Clostridium botulinum	Intoxication	Lethargy, weakness, dizziness, double vision, difficulty speaking, swallowing, and/or breathing; paralysis; possible death	Inadequately processed, home-canned foods; sausages; seafood products; chopped bottled garlic; noney	18–36 hours
Clostridium perfringens	Infection	Intense abdominal cramps, diarrhea	Meats, meat products, gravy, Tex-Mex type foods, other protein-rich foods	8–24 hours
Escherichia coli group	Infection	Watery diarrhea, abdominal cramps, low-grade fever, nausea, malaise	Contaminated water, undercooked ground beef, unpasteurized apple juice and cider, raw milk, alfalfa sprouts, cut melons	12–72 hours
Listeria Monocytogenes	Infection	Nausea, vomiting, diarrhea; may progress to headache, confusion, loss of balance and convulsions; may cause spontaneous abortion	Ready-to-eat foods contaminated with bacteria, including raw milk, cheeses, ice cream, raw vegetables, fermented raw sausages, raw and cooked poultry, raw meats, and raw and smoked fish	Unknown; may range from a few days to 3 weeks
Salmonella species	Infection	Abdominal cramps, diarrhea, fever, headache	Foods of animal origin; other foods contaminated through contact with feces, raw animal products, or infected food handlers. Poultry, eggs, raw milk, meats are frequently contaminated.	12–72 hours
Shigella	Infection	Fever, abdominal pain and cramps, diarrhea	Fecally contaminated foods	12–48 hours
Staphylococcus aureus	Intoxication	Nausea, vomiting, abdominal cramping	Foods contaminated by improper handling and holding temperatures—meats and meat products, poultry and egg products, protein-based salads, sandwich fillings, cream-based bakery products	1–12 hours
Hepatitis A	Infection	Jaundice, fatigue, abdominal pain, anorexia, intermittent nausea, diarrhea	Raw or undercooked molluscan shellfish or foods prepared by infected handlers	15–50 days
Norwalk-type viruses	Infection	Nausea, vomiting, diarrhea, abdominal cramps	Shellfish grown in fecally contaminated water; water and foods that have come into contact with contaminated water	12–48 hours
Giardia lamblia	Infection	Diarrhea, abdominal cramps, nausea	Water and foods that have come into contact with contaminated water	1–2 weeks
Trichinella spiralis	Infection	Nausea, diarrhea, vomiting, fatigue, fever, abdominal cramps	Raw and undercooked pork and wild game products	1–2 days

party at Robin's was the best time they had all summer, but a day or two after the party, Robin and her friends were all sick. They all had diarrhea, fever, stomach cramps, and had vomited more times than they had ever imagined possible. Why? Robin and her friends were among the nearly 250,000 Americans who became ill after eating ice cream that fall. The culprit? *Salmonella enteritidis* bacteria. Unseen, odorless, and tasteless, the microscopic organisms contaminated ice cream ingredients on the truck ride to the ice cream factory. The reason? The truck had not been cleaned from its previous load: unpasteurized raw eggs, a prime breeding ground for salmonella.

What Is Food Poisoning?

Food poisoning is a serious public health concern in the United States and around the world. The Centers for Disease Control and Prevention (CDC) estimates that there are at least 250 food-borne illnesses. Even though most food poisoning is not severe enough to require treatment by a doctor, food poisoning in the United States costs between \$5 and \$6 billion every year in direct medical care and lost productivity every year.

Food poisoning is caused by eating foods contaminated with a harmful virus, bacterium, parasite, or chemical. Organisms that can contaminate food live in the soil, raw meat, raw milk products, in animal feces, on bugs, rodents, and on unwashed hands and food-related equipment. Food can be contaminated any time that food handling, preparation, or equipment is unsanitary, and at any point in the farm to table fork cycle. Some common causes of contamination are unrefrigerated, perishable* food; raw or undercooked foods; or preserved foods that were not cooked at high enough temperatures. The CDC estimates that about 97 percent of all food poisoning comes from improper food handling. Of that, 80 percent occurs from food prepared in businesses (e.g., restaurants or cafeterias) or institutions (e.g., schools or jails). The remaining 20 percent occurs from food prepared at home.

Although the food in the United States is among the cleanest and safest in the world, the CDC estimates that 76 million cases of food poisoning occur in the United States each year. Most cases of food poisoning are mild, but about 325,000 individuals are hospitalized for food poisoning each year in the United States, and about 5,000 die. In underdeveloped nations where water supplies are often contaminated and refrigeration is rare, food poisoning may cause a billion illnesses and 4 to 6 million deaths each year. The very young, the elderly, and people with illnesses such as HIV*/AIDS* that weaken the immune system are at the highest risk of dying from certain kinds of food poisoning.

