. It is usually caused by a bacterial infection of the epiglottis and can result in a blockage of the trachea (windpipe) and severe breathing difficulty.*

What Is Epiglottitis?

Epiglottitis, also known as supraglottitis (su-pra-glah-TIE-tis), is characterized by inflammation and swelling of the epiglottis and other upper airway structures. The epiglottis can become dangerously swollen within just a few hours, leading to narrowing of the airway and severe breathing difficulty.

Epiglottitis is usually caused by bacterial infection. *Haemophilus influenzae* type B (Hib) bacteria accounted for the majority of epiglottitis cases before the widespread use of the Hib vaccine. *Staphylococcus aureus*; *Streptococcus pneumoniae* and group A, B, and C streptococci bacteria; certain viruses; traumatic injuries; scalding; and severe smoke inhalation (causing burns in the upper airway) can also lead to epiglottitis.

Who Gets Epiglottitis?

Epiglottitis is most common in children under seven years of age. In the United States, cases of epiglottitis declined greatly after the Hib vaccine was introduced in 1985.

Epiglottitis itself is not contagious, but the bacterial infections that can lead to the condition are. Therefore, the bacteria can spread through person-to-person contact, often in drops of moisture from the respiratory tract when someone sneezes, coughs, or breathes.

What Are the Signs and Symptoms of Epiglottitis?

Epiglottitis often begins with a sore throat. Symptoms may come on suddenly and include the following:

- high fever
- inability to swallow and drooling
- difficulty breathing
- muffled voice
- stridor (STRY-dor, a high-pitched, squeaking noise that occurs while breathing in; it is present usually only if there is narrowing or blockage of the upper airway)
- a “sniffing” posture (when a young child leans forward, with chin extended, to make it easier to breathe)

Because their airways are smaller than those of adults, children with epiglottitis are at higher risk for developing severe breathing problems.

How Do Doctors Diagnose and Treat Epiglottitis?

Epiglottitis is a medical emergency that must be treated in a hospital. Ensuring that the person is able to breathe is the first and most important response. Often a procedure called intubation (in-too-BAY-shun) is performed, in which a tube is inserted into the windpipe through the mouth or nose to ensure that air can continue to flow into the lungs. In some cases, an emergency tracheostomy* must be performed to bypass the blocked part of the person's airway.

Doctors usually diagnose epiglottitis based on a physical examination and the patient's medical history. If the diagnosis is not clear, a doctor may order an x-ray of the neck that will show if the epiglottis is swollen. Blood cultures or other blood tests may be used to confirm that the person has a bacterial or viral infection.

Intravenous* (IV) antibiotics are usually given to combat the infection that led to epiglottitis. Corticosteroid* medication is sometimes given to further reduce the swelling of the upper airway so the person can breathe more easily.

How Long Does It Take to Recover from Epiglottitis?

People with epiglottitis are hospitalized, usually in intensive care, for several days to a week or more to manage the infection that led to epiglottitis. The time it takes to fully recover varies depending on the particular infection.

Possible complications of epiglottitis include pneumonia*, ear infection, and, rarely, meningitis* or bacteremia* caused by the same microorganism that caused the epiglottitis.

If not treated quickly, epiglottitis can result in complete airway obstruction (air can no longer flow into the lungs) and death.

Can Epiglottitis Be Prevented?

The best way to prevent epiglottitis is to avoid infection by the bacteria that most commonly cause it. The Hib vaccine, which is part of the routine childhood immunization schedule in the United States, has been extremely successful in decreasing the number of cases of epiglottitis resulting from *H. influenzae* infection. The Hib vaccine is given as four separate injections (shots) before individuals are two years of age.

Epilepsy

Epilepsy (EP-i-lep-see) is a condition of the nervous system characterized by recurrent seizures that temporarily affect a person's awareness, movements, or sensations. Epileptic seizures occur when powerful, rapid bursts of electrical energy interrupt the normal electrical patterns of the brain. Some cases of epilepsy are hereditary, or run in families, but scientists do not know the cause of epilepsy in most other cases. Epilepsy is not contagious.

Erin's Story

It happened at her birthday party. Eleven-year-old Erin was ready to blow out the candles on her cake when she suddenly released a loud cry and dropped to the carpet and lost consciousness. Her entire body became rigid, and her girlfriends got scared. They became even more alarmed when Erin's arms and legs began to twitch and then to violently thrash about. Her friends called to her, but she did not respond. Her mother had seen this before and rushed to Erin's side, while telling the girls to move away nearby chairs and the glasses and other items that were near the edge of the table. She knelt beside her daughter and, to make sure her daughter could breathe easier, turned Erin onto her side and loosened the top button on her shirt. She also asked one of the girls to get Erin's older brother and

Epileptic seizures have different phases, as shown on these positron emission (PET) scans. The stage shown in the middle is the most severe. *Science Source/Photo Researchers, Inc.*

another to bring over a pillow from a sofa. She put the pillow under her daughter's head to keep it from banging on the floor. The thrashing seemed to go on for a long time, but it actually lasted less than two minutes. Once it slowed down and finally stopped, her friends became concerned again because Erin just laid there. Her mother continued to watch Erin, and Erin's brother explained to the girls that his sister had had an epileptic seizure that caused her to lose consciousness and made her body jerk around. He said Erin would come around in a minute or two and would be fine as soon as she had time to rest, and then he asked the girls to follow him out of the room. Erin regained consciousness just as her brother said she would. She was exhausted and more than a little embarrassed that her friends had seen what had happened. She was also frightened, because she had had a seizure before and now she was concerned that she would have more in the future. Erin was glad her mother was there to comfort her.

What Is Epilepsy?

In a normal brain, millions of tiny electrical charges pass between nerve cells and to all parts of the body. Those cells “fire” in an orderly and controlled manner. This is not the case with epilepsy. In the brain of a person with epilepsy, nerve cells in parts of the brain fire simultaneously and repeatedly, sending out powerful, rapid electrical charges that disrupt the brain's normal function. During a seizure such as the one experienced by Erin, brain cells can fire at up to four times their normal rate, temporarily affecting how a person behaves, moves, thinks, or feels.

Many people with epilepsy can sense that they are about to have a seizure by something called an aura*. An aura is a strange feeling—often of unease, anxiety, or discomfort—that may be accompanied by sensing or seeing flickering lights. Despite these warning signals, people with epilepsy still cannot stop the oncoming seizure.

What Causes Epilepsy?

Because epilepsy is not contagious, one person cannot catch epilepsy from another. In about 7 out of 10 cases, doctors describe the disease as idiopathic (id-ee-o-PATH-ik), which means the cause is unknown. Most people with idiopathic seizures are between 5 and 20 years of age and have no brain injuries or abnormalities. Many do, however, have a family history of epilepsy or seizure disorders.

Some cases of the disease have known causes, which include the following:

- Maternal injury, infection, or illness that affects a developing fetus during pregnancy.
- Brain injury. Although brain injuries can occur at any age, the highest incidence is among young adults. These injuries often result from car collisions, sports accidents, and falls. Blows to the head and gunshot wounds, particularly those that injure brain

The United States and the World

- Epilepsy is a common neurologic disease in the United States, affecting more than 6 out of every 1,000 people.
- Epilepsy can begin at any age, but most frequently it begins in early childhood, during adolescence, or after age 65.
- Among people with epilepsy, 20 percent develop the disorder before 5 years of age, and 50 percent develop it before age 25.
- Worldwide, some form of epilepsy affects about 50 million people, according to the World Health Organization. Some estimates indicate that up to 60 percent of people with epilepsy live in developing countries and have inadequate access to medical treatment.

* **aura** is a warning sensation that precedes a seizure or other neurological event.

* **withdrawal** a group of symptoms that occurs when a drug that causes physical or psychological dependence is regularly used for a long time and then suddenly discontinued or decreased in dosage.

membranes and tissues, can lead to epilepsy. In general, the more severe the injury, the greater the chance of developing the disease.

- Brain tumor or stroke. Either of these problems can lead to injury or irritation of brain tissue. Especially among people 65 years old and older, stroke is a common cause of epilepsy.
- Metabolic abnormalities that result from complications from diabetes, kidney failure, lead poisoning, use of alcohol or drugs, or withdrawal* from alcohol or drugs.
- Degenerative disorders, such as cardiovascular disease and Alzheimer's disease. Along with stroke, these are common causes of epilepsy among people over 65.
- Infections. Epilepsy may develop after a major brain illness such as meningitis, encephalitis, brain abscess, or severe infections of any part of the body. Less frequently, mumps, measles, and diphtheria can lead to the disease.
- Complications of AIDS or other immune disorders, including systemic lupus erythematosus.

What Triggers a Seizure?

Anyone can have a seizure, but seizures are usually very few and far between. A person with epilepsy, by contrast, has many more seizures and experiences them over a longer period of time. For a person with epilepsy, many conditions that affect the brain can trigger a seizure. These triggers include

THE ROAD TO UNDERSTANDING

Ancient Greeks believed epileptic seizures were blessed visitations from the gods. By contrast, during the Renaissance, a seizure was seen as a sign that a person was possessed by the devil.

Around 400 B.C.E., the Greek physician Hippocrates challenged the idea that epilepsy had a supernatural origin; he explained that it was a disease like any other. In his book on the subject, he described epilepsy as a brain disorder that “has a natural cause from which it originates like other affections.”

People had misunderstandings of epilepsy well into the early 1800s. At that time many believed they could catch it from those who had the disease, and often locked these individuals away in hospitals or “epileptics-only” sanitariums.

That changed in the mid-1800s, when neurologists (doctors who treat disorders and diseases of the brain and spinal cord) began to investigate epilepsy and understand it better. Their work removed the lingering and undeserved stigma associated with epilepsy and ushered in the modern understanding of the disease.

hormonal changes, such as those that occur during the menstrual cycle* or pregnancy; hunger; exhaustion or sleep deprivation; and rhythmic patterns of sound, touch, or light (particularly strobe lights). In many cases, an epileptic seizure is not a medical emergency. However, if a person goes into something called status epilepticus, in which a seizure lasts longer than 30 minutes or two seizures rapidly follow one another, his or her life may be in danger, and onlookers should summon medical assistance at once.

How Do Seizures Differ?

Because of the way a person appears during or after an attack, others sometimes mistakenly believe the person is drunk, drugged, or mentally ill. Epileptic seizures have different symptoms or characteristics depending on where the seizure begins in the brain and how the electrical discharge spreads across the brain. Epileptic seizures fall in two categories: generalized seizures and partial seizures.

Generalized seizures Generalized seizures affect nerve cells throughout the cerebral cortex* (the cauliflower-like outer portion of the brain), or across all of the brain. The most common generalized seizures are:

- **Generalized tonic-clonic seizure** (formerly called grand mal). Erin had this kind of seizure at her party. During the tonic phase of this seizure, people often lose consciousness, drop to the ground, and emit a loud cry as air is forced through their vocal cords. In the clonic phase, body muscles can contract at once or in a series of shorter rhythmic contractions. Usually, this kind of seizure lasts for about one or two minutes, and a period of exhaustion (called the postictal state) follows before the individual regains consciousness. Afterward, the individual may be sleepy and possibly have a headache. Incontinence* often occurs during this type of seizure.
- **Absence seizure** (formerly called petit mal). Loss of consciousness in this seizure is often so brief that a person does not even change positions. The person may display a blank stare, rapid blinking, or chewing movements. Facial or eyelid muscles may jerk rhythmically. Absence seizures often are genetic and occur mostly in children.

Partial seizures Partial seizures are contained within one region of the cerebral cortex. Types of partial seizures include the following:

- **Simple partial.** In this type of seizure, the strong and rapid bursts of electrical energy are only located in one part of the brain. The patient is awake and alert during the seizure. Symptoms, which vary depending on what area of the brain is involved, may include jerking movements in one part of the body, emotional symptoms such as unexplained fear, or an experience of abnormal smells or nausea.
- **Complex partial.** In this type of seizure, a person loses awareness of surroundings and is unresponsive or only partially responsive, because the seizures affect the part of the brain that controls awareness. An

* **menstrual cycle** (MEN-stroo-al SYkul) culminates in menstruation (men-stroo-AY-shun), the discharging through the vagina of blood, secretions, and tissue debris from the uterus that recurs at approximately monthly intervals in females of reproductive age.

* **cerebral cortex** (suh-REE-brul KOR-teks) is the part of the brain that controls functions such as conscious thought, listening, and speaking.

* **incontinence** (in-KON-ti-nens) is loss of control of urination or bowel movement.

* **convulsions** (kon-VUL-shuns), also called seizures, are involuntary muscle contractions caused by electrical discharges within the brain and are usually accompanied by changes in consciousness.

* **neurologist** (new-RHAL-eh-jist) a physician who specializes in diagnosing and treating diseases of the nervous system.

individual with this type of seizure may experience a blank stare, chewing movements, repeated swallowing, or other random activity. After the seizure, the patient has no memory of it. In some cases, the person who has had the seizure may suddenly become confused, begin to fumble, to wander, or to repeat inappropriate words or phrases.

Other seizures There are two other types of mild seizures:

- **Febrile seizures.** Two to five percent of children ages three months to five years of age have convulsions* caused by a sudden spike in body temperature often from an infection. Simple febrile seizures—the most common form—last from a few seconds to ten minutes and stop on their own. Complex febrile seizures last more than fifteen minutes. They may occur more than once in 24 hours and may also be confined to one side of the child's body. Children commonly outgrow febrile seizures.
- **Jacksonian seizures.** Named for British neurologist* John Hughlings Jackson (1835–1911), in Jacksonian seizures, abnormal electrical activity in a localized area of the brain causes brief alterations in movement, sensation or nerve function. Seizures of this type typically cause no change in awareness or alertness and are temporary and swift.

How Is Epilepsy Diagnosed?

Because not every person who has a seizure necessarily has epilepsy, the doctor must determine the seizure's cause by a physical exam and medical history, including descriptions of the seizures that have already occurred. The doctor must assess risk factors such as sleep deprivation and alcohol use, as well as possible head injuries, childhood seizures, or family history of seizures.

The physician also wants to know if the patient has experienced an aura; having experienced an aura helps confirm that the seizure is a brain disorder and establishes its location. The doctor also asks about the nature of the movements the person made during a seizure.

If the patient has indeed experienced an epileptic seizure, the doctor then tries to identify the type of seizure. The first tool doctors use is an electroencephalograph (e-lek-tro-en-SEF-a-lo-graf). Commonly known as an EEG, this machine records electric currents in the brain and can track abnormal electrical activity. If the EEG does not show the seizure activity, or if certain other features in the patient's physical exam or medical history are present, then the doctor may try other types of scans, including CT (computerized tomography) scans or MRIs (magnetic resonance imaging).

How Is Epilepsy Treated?

Treating epilepsy has three goals: to eliminate seizures or at least reduce their frequency, to avoid side effects of long-term medical treatments, and to assist in maintaining or restoring normal activities of daily living.

FYODOR DOSTOYEVSKY

The Russian writer Fyodor Dostoyevsky (1821–1881) is considered one of the world’s great novelists. With brilliant psychological and philosophical insight, Dostoyevsky examined the human soul in *Notes from the Underground*, *Crime and Punishment*, and his 1880 masterpiece, *The Brothers Karamazov*.

Dostoyevsky had epilepsy, and his fiction includes characters who have the condition. His book *The Idiot*, for example, describes the aura that many people with epilepsy experience just before they have a seizure, which he calls a “fit”:

He remembered that during his epileptic fits, or rather immediately preceding them, he had always experienced a moment or two when his whole heart, and mind, and body seemed to wake up with vigour and light; when he became filled with joy and hope, and all his anxieties seemed to be swept away for ever; these moments were but presentiments, as it were, of the one final second ... in which the fit came upon him.

Medication Anticonvulsant* medications can fully or partially control most cases of epilepsy. If a person is free of seizures for several years, doctors may reduce or even eliminate medication. In many cases, however, epilepsy remains a lifelong, chronic condition with no medical treatment guaranteeing remission* or a permanent cure.

Surgery If drug therapy does not work, a surgical procedure can remove the damaged cells that cause partial seizures. Cases qualify for surgery if the tissue resides in one small area of the brain and the surgeon can remove this tissue without harming a person’s mental abilities or personality. Surgery on adults is sometimes successful, but it usually has better results when performed on children and infants.

Diet Although it was discontinued as a therapy when medicines became available, a ketogenic diet (a doctor-monitored, high-fat, high-calorie diet) was reinstated in the treatment arsenal for epilepsy, especially for children who do not respond to medicines. It does not, however, work for all patients. Some people believe the diet can stop seizures by creating ketosis (ke-TO-sis), a condition in which the body burns fat for energy instead of glucose. Researchers continued as of the early 2000s to wonder why diet has an impact on seizures.

Biofeedback When combined with other therapies, biofeedback has been beneficial to some patients. Biofeedback uses electronic instruments

* **anticonvulsants** (an-tie-kon-VUL-sents) are medications that affect the electrical activity in the brain and are given to prevent or stop seizures.

* **remission** is an easing of a disease or its symptoms for a prolonged period.

Medical Alert Tags

People with epilepsy often wear medical alert identification tags or bracelets that provide vital information for caregivers during seizures.

Some companies offer tags with identification numbers so that medical personnel anywhere can retrieve a patient's medical history.

to monitor a person's brain waves, blood pressure, heart rate, and skin temperature. The patient learns techniques to lower these bodily functions to more relaxed levels.

Other treatments In the early 2000s epilepsy research was an active field. One promising technique called vagus nerve stimulation uses an implanted device to prevent or at least lessen seizures by sending small, regular bursts of electricity through the vagus nerve in the neck to the brain.

Can Epilepsy Be Prevented?