How Does Food Poisoning Occur?

Food poisoning has two basic causes: infectious organisms and illness caused by chemicals. The organisms that cause food poisoning are bacteria, viruses, and parasites. Chemicals can be either natural toxins (poisons)

- * **perishable** means able to spoil or decay, as in perishable foods.
- * **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

Preventing Food Poisoning

- Organisms grow best at room temperature. Keep hot foods hot (above 140°F or 60°C) and cold foods cold (below 40°F or 4°C).
- Do not eat perishable foods that have been standing at room temperature more than two hours.
- Do not eat raw or undercooked eggs, poultry, or meat. Food should be cooked to an internal temperature of between 140°F and 180°F (60 to 83°C).
- Do not eat raw or unpasteurized dairy products.
- Wash fruits and vegetables before eating them.
- Wash thoroughly all plates, cutting boards, counters, and utensils that have come into contact with raw meats or poultry before using them for something else; do not place cooked food on the same plate that contained raw food without first washing the plate.
- Wash hands and utensils thoroughly between handling raw meat and other items.
- Wash hands thoroughly after using the bathroom.
- Wash hands thoroughly after having any contact with animals, especially reptiles, which sometimes carry bacteria on their skin.
- Defrost food in the refrigerator or microwave and not on the counter at room temperature. Cook promptly when defrosted.

found in plants (e.g., poisonous mushrooms) and animals (e.g., Japanese puffer fish) or they can be human-made chemicals such as pesticides or herbicides. For example, in 2008 the chemical melamine was found to have been improperly added to milk in China, causing hospitalizations and deaths of many children.

Bacteria are a common cause of food poisoning. A single bacterium that divides every half hour can produce 17 million offspring in 12 hours. Bacteria fall into two general categories. One group causes symptoms of food poisoning by directly infecting the intestines causing irritation and diarrhea. The other group release toxins as they grow and reproduce. These toxins affect the digestive system and often cause vomiting and/or diarrhea. Many bacteria cause food poisoning. The following are a few of the more common ones.

- Various *Salmonella* bacteria are found most often in eggs, poultry, dairy products, and beef.
- Bacteria of the genus *Campylobacter* cause more diarrhea illnesses worldwide than any other group of bacteria. They are commonly found in raw chicken and turkey. Putting cooked food on the same spot where raw poultry has been placed is a leading cause of food poisoning from *Campylobacter*.
- *Escherichia coli* are a large group of bacteria, only some of which cause food poisoning. *E. coli* that causes severe food poisoning have been found in undercooked hamburger and in ready-to-eat raw spinach.

A large group of viruses called Norwalk, Norwalk-like, or noroviruses are an extremely common cause of food poisoning. In the early 2000s, Norwalk viruses were often in the news for causing outbreaks of diarrhea and vomiting on cruise ships and in nursing homes. These viruses are usually transferred onto food from infected food handlers.

Parasites that cause food poisoning usually come from contaminated water. They often cause mild symptoms that develop slowly but last for several weeks. *Giardia* and *Cryptosporidium* are two common waterborne parasites that cause diarrhea.

Natural poisons found in some wild mushrooms can cause various symptoms, including nausea and vomiting, hallucinations, coma*, and death, depending on the amount and species of mushroom eaten. Mushroom poisoning is a medical emergency. Oysters, clams, mollusks, and scallops can contain toxins that affect the nervous system. Individuals often feel tingling in the hands and feet and may become dizzy and have difficulty breathing. Shellfish poisoning is a medical emergency because the muscles needed for breathing may become paralyzed. Certain fish, which has been properly refrigerated or which contains toxins can also cause illness.

Human-made poisons include all pesticides, fertilizers, disinfectants, and any other chemicals remaining in food when it is eaten that can cause illness. Contamination is usually the result of ignorance or a misunderstanding of how to apply a chemical. Symptoms vary depending on the chemical. Any suspected chemical poisoning requires prompt medical evaluation.

A KANSAS CANNERY

Poisoning that results from eating food contaminated by *Clostridium botulinum* bacteria is called botulism. The word “botulism” is derived from the Latin word “botulus,” which means sausage.

Originally, scientists believed that the botulinum toxin could only be produced in the presence of animal protein, such as meat. In 1919, however, a botulism outbreak was traced to canned vegetables from a commercial cannery in Kansas. That same year, another botulism scare involved canned olives. Both incidents prompted stricter regulatory control of food processing technology. Most cases of botulism in the United States in the 20th century occurred in improperly home-canned foods or from a honey containing *C. botulinum* given to infants.

In the early 2000s, people realized that *C. botulinum* produces a toxin that affects the nervous system and causes paralysis. If left untreated botulism is often fatal. However, with the development of artificial respirators, the fatality rate for treated botulism is around 2 percent in the United States.