Many cases of epilepsy have no known cause, which makes prevention a challenge. Those cases of epilepsy that result from injuries to the brain can, however, often be prevented through safety precautions and good health practices. These strategies include:

- Buckling seat belts and observing speed limits when in a car
- Wearing approved helmets and protective headgear while skating, bicycling, playing sports, or riding motorcycles
- Using drugs only as prescribed
- Immunizing children against infectious diseases

Living with Epilepsy

Most people with epilepsy can lead normal and active lives, although they must follow a few safety restrictions. People with epilepsy must be free of seizures for a period of time specified by their home state before they are permitted to drive. Laws prohibit people with uncontrolled seizures from driving a car.

A person with a seizure disorder should avoid working in jobs that involve heights, dangerous machinery, or underwater environments. To avoid the risk of drowning during a seizure, taking showers is safer than taking baths, and swimming in a pool or lake with other people is safer than swimming alone.

People with epilepsy also are at risk for depression. In part, the depression may stem from loss of mobility or from the effects of prejudice at school or at work. Prejudice results when people fear the condition and do not understand it. Children with epilepsy may become depressed if their parents become overly protective and prevent them from engaging in normal childhood activities. Depression is a particular problem among adolescents, who may refuse to take their medication on schedule and, therefore, may run the risk of additional seizures.

In addition, alcohol consumption makes people who have epilepsy more susceptible to seizures, and the combination of alcohol and anticonvulsant medications can be deadly.

Understanding the facts about epilepsy and providing a positive environment in which treatment becomes a part of everyday life can help people with epilepsy and their families.

Erectile Dysfunction

Erectile Dysfunction (ED) is a medical condition in which a man cannot develop or maintain an erection of the penis. The condition may have physiological, psychological, or lifestyle related causes. While many causes are treatable and can be remedied with medication, there may be more serious underlying health conditions present. Erectile dysfunction can cause a great deal of emotional strain on both the patient and his partner.

What Is Erectile Dysfunction?

Erectile Dysfunction (ED) is a medical condition that affects more than 18 million American men. Men with ED are unable to achieve and maintain an erection long enough to have sexual intercourse. In order to understand what causes ED, it is important to know how the penis becomes erect.

Anatomy of the human male reproductive system. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **semen** (SEE-men) is the sperm-containing whitish fluid produced by the male reproductive tract.

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

* **norepinephrine** (NOR-e-pi-ne-frin) is a body chemical that can increase the arousal response, heart rate, and blood pressure.

Anatomy of an Erection The shaft of the penis contains several structures that work together to make the penis erect. The corpus cavernosum are two long, sponge-like structures that run along the length of the penis. They contain erectile tissue, two main arteries, several veins, and nerves. Beneath the corpus cavernosa is the urethra, the tube that carries semen* and urine* to the outside of the body through the meatus, the opening in the head at the end of the shaft.

An erection occurs due to a combination of factors, both physical and mental. When a man becomes sexually aroused, his brain sends chemical signals such as epinephrine, norepinephrine*, acetylcholine, prostaglandins, and nitric oxide to the nerves inside the penis. When the nerves receive these signals, the muscles in the penis relax and the spongy corpus cavernosum fill with blood, causing the penis to become erect. As long as a man continues to be aroused, the volume of blood flowing into the penis remains high, maintaining his erection.

Understanding Erectile Dysfunction Sometimes, even when a man is sexually aroused, he may have difficulty developing an erection. Other times, a man may achieve an erection, but it does not last long enough to allow him to engage in sexual intercourse. Usually this happens because of a problem with the extra blood flow that the penis needs in order to maintain an erection. Many factors can cause ED. Sometimes, ED is caused by psychological factors such as depression, anxiety, and stress, and in other cases, a serious underlying medical condition present.

What Causes Erectile Dysfunction?

At one time, many physicians believed that erectile dysfunction was either psychological or a natural part of aging. In the early 2000s, however, physicians understand that ED is often linked to underlying, treatable medical conditions. These can include heart disease, neurological issues,

psychological problems, or lifestyle-related causes. Sometimes, the medication that a person takes may also contribute to erectile dysfunction.

Cardiovascular disease Heart disease*, one of the most common underlying medical conditions in men with ED, is the leading cause of death among men in the United States. Heart disease as a term encompasses several cardiovascular conditions, including coronary heart disease, atherosclerosis, heart failure, cardiomyopathy, and hypertensive heart disease. When a patient is suffering from heart disease, his heart has difficulty pumping blood to the different regions of the body, including the penis, which can lead to erectile dysfunction. Men need to speak frankly about their condition so that their physician can find and treat the underlying cause of ED.

Neurological causes Erections begin in the brain. After some sort of physical or mental stimulation, the brain sends chemical signals along the body's nerve pathways to the penis. The muscle tissue in the penis begins to relax and the penis fills with blood, becoming erect. For some people who suffer from neurological conditions, these pathways become blocked, resulting in erectile dysfunction. Neurological conditions that can cause ED include Parkinson's disease*, multiple sclerosis, spinal cord and brain injuries, Alzheimer's (ALTS-hy-merz) disease* and stroke*.

Psychological causes About 10 to 20 percent of all ED cases are related to psychological disorders. Because many of these are treatable, it is important for patients to discuss any emotional concerns they have with their physician. Often, therapy and/or medication may be helpful in resolving ED in these patients. Some common psychological causes of ED include stress, depression, anxiety, low self-esteem, and panic disorder. The issues may be related to sexual abuse or trauma, as well.

Pharmaceutical and Lifestyle Causes Sometimes, the use of different prescription and over-the-counter medications may be directly related to ED. Many of these medications contain ingredients that can interrupt blood flow or nerve impulses. Drug classes that may lead to ED include diuretics*, antihypertensive drugs, antidepressant medications*, anti-inflammatory drugs, muscle relaxers, and certain prostate cancer drugs. It is important for men to discuss with their doctors other medications that they are taking.

Lifestyle choices that may lead to ED include obesity* and the abuse of alcohol and recreational drugs.

How Is Erectile Dysfunction Diagnosed?

Most men have sexual performance problems some of the time. However, men who find it difficult to develop or maintain an erection at least 50 percent of the time are considered to have ED. Erectile dysfunction can affect a man's relationships, his self-esteem, and many other aspects of his life. Sometimes, a physician will refer men with ED to a urologist who specializes in the condition and its many treatments.

* **heart disease** is a broad term that covers many conditions that prevent the heart from working properly to pump blood throughout the body.

* **Parkinson's disease** is a disorder of the nervous system that causes shaking, rigid muscles, slow movements, and poor balance.

* **Alzheimer's (ALTS-hy-merz) disease** is a condition that leads to gradually worsening loss of mental abilities, including memory, judgment, and abstract thinking, as well as changes in personality.

* **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

* **diuretics** (dye-yoor-EH-tiks) are medications that increase the body's output of urine.

* **antidepressant medications** are used for the treatment and prevention of depression.

* **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

* **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

ED MEDICATIONS AS DANGEROUS RECREATIONAL DRUGS

After the introduction of Viagra in 1998, there was an alarming trend among young men who take ED medications recreationally. While these young men do not suffer from erectile dysfunction, they sometimes combine ED drugs with methylenedioxymethamphetamine (Ecstasy), never really considering the dangerous and potentially deadly effects doing so may have. People using Viagra, Cialis, or Levitra for recreational purposes may experience a dangerous drop in blood pressure, painful erections that require medical intervention to reverse, and death. Studies have shown that these groups also experience much higher rates of STDs and HIV*/AIDS*.

Treatment Options

Fortunately, there are many treatments available for men with ED. The treatment options range from simple to invasive, and with the guidance of a physician, each individual must choose the option that is best for him.

- In some cases, simple changes in lifestyle may resolve ED. Diet and exercise, stress reduction techniques, and avoidance of alcohol and drugs are all positive changes that can lead to more frequent and lasting erections.
- ED medications such as sildenafil citrate (Viagra), tadalafil (Cialis), and vardenafil (Levitra) work by helping the muscles and vessels in the penis to relax so that more blood can flow to them, which allows the penis to become erect. These drugs have been successful in treating ED for many men, but they can be dangerous when combined with other medications and should only be used according to the directions given by a physician.
- Certain sexual aids can be helpful in achieving and maintaining erections. A penis pump works by creating a vacuum around the penis that encourages increased blood flow, allowing an erection. Once an erection develops, a penis ring can be placed at the base of the shaft to maintain the erection by preventing the flow of blood back out of the penis.
- Surgical intervention is also an option for men with ED. One type of surgical intervention involves the placement of a flexible rod in the penis that can be unfolded, making the penis erect and able to engage in sexual intercourse. Another option is the implantation of fluid filled sacs that can be pumped up to create an erection.

Some men may be enticed to purchase herbs and medications online that claim to cure ED. The FDA warns men against purchasing these

products, as they may contain ingredients that can be harmful. While it has been suggested that certain herbal treatments can be helpful in the treatment of ED, there has not been enough research as of 2009 into these claims to prove or disprove them. It is up to each individual to discuss the pros and cons of the various available treatments with his physician and choose the one that suits his needs.

Evaluation See *Diagnostic Tests; Testing and Evaluation*.

Ewing's Sarcoma

Ewing's sarcoma is a rare type of tumor that usually occurs between the hips, in the upper arm, in the thigh bones, or in the ribs but may also show up in other tissues of the body. About half of the people with this disease are younger than 15 years of age. Recovery from Ewing's sarcoma depends on many factors, including how early the tumor is diagnosed, its size and location, and whether it has spread to other areas of the body.*

It Felt like a Pulled Muscle: Tom's Story

Tom woke up one morning with a pain like a pulled muscle in his right leg about halfway up the upper leg bone. He noticed a tiny lump there, but he figured he had just gotten a bump when he was playing basketball

* **tumor** (TOO-mor) is an abnormal growth of body tissue that has no known cause or physiologic purpose. A tumor may or may not be cancerous.

▲
Ewing's sarcoma seen under a microscope. Darkly stained cancerous cells with large purple nuclei are seen spreading outwards in bone tissue. *National Cancer Institute/Photo Researchers, Inc.*

* **malignant** (ma-LIG-nant) refers to a condition that is severe and progressively worsening.

* **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

a day earlier, and it would go away. When the lump and the pain were still there the next day, he mentioned it to his mother. She told him to wait a few days and see if it got better. It did not. She scheduled an appointment with his doctor, who examined Tom and ordered several tests, including an x-ray. No long afterward, the doctor called to tell her that Tom had Ewing's sarcoma and should begin treatment right away. Tom was lucky because the doctor found the tumor when it was still very small. Surgery removed the tumor. Tom had to undergo physical therapy and had to stop playing basketball or other sports, but he recovered and returned to school.

What Is Ewing's Sarcoma?

Ewing's sarcoma is a rare type of cancer in which a malignant* tumor forms in the bone or in soft tissues near the bone. Usually, these tumors appear in the middle of the upper arm or upper leg bone, although they may show up elsewhere in the body, such as the ribs or the hip bones. People with this disease usually experience pain, tenderness, and/or swelling at site of the tumor. Sometimes, however, individuals have a tumor for many months before they have any pain or swelling. Ewing's sarcoma is a dangerous cancer, because it can spread to other areas of the body. A number of treatments are available and can be quite successful, especially if doctors find the tumors and diagnosed Ewing's sarcoma early and before it has spread.

Some medical professionals once used the name primitive neuroectodermal (ner-o-ek-toe-DERM-ul) tumor (PNET), sometimes called peripheral neuroepithelioma, when referring to Ewing's sarcoma, but while PNET is similar to Ewing's sarcoma, it is not the same. As of 2009, medical professionals refer to PNET as being in the "Ewing's family of tumors" (EFT) or a "tumor of the Ewing's family" (TEF). According to the American Cancer Society, Ewing's sarcoma is by far the most common tumor in this family, and it makes up 87 percent of TEFs.

Who Gets Ewing's Sarcoma?

Many types of cancer affect adults more frequently than they do children, but such is not the case of Ewing's sarcoma. This tumor occurs more often in teenagers than in people of other age groups. Nonetheless, the American Cancer Society reports that Ewing's sarcoma is very rare. Only about 150 children and adolescents in the United States each year find out they have a TEF. Of those who are diagnosed with a TEF, four-fifths are white, nearly two-thirds are between the ages of 10 and 20 years of age, and most are males. All told, Ewing's sarcoma makes up 2 percent of all teen cancers.

What Causes Ewing's Sarcoma?

Ewing's sarcoma results from an unusual arrangement, called translocation, of two of the patient's chromosomes. Chromosomes are packages of DNA*, as well as various proteins, that are found in a cell's nucleus. They

carry an individual's genes*, which carry the instructions for a person's cells to work properly. The two chromosomes* involved in Ewing's sarcoma are chromosome number 11 and chromosome number 22. The translocation of the two chromosomes allows a gene on one of the chromosomes to fuse to a gene on the other, and it is this fusion of genes that brings about Ewing's sarcoma. As of 2009, medical professionals and other scientists did not know what causes the translocation. They had found no evidence that it is something that is inherited from a parent, nor had they found a link to diet or to anything else in the individual's background. In other words, researchers knew of nothing that parents could have done differently to prevent Ewing's sarcoma in their children. This is important information for parents who may feel they are somehow to blame for a child's genetic disease.

What Are the Symptoms of Ewing's Sarcoma?

A typical symptom of Ewing's sarcoma is pain, sometimes accompanied by swelling, at the site of the tumor. Depending on the position of the tumor and how nearby it is located to nerves, the pain can be quite severe. Often, the tumor is located in the middle of the upper arm bone (the humerus) or the upper leg bone (the femur), but tumors may also be located in the area between the two hips (the pelvis), in the chest, or in the back. A lump may appear at the site of the tumor, and the patient may feel warmth at the site.

Besides these symptoms, a patient may experience a fever, fatigue, little or no appetite, and weight loss. Occasionally, individuals with Ewing's sarcoma break a bone even though they have had no accidents or other injuries that would cause a broken bone. Such a break happens because the disease can weaken the bones. Sometimes, individuals have no other symptoms of a tumor until a bone breaks, and this broken bone is what leads a doctor to diagnose the tumor.

In addition, tumors that are located near nerves can cause patients to feel numbness or tingling and can occasionally cause paralysis* or incontinence*.

In some cases, individuals may have a tumor for many months before it begins to cause symptoms, because a tumor starts out small and grows over time. Individuals may have no symptoms when the tumor is small but may begin to experience pain and/or swelling when the tumor get larger.

How Is Ewing's Sarcoma Diagnosed?

After hearing about the symptoms an individual is having, a doctor may order a number of tests to look more closely at the affected area. These can include x-rays, bone scans, magnetic resonance imaging*, or CT scans*. If these tests point to a tumor, the doctor will then conduct a biopsy (BY-op-see) that removes a tiny piece of tissue. A medical professional will then look carefully at that sample under a microscope to find evidence of cancer. In addition, doctors may conduct tests to look at chromosomes 11 and 22 to see if they are translocated.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **chromosomes** (KRO-mo-somz) are threadlike chemical structures inside cells on which the genes are located. There are 46 (23 pairs) of chromosomes in normal human cells. Genes on the X and Y chromosomes (known as the sex chromosomes) help determine whether a person is male or female. Females have two X chromosomes; males have one X and one Y chromosome.

* **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.

* **incontinence** (in-KON-ti-nens) is loss of control of urination or bowel movement.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

- * **bone marrow** is the soft tissue inside bones where blood cells are made.
- * **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.
- * **radiation therapy** is a treatment that uses high-energy radiation from x-rays and other sources to kill cancer cells and shrink cancerous growths.
- * **grafts** are tissue or organ transplants.
- * **amputation** (am-pyoo-TAY-shun) is the removal of a limb or other appendage or outgrowth of the body.

Once Ewing's sarcoma is diagnosed, the doctor may order additional tests to determine whether cancer has spread from the site of the tumor to other areas of the body. This information helps determine how the doctor will treat the disease. If Ewing's sarcoma has spread, it usually moves into the lungs. It may also move into other bones or into the bone marrow*.

How Is Ewing's Sarcoma Treated?

The treatment for Ewing's sarcoma usually involves chemotherapy*, radiation therapy*, and/or surgery. Radiation or surgery are the typical treatments for tumors that have not spread elsewhere. A doctor's first choice is usually to remove the tumor surgically. Sometimes, however, doing so proves difficult because the tumor is located in such a spot that the doctor thinks its surgical removal may harm the person's use of that particular body part. In that case, the doctor may turn to radiation therapy to kill the tumor cells. The doctor may also use a combination of surgery and radiation. For instance, if surgery does not remove all of the tumor, the doctor may then use radiation to treat the leftover tumor. In addition, doctors sometimes use radiation to make sure the cancer does not return.

Doctors turn to chemotherapy especially when the tumor has spread, because chemotherapy kills both tumor cells and additional cancer cells in other areas of the body. The doctor will observe the tumor continuously as the patient is undergoing chemotherapy to determine whether the tumor is shrinking. When the tumor has shrunk sufficiently, a surgeon may remove it.

During surgery for Ewing's sarcoma, a doctor removes the tumor and makes repairs at the tumor site. Repairs may include reconstructing the bone or joint, and perhaps using artificial joints or bone grafts*. A bone graft is new bone or another material, such as a metal rod, that replaces the bone that was lost in the surgery. These artificial joints and bone grafts, along with physical therapy after the surgery, can help individuals return to many of their normal activities. The doctor directs the patient to avoid athletic competition and other movements that put too much stress on the repaired bones or joints. Occasionally, individuals need additional operations later in life to keep bones or joints functioning properly. Subsequent operations occur often among children, whose bones are still developing. Doctors may need to do several surgeries to lengthen the repaired bone as the child grows.

In the late 20th century, amputation* of arms or legs was a common treatment for Ewing's sarcoma. That is no longer the case. In the early 2000s, doctors can remove the tumors in most patients without having to amputate a limb. Occasionally, however, some patients with Ewing's sarcoma must have a limb amputated. After an amputation, individuals typically receive an artificial limb, called a prosthesis, and work with physical and occupational therapists to learn how to use it to the greatest advantage.

Even after individuals have the tumor removed, they still have to return for follow-up care to make sure that the tumor is indeed

gone. This care may include additional diagnostic tests, such as x-rays or bone scans. Overall, the survival rate for Ewing's sarcoma varies greatly and depends to a great extent on many factors. Some of these factors are:

- The size of the tumor
- The location of the tumor
- Whether the cancer has spread to other parts of the body
- How well the tumor responds to chemotherapy or other treatment
- The overall health of the patient

In addition to these treatments, a doctor may recommend psychological therapy to help individuals cope with the disease and its effect on their life. Teenagers may especially benefit from psychological therapy because they are also dealing with adolescent issues that can already be quite challenging.

Can Ewing's Sarcoma Be Prevented?

As of 2009, researchers knew of no way to prevent individuals from developing Ewing's sarcoma.

F

Factitious Disorder

Factitious disorder is a psychiatric condition in which an individual deliberately produces or falsifies symptoms of an illness for the sole purpose of assuming the role of a patient. Individuals with factitious disorder want to be under medical care, perhaps to obtain attention, care, or nurture. Generally this disorder signifies a very serious unmet psychological need or psychological trauma.

Anjali's Story

Anjali needed extra hours of volunteering at the hospital to fulfill her high school community service obligation. For some reason, this year there was less demand for the volunteers than in previous years. Therefore, she found herself serving at a third hospital in as many months when most students could expect to stay at one hospital the entire year. In many ways the hospitals were similar, but every difference in this new hospital reminded her that she wanted a “home” site. While she was thinking this, she felt relieved to see a familiar face. She saw someone she knew being pushed in a wheelchair by a nurse. Deanna had been a patient at Anjali's first hospital.

One night when Anjali was on duty, Deanna wanted someone to talk to, and Anjali spent some time with her. Deanna told her all about her illness. It was a strange one that the doctors did not understand. The day that Deanna was released, Anjali overheard some nurses commenting that her illness was not so serious and that she would be all right.

Now, Anjali was wondering why Deanna was back in the hospital. “Hi, Deanna!” she called out, but Deanna did not respond. “Do you remember me?”

Deanna looked a bit shocked to recognize Anjali, but muttered “Oh, hello.”

“Are you all right?” Anjali asked.

“Yes,” said Deanna. “I just had a relapse.”

The nurse pushing Deanna's wheelchair had a quizzical smile.

“Relapse? You mean you have had this before? You should have told the ER doctor.”

“Oh, well, that time was not as bad as this time,” Deanna replied

After the nurse settled Deanna in her hospital room, Anjali asked the nurse. “Is she all right?”

* **malingering** (ma-LING-er-ing) means intentionally pretending to be sick or injured to avoid work or responsibility.

“Yes,” said the nurse. “She thinks she has some form of exotic infection. The doctor thinks she has Munchausen syndrome.” Anjali had to look up the term. She found it is the most common factitious disorder.

What Is Factitious Disorder?

Factitious disorder is when a person seeks medical treatment for a falsified condition. The person with a factitious disorder visits the doctor persistently complaining of different symptoms of illnesses. The doctor can find no physical or mental condition associated with the symptoms. There is no external reward for faking an illness such as collecting workman’s compensation or escaping some stressful situation. The main motivation appears to be the desire to be treated as a sick person.

Underlying motives distinguish factitious disorder from malingering*. Someone who is malingering is seeking immediate external reward by faking a sickness. The motivation may include absence from work, avoidance of responsibility, receiving financial compensation, or obtaining prescription drugs. The main focus in handling malingering has been on how to detect the malingerer. The goal has been to prevent unfair worker’s compensation, escape from military service, and unnecessary medical expenses.

Factitious disorder is also distinguished from conversion disorder. With conversion disorder, afflicted persons actually believe they have the physical symptoms. Patients may actually appear to have the symptoms, but the cause is psychological, not physical, relating to internal conflict or external stressors. Conversion disorder may be the result of dissociation, characterized by a disconnection between past and present, lack of identity, no immediate sensations, and loss of control of the body. Dissociation is caused by trauma, extreme problems, or harmful relationships.

Factitious disorder is the name for any self-induced disease. The symptoms are voluntarily controlled. There is a conscious awareness on the part of the deceiver. There is evidence of internal compulsion. The person appears to be unable to control the urge to adopt the symptoms. Additionally, the person seems to maintain the illness because of psychological stressors. The person with factitious disorder needs help from a mental health professional because the feigned illness can do considerable, even irreparable damage to the health of the afflicted person. The three most common types of factitious disorder are Munchausen syndrome, Munchausen by proxy, and Ganssen syndrome.

Factitious disorder is a continuum based on the seriousness of the symptoms and the intensity with which the afflicted person is looking for medical attention. However, nowhere on this continuum is there any observable extrinsic incentive for the behavior. It is important to note that people afflicted with factitious disorder have the goal of being sick; they want to be sick even when there is no one around to impress.

Depending on the persistence, strength, and danger of the deceit, individual cases of the syndrome may be considered mild to severe. If the symptoms and the portrayal of the afflicted do not change their life much, then the disorder is considered mild. However, if the afflicted people

are persistent to the point of enduring very painful symptoms, financial difficulties, and lifestyle disruptions, then the disorder is considered severe. On the severe end of the continuum is Munchausen syndrome named in 1951 by British doctor Richard Asher based on the popular perception of Baron Freiherr von Münchhausen, who exaggerated his exploits in the Russian-Turkish war. Munchausen syndrome involves reporting the symptoms of physical illnesses. Another less common disorder is Ganssen syndrome, which involves reporting the symptoms of psychological illnesses.

Munchausen syndrome Munchausen syndrome is the most common factitious disorder. The symptoms reported are from physical maladies. These symptoms may be naturally occurring, but they are exaggerated or made worse by the afflicted. However, the symptoms may also be self-inflicted. The afflicted is willing to receive treatments for the feigned physical ailments but is usually resistant to treatment for the psychological disorder.

Ganssen syndrome Ganssen syndrome is the factitious disorder in which symptoms of psychological disorders such as dementia* or schizophrenia* are mimicked. Ganssen syndrome is very rare and has mostly been reported in prison populations. One of the characteristics of Ganssen syndrome is the response of “approximate answers.” The patient gives logically ridiculous answers to simple questions but responds with a number to a question requiring a number answer or with a color to a question requiring a color answer. It is listed in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*) as a dissociative disorder; however, it is so rare that the true cause, whether dissociative or factitious, may not be known.

Munchausen by proxy Munchausen by proxy was named in 1977 by British pediatrician Roy Meadows, who is credited with its discovery. It is a form of caregiver abuse of children or dependent others. Munchausen by proxy most often occurs in a mother seeking medical treatment for a child with a feigned illness. In this case, the mother has the disorder and tries to receive attention for being the mother of a sick child. Although the mother faking illness in her child is the most common scenario, Munchausen by proxy could affect a father faking illness in his child or any individual in the position of caregiver who seeks medical help for the person in their care when the illness is feigned. In any scenario, Munchausen by proxy is purposeful, abusive behavior toward the individual receiving care by the caregiver. The only cause for it is the mental disturbance of the perpetrator.

The characteristics include the parent constantly seeking medical attention for the child, always presenting the child to the doctors as weak and sickly, vulnerable to a number of ailments. The parent with this disorder will allow the child to go through any number of physical examinations, even the most intrusive and uncomfortable. If the parent

* **dementia** (dih-MEN-sha) is a loss of mental abilities, including memory, understanding, and judgment.

* **schizophrenia** (skit-so-FREE-nee-ah) is a serious mental disorder that causes people to experience hallucinations, delusions, and other confusing thoughts and behaviors, which distort their view of reality.

gets hold of the laboratory reports, the parent will tend to reach separate judgments from them. If the doctor tells the parent that there is nothing wrong with the child, the parent will not accept the doctor's conclusion. The typical behavior of the parent in receiving the doctor's conclusion is to selectively hear the doctor's report, focusing on the small phrases that could support the parent's contention that the child is seriously ill. Otherwise, the parent might argue with the doctor, find another doctor, or not acknowledge hearing anything that the doctor said. Always the parent acts like a responsible, caring parent.

As with the other factitious disorders, there is no extrinsic incentive for this pretense to either the afflicted caregiver or the person in his or her care. Also, as with the other factitious disorders, Munchausen by proxy can range in the degree of severity. On the mild end, a mother may be only exaggerating symptoms that currently naturally exist in the child. On the severe end, a parent may be actually causing the child to be sick or injured. This may be done by giving the child something toxic to eat or by ignoring the treatment prescribed by the doctor.

The motivations for Munchausen by proxy vary. While the most common motivations are pathological, there are cases in which the mother is extremely stressed by her responsibilities, and her deceit is her way of making a desperate plea for help. When this is the motivation, she is relieved to be discovered, and therapy involves education in the areas in which she feels most vulnerable. There are also parents who are micromanagers of their children's health. These individuals might try to second-guess the doctor's advice, seek out the opinions of other doctors, and meticulously monitor the child's progress. While this behavior may be extreme and obstructive to the child's therapeutic relationship with the doctor, it is not factitious or pathological.

There are two general pathological motivations for this behavior. The first is an obsession with obtaining medical treatment, which is commonly referred to as a "doctor addiction". The perpetrator is more likely to exaggerate an existing illness than to actually bring on some malady in the child.

The second pathological motivation is more common and more dangerous. The parent is trying to gain a sense of power by deceiving the doctors who are perceived as highly trained and intelligent. The parent also finds a sense of esteem in the role of a parent of a sick child. These parents are more likely to actively induce sickness in their children. This is the most serious level of Munchausen by proxy. When a physician in good faith suspects a case of Munchausen by proxy towards a child, the doctor is obligated to contact child protection authorities, since the health of that child may be in danger. This behavior of the parent may be life-threatening to the child. However, such accusations are hard to prove and require constant monitoring. When the perpetrator of Munchausen by proxy is found out, psychological interventions have limited success.

What Characterizes People Who Have Factitious Disorders?

It is difficult to develop a typical profile for someone with a factitious disorder because the reported cases are so few. An early study of Munchausen syndrome found more women than men tended to have the disorder. The afflicted was usually a young woman with poor psychosocial development. For most of her life, she had been dependent on her mother, but her dependency needs remained unfulfilled. She tended to have very little emotional support from her father and her verbal skills were poor. This pattern implies that she is looking to fulfill unmet needs but does not have the social skills necessary to seek them in direct, adaptive manners. Ganssen syndrome mostly afflicts men, but this finding may be based on the prison context of most studies. Most of those afflicted with Munchausen by proxy are young mothers.

How Do Doctors Diagnose and Treat Factitious Disorder?

Factitious disorders are very difficult to diagnose and treat. Because of the persistent deceit on the part of the afflicted, it is not easy for the doctor to determine what the problem actually is. The doctor must first rule out the possibility that the symptoms are real. If a factitious disorder is suspected, the doctor must determine how well the patient is familiar with the disease being faked. The patient may know the symptoms but not their proper order. If the patient then reports something unusual, such as the symptoms appearing in the wrong sequence, then the doctor may be cued that the patient does not really have the illness.

A complete diagnosis should involve a careful reading of the medical records for any inconsistencies or abnormalities. The doctor should also interview friends and family. Because the factitious disorder patient is not trying to get well, there should be some system of monitoring the patient's compliance with treatment.

Treatment is not easy because the causes of these disorders usually signify deep psychological problems, likely an underlying personality disorder. The mental health professional offering therapy has to be careful at first to develop a supportive relationship with the afflicted. There should be no early confrontation regarding the patient's lies except in a crisis situation. Therapy can follow a conventional pattern after the rapport has been established. However, the therapist has to be constantly aware that the patient has a weak ego and low self esteem.

Can Factitious Disorder Be Prevented?

As of 2009, there were no preventative measures. In most mental health issues, the person's family should be able to notice behavioral irregularities and provide the necessary support. However, if early studies of Munchausen syndrome are correct, afflicted individuals often do not have family support. Ganssen syndrome did not appear to be preventable either.

Fainting (Syncope)

Fainting is a brief loss of consciousness caused by a temporary drop in blood flow to the brain.

Marie Osmond Passes Out

One minute, Marie Osmond was finishing a performance with her partner on the television show *Dancing with the Stars* and waiting for their scores from the judges. The next minute, she was peering up at the concerned faces of her dance partner and the show's host. She had just had a fainting spell, and this was not her first. The 2007 incident made the news because it happened on live TV to a famous person, but fainting is common. As often happens with people who experience fainting spells, Osmond recovered within minutes and had no lasting effects from the incident.

What Is Fainting?

Fainting, also known as syncope (SING-ko-pee), is a brief loss of consciousness caused by a temporary drop in the flow of oxygen-carrying blood to the brain. Without enough oxygen, brain processes slow down, and the person may pass out briefly. The sudden drop in blood flow can occur for several reasons, including an irregular heart rate or rhythm, a dip in blood pressure, or the pooling of blood in the legs usually after a prolonged period of standing. Although fainting can be scary and embarrassing, it usually is not a cause for panic. Healthy people sometimes faint

BLACKING OUT IN BLUE SKIES

In World War II, fighter pilots sometimes lost their lives because of fainting.

During high-speed flight, very rapid changes in speed create a force that is expressed as a unit of gravity (g). A force of 4 to 6 g makes blood become very heavy and pool in the lower part of the body, robbing the brain of its blood supply. Many high-speed moves create a force this great. For example, pulling out of a dive can produce a force up to 9 g. When this happened to the pilots, they sometimes fainted and crashed.

Scientist Wilbur R. Franks (1901–1986) had the job of finding a solution to this problem. In 1942, he invented the first anti-gravity suit, a flight suit with special pants that apply pressure to the legs and belly, forcing blood back into the upper part of the body. Franks's invention gave Allied pilots a competitive edge during the war. The suits later worn by jet pilots and astronauts were based on his design.

when they are extremely tired, get bad news, or see something upsetting. In other cases, however, fainting may be a sign of a more serious medical condition.

What Causes Fainting?

One in three people faint occasionally. The problem occurs in people of all ages, although it is most common in people over 65 years of age. Fainting has many possible causes. Some of the more frequent ones are described below.

Heart disorders The most serious causes of fainting usually involve the heart or blood vessels. In some cases, the heart beats too fast or with an irregular rhythm, reducing the amount of blood it pumps. In other cases, individuals may have a narrowing of the valve that lets blood out of the heart or a partial blockage of the blood vessels that carry blood to the head, limiting blood flow to the brain.

Emotional stress Stress, fright, or sudden pain can arouse the nervous system, which, in turn, can signal the heart to slow down or the blood vessels to widen. If such changes happen too quickly a person's blood pressure can drop suddenly, which reduces blood flow to the brain, and the person may faint.

Heavy sweating Sweat contains sodium, a mineral that plays a key role in blood pressure control. Heavy sweating is another possible cause of a sudden dip in blood pressure. People who take part in strenuous physical activities under hot, humid conditions may experience this problem.

* **nervous system** is a network of specialized tissue made of nerve cells, or neurons, that processes messages to and from different parts of the human body.

DANCING MANIA AND MASS FAINTING

The phenomenon of mass fainting was reported to have occurred in the Middle Ages as a result of what was known as dancing mania.

Minstrels who played intoxicating music at medieval festivals reportedly induced dancing mania. The music stimulated fits of wild dancing, leaping, hopping, and clapping that led to hyperventilation, heart palpitations, and other symptoms.

Dancing mania curiously parallels the fainting that sometimes occurs at present-day rock concerts.

Standing up quickly When most people stand up, the nervous system* triggers a reflex response that increases the heart rate and blood pressure. This response insures that enough blood gets to the brain. In some people, particularly the elderly, these responses may not occur fast enough. Blood may pool in the legs. When too little blood reaches the brain, the person may faint.

What Happens When People Faint?

Symptoms Some people simply lose consciousness and slump down without warning. However, many people feel dizzy, lightheaded, or sick to their stomach just before they faint. They may become sweaty and pale, and they may have a graying out of vision. By definition, a faint does not last long. Falling down locates the head at the same level as the heart. This position helps restore blood flow to the brain. The person soon regains consciousness, usually within a minute or so.

Treatment A person who is feeling faint should lie down immediately and not try to stand or walk. If the person who faints does not regain consciousness within a minute or two, someone must get emergency medical help for that person. While awaiting emergency help, adult bystanders probably will elevate the legs of the person who has fainted; loosen belts, collars, or tight clothing; and check that the person's airway remains open, as people who faint may vomit as well. They will not move the person who has fainted until medical help arrives, because the fall may have injured the person.

The person who has fainted probably will regain consciousness quickly but may continue to feel a bit weak for a little while. To prevent fainting again, the person should continue lying down for a few minutes.

Even when people recover promptly, they should contact their doctors about a first fainting attack, about repeated fainting spells, or about other

possible symptoms, including irregular heartbeat, chest pain, shortness of breath, blurred vision, confusion, or trouble talking.

Familial Mediterranean Fever

Familial Mediterranean fever is an inherited inflammatory disorder that causes repeated episodes of fever, inflammation, and pain.

What is Familial Mediterranean Fever?

Familial Mediterranean fever (FMF) is an inherited inflammatory disorder that causes repeated episodes of fever, inflammation, and pain. The episodes develop over two to four hours and may last from several hours to several days. The periods of illness usually resolve without treatment but may damage body organs over time.