Sing Your Way to Clean Hands

One of the ways to be sure your hands are clean is to wash them under warm running water with soap for at least 15 to 20 seconds. That is the length of time it takes to sing the “A-B-C Song.”

- * **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.
- * **cultures** (KUL-churz) are tests in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.
- * **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

What Are the Symptoms of Food Poisoning?

Symptoms of food poisoning usually occur as soon one hour and as long as three days after contaminated food is consumed. The symptoms usually begin suddenly. People with food poisoning often have nausea, violent vomiting, frequent diarrhea, painful stomach cramps, and fever. They may also feel dizzy, have blurred vision, or difficulty breathing.

How Is Food Poisoning Diagnosed?

Doctors diagnose food poisoning by asking about symptoms, conducting laboratory stool cultures* that test for the presence of specific bacteria in feces, and having food samples analyzed. In mild cases, it usually is not necessary to determine exactly which organism is causing the symptoms. In the case of chemical and natural toxins, it is much more important to determine the exact cause of the food poisoning so that specific treatment can be given. Large outbreaks of food-borne illness may be investigated by the local or state department of health or by national organizations such as the CDC.

How Is Food Poisoning Treated?

Food poisoning lasts for one to seven days and usually does not require hospitalization. Hospitalization is necessary for serious cases of certain types of food poisoning or when the diarrhea or vomiting has caused dehydration*. Diarrhea and vomiting can cause large amounts of fluid

to be rapidly lost from the body. Young children are especially prone to dehydration and should be monitored closely. They can be given replacement pediatric rehydration fluids (e.g., Pedialyte), which are available at supermarkets and pharmacies without a prescription. To treat severe dehydration, the doctor may give a person fluids intravenously, (directly into a vein). If the food poisoning is caused by a bacterium, doctors will prescribe antibiotics to fight the infection.

Prevention

Following basic guidelines will help prevent most food poisoning:

1. Do not eat perishable foods that have been at room temperature for more than two hours.
2. Wash hands and utensils before and after handling any food, after using the bathroom, and after handling raw meat, poultry, or eggs.
3. Cook food thoroughly, and do not eat marinade from raw meat or poultry until it has been thoroughly boiled.

Even when individuals keep themselves and their food clean, contamination may have happened earlier in the production process, as with Robin's ice cream. Food processors, growers, and distributors also need to take steps to keep food safe (e.g., clean processing plants and safe and sanitary storage of food). The Department of Agriculture, the Food and Drug Administration, and local state and city health departments have strict rules for these businesses that are carefully enforced.

Fungal Infections

Fungal (FUNG-gul) infections are caused by fungi (FUNG-eye) that can grow on the skin, nails, and hair and within internal organs.

What Are Fungal Infections?

Fungal infections are caused by fungi, tiny microbes* found in soil, air, and water, as well as on plants, animals, and people. Fungi feed on other organisms, living or dead, and play an important role in helping dead plants and animals decay. There are at least 100,000 species of fungi. The most familiar types of fungi are the mushrooms, the fuzzy white or blue-green mold that grows on forgotten foods in the back of the refrigerator, and the mildew on the shower curtain. Fungi grow best in warm, moist areas such as a steamy bathroom or the spaces between the toes.

Relatively few species of fungi cause fungal infections, also called mycoses (my-KO-seez), in humans. Fungal infections are of two basic types: superficial infections and systemic infections. Superficial infections affect the surface of the body, the skin, the nails, and the hair. They most often occur in moist areas, such as between the toes, in the crotch, or in the mouth.

Systemic infections take hold inside the body, in individual organs or throughout the body, and can cause severe or even fatal illness. Systemic

* **microbes** (MY-krobes) are microscopic living organisms, such as bacteria, viruses and fungi.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **ringworm** is a fungal infection of the skin or scalp that appears as a round, red rash.

infections are most likely to develop in people who have weak or suppressed immune systems*, such as the following:

- People with leukemia (cancer of the blood cells), Hodgkin's disease, or other kinds of lymphomas (cancers of the immune system)
- People receiving chemotherapy* or radiation treatment
- People with AIDS*
- People who have uncontrolled diabetes*
- People who have received an organ transplant
- People who are taking any type of drug that suppresses the immune system. For example, in September 2008, the U. S. Food and Drug Administration began an investigation into the risk of increased fatal fungal infections in people taking immunosuppressant drugs for rheumatoid arthritis.

In these people, the infections can cause chronic* disease and, in some cases, death.

What Are the Common Signs and Symptoms of Fungal Infections?