The gene* associated with FMF is called the Mediterranean fever gene (MEFV). FMF is inherited and develops in individuals who get two copies of the recessive* MEFV gene from their parents. Individuals with one copy of the gene are considered carriers of the disease. The children of two carriers have a 25 percent chance of having the disease, the children of a carrier and someone with FMF have a 50 percent chance of having the disease, and children of two FMF individuals are certain to have the disease. FMF is seen among only certain ethnic populations, and it is not as widely known in the United States. The symptoms associated with FMF may resemble symptoms of other more common medical disorders and be misdiagnosed.

Who Gets Familial Mediterranean Fever?

FMF occurs among people who live in areas around the Mediterranean Sea. Among Ashkenazi Jewish people, who make up a large portion of the Eastern European and American Jewish population, the FMF incidence* is one case per 73,000 people. Sephardic Jewish people, who are descended

ABCC6: Pseudoaxanthoma elasticum (16)

▲ Chromosome 16 controls familial Mediterranean fever. *Illustration by Argosy. Reproduced by permission of Gale, a part of Cengage Learning.*

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **recessive** describes a gene that is not dominant, one that requires a second identical recessive gene in order for the trait to show in the individual. When a recessive gene is paired with a dominant one, the individual is said to be a carrier of the trait.

* **incidence** means rate of occurrence.

- * **appendicitis** (ah-pen-dih-SY-tis) is an inflammation of the appendix, the narrow, finger-shaped organ that branches off the part of the large intestine in the lower right side of the abdomen.
- * **appendectomy** a surgical procedure in which the appendix is removed.
- * **gout** occurs when deposits of uric acid in the joints cause inflammation and pain.
- * **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.
- * **amyloidosis** a condition in which excessive amounts of a protein known as amyloid are created by the body and deposited in tissues causing damage.

from Jewish populations in Spain, have a rate of one FMF case per 250 to 1,000 people. Some studies have shown that Arabic populations have a rate of one case per 2,600 people for FMF, and Turkish populations have a rate of one case per 1,000. Studies done on Armenian populations have shown a rate of one case per 500 people, although some studies have shown even higher rates for Armenians. FMF occurs more often in adult men than women and is usually seen in individuals younger than 40 years of age.

What Are the Symptoms of Familial Mediterranean Fever?

FMF symptoms include fever, which may range from 100 to 104 degrees Fahrenheit. If an episode is a mild one, the fever may be the only symptom. Most people with FMF experience episodes of abdominal pain and inflammation, which may be misinterpreted as appendicitis*. Consequently, people with FMF sometimes have procedures they do not really need, such as appendectomies*.

FMF sometimes causes inflammation of the tissue surrounding the lungs and heart. Inflammation of the joints is more common and usually involves the wrists, knees, and ankles. Joint symptoms may resemble those of more common medical problems such as gout*. FMF sufferers may experience skin rashes, especially on the lower extremities. Muscle pain may be confused with other muscle disorders. Male FMF sufferers may have painful inflammation of the scrotum, while females may experience pelvic inflammation. One-third of females with FMF are infertile, and FMF causes a higher rate of miscarriage*.

FMF sufferers sometimes develop amyloidosis* where a protein called amyloid is deposited in body tissues, which can damage both the tissues and the kidneys that filter excess proteins from the blood. Kidney failure can occur in some patients who are not treated with medicine.

How is Familial Mediterranean Fever Treated?

Individual bouts of FMF usually end without medical help, but repeated inflammation can damage body organs and cause other medical complications. Therefore, doctors try to reduce the number of attacks and decrease the inflammation during attacks. The drug colchicine is commonly prescribed. People who take this drug usually have fewer complications and a longer lifespan. An additional benefit is that colchicine treatment may improve the chances of women having a successful full-term pregnancy. However, as of the early 2000s, colchicine had not been proven safe for use by pregnant women. The potential benefits need to be weighed against the potential risk.

Do People with Familial Mediterranean Fever Get Better?

FMF is a difficult disease to live with due to its recurrent, painful, and disruptive nature. Patients who are not receiving colchicine therapy may develop kidney failure and die before the age of 50. If amyloidosis is a

complication, the risk for renal failure is greater and death by the age of 50 is more likely. Daily therapy with colchicine greatly improves the chance of survival. Individuals with FMF on colchicine may have a normal lifespan if therapy is initiated before the development of excessive protein for the kidneys to filter and before kidney damage occurs.

- * **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.
- * **pre malignant** medical term used to describe a disease or condition considered highly associated with future cancer.
- * **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.
- * **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

Fanconi Anemia

Fanconi anemia is a rare genetic syndrome, involving failure of the bone marrow to produce blood cells.*

What Is Fanconi Anemia?

Fanconi anemia (FA) is a rare genetic* syndrome, involving failure of the bone marrow to produce blood cells. FA is a premalignant* medical disorder, which means that individuals with FA often eventually develop some form of cancer. However, the most common cause of death among people with FA is bone marrow failure leading to a life-threatening anemia*. FA patients often have various characteristic birth defects and other medical problems in addition to the anemia and cancer.

What Is the Connection Between Fanconi Anemia and Blood Production?

The cells that make up blood include red blood cells that carry oxygen to body tissues, white blood cells that function as part of the immune system* to fight off infections, and platelets, which are necessary for blood clotting and wound closure. Each blood component is critical to maintaining life. Bone marrow has an essential role in the production

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

* **platelets** (PLATE-lets) are tiny disk-shaped particles within the blood that play an important role in clotting.

of mature blood cells. FA involves a type of anemia known as aplastic anemia, in which all three types of blood cells are deficient due to bone marrow failure. Having such critical body components deficient leads to many different medical problems that can be life threatening.

How Is Fanconi Anemia Inherited?

FA is an autosomal recessive genetic disorder. Autosomal recessive disorders are diseases in which both parents must be carriers of the gene in order for their child to inherit the condition. If both parents are carriers, there is a 25 percent risk for the child to be affected by the disease. There are at least 13 known genes* that can be mutated (changed) and cause FA. Only one of these 13 is needed to cause the disease. The proteins expressed by these genes may cause DNA* damage that affect bodily processes such as blood production by the bone marrow and the start of cancer. However, the exact mechanism by which these gene mutations cause birth defects, bone marrow failure, and cancer was not known as of 2009.

Who Inherits Fanconi Anemia?

In the United States, one in 300 individuals carry the mutated genes that can cause FA. About one in 360,000 people in the United States are born with the disease. In the United States, the Ashkenazi Jewish population has a higher rate of one carrier per 90 people and one case per 30,000 people. In other countries, FA occurs at similar rates. Certain ethnic groups have higher rates of carrying the FA genes. These groups include sub-Saharan Black people and Spanish gypsies.

What Causes Fanconi Anemia?

FA is a genetic disorder caused by mutations in one of 13 different genes, but how this mutation happens was not known as of 2009. The cells affected by these mutated genes may be more susceptible to environmental factors that cause cancers or the cells may not have the self-protective mechanism that healthy cells have.

What Signs and Symptoms Are Typical in Fanconi Anemia?

Babies born with FA typically have low birth weight. Three-fourths of all people with FA have visible birth defects, too. Altered skin pigment known as café au lait spots for their light brown color is characteristic. Many children with FA are short and have small heads. They may also have abnormal thumbs, eyes, and ears, along with impaired sight and hearing. Multiple internal organs may also be defective, such as the kidneys, gastrointestinal tract (often esophagus, small intestine, or anus), heart, or lungs.

As children with FA continue to grow, bruises and small blood hemorrhages under the skin may be the first sign of blood problems associated with aplastic anemia and suggest platelets* deficiency. These individuals

have pale skin and tire easily, which is caused by red blood cell deficiency and decreased oxygen delivery to tissues. Frequent infections are caused by white blood cell deficiency.

How Is Fanconi Anemia Diagnosed and Treated?

The combination of obvious birth defects and blood disorders indicate FA. In one-fourth of FA patients, however, a diagnosis of FA only occurs after leukemia* or some other form of cancer is discovered. DNA tests can detect mutations in the known FA genes.

FA patients are often treated by a team of physicians, each of whom may address a different aspect of the disease. Treating the aplastic anemia may call for a bone marrow transplant. If appropriate bone marrow is not available, blood transfusions* may be performed to replenish blood cells needed by the body. Specific drugs that enhance blood cell production may also be prescribed. These drugs cannot correct the problem, but they may help reduce symptoms. For example, some drugs can help reduce bleeding. Blood counts are performed at least every three months, and bone marrow examination is necessary at least once per year. Sometimes surgery can help correct certain birth defects.

How Does Fanconi Anemia Cause Cancer?

Having FA makes a person likely to develop many kinds of cancer, even after bone marrow transplantation. People with FA often develop leukemia, a cancer originating in blood cells. The type of leukemia most often associated with FA is called acute myelogenous leukemia (AML), which is characterized by a rapid and unhealthy increase in immature white blood cells that cannot be used by the body to fight infection. The accumulating immature cells replace the normal bone marrow as well as the normal blood cells and are cancerous. This condition is life threatening. AML progresses rapidly and is typically fatal within weeks or months if left untreated. Other types of cancer associated with FA are characterized by tumors of the head and neck or tumors of the esophagus, reproductive tract, brain, liver, kidney, and lung.

What Can People with Fanconi Anemia Expect?

FA is a fatal disorder if left untreated and is sometimes fatal at an early age even with treatment. If a patient undergoes a bone marrow transplant along with other supportive treatments and has any severe birth defects corrected in a manner that sustains the person's life, then the prognosis is improved. With the best medical care and circumstances, a person with FA may live about 30 years. Making a diagnosis of FA early in the course of the disease improves the prognosis, as well as early cancer detection. However, the quality of life may be severely affected by frequent medical tests and procedures, complications such as birth defects or cancer, and various possible physical limitations.

* **leukemia** (loo-KEE-me-uh) is a form of cancer characterized by the body's uncontrolled production of abnormal white blood cells.

* **blood transfusions** (trans-FYOO-zhunz) are procedures in which blood or certain parts of blood (such as specific cells) are given to a person who needs them due to illness or blood loss.

Farsightedness

Farsightedness is an eye disorder that causes objects that are close to a person to appear out of focus or blurry, while objects at a distance appear clear.

What Happens If You Are Farsighted?

To people with farsightedness, the words on this page would seem blurry, unless they were wearing prescription (pre-SKRIP-shun) eyeglasses or contact lenses designed to correct the problem. But if they looked up from the page to read a sign across the room, they probably could read it easily.

What Is Farsightedness?

In most cases, farsightedness occurs when the eyeball is shorter than normal. For an object to appear clear, the light passing through the eye must focus on the retina, a layer of photosensitive* cells on the back of the eye. The retina is like the film in a camera. It is where the image passing through the eye is projected and then sent along the optic nerve* to the brain. In the brain, the image is developed into what we see. If the eyeball is too short, the image that is projected onto the retina by close objects is blurred, and the person is said to be farsighted.

Normal vision: near object is focused on the retina

Farsightedness: near object is focused behind the retina

Anatomy of the eye showing normal and farsighted focus. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

People with farsightedness usually have the disorder from birth. It is probably inherited from parents; however, just because a parent is farsighted does not mean the child necessarily will develop the problem too. Babies and younger children often are able to adapt to the problem. Muscles around the eyeball can change its shape, making it longer and allowing the image to be focused properly on the retina. As a child gets older, however, the muscles cannot do as good a job changing the eyeball's shape, and images close up are out of focus.

How Do Doctors Diagnose and Treat Farsightedness?

It can take many years for the symptoms of farsightedness to become noticeable. Eventually, people with farsightedness notice problems while reading or seeing objects that are close, whereas objects that are farther away remain clear. They also may start to get headaches after reading or doing other close work, and they may feel as if their eyes are tired.

An ophthalmologist* can diagnose farsightedness and correct it easily with prescription eyeglasses or contact lenses. These lenses change the focus of the images passing into the eye so they are projected properly onto the retina. Surgery to correct the problem is available, but it is not as widely used as surgery to correct nearsightedness.

Presbyopia Many people become more farsighted as they age. They develop a condition known as presbyopia (pres-be-O-pe-a), which is Latin for “old eyes,” that causes close objects to appear out of focus. Presbyopia results because the lens at the front of the eyeball becomes thicker and less flexible as a person ages. This change causes the eye to have trouble focusing the images passing through the lens. The first sign of presbyopia may be noticed when adults pass age 40. They start to find they cannot read the newspaper as well. People joke that their arms are too short because they try holding the paper or book farther away so they can see it clearly. People with farsightedness may need stronger prescription eyeglasses once they pass age 40. People with nearsightedness may need bifocals*.

Fears and Phobias

Fear is a normal emotion, experienced when a person senses danger. Fear includes physical, mental, and behavioral (bee-HAY-vyor-al) reactions. Certain childhood fears are common and normal.

A phobia is an intense, persistent fear of a particular object or situation. Phobias can be narrowly focused or more general in nature. A broad spectrum of phobias have been reported. Social phobia is an intense, persistent fear of being painfully embarrassed in a social setting. Agoraphobia is fear of being in any situation that might provoke a panic attack* or from which escape might be difficult.

What Is Fear?

Fear is the emotion that people feel when they sense that they are in danger. It is a protective emotion, which signals danger and helps a person to prepare for and cope with it. Fear includes physical, mental, and behavioral* reactions.

The physical reaction to fear is called the “fight or flight” response. Fight or flight is an involuntary response, a response that a person cannot control consciously but that is controlled by the body’s nervous system*. It is the body’s way of preparing to run from danger or to fight. The heart

► Cross-section of a brain showing the amygdala and caudate nucleus—the structures believed to be linked to negative emotions such as fear and anger. The amygdala is believed to be fully developed by the time a baby is born. The prefrontal cortex (the front of the brain) where thinking and planning take place, takes longer to mature. This may explain why it takes time for children to learn how to control their fears. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

beats faster, and the blood pressure and breathing rate increase. Oxygen-rich blood rushes to the large muscles of the body, which are tensing to prepare to fight. The pupils of the eyes grow larger to help the eyes scan for danger. Epinephrine*, also called adrenaline*, is released to prepare the body for quick action. Sweat is produced to cool the body.

Mentally, fear triggers thoughts about the danger or threat that the person senses. These thoughts may size up the danger, anticipate what might happen, or imagine ways to avoid harm. Behaviorally, the person may startle or jump and then run, freeze, or get ready to fight.

Different Kinds of Fear

Fear and anxiety Fear and anxiety (ang-ZY-e-tee) are similar emotions but with an important difference. Fear is the emotion that people feel when a danger is actually present, while anxiety is the fear connected with worrying about danger that might happen.

Childhood fears Certain fears are common and normal during childhood. In fact, all children have fears at times during their lives. Because so much of the world is new to children, they may fear certain things until they understand them better or are better able to cope. Fear serves a protective purpose, keeping children appropriately cautious while they learn about what is safe and what is dangerous.

Fears of animals, loud noises, or being in water are common in very young children, who are still learning to understand the information their senses are gathering. Babies as young as eight months old may fear strangers, and this is a sign that the baby is able to recognize his parents and to tell them apart from strangers.

Young children often fear imaginary creatures such as monsters, ghosts, and witches. Because imagination is developing at a rapid pace but the young child has not yet developed the ability to tell the difference between what is real and what is make-believe, these imaginary things can seem dangerous. Children tend to outgrow fears of imaginary creatures as soon as they are able to understand the difference between real and pretend.

Older children are more likely to fear real-life things such as burglars, being hurt or lost, or natural disasters such as earthquakes and extreme weather like hurricanes. These children may need reassurance and support from parents while they learn to cope with worry and fear and gain confidence in dealing with life's challenges.

Learned fears Fearful parents tend to have fearful children. Without realizing it, parents may teach children to be too fearful or cautious of certain things, not so much by what they say but by how they act. If a mother always crosses the street to avoid dogs and gets a little pale when a dog is nearby, chances are the child will learn to be afraid of dogs. Research has found that fears or worries can run in families. It may be that certain fear reactions are inherited, but people do not have to live with them just because they may be inherited.

What Is So Scary to Children?

Most school-age children report that they have between five and seven fears at any one time. Here are some of the most common childhood fears and the age they usually occur:

- **infants (up to 2 years old):** fear of falling, loud noises, strangers
- **toddlers (2–3 years old):** fear of loud noises, flushing the toilet, dogs and other animals
- **preschoolers (3–5 years old):** fear of monsters, imaginary creatures, getting lost, the dark, insects, thunder and lightning, injury, shots
- **early-school-age children (6–10 years old):** fear of burglars, divorce, tornadoes, hurricanes, injury, being bullied, losing a parent.

* **epinephrine** (eh-pih-NEH-frin) is a chemical substance produced by the body that can also be given as a medication to constrict, or narrow, small blood vessels, stimulate the heart, and cause other effects, such as helping to open narrowed airways in conditions like asthma and croup.

* **adrenaline** (a-DREN-a-lin), also called epinephrine, (ep-e-NEF-rin), is a hormone, or chemical messenger, that is released in response to fear, anger, panic, and other emotions. It readies the body to respond to threat by increasing heart rate, breathing rate, and blood flow to the arms and legs. These and other effects prepare the body to run away or fight.

Fear + Distress or Fear + Excitement?

The feelings and sensations people get when they are afraid or anxious are similar to the excited thrill people feel when they go on a scary ride at an amusement park or see a scary movie. Some people actually like the feeling, while others do not. Research psychologists (sy-KOL-o-jists) have described anxiety as a complex emotion that is made up of fear plus one or more other emotions, such as distress, anger, excitement, shyness, or guilt. Anxiety that is made up of fear plus excitement will be experienced differently from anxiety that is made up of fear plus distress, for example.

* **cognitive behavioral therapy** (KOG-nih-tiv be-HAY-vyuh-rul THAIR-uh-pee) is treatment that helps people identify negative ways of thinking and behaving and change them to more positive approaches.

Fears can be “unlearned.” If the fearful child watches another child calmly approach and pat a dog, she is learning that petting a dog can be safe and pleasant. By watching and then learning to go toward the dog slowly herself, with the right adult support, she can learn to overcome her fear of dogs. When leaving home, even to go to school, is too scary or when people avoid important activities because of fearfulness, professional help may be needed to help “unlearn” fears.

Are All Fears Outgrown?

Most childhood fears pass with time, maturing, and support from caring adults. Childhood fears do not get better by teasing, threatening, or forcing the child to meet the feared object or situation. Such remedies are likely to produce shame and lower self-esteem, and they may even worsen fear. The protective emotion of fear is not outgrown. People feel fear throughout life whenever they sense danger.

When to Get Help for Fears

Sometimes a normal childhood fear can become intense or last well beyond the age when a child usually outgrows it. If this happens, or if fears cause so much distress that they interfere with everyday life, professional help may be needed to help get over their fears.

Cognitive-behavioral therapy* is often helpful. It may involve teaching coping skills, supporting the child’s gradual approach to the feared situation, and coaching parents to provide needed reinforcement and support.

Hannah’s Story

Whenever 15-year-old Hannah entered a building with more than two stories, she checked to see if the building had stairs. Hannah was intensely afraid of riding in elevators. Her friends teased her, and she readily admitted that her fears were “silly.” But when an elevator door closed, Hannah began to sweat and her heart started to beat faster. “It’s like I’m trapped,” she told her friends. “As if I’ll never, ever escape.”

What Are Phobias?

A phobia (FO-bee-a) is an intense fear of a specific thing, such as dogs or spiders or riding in elevators. With a phobia, the fear a person feels is out of proportion to the real danger. The person with a phobia is very worried about the possibility of seeing the feared object or experiencing the feared situation. People with phobias may go to great lengths to avoid any situation that might bring them face to face with the object of their fear. Because of all the worry and avoidance, a phobia can interfere with a person’s everyday life.

Social phobias At some time in their lives, people find themselves in a social situation that makes them uncomfortable. But phobias involve more than social discomfort, and they take several forms. For

individuals with a social phobia, the exposure to a particular event provokes such enormous anxiety that it can trigger a panic attack*. A person with a social phobia will do almost anything to avoid similar social situations.

Social phobias are often associated with persistent fears of humiliation or embarrassment. These occur commonly in situations such as walking into a classroom or even leaving one's home. Individuals may feel as if everyone is looking at them. This phobia often persists. It may intensify with the result that when affected people venture into social situations, they spend all of their time alone, attempting to avoid other people.

Triggers When exposed to the trigger for a specific phobia, individuals may experience elevated levels of anxiety, including a panic attack. People with specific fears, such as Hannah with her fear of elevators, may know that their fear might be seen as “silly” or “irrational,” by others, but the fear still produces significant distress for them. Sometimes, particularly with children, affected individuals may not understand that their fears are excessive or unwarranted.

Trauma Traumatic events often contribute to the development of specific phobias. Social phobias often begin in mid-teens, with the average onset between the ages of 15 and 20, although some social phobias can begin in childhood. However, phobias can start at any age. Phobias may begin when two unrelated events are associated in someone's mind. Research has shown that social phobias may have a hereditary component.

What Are Common Types of Phobias?

The most common variety of phobia involves social situations. Social phobia is a persistent fear of humiliation or embarrassment in social settings. Closely related to social phobia is agoraphobia (literally “fear of the market place”), which is a fear of being in locations or situations from which escape might be difficult or embarrassing. People suffering from agoraphobia believe that they may suddenly develop a panic attack. To cope, people with agoraphobia avoid crowds or situations they find threatening. When they cannot do so, they are often filled with anxiety.

Other specific phobias such as arachnophobia (fear of spiders) or hydrophobia (fear of water) can cause people to avoid specific situations in which they might confront what frightens them.

How Are Phobias Treated?

Several prescription medications are used to treat social phobias. People with specific phobias may also benefit from psychotherapy* that uses systematic or progressive desensitization. In this form of therapy, affected persons work with a therapist in a safe environment. They are gradually exposed to the situations or objects that cause fear. They learn techniques

Examples of Phobias

The specific phobias that affect people are numerous and varied. Ablutophobia, is a fear of washing or bathing; zoo-phobia is an unrealistic fear of animals. Other common (and uncommon) phobias include the following:

- Arachibutyrophobia: fear of peanut butter sticking to the roof of the mouth
- Arithmophobia: fear of numbers
- Genuphobia: fear of knees
- Ichthyophobia: fear of fish
- Melissophobia: fear of bees but not other insects
- Pupaphobia: fear of puppets
- Pteromerhanophobia: fear of flying
- Testophobia: fear of taking tests
- Triskaidekaphobia: fear of the number 13

* **panic attack** is a period of intense fear or discomfort with a feeling of doom and a desire to escape. The person may shake, sweat, be short of breath, or have chest pain.

* **psychotherapy** (sy-ko-THER-a-pea) is the treatment of mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth.

involving relaxation, guided imagery, and deep breathing that allow them to work through their fears in a gradual manner.

Feeding Disorders of Infancy and Early Childhood

Feeding disorders of infancy and early childhood occur when a child fails to consume enough to gain weight and grow normally. Unlike children who are finicky but otherwise get sufficient nutrients, children with feeding disorders miss out on some nutrients their bodies need.

The Growing Child: What is Normal?

During the first year, babies grow more than they grow at any other stage of life. Parents give their babies breast milk or formula* until they are at least four months old, and then slowly start adding solid foods, first infant cereal and then baby food. Younger babies drink more often but in smaller doses than older babies. A one-month-old baby, for instance, usually drink two to four ounces of breast milk or formula six to eight times a day, whereas a five-month-old may drink six to seven ounces five to six times a day. During the first year on a healthy diet, a baby gains about one to two pounds per month and about an inch in length for each of the first six months, about a pound and 0.5 inches per month from the age of six to 12 months old.

Throughout infancy and as the child grows up, the doctor continues monitoring the youngster's height and weight. The doctor uses these measurements and other tools to ensure that each child is healthy and developing well. Sometimes, doctors find that certain children are not developing well, and one of the reasons may be a feeding disorder.

What Are Feeding Disorders?

Infants and children with feeding disorders do not eat or drink enough, or do not consume a wide enough range of foods to get a sufficient amount of the nutrients they need to grow up healthy. This pattern often becomes evident when children gain too little weight or even lose weight and show signs that they are not developing properly. Medical professionals often call this "failure to thrive." Besides a slowing of or a stop in physical growth, children with feeding disorders sometimes also develop other problems, including difficulties with cognition, which includes learning, reasoning, analyzing, and other thought processes.

Feeding disorders often are the result of difficulties in one of a number of different areas of the digestive system that process food. These areas include the following:

- Mouth
- Pharynx (FARE-inx; a short tube that extends from the mouth to the esophagus)
- Esophagus (a tube that connects the pharynx to the stomach)
- Stomach, including the pylorus (portion of the stomach that attaches to the duodenum, the first part of the small intestine)
- Small intestine (a long tube that completes digestion and moves waste matter to the large intestine for elimination)

A variety of feeding disorders occur in each of these parts of the digestive system. Examples are listed below.

Mouth-related feeding disorders While many feeding disorders are noticeable only after a baby begins to lose weight, cleft palate* and lip are evident immediately at birth. Cleft palate and cleft lip are birth

* **formula** is a prepared, nutritious drink or a dry drink mix designed specifically for infants.

* **cleft palate** is a gap or split in the roof of the mouth (the palate). It occurs when the palate of a fetus does not develop properly during the first months of pregnancy.

defects in which the two halves of the roof of the mouth, called the palate (PAL-ut), did not join. The result ranges from a notch in the upper lip to a large gap in the front of the face that runs from the upper lip to the nose. Clefts are fairly common, affecting one in every 600 to 800 newborns. A child may inherit the condition as a result from a genetic mutation, or it may occur from other causes, such as the mother's diet or use of drugs during the pregnancy. Infants with a cleft palate and/or lip usually have trouble eating, because they cannot make a good seal with their lips and therefore have difficulty getting the suction necessary to draw milk from a mother's breast or from a bottle. The treatment for these problems is surgery. Children who receive the surgery early in their lives usually do well. Unfortunately, some children's families, particularly those in developing countries, cannot afford surgery, and these individuals must go through their lives with the obvious facial defect. These children typically have difficulties speaking and may become withdrawn, sometimes developing behavioral problems.

Children may have other feeding disorders related to abnormalities in the mouth. For instance, a child may have ankyloglossia (an-kih-lo-GLOSS-ee-uh) (be tongue-tied). In this condition, the child's tongue cannot move normally because the piece of tissue (called a lingual frenulum) that anchors it to the floor of the mouth holds the tongue down. Because of this condition, the child may not be able to lift his or her tongue very much. In infants, this can affect their ability to suck from a mother's breast or from a bottle. The condition affects from 4 to 10 percent of all newborns. Sometimes children "grow out of it" because the anchoring tissue may begin to allow more movement by the time the child reaches six years of age. In other cases, the child can learn to live with the condition. Sometimes when the tongue continues to be severely restricted in its movement, however, surgery is necessary.

Pharynx- and esophagus-related feeding disorders From the mouth, food moves into the pharynx and toward the esophagus. A ring of muscle at the top of the esophagus opens long enough for the food to enter. The food travels down to the bottom the esophagus, where another ring of muscle opens temporarily to allow the food to enter the stomach.

In some children, this process does not go smoothly. For example, the ring of muscle at the top of the esophagus—known as the cricopharyngeus (KRY-ko-fare-in-GEE-us) muscle—may not open enough for food to move from the pharynx into the esophagus. This very rare birth defect is called cricopharyngeal achalasia. Doctors sometimes prescribe drugs to relax the muscles, and studies as of 2009 were under way on possible other treatments.

A different feeding disorder may result from another birth defect: the esophagus ends in a pouch instead of connecting to the stomach as it should. This condition, called esophageal atresia (uh-TREE-zee-uh), affects about one in 4,500 newborns. A telltale symptom of this disorder is excessive drooling, sometimes accompanied by choking, coughing,

sneezing, and/or a bluish tint to the skin. The treatment for esophageal atresia is surgery to connect the esophagus and stomach.

Disorders related to the stomach and intestines Experienced parents often slip a towel over their shoulder before laying their infant's head there, because they are so used to their infants spitting up. This frequent regurgitation, which doctors call gastroesophageal reflux, is normal among healthy babies. It occurs because the ring of muscle at the bottom of the esophagus opens up after a baby has eaten so that gas in the stomach can exit up through the esophagus and out of the mouth as a burp. In infants, food in the stomach may also come up with the gas, which results in regurgitation.

Sometimes, however, the regurgitation can become severe and is a sign of a feeding disorder called pyloric stenosis (py-LOR-ik sten-O-sis), which affects about three of every 1,000 babies born in the United States. In this disorder, the infant not only vomits often but begins projectile vomiting, which means that the vomit shoots out of the mouth, sometimes for a distance of two or more feet. Other symptoms, all of which typically begin when the baby is about three weeks old, may include a noticeable decrease in the number and the size of stools, which occurs because too little food is remaining in and being processed by the baby's digestive system; a decrease in the number of wet diapers; no weight gain or an actual loss of weight; tiredness; noticeable rippling movements after a feeding (resulting from contractions of the stomach); a dip or "soft spot" on their heads; and wrinkly skin on the stomach, upper arms, and upper legs.

Pyloric stenosis occurs when the muscles of the pylorus become thickened. This condition results in a smaller opening between the stomach and small intestine. Because of this narrower opening, food can no longer easily progress through the digestive system, and the baby's system ejects it. As of 2009 medical experts were unsure of the cause of this disorder. To diagnose the condition, a doctor asks the parent about the vomiting, checks the baby's weight history, and may press on the baby's stomach to feel for a small bump. The doctor also may order an ultrasound* or blood tests. The treatment is surgery that widens the opening through the pylorus. After successful surgery, babies recover quickly, often returning home within two days.

One especially dangerous condition involving the large intestine is necrotizing enteritis (NEK-ro-ty-zing en-ter-I-tis), which can also cause an infant to stop feeding. It occurs in fewer than five out of every 2,000 newborns, and the vast majority of its victims are premature babies. In this condition, the tissue of the large intestine dies. The treatment typically involves antibiotics and other medical care and sometimes includes surgery. As of 2009 medical professionals were unsure what causes necrotizing enteritis, but the occurrence of occasional outbreaks in the neonatal* intensive care units at hospitals suggests that an infectious agent, such as a bacteria or virus, may be involved.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **neonatal** (ne-o-NAY-tal) means pertaining to the first 4 weeks after birth.

- * **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.
- * **cerebral palsy** (se-RE-bral PAL-zee) is a group of conditions, all of which affect a person's ability to move. They are usually caused by injury to the brain before or soon after birth.
- * **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.
- * **hypothyroidism** (hi-po-THY-royd-ih-zum) is an impairment of the functioning of the thyroid gland that causes too little thyroid hormone to be produced by the body. Symptoms of hypothyroidism can include tiredness, paleness, dry skin, and in children, delayed growth and mental and sexual development.

Are Other Systems Involved in Feeding Disorders?

Disorders involving other bodily systems, such as the cardiovascular (heart and blood), endocrine (relating to hormones*), and central nervous system (including the brain), also may interfere with food intake or nutrition and have an adverse effect on a child's growth and development. For instance, some nervous system disorders, such as cerebral palsy* or meningitis*, can cause swallowing problems. In hypothyroidism* (hi-po-THY-roid-izm), symptoms may include choking and a large, protruding tongue, which can make feeding difficult. In this condition, which sometimes occurs in infants and children, a hormone-producing gland called the thyroid gland does not produce a sufficient amount of certain important hormones. Many other examples exist. Some diseases do not cause feeding problems but affect the body's ability to break down or use the nutrients that have already made their way into the stomach and small intestine.

In addition, some children have digestive systems that work fine but have other medical disorders that can affect their feeding behaviors. An example is pica. In this condition, children eat inappropriate items over a period lasting a month or more. For instance, a child who is old enough to know better, may eat dirt, paper, chalk, or other non-food items, or

MOTHER'S MILK IS BEST

The milk that infants receive from their mothers is one of the most important meals they will ever have. Breast milk is important in the baby's growth and development. In addition, the first few days of mother's milk is particularly important. This first milk, called colostrum (ko-LAH-strum), is different from any other milk the mother's breasts will produce. It contains only a little fat, but a high concentration of carbohydrates and protein, as well as antibodies. These antibodies help protect the baby from diseases.

While the research is very clear on the benefits of breast milk, not all babies get it. Women in some cultures around the world do not breastfeed their babies at all, or stop breastfeeding them long before 12 months or more, as many experts recommend.

For instance, in the Asia-Pacific region overall, the breastfeeding rate for the first six months of a child's life is about 35 percent, but in the Philippines, it is just 16 percent and in Hong Kong, only 12 percent. Experts differ on the reasons for the low numbers, but some believe that aggressive marketing by formula-making companies or the belief that formula is some sort of status symbol might be to blame in some instances. By comparison, about 74 percent of U.S. mothers breastfeed newborns, according to the Centers for Disease Control and Prevention. That number drops to about 43 percent by the time the baby reaches six months old, and to 21 percent for 12-month-olds.

large amounts of foods, such as flour or salt, that are typically used as ingredients rather than eaten right out of the box or bag. Medical experts are unsure what causes pica, but some believe it may be caused by an iron deficiency, a psychological or developmental problem, or malnutrition. To treat pica, experts typically recommend that parents work with their doctor, in addition to a psychologist and social worker.

A Mother's Role

Breast milk is very important to the growth and development of healthy babies. It not only provides them with all the nutrients they need to thrive but also helps to protect them from illness because it transfers disease-fighting antibodies* from the mother to the baby. In some cases, however, infants may not take in adequate nutrition because they do not receive enough milk from their mothers. This can happen for several reasons.

One reason is mastitis (mas-TITE-is), which is an inflammation (and sometimes an infection) of the breast tissue that can cause it to redden, swell, and become painful. Although mastitis usually only affects one breast, it still may cause women to cut back on or stop breastfeeding their babies. In the United States, mastitis affects about 10 percent of breastfeeding women. Another quite common problem may also occur. About two to five days after women give birth, their breasts normally swell as they begin to produce milk for the nursing baby. Sometimes, the breasts become very swollen, hard, and painful. The mother may also develop a fever. This condition, called engorgement, may happen if the baby is not nursing frequently enough or is not drinking enough when nursing. When breasts are engorged, the baby may have a difficult time breastfeeding, and even if the baby is able to breastfeed, engorgement may cause the breasts to stop producing as much milk. Women can work with their physicians to help prevent both mastitis and engorgement and to treat these conditions should they occur.

While the majority of women produce enough milk for their babies, occasionally certain mothers do not. This may result because the woman does not feed her baby often enough (or alternately does not frequently enough use a breast pump to remove the milk, which will be fed to the baby later by bottle). Infrequent feeding can trigger the breast to slow its milk production. Low breast milk production can also stem from other factors. For instance, a mother who is taking certain drugs or herbal supplements or is a cigarette smoker may not make enough milk. Mothers with this problem should talk to a medical professional, who may be able to help them boost their milk production.

How Are Feeding Disorders Diagnosed and Treated?

Many feeding disorders are diagnosed when the parent or the doctor notices that the child is not growing at an expected rate. This is why doctors so frequently check a child's weight and height. Parents may also

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

alert a doctor to a possible feeding disorder by reporting any difficulties they may notice when their child is eating, such as excessive vomiting, or a refusal to eat an entire group of foods. Depending on the specific symptoms, a doctor may then order blood tests or other tests to help identify the particular feeding disorder and its cause.

For some feeding disorders, the doctor may simply tell the parent to carefully monitor the child because the condition often disappears on its own. For others, the doctor may prescribe antibiotics or other drugs, may recommend surgery, or may advise one of a variety of other treatments. The exact strategy is determined by the particular feeding disorder the child has and it takes into consider the child's age and overall health.

Fetal Alcohol Spectrum Disorders

Fetal alcohol spectrum disorders (FASD) include such conditions as fetal alcohol syndrome (FAS), including partial FAS (pFAS); fetal alcohol effects (FAE); alcohol-related neurodevelopmental disorder (ARND); and alcohol-related birth defects (ARBD). These conditions result in varying degrees of physical, mental and behavioral problems that may develop in a child whose mother drank alcohol during pregnancy. FASD are the most common, known cause of mental retardation in the United States. This entry focuses on fetal alcohol syndrome (FAS) and fetal alcohol effects (FAE).

The brain of a normal infant (left); the stunted brain of an infant with fetal alcohol syndrome (right). Fetal alcohol syndrome is caused by excessive drinking by the mother during pregnancy. *Sterling K. Clarren. Reproduced by permission.*

Sarah, Child of Alcohol

Sarah was quiet and never caused any trouble in elementary school, but she had few friends and never fit in. Although she got fair grades, the teachers never knew how difficult the lessons were for her. When Sarah got to high school, however, she stopped trying to learn the lessons that were difficult for her, and she just barely graduated. Sarah had fetal alcohol effects (FAE), which were the result of her mother's drinking alcohol during pregnancy.

A person with FAE has some of the symptoms of fetal alcohol syndrome (FAS), but not enough to be diagnosed with the full syndrome*. Many of Sarah's teenage friends outgrew their immaturity, forgetfulness, and learning problems, but Sarah did not. The effects of her mother's drinking while pregnant with Sarah continue to follow Sarah throughout her life.

Not everyone with FAS or FAE has been identified, and researchers estimate that as many as one in every 500 children may have FAE or FAS. FAE and FAS are not contagious.

What Causes Fetal Alcohol Syndrome?

Alcohol use during pregnancy can cause fetal alcohol syndrome. When a woman drinks alcohol during pregnancy, it can have a range of effects on the fetus*, from subtle symptoms, such as Sarah had, to full fetal alcohol syndrome. Fetal alcohol syndrome is a group of similar characteristics found in affected babies. These characteristics may include low birth weight, distinctive facial features, learning problems, and mental retardation.

Like most drugs, alcohol passes through the mother's placenta* directly into the fetal bloodstream. In the fetus, alcohol slows down the central

* **syndrome** is a group or pattern of symptoms or signs that occur together.

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

* **placenta** (pluh-SEN-ta) is an organ that provides nutrients and oxygen to a developing baby; it is located within the womb during pregnancy.

* **cleft palate** is a gap or split in the roof of the mouth (the palate). It occurs when the palate of a fetus does not develop properly during the first months of pregnancy.

nervous system and is broken down by the immature liver of the fetus, which cannot handle this poisonous substance effectively. Alcohol stays in the fetus for a long period, even after it has left the mother's body.

The more the mother-to-be drinks the greater the danger to the unborn baby. Women who have three or more alcoholic drinks per day and women who are binge drinkers (drinking heavily but not every day) are likelier to have children with fetal alcohol syndrome. All types of alcohol can cause damage. The same amount of alcohol is found in one beer, one glass of wine, and one shot of hard liquor such as gin, whiskey, or vodka.

What Happens When Babies Have Fetal Alcohol Syndrome?

Babies show signs of fetal alcohol syndrome in various ways.

Facial characteristics Babies with fetal alcohol syndrome have a distinctive appearance. Characteristics may include:

- Small openings for the eyes, which appear widely spaced
- Flat cheekbones
- Flatter ridges between the nose and upper lip
- Low and flat bridge of the nose
- Unusually thin upper lip
- cleft palate*
- Epicanthal (ep-i-KAN-thal) folds (folds of skin at the inner corner of the eye)
- Minor abnormalities in the shape and placement of ears
- Shorter nose and an elf-like appearance

Other characteristics The general characteristics associated with fetal alcohol syndrome include:

- Premature birth
- Low birth weight; babies with FAS are small at birth and may continue to grow slowly after birth as well
- Possible heart defects
- Possible skeletal problems or differences in the hands
- Misaligned or misshapen teeth
- Central nervous system problems, which may include microcephaly (my-kro-SEPH-a-lee) (an abnormally small head) and varying degrees of brain damage
- Mental retardation, ranging from mild to severe
- Problems concentrating and understanding concepts such as time, money, and cause and effect
- Difficulty making friends and controlling impulses, along with tendency to get into trouble at home and at school

2,500 YEARS OF WARNINGS ABOUT ALCOHOL AND PREGNANCY

In 1973 researchers at the University of Washington named the group of symptoms that can result from alcohol use during pregnancy “fetal alcohol syndrome.” In 1987 the U.S. Surgeon General said that no known safe level of alcohol use during pregnancy exists. Among those who issued earlier warnings were:

- Hebrew Bible and Talmud
- Plato (c. 428–348 B.C.E.), Greek philosopher
- Aristotle (384–322 B.C.E.), Greek philosopher
- Plutarch (c. 46–119), Greek biographer
- Francis Bacon (1561–1626), English philosopher
- William Sullivan, a U.S. doctor who conducted the first scientific study of the fetal effects of alcohol (1899)
- Taav Laitenen, a Finnish doctor who observed the low birth weight of babies born to mothers who drank alcohol during pregnancy (1910)
- Paul Lemoine, a French pediatrician who described facial features, growth retardation, and central nervous system problems resulting from alcohol use during pregnancy (1968).

Fetal alcohol effects Children with fetal alcohol effects may not have the facial and physical characteristics of children with fetal alcohol syndrome, but they do have many of the same behavior and learning problems caused by prenatal alcohol exposure.

How Can Fetal Alcohol Syndrome Be Prevented?

Fetal alcohol syndrome is 100 percent preventable. A pregnant woman should not drink at all. Because there is no amount of alcohol that has been proven safe to drink, the best choice for the mother-to-be is not to drink alcohol at all.

Fetishism

Fetishism involves assigning increased value or power to an inanimate object or non-sexual body part.

What Is Fetishism?

Fetishism involves being fixated on inanimate objects or non-sexual body parts. The person assigns special significance or power to the object for the purpose of mental or sexual stimulation. Fetishes are considered a common part of human sexuality. Fetish objects may play a role in masturbation or sexual fantasies. Fetishism is more common among men than women.

LARS AND THE REAL GIRL (2007)

The award-winning movie, *Lars and the Real Girl* explores the phenomena of fixation and fetish and shows how these psychological conditions can develop from early childhood loss. Lars is fixated on a baby blanket his mother made for him. She died giving birth to him, and as he grew up he became convinced that he was responsible for her death. As an adult Lars wants to connect with others, but the fear of loss isolates him, and he turns instead to a substitute love object, a blowup doll, which he believes is a living female with a disability. Through the support of family, community members, and a sensitive physician, Lars comes to understand that loss happens and people can still take the risk of engaging in human relationships.

Are There Different Types of Fetishism?

There are two different categories for fetishes.

Form fetishes are those that focus on the shape and appearance of concrete objects such as high heeled shoes, lingerie, lipstick, or gloves.

Media fetishes tend to be more focused on the texture or feel of certain objects. These might include leather, rubber, or silk.

Fetishists use the items that they desire during masturbation or during sexual activity with their partners to achieve sexual satisfaction. Often, they need these items to become aroused. In many cases, fetishists simply need to see the object to become aroused, but more often, they prefer to touch, rub, and smell the object. Many fetishists prefer objects that have been worn or used, although they have no interest in the person who has used the object, only the object itself.

What Are the Most Common Fetishes?

Various items may be the desire of fetishists. Common fetishes include the following:

- shoe
- foot
- doll
- leather
- lingerie
- rubber
- glove

What Are the Symptoms of Fetishism?

Some people find certain objects or body parts sexually stimulating and even use them as a part of their sexual fantasies or sexual activity. However, as long as these people do not become fixated on the objects or body parts, they probably do not have a fetish. A fixation is an unhealthy preoccupation with or attachment to an object, and the fixated person invests the object with sexual meaning or value.

When people become fixated to the point that they can only become minimally aroused without a certain object or they can no longer become sexually aroused without it, they are considered fetishists. When an object is not available, the fetishist may fantasize about it as the only way to satisfy the desire.

Fetishists exhibit certain characteristics and behaviors. First, these individuals have fantasies involving the item of choice for at least six months. These are fairly common. More serious fetishes may cause disturbances in a person's ability to relate to others. Some people may find a line of work that helps satisfy their fantasies. For instance, a person with a panty fetish may find work in a lingerie store.

Just a Figure of Speech

A figure of speech, or locution (low-Q-shun), is a word or phrase that is used for effect and is not meant to be taken literally. The word "fetish" can be used loosely to mean "particular liking for." For instance, when Jenny tells her friend that she has a shoe fetish, she probably means that she really likes to shop for new footwear, not that she has a true fetish for shoes.

* **psychological** (SI-ko-LOJ-i-kal) refers to mental processes, including thoughts, feelings, and emotions.

* **psychoanalysis** (sy-ko-a-NAL-i-sis) is a method of treating a person with psychological problems, based on the theories of Sigmund Freud. It involves sessions in which a therapist encourages a person to talk freely about personal experiences, and the psychoanalyst interprets the patient's ideas and dreams.

What Causes Fetishism?

Fetishism is a complicated psychological* condition that is not fully understood. Many experts believe that fetishism results from difficult physical or emotional experiences during childhood, adolescence, or young adulthood.

Can Fetishism Be Cured?

Fetishism is not a condition that requires treatment or cure, unless the person finds it prevents or blocks some aspect of human experience or relationship. If the person with the fetish wishes to seek out treatment, however, there are resources available. These include psychoanalysis*, cognitive and behavioral therapies, hypnosis, and sometimes, medication. The primary focus tends to be counseling and understanding what caused the fetish to develop.

Fever

Fever is an abnormally elevated body temperature that usually occurs during an infection, inflammation, or some other kind of illness. Fever is not a disease itself, but it is one of the most common signs of illness, especially among children.

How Is Body Temperature Controlled?

The body adjusts its temperature in much the same way that the thermostat in a house works. With a thermostat, people set the temperature they want, and the heating or cooling system clicks on until the inside of the house reaches the right temperature. After that, the heater or air conditioner clicks on and off automatically to keep the temperature in the house hovering around the desired temperature.

The body's thermostat is located in the hypothalamus (hy-po-THAL-a-mus), a small part of the brain that also helps to regulate hunger, thirst, awareness of pleasure, and awareness of pain. The thermostat region of the hypothalamus, called the thermoregulatory (ther-mo-REG-u-la-tor-ee)

center, normally keeps the body's temperature hovering at around 98.6 degrees Fahrenheit (F) (36.8 degrees Centigrade [C]).

Like a house, the body has sensors that tell the thermostat if the temperature inside is rising or falling. In the body, these sensors are cells located in the skin and in the brain itself. If the sensors report that the body's temperature is rising, the body's cooling system clicks on, telling the cells to burn less fuel and produce less heat. The blood vessels expand to let heat escape from the skin (the evaporating sweat draws heat away from blood vessels), sweat pours out to cool the body as it evaporates, and the brain may get a bright idea: "Let's go into the shade and have a cold drink."

Fever With fever, the thermostat in the brain is reset to a higher temperature. Instead of keeping the body's temperature hovering at around 98.6 degrees F, the body's heating and cooling systems may keep the temperature at 100 to 102 degrees F or even higher.

Normal temperature varies a bit from person to person and from morning to evening, making it hard to state precisely where normal ends and fever begins. In fact, temperature measured at different places in the body can also be different. Temperature measured at the mouth can be one whole degree Fahrenheit lower than the actual core body temperature. For this reason, core body temperature is best measured at the rectum or at the ear. Most doctors say that a core body temperature at or above 100.4 degrees F (38 degrees C) should be considered a fever. Core body temperature above 104 degrees F (40 degrees C) is generally considered a high fever.

Hyperthermia Sometimes a person's temperature can rise for a different reason. Hyperthermia (hy-per-THER-me-a), quite different from fever, occurs when the heat outside is too much for the body's cooling system to handle, making body temperature (and the set point) rise. The most severe cases of hyperthermia tend to occur in people who cannot sweat as much as others, such as elderly people or those taking certain medications.

How Does Illness Cause Fever?

Bacteria and viruses themselves, as well as toxins (poisonous waste products) produced by some bacteria, cause fever. In some cases, they work directly on the brain to raise the thermostat. More commonly, they cause the body's immune system* to produce proteins called cytokines (SY-to-kines). The cytokines help fight the infection, but they also reset the brain's thermostat, causing fever.

Any substance that causes fever is called a pyrogen (PY-ro-jen), from the Greek word for "fire-causer." If the substance comes from outside the body, such as a toxin from bacteria, it is called an exogenous (ek-SOJ-e-nus) pyrogen. The prefix "exo-" means "outside" in Greek. If the substance comes from inside the body, such as a cytokine, it is called an endogenous (en-DOJ-e-nus) pyrogen. The prefix "endo-" means "inside" in Greek.

Ups and Downs

A person's temperature normally varies in the course of a day by about 1 degree F (0.6 degree C). It is lowest in the early morning and highest in the late afternoon. This daily variation is called the circadian (sir-KADE-ee-an) rhythm. When a person has a fever, it usually follows the same daily pattern.

Other factors also can affect what is a normal body temperature. In women of childbearing age, for instance, the early morning temperature usually goes up each month just before ovulation (ov-u-LA-shun), the release of an egg from the ovary. It stays elevated briefly and then returns to the lower level.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

- * **autoimmune disease** (aw-toh-ih-MYOON) is a disease in which the body's immune system attacks some of the body's own normal tissues and cells.
- * **rheumatoid arthritis** (ROO-mah-toyd ar-THRY-tis) is a chronic disease characterized by painful swelling, stiffness, and deformity of the joints.
- * **lupus** (LOO-pus) is a chronic, or long-lasting, disease that causes inflammation of connective tissue, the material that holds together the various structures of the body.
- * **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.
- * **leukemia** (loo-KEE-me-uh) is a form of cancer characterized by the body's uncontrolled production of abnormal white blood cells.
- * **lymphoma** (lim-FO-muh) refers to a cancerous tumor of lymphocytes, cells that normally help the body fight infection.
- * **transfusion** (trans-FYOO-zhun) is a procedure in which blood or certain parts of blood, such as specific cells, is given to a person who needs it due to illness or blood loss.

Sometimes the immune system produces pyrogens even without an infection. For instance, this may happen if a person has the following:

- an autoimmune disease*, such as rheumatoid arthritis* or lupus*
- inflammation* anywhere in the body
- cancer, such as leukemia* or lymphoma*
- received a blood transfusion* that is not compatible with his or her own blood type
- has a reaction to a medication

THE NAME IS FAMILIAR

Many infectious diseases are named for the major symptom of fever. Most of those listed below lead to fevers of about 102 to 104 degrees F (39 to 40 degrees C). Dengue fever, Lassa fever, and yellow fever are caused by viruses. The others are caused by bacteria.

- Dengue (DEN-gay) fever causes sudden high fever, headache, extreme tiredness, severe joint and muscle pain, swollen lymph nodes, and a rash. It is spread by mosquitoes.
- Lassa (LAH-sa) fever causes fever, headache, dry cough, back pain, vomiting, diarrhea, sore throat, and facial swelling. It is spread by rats and from person to person.
- Q fever causes sudden high fever, severe headache, and chills. It is spread by farm animals and insects.
- Rheumatic (roo-MAT-ik) fever causes painful, swollen joints, fever, and heart murmurs (abnormal heart sounds). It can follow an infection with the same bacterium that causes strep throat.
- Rat-bite fever causes sudden chills, fever, headache, vomiting, back pain, a rash on the hands and feet, and temporary arthritis (joint inflammation). It is spread by rats and mice.
- Relapsing (re-LAPS-ing) fever causes sudden chills and high fever, fast heartbeat, severe headache, vomiting, muscle pain, and sometimes mental confusion. Symptoms can recur several times. It is spread by ticks and lice.
- Rocky Mountain spotted fever causes fever, headache, skin ulcers (open sores), and a rash. It is spread by ticks.
- Scarlet fever causes high fever, sore throat, flushed cheeks, and a rash, especially in children. It is caused by the same bacterium that causes strep throat.
- Typhoid (TY-foid) fever causes fever along with abdominal pain, headache, and extreme fatigue. It is spread by food and water that contain salmonella bacteria.
- Yellow fever causes sudden fever, slow pulse, nausea, vomiting, constipation, muscle pains, liver failure, and severe fatigue. It is spread by mosquitoes.

People sometimes say that fever is a sign that the immune system is active, working to protect the body from illness. That may be true in some cases, but it is not always so. People often get fevers, for instance, if their immune system is weak or damaged. Scientists are not sure exactly what, if anything, fever indicates about the state of the immune system.

Who Gets Fever?

Fever is caused by so many common illnesses, including colds and flu, that it happens to everyone many times in the course of a lifetime. Young children are particularly likely to get bacterial and viral infections, such as strep throat and ear infections, that cause fever. Sometimes minor viral infections cause high fevers in children, whereas illnesses that are more serious cause milder fevers. People of all ages get fever.

Helpful fever Some evidence suggests that an elevated body temperature can make the immune system more effective and weaken certain bacteria. However, most of this evidence comes from animals or experiments on human cells in test tubes. Scientists really do not know whether fever actually helps people fight off infections. It may be that fever helps in certain cases but not in others.

Fever often can be helpful in another way. It can be an important sign that a person is sick. The movements of temperature up and down can indicate whether a person is getting better or worse.

Harmful fever Fever often makes an illness more unpleasant. In addition, a feverish body needs more oxygen, which means that the heart and lungs have to work harder as the fever rises, which can be a problem for people who already have heart or lung problems.

Fever can make mental problems worse for elderly people who have dementia (de-MEN-sha), which is a form of mental confusion and loss of memory that can develop gradually as people age. High fever also can cause temporary mental confusion, called delirium (de-LEER-e-um), even in healthy people.

Febrile convulsion Children under five years of age can have a different problem if their temperature rises quickly. They may experience a kind of seizure* called a febrile convulsion (FEB-ryl kon-VUL-shun). Their muscles may twitch, and they may lose consciousness for several minutes. Usually, a febrile convulsion needs no treatment and may not recur. However, febrile convulsions can be frightening. They also can lead to injury; for example, if a child falls.

Extremely high temperatures of around 107 degrees F or higher can cause permanent brain damage at any age if they last for a long time. Temperatures that high usually result from hyperthermia, not from an illness-related fever.

Fever of Unknown Origin

Sometimes a person has a fever that lasts for two to three weeks, and the doctor cannot find a cause, despite performing the usual array of medical tests. This condition is referred to as fever of unknown origin.

In about 90 percent of cases, medical professionals eventually find a cause. The most common causes are infectious diseases. Fever of unknown origin is particularly common in people infected with HIV, the human immunodeficiency virus that causes AIDS.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

Fiery Language

Many medical terms dealing with fever start with the prefix “pyro-” or “pyr-,” from the Greek word for “fire.” Fever itself is called pyrexia (pi-RECKS-ee-a). Substances that cause fever are called pyrogens, and medicines that reduce fever are called antipyretics.

The same Greek root has given rise to words outside medicine. A funeral pyre is a consuming blaze used to cremate a body (turn it to ashes). Pyromania is a compulsion to set fires. Pyrotechnics are fireworks. Pyrex is the trade name for a kind of glass used as baking dishes because it can withstand high heat.

How Is Fever Diagnosed?

People with a fever often feel hot, tired, achy, and generally sick. They sometimes have shaking chills as their temperature rises. Shaking helps raise the temperature to the feverish level that has been set by the body’s thermostat. They may sweat heavily when the fever “breaks” (starts to go away) or if it falls temporarily as part of an up-and-down pattern. Sweating helps lower the temperature to the new, lower point set by the thermostat.

Although the classic way of checking for fever at home is to touch the person’s forehead to see how warm it feels, doing so often does not work. The only way to tell for sure if a person has a fever is by taking the temperature with a thermometer. Three kinds of thermometers are available: digital, mercury, or tympanic.

Digital thermometers, usually used in medical offices and hospitals as well as at home, are electronic. They can take an oral temperature when placed under the tongue, a rectal temperature when placed into the rectum, or an axillary (AK-si-lar-y) temperature when placed in the armpit. The measured rectal temperature is the closest to what the core of the body actually feels and thus is considered to be the most accurate.

Mercury thermometers, which used to be the only kind available, are made out of glass and contain liquid mercury. They come in oral or rectal versions. Either kind can be used in the armpit as well. They are cheaper than digital thermometers, but they take longer to use.

Tympanic (tim-PAN-ik) thermometers are a special kind of digital thermometer that is placed into the ear. While the other thermometers take several minutes to give a reading, the tympanic thermometer takes only a few seconds. However, tympanic thermometers are more expensive and can be inaccurate if placed improperly in the ear.

When Should a Doctor Be Consulted?

A doctor should be consulted if a fever is high, lasts longer than a few days, or is accompanied by other symptoms, such as a rash; pain in the joints, neck, or ears; unusual sleepiness; or a dazed or very sick feeling. For babies under about three months of age, a doctor should be consulted about any fever.

The doctor will try to find and treat the underlying cause of the fever. Antibiotics can cure many bacterial infections, such as those that cause many earaches and sore throats. No medications are available to treat most viral infections.

How Is Fever Treated?

In a basically healthy adult or older child, there usually is no medical reason to treat the fever itself unless it is very high. In fact, lowering the fever with drugs can make it harder to tell if a person is actually getting better or if the drugs are just keeping the fever down. In younger

children, though, doctors often treat fevers above 100 degrees F, in part to avoid febrile convulsions. Of course, if a person of any age is very uncomfortable or unable to sleep, even a low fever can be treated to provide relief.

Fever can be lowered by drugs called antipyretics (an-ti-py-RET-iks) that do not require prescriptions. The major ones are acetaminophen (a-seet-a-MIN-oh-fen), ibuprofen*, and aspirin. However, aspirin should not be given to children or teenagers with a fever. If children have a viral illness, such as influenza or chickenpox, aspirin makes it likelier that they may get a rare but dangerous illness called Reye's syndrome*. This possibility does not exist with their taking acetaminophen* or ibuprofen.

Antipyretic medicines are available in pills for adults, chewable tablets for children, and liquid drops for babies. Acetaminophen also comes in suppositories (su-POZ-i-tor-eez), waxy pellets that are inserted into the rectum. They are used for people who cannot take medicine by mouth for whatever reason.

A lukewarm bath can also help lower a high temperature. However, cold water or alcohol rubs can do more harm than good by causing the body to shiver, which just raises body temperature more. In addition to these treatments, it is important for a person with a fever to drink plenty of liquids to avoid dehydration*. In extreme cases, a person in the hospital with a very high fever may be wrapped in a special cooling blanket or immersed in ice water.

How Can Fever Be Prevented?

Many of the diseases that cause fever can be prevented by vaccination*. These include influenza, measles, mumps, rubella (German measles), chickenpox, diphtheria, and typhoid fever. A number of other diseases that cause widespread fever in poorer nations have been eradicated in the United States by good sanitation systems and access to clean water. Still other diseases, such as colds and strep infections, often can be prevented by washing the hands properly before eating and, if possible, by avoiding contact with people who already have these infections.

Resources

Books and Articles

Calamandrei, Camilla. *Fever*. Tarrytown, NY: Marshall Cavendish Benchmark, 2009.

* **ibuprofen** (eye-bew-PRO-fin) is a nonsteroidal anti-inflammatory drug (NISAD) used to reduce fever and relieve pain or inflammation.

* **Reye's syndrome** (RYES SIN-drome) is a rare condition that involves inflammation of the liver and brain, and sometimes appears after illnesses such as chicken pox or influenza. It has also been associated with taking aspirin during certain viral infections.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.

* **menstrual cycle** (MEN-stroo-al SYkul) culminates in menstruation (men-stroo-AY-shun), the discharging through the vagina of blood, secretions, and tissue debris from the uterus that recurs at approximately monthly intervals in females of reproductive age.

* **menstruation** (men-stroo-AY-shun) is the discharge of the blood-enriched lining of the uterus. Menstruation normally occurs in females who are physically mature enough to bear children. Most girls have their first period between the age of 9 and 16. Menstruation ceases during pregnancy and with the onset of menopause. Because it usually occurs at about four-week intervals, it is often called the monthly period.

Fibrocystic Breast Disorder

Fibrocystic (fy-bro-SIS-tik) breast disorder is the general term used to describe noncancerous changes in the breast, such as the formation of fluid-filled sacs called cysts.

When Is a Breast Lump Not Breast Cancer?

It is estimated that more than half of all women experience the breast changes that are known as fibrocystic breast disorder at some time during their lives. The symptoms vary from person to person. Some women have no symptoms at all. Others notice a lump that feels like a smooth grape under the skin. These lumps, or cysts, are sometimes painful or tender to the touch.

What Causes Fibrocystic Breast Disorder?

The breast is made up of fatty tissue filled with pockets called lobes, each of which contains many smaller pockets called lobules. After a woman gives birth, these lobules produce milk. As a woman goes through her menstrual cycle*, the body releases hormones that cause the pockets in the breast to enlarge and hold extra fluid. At the end of the cycle, this swelling disappears, but fluid can sometimes get trapped in these openings. Over time, cysts can form.

Fibrocystic breast disorder usually affects women between the ages of 30 and 50. The lumps often are especially noticeable before and during menstruation*. When a woman reaches her 50s or 60s and stops menstruating, these symptoms usually disappear as well.

How Does the Doctor Know if the Lumps Are Not Cancer?

A doctor starts with a physical examination and mammogram, or x-ray of the breast, because benign* breast lumps often look and feel different from cancerous ones. If the lump turns out to be a cyst, the doctor may use a small needle to drain the fluid. If the fluid is bloody or appears unusual in any way, it may be sent to the laboratory for analysis. In most cases, no other treatment is needed.

If the lump is solid, a biopsy (BY-op-see) is performed. During this procedure, some or all of the tissue is removed and examined under a microscope for the abnormal cell shapes and growth patterns that indicate cancer. Researchers have investigated whether there is a connection between fibrocystic breast disorder and a woman's risk for breast cancer without reaching a conclusion as of the early 2000s.

Fibroid Tumors/Fibroids See *Menstruation and Menstrual Disorders*.

Fibromyalgia

Fibromyalgia (fi-bro-my-AL-ja) is a chronic disorder that causes generalized aching, stiffness, and fatigue in the muscles and joints.*

What Is Fibromyalgia?

Fibromyalgia is a later term for an old disorder that was once called fibrositis (fi-bro-SY-tis). Fibromyalgia means pain in the muscles and joints*. Three to six million Americans are thought to be affected by fibromyalgia. It occurs mostly in women aged 50 and older. Fibromyalgia is found throughout the world, among all ethnic groups. It is only rarely seen in children.

* **benign** (be-NINE) refers to a condition that is not cancerous or serious and will probably improve, go away, or not get worse.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **joints** are places in the body where two bones fit together, usually in such a way as to allow motion.

* **chronic fatigue syndrome** (KRON-ik fat-TEEG) a debilitating and complicated disorder in which individuals feel intense fatigue that lasts six months or longer. Symptoms may include insomnia, muscle pain, and impaired concentration. Because other illnesses have these symptoms, doctors must rule out a number of conditions in order to make a diagnosis.

* **antidepressant medications** are used for the treatment and prevention of depression.

What Causes Fibromyalgia?

As of the early 2000s, researchers had been unable to identify the cause of fibromyalgia, but they put forth several theories. One was that fibromyalgia is caused by injury to the central nervous system (the brain and spinal cord), which sends messages to the muscles. A second theory was that biochemical changes in muscle tissue cause fatigue and loss of strength. A third theory suggested that fibromyalgia may be caused by a virus. Some patients with fibromyalgia have psychological problems, but it is unclear whether there is any relationship between the psychological state and the physical condition.

How Do People Know If They Have Fibromyalgia?

Fibromyalgia begins gradually. The main symptom is pain in the muscles and joints. The pain moves around but is most common in the neck, chest, arms, legs, hips, and back. In addition, patients may complain of headaches, tiredness, sleep disorders, digestive disturbances, anxiety, or depression.

Fibromyalgia can be frustrating to diagnose for both the doctor and the patient. The muscles hurt, but they look normal. Blood and x-ray tests are also normal. The symptoms can resemble those of a variety of illnesses, including infections, and the doctor needs to rule out such possibilities. Fibromyalgia also shares similarities with chronic fatigue syndrome*. If no other explanation for a patient's symptoms is found, a doctor may diagnose fibromyalgia if the pain keeps coming back, occurs in many different muscles, and has lasted for more than three months.

How Is Fibromyalgia Treated?

A doctor who suspects fibromyalgia will reassure the patient that the condition does not harm the muscles. The most effective treatment is a combination of exercise, medication (sometimes including antidepressant medications*), physical therapy, and relaxation. Other approaches, such as massage and acupuncture, do not seem to be particularly helpful. There is no known way to prevent the condition.

Living with Fibromyalgia

Fibromyalgia is a chronic disorder, which means that the symptoms may get better or worse but can last for months or years. Many communities have support groups for patients with fibromyalgia.

What Progress Is Being Made in Treating Fibromyalgia?

Because fibromyalgia is a source of serious disability for many people, organizations such as the National Institute of Arthritis and Musculoskeletal and Skin Diseases sponsor research to help diagnose, treat, and prevent it. For example, researchers study how structures of the brain are involved in the painful symptoms of fibromyalgia. They also use sophisticated imaging technologies to study how the muscles perform.

Fifth Disease

Fifth disease, also known as erythema infectiosum (air-uh-THEE-muh in-fek-she-O-sum), is a common viral infection of infants and young children that causes a characteristic slapped-cheek rash.

What Is Fifth Disease?

Fifth disease, sometimes called slapped-cheek disease, is an infection caused by the virus human parvovirus B19. Its most characteristic feature is a bright red rash that begins on the face, making the cheeks look as if they have been slapped. After a few days, the rash may spread down the body and onto the arms and legs. As it spreads, the rash takes on a pink, lacy appearance.

Most people with fifth disease have mild symptoms and do not become seriously ill; some may not have any symptoms at all. However, the disease can be serious for people with certain blood disorders, such as sickle-cell disease*, because parvovirus B19 can temporarily cause or worsen existing anemia*. For most people, temporary anemia is not a problem, but for those who already have anemia, the condition can become severe, causing paleness, fatigue, and a fast pulse. People with weakened immune systems, such as those who have AIDS*, cancer, or who have had an organ transplant, can also develop severe anemia as a result of fifth disease.

▲ A few days after infection with the virus that causes fifth disease, the telltale “slapped cheek” rash appears on the face. S. Miller/Custom Medical Stock Photo, Inc. Reproduced by permission.

- * **sickle-cell disease** is a hereditary condition in which the red blood cells, which are usually round, take on an abnormal crescent shape and have a decreased ability to carry oxygen throughout the body.
- * **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

- * **strains** are various subtypes of organisms, such as viruses or bacteria.
- * **immunity** (ih-MYOON-uh-tee) is the condition of being protected against an infectious disease. Immunity often develops after a germ has entered the body. One type of immunity occurs when the body makes special protein molecules called antibodies to fight the disease-causing germ. The next time that germ enters the body, the antibodies quickly attack it, usually preventing the germ from causing disease.
- * **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.
- * **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

Parvoviruses can infect animals, but these are not the same strains* that affect humans. Therefore, a person cannot catch fifth disease from a dog or cat, and a pet cannot catch it from an infected person.

How Common Is Fifth Disease?

Fifth disease occurs most commonly in children between the ages of 5 and 15 years, but adults can also get it. It often occurs in outbreaks (for example, among classmates at school or children in a child-care center) in the winter and spring, but people can get it throughout the year.

Fifth disease spreads quickly. At home, up to half of family members exposed to someone with fifth disease become infected. If an outbreak occurs in school, up to 60 percent of students may get the virus.

A person with fifth disease can spread the infection in the early part of the illness, before the rash develops. By the time the rash appears (about a week after being exposed to the virus), a person likely is no longer contagious. Once someone is infected with parvovirus B19, that person develops immunity* to it and will not usually become infected again.

Parvovirus B19 passes from one person to another through nose and mouth fluids, such as mucus and saliva. Any direct contact with the fluids of an infected person, whether through a cough or sneeze or by sharing drinking glasses or utensils, can spread the infection.

Fifth disease can also be passed from pregnant women to their unborn babies. Most of the time, the baby is not harmed. Occasionally the infection can cause severe anemia in the baby and lead to miscarriage*, especially if the baby was infected in the first half of pregnancy.

What Happens When People Get Fifth Disease?

Signs and symptoms The first symptoms of fifth disease are similar to those of a common cold and include low fever, a runny or stuffy nose, sore throat, cough, headache, diarrhea, and fatigue. During this early period fifth disease is most contagious. After a few days, especially in children, the slapped-cheek rash usually first appears on the face, and it soon begins to involve the rest of the body in a pink, lacy-looking pattern. Not everyone with fifth disease develops this rash, but it is much more likely to appear in children under 10 years of age. For some people the rash fades and reappears if triggered by heat, exercise, stress, or exposure to the sun. Sometimes the rash itches, and adults in particular may experience pain and swelling of the joints in the hands, or the wrists, knees, or ankles.

Diagnosis In children, doctors can usually diagnose fifth disease simply by looking for the telltale rash on the face and body. In cases in which there is no rash, blood tests can confirm the presence of parvovirus B19.

Treatment Most people with fifth disease do not require treatment. Antibiotics do not help because the illness is caused by a virus rather than bacteria. Symptoms such as fever or joint pain may be treated with acetaminophen*.

NAMING A DISEASE

Fifth disease was named in the late 1800s. It was the fifth classic childhood rash-associated disease to be named, following measles (first disease), scarlet fever (second disease), rubella or German measles (third disease), and a fourth condition with a rash that is unknown to doctors today (fourth disease). The name fifth disease probably stuck because it is a lot easier to say than erythema infectiosum.

The rash clears up on its own, often within one to three weeks. Joint pain and swelling can take longer to go away, sometimes up to several months. People with joint pain may need to rest and restrict their activities until they feel better.

People with blood disorders or immune deficiencies who develop severe anemia as a result of fifth disease may require blood transfusion* and other specialized medical care.

Complications The vast majority of people who are infected with parvovirus B19 recover completely without any complications. Severe anemia, the complication most often associated with fifth disease, usually affects people with weakened immune systems or blood disorders and, rarely, unborn babies who were infected during the first half of pregnancy.

In healthy people, parvovirus B19 infection can sometimes affect the ability of the bone marrow (the soft tissue inside bones where blood cells are made) to make new red blood cells, but this effect is usually temporary and does not cause significant anemia or other problems.

Can Fifth Disease Be Prevented?

There is no vaccine to prevent fifth disease. The best way to prevent the spread of infection is to practice good hygiene, including frequent hand washing and not sharing drinking glasses and eating utensils. Because the disease is most contagious before the telltale rash appears, it is difficult to keep the infection from spreading among family members or young children in school or day care. By the time the rash appears and the illness is diagnosed, the person is usually no longer contagious.

Filariasis

Filariasis (fih-luh-RYE-uh-sis) is a tropical disease caused by tiny worms.

What Is Filariasis?

Filariasis is caused by different species of microscopic parasitic* roundworms that are passed to people through the bites of insects, most commonly mosquitoes. Several strains* of these worms, known as filariae (fih-LAIR-e-e), can infect humans, including *Wuchereria bancrofti* (voo-ker-E-re-ah ban-CROFT-e). There are also different types of filariasis itself, including cutaneous* or skin-related, body cavity, and lymphatic* infections. In the cutaneous disease, the worms live in the layers of the skin; in body cavity filariasis, they inhabit certain body openings and surrounding tissue; and in the lymphatic form of infection, they invade the vessels of the lymphatic system and the lymph nodes*.

Lymphatic filariasis, which can progress to a condition called elephantiasis*, is the most serious form of the disease. It begins when an infected female mosquito injects worm larvae* into a person's blood while feeding. The larvae travel to the lymphatic vessels, where they grow into adult worms. As adults, the worms can survive and reproduce for up to seven years. The gradual buildup of worms in the vessels hinders the lymphatic system's ability to fight infection and causes lymph fluid to collect—typically in the arms, legs, breasts, and male genitals—leading to swelling and disfigurement.

How Common Is the Infection?

Filariasis is most common in tropical and subtropical regions, including parts of Africa, the western Pacific, Asia (especially India), and Central and South America. In these areas, in the early 2000s, the number of cases of filariasis continued to rise. It was estimated that more than 120 million people worldwide had the lymphatic form of illness, and approximately 40 million of them were disabled or disfigured by the disease. Although contracting filariasis is not a risk in the United States, some immigrants may have it, and people who travel to other countries can contract the

disease as well. For example, missionaries and Peace Corps volunteers are considered to be at risk.

Is Filariasis Contagious?

The disease does not spread from direct person-to-person contact. Instead, it is transmitted by the bite of a mosquito. When one of these insects bites someone who is infected, it takes in the parasites along with its meal of blood. The mosquito then can pass those parasites on to the next person it bites. Usually, someone must be bitten many times, typically over a long period, to develop symptoms of filariasis.

What Are the Signs and Symptoms of the Disease?

The lymphatic form of filariasis usually produces fever, swollen or painful lymph nodes in the neck and groin, pain in the testicles*, and swelling in the limbs or genitals. Males and the male urinary and genital systems are particularly likely to be affected. In elephantiasis, a severe form of chronic* lymphatic filariasis, the blocked flow of lymph causes one or both legs to swell significantly. Over time, the skin on the leg can also change, taking on a rough texture so that it resembles the skin of an elephant. Although elephantiasis is unusual, up to half of all men with lymphatic filariasis may show serious symptoms, such as swelling of the scrotum*. In some cases people may have no obvious symptoms, but they still may have serious damage to the kidneys and lymphatic system.

Making the Diagnosis

Knowing that the person lives in or has spent time in a country where filariasis poses a risk can help a doctor diagnose the disease. The doctor may also take skin and blood samples from the patient to look for signs of the parasite.

What Is the Treatment for Filariasis?

Ideally, treatment begins as soon as possible after the patient becomes infected. Prompt treatment may not be possible, however, because the disease can be difficult to detect in its early stages. When the diagnosis is made, treatment may include:

- medication to kill the young worms in the bloodstream and stop the parasite's life cycle (although the medicine cannot kill adult worms)
- exercising and moving swollen limbs to improve lymph flow
- bed rest and compression bandages to treat swelling
- medications to lessen swelling and discomfort
- hospitalization and intravenous* (IV) antibiotics for secondary infections that might appear because the damaged lymphatic system is less able to assist in defending the body against infectious agents
- surgical treatment for deformities, such as enlarged limbs and scrotum, sometimes with several procedures and skin grafts* to correct cases of disfigurement

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **elephantiasis** (eh-luh-fan-TIE-uh-sis) is the significant enlargement and thickening of body tissues caused by an infestation of parasites known as filaria.

* **larvae** (LAR-vee) are the immature forms of an insect or worm that hatches from an egg.

* **testicles** (TES-tih-kulz) are the paired male reproductive glands that produce sperm.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **scrotum** (SKRO-tum) is the pouch on a male body that contains the testicles.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

* **grafts** are tissue or organ transplants.

* **stigma** is a mark of shame.

How Long Does the Disease Last and What Are the Complications?

Filariasis can last a lifetime, and without treatment it can worsen. The disease can lead to permanent disfigurement and damage to the lymphatic system and kidneys, secondary infections, hardening and thickening of the skin, and sexual and psychological problems. In countries in which the disease is common, a serious social stigma* often accompanies it, meaning that people in these countries look down on individuals who have symptoms of the disease.

Can Filariasis Be Prevented?

There is no vaccine to prevent filariasis, but controlling the populations of blood-sucking insects, especially mosquitoes, can limit the spread of the disease. In some areas where filariasis is common, people are treated yearly with preventive medicine to kill any immature worms in their blood. To protect themselves, people can also do the following:

- Stay inside as much as possible from dusk to dawn, when mosquitoes are most active.
- Sleep under mosquito netting.
- Place screens in all windows.
- Use insecticides around living areas.
- Apply insect repellent to exposed skin.

Flat Feet

Flat feet have flat inner arches and soles that completely touch the ground when the person is standing.

What Are Flat Feet?

Flat feet can happen at any age, and babies are born with them. Babies have fatty pads in the soles of the foot and in front of the heel, which fills the arch and gives feet their flat appearance. By three years of age, when children are walking properly, their feet no longer have a flat look. When children are between three to six years of age, the muscles of their feet become stronger, the fat disappears, and an arch develops. If the arches have not appeared by about age five or six—as happens with approximately one in every 10 children—a child is likely to have flat feet through adulthood.

Adults may have flat feet but still have good muscle tone and no pain. If feet are extremely flat, a doctor may recommend orthotics (arch supports) and a firm shoe to enable the person to walk without foot strain. Upwards of 75 percent of Americans have foot pain at some time, and flat feet may be the cause.

What Makes Feet Flat?

For some people, flat feet are the result of congenital bone malformation, evident if the doctor takes x-rays. For others, flat feet develop later. Each day as people walk, they take 8,000 to 10,000 steps on pavement, floor, tile, and other surfaces. With each step a person takes, gravity-induced pressure puts three to four times the body's weight on each foot. Over the years, the imbalance on the muscles of the feet may cause a disorder in the natural arch, weakening the posterior tibial tendon of the foot. Excessive weight or pounding stress may cause the longitudinal (lonj-i-TOO-di-nal) arch (which runs the length of the foot) or the metatarsal (met-a-TAR-sal) arch (which runs perpendicular to the longitudinal arch, from one side of the foot to the other) to fall, or flatten.

Other causes of flat feet are shoes that do not fit well, obesity*, rickets*, and metabolic disorders that may cause the arch muscles to weaken. In older adults, decreased exercise and increased weight can cause mechanical disturbances in the foot.

What Is Bad about Flat Feet?

Flat feet in themselves are not a problem. However, running on flat feet is almost like running on gelatin. Flat feet turn inward (pronation*), causing legs to turn inward, and contribute to such overuse injuries as shin splints* and back problems. Flat feet can also produce heel spurs*.

Correcting Flat Feet

Reducing pronation can help to prevent further problems. Experts recommend the following:

- Wearing shoes with arch support
- Wearing shoes that are motion controlled
- Avoiding shoes with lots of cushioning and little support
- Avoiding uneven running surfaces such as golf courses and trails.

Surgery is rarely recommended for flat feet alone.

* **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

* **rickets** (RICK-kets) a condition of bones that causes them to soften and bend creating deformity. In the early twentieth century, rickets was caused by lack of sunlight and the lack of vitamin D, calcium, and phosphorus. As enriched foods and improved diets became more widespread, rickets practically disappeared in industrialized countries.

* **pronation** is the rotation of the foot inward and downward so that, in walking, the foot comes down on its inner edge.

* **shin splint** is inflammation in the front part of the tibia (the big bone below the knee), due to overuse, as in running too much on hard surfaces.

* **heel spur** is a bony growth under the heel that causes pain when a person walks.

* **ions** are positively or negatively charged elements or compounds, such as hydrogen, sodium, potassium, and phosphate, which are necessary for cellular metabolism.

Flu See *Influenza*.

Fluid and Electrolyte Disorders

Fluid and electrolyte disorders are abnormalities in the distribution of water and ions in the body that result in health problems.*

What Are Electrolytes?

Electrolytes are charged particles (ions) that form when certain compounds are dissolved in water. Positively charged ions are called cations. Negatively charged ions are called anions. Some of the electrolytes that are important to maintaining health are sodium, potassium, calcium, magnesium, chloride, phosphate, bicarbonate, and sulfate.

Fluids and electrolytes are not evenly distributed in the body. About two-thirds of the fluid in the body is found inside cells and is called intracellular fluid (ICF). The remaining one-third is found in the spaces between cells, in the circulatory system, and in smaller amounts in the stomach, bladder, and a few other places. This fluid is called extracellular fluid (ECF). The distribution of fluid in the body is closely related to the distribution of electrolytes, particularly sodium and potassium. To understand this connection, it is necessary to understand what causes water to move in and out of cells.

Water follows electrolytes. Water passes easily across cell membranes. When fluid with two different concentrations of electrolytes is separated

by a cell membrane, there is pressure (called osmotic pressure) for water to flow across the membrane from fluid that contains fewer electrolytes (less concentrated) into fluid that contains more electrolytes (more concentrated). If osmotic pressure were the only factor affecting the movement of water, water and electrolytes would be evenly distributed inside and outside of cells. However, chemical reactions in the cell membrane actively prevent this from happening. Different types of cells have membranes that allow some electrolytes to pass across them while blocking others. The cell uses energy to drive this selection process and to maintain different concentrations of electrolytes on either side of the membrane.

The concentration of electrolytes in the body is highly dependent on how much water is in the body. The kidney is the main regulator of body fluids. As blood passes through the kidney, water, electrolytes, glucose (sugar), and wastes are filtered out of the blood into many tiny collecting tubules. If there is too little water in the body, the pituitary* secretes a hormone* called antidiuretic hormone (ADH). ADH signals the cells of the collecting tubules to allow water to pass back into the blood. If there is too much water in the body, little or no ADH is secreted, and instead of water returning to the blood, it is removed from the body in urine*. Other hormones help the kidney to regulate the amount of electrolytes that are returned to the blood. The filtering process helps rebalance the level of fluids and electrolytes in the body and maintain them within the narrow range needed for the body to function properly.

Maintaining the correct distribution of electrolytes inside and outside different types of cells is important because electrolytes play a role in most of the cellular activities that maintain life. For example, they perform the following:

- Help to control water balance and fluid distribution in the body
- Create an electrical difference across cell membranes that is necessary for muscle contraction and nerve transmission
- Regulate the acidity (pH) of the blood to keep it within the narrow limits that support life
- Help to regulate the level of oxygen in the blood
- Help move nutrients into cells and waste products out of cells

When the body is functioning correctly, it is able to perform the complex regulatory events that keep conditions within the body stable despite variations in the amount of food and water a person consumes. When there is an imbalance in electrolytes, many systems in the body are affected, and serious, even fatal, health problems, can result.

What Causes Fluid and Electrolyte Disorders?

Dehydration Dehydration is the most common cause of a fluid and electrolyte imbalance. Dehydration occurs when more water is lost from the body than is taken in through food and drink. This condition is often temporary; however, a 20 percent loss of water can be fatal. The average

Weighing In

The percentage of body weight that is made up of water changes as people age. Newborns have the most water—about 70 to 80 percent of their body weight. Older children and adults are about 60 percent water, while in elderly people only between 46 and 52 percent of body weight is water. Obese people's bodies contain a lower percentage of water than normal-weight people because fat cells do not store fluids. A woman's body contains less water than a man's body of the same weight because pound for pound, women have more fat cells.

* **pituitary** (pih-TOO-ih-tare-e) is a small oval-shaped gland at the base of the skull that produces several hormones—substances that affect various body functions, including growth.

* **hormone** is a chemical substance that is produced by a gland and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

Too Much Water

Flooding the body with water, just like its opposite severe dehydration, can be fatal, although the condition, called water intoxication, is much less common. In 2007, a Sacramento, California, woman died when she participated in a radio station contest that involved drinking large amounts of water in a short period. Water intoxication caused fatal swelling of her brain.

* **anorexia nervosa** (an-o-REK-se-a ner-VO-sa) is an emotional disorder characterized by dread of gaining weight, leading to self-starvation and dangerous loss of weight and malnutrition.

* **bulimia** (bu-LEE-me-a) is an eating disorder in which a person has episodes of out-of-control overeating, or binges, and then tries to make up for them by making themselves vomit, by taking laxatives, or by exercising to excess to avoid gaining weight.

* **endocrine system** is a system of ductless glands, including the thyroid and pituitary among others, that secrete hormones and control many bodily functions.

* **adrenal glands** (a-DREEN-al glands) are the pair of endocrine organs located near the kidneys.

* **corticosteroid** (KOR-ti-ko-STER-oid) is one of several medications that are prescribed to reduce inflammation and sometimes to suppress the body's immune response.

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

adult man loses about 10 cups (2.5 L) of water daily through urine, bowel movements, sweating, and breathing out water vapor from the lungs, but many conditions increase the amount of water lost. The following are some examples:

- Heavy exercise in hot weather causes loss of sodium and water through sweating.
- Severe vomiting and diarrhea cause large amounts of water and many electrolytes that would normally be absorbed in the intestines to be lost. Small children with diarrhea can become seriously dehydrated in less than one day. Infants can become dehydrated within hours.
- High fever, especially in infants and young children, increases water loss through the skin.
- Severe burns cause water to be lost from the surface of the body when the skin is not there to prevent evaporation. In addition, as large numbers of damaged cells die, they release their electrolytes into interstitial fluid, upsetting electrolyte balance.
- Limited fluid intake is a particular problem with the elderly, especially those who are unable to walk or who are bedridden. In addition, the receptors that trigger the sense of thirst and the need to drink are less sensitive in the people over age 60.

Diseases and disorders A great many diseases can upset the balance of electrolytes and thus the functioning of the body. Often more than one electrolyte is affected. These diseases include the following:

- Any disease that damages the kidney and causes reduced kidney function or failure. This situation is a common cause of electrolyte imbalances in the elderly and can be fatal.
- The eating disorders anorexia nervosa* and binge-and-purge bulimia*
- Disorders of the endocrine system* in which too much or too little of any hormone that affects the kidneys is produced. An example is Conn's syndrome in which the adrenal glands* produce too much aldosterone, a hormone that affects potassium reabsorption.
- Certain cancer tumors that produce hormones
- Injury to or surgery on the pituitary gland

Drugs Some medications selectively increase the excretion of certain electrolytes, cause the body to retain excess water, or stimulate the kidneys to produce excess urine. Diuretic drugs (so-called water pills) are the most widely used drugs to affect fluid and electrolyte balance. These drugs rid the body of water, but at the same time often cause excess loss of electrolytes (most often potassium) in urine. By contrast, corticosteroid* drugs generally cause fluid retention (edema). Many chemotherapy* drugs also affect fluid and electrolyte balance as do some herbal supplements.

How Are Fluid and Electrolyte Imbalances Diagnosed and Treated?

Fluid and electrolyte imbalances may show with certain symptoms, including abnormal blood pressure, rapid pulse, abnormal breathing, and abnormal skin appearance, but none of these symptoms is specific to an electrolyte disorder. The definitive way of diagnosing an electrolyte imbalance is with urinalysis and blood tests. An electrolyte panel is a standard blood test that measures the concentrations of major electrolytes found in blood serum.

Treatment of dehydration involves replacement of fluids either intravenously* or by mouth with a fluid that contains a balance of electrolytes similar to that found in a healthy body. In mild cases of dehydration, young children can be given replacement pediatric rehydration fluids (e.g., Pedialyte), which are available at supermarkets and pharmacies without a prescription. Athletes frequently treat or prevent dehydration by using sports drinks that are formulated to replace electrolytes lost through sweating.

When the fluid and electrolyte imbalance is caused by an underlying disease, such as food poisoning that causes severe diarrhea, kidney failure, or an endocrine disease, that disease is treated. People with severe diarrhea and vomiting, cancer patients, people with hormonal imbalances, and other very ill people often need short-term fluid and electrolyte replacement therapy. Untreated electrolyte imbalances can cause health problems that range from chronic to rapidly fatal.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

Food Poisoning

Food poisoning results from eating food or drinking water that is the contaminated with a virus, bacterium, parasite, or chemical that causes illness. This condition can result when foods have not been properly prepared or stored or when water has not been adequately treated to remove contaminants. Food poisoning can also result from eating poisonous plants or animals.

Robin's Story

Robin and her friends squeezed every pleasure they could into the early days of September before school started. The make-your-own-sundae

Microorganisms responsible for common food-borne illness

Microorganism	Food-borne illness	Symptoms	Common food sources	Incubation
Bacillus cereus	Intoxication	Watery diarrhea and cramps, or nausea and vomiting	Cooked product that is left uncovered—milk, meats, vegetables, fish, rice, and starchy foods	0.5–15 hours
Campylobacter jejuni	Infection	Diarrhea, perhaps accompanied by fever, abdominal pain, nausea, headache, and muscle pain	Raw chicken, other foods contaminated by raw chicken, unpasteurized milk, untreated water	2–5 days