Superficial fungal infections, such as jock itch, vaginal yeast infection, athlete's foot, and ringworm*, typically are annoying but not very serious. Their symptoms generally include itchy, dry, red, scaly, or irritated skin. Systemic fungal infections often begin in the lungs and take time to develop. Severe infections occur in people whose immune systems have been weakened, allowing the infection to spread beyond the lungs to other organs. Symptoms of systemic fungal infections depend on which organs become infected and may include respiratory problems, extreme tiredness, coughing, weight loss, fever, night sweats, and headache.

What Are Some Specific Fungal Infections?

Tinea (TIH-nee-uh) is a general term given to a group of superficial fungal infections that affect the nails, feet (athlete's foot), groin area (jock itch), scalp, or skin (ringworm). *Trichophyton* and *Microsporum* fungi cause these related infections. Ringworm is identified by a red, scaly patch on the skin that looks like an expanding ring around a clearing center. Symptoms of athlete's foot include redness and cracking of the skin between the toes, and infected nails on the hands or feet usually look white and appear to be crumbling.

Candidiasis (kan-dih-DYE-uh-sis) is a superficial fungal infection caused by various strains of *Candida* (CAN-dih-duh) fungi. *Candida* is a yeast-like fungus often found in the mouth and the lining of the intestinal tract of healthy people. In people with weak immune systems, however, it can grow out of control, leading to an infection. A *Candida* infection of the mouth and throat is known as oropharyngeal (or-oh-fair-in-JEE-ul) candidiasis (OPC) or thrush, and infection of the vagina is known as

vulvovaginal (vul-vo-VAH-jih-nul) candidiasis (VVC) or vaginal yeast infection. OPC can affect newborns, people with AIDS or diabetes, and other people with weak immune systems. Its symptoms include white, thick patches on the tongue, mouth, and throat. *Candida* infection commonly occurs in newborns in the form of thrush or diaper rash. VVC is associated with vaginal burning or itching and a thick, cheese-like discharge. In certain situations, *Candida* can enter the bloodstream and spread to internal organs. These cases are seen most frequently in hospitalized patients who have weak immune systems and have received powerful antibiotics for other conditions.

Aspergillosis (as-per-jih-LO-sis) is the name for a variety of systemic infections caused by *Aspergillus* (as-per-JIH-lus) fungi. If it is inhaled through the mouth or nose, the fungus can cause a mild allergic reaction or a more serious infection of the sinuses* and lungs. Symptoms of aspergillosis vary and may include fever, cough, chest pain, and wheezing. In severe cases, typically seen in people with weak immune systems, the infection can spread to other organs, including the brain, skin, and bones.

Blastomycosis (blas-toh-my-KO-sis) is a systemic infection caused by the *Blastomyces dermatitidis* fungus commonly found in soil in the southeast, midwest, and south-central United States. The disease's symptoms resemble those of the flu: joint and muscle pain, a cough that brings up sputum*, fever, chills, and chest pain. If it progresses, it can lead to chronic pulmonary* infection, causing permanent lung damage, or widespread disease that affects the bones, skin, and genital and urinary tracts. Blastomycosis leads to death in about 5 percent of patients.

Coccidioidomycosis (kok-sih-dee-oyd-o-my-KO-sis) is a systemic infection caused by *Coccidioides immitis*, a fungus found in soil in the southwestern United States, in Mexico, and in South America. Most people with coccidioidomycosis have no symptoms, but 40 percent of patients experience a flu-like illness, with fever, rash, muscle aches, and cough. Also known as valley fever, the infection can cause pneumonia* or widespread disease affecting the skin, bones, and meninges*, which are the membranes covering the brain and spinal cord.

Cryptococcosis (krip-toh-kah-KO-sis) is a systemic infection caused by the fungus *Cryptococcus neoformans*, usually found in soil or bird droppings. Typically, the fungus enters the body through the mouth or nostrils when someone inhales fungi spores*, and symptoms of a lung infection, such as cough and chest pain, may develop. Although infection with *Cryptococcus* usually produces no symptoms or only mild symptoms in healthy people, the infection may spread in people who have weak immune systems. If it spreads to the central nervous system, it can cause inflammation of the meninges. This complication is especially common among people with AIDS.

Histoplasmosis (his-toh-plaz-MO-sis) is usually a mild systemic infection caused by *Histoplasma capsulatum*. This fungus is found in the eastern

▲ The *Trichophyton* fungus, photographed under an electron microscope at more than 4,000 times its original size, causes ringworm of the scalp (tinea capitis). The fungus is reproducing by flowering. Oliver Meckes/Photo Researchers, Inc.

- * **sinuses** (SY-nuh-ses) are hollow, air-filled cavities in the facial bones.
- * **sputum** (SPYOO-tum) is a substance that contains mucus and other matter coughed out from the lungs, bronchi, and trachea.
- * **pulmonary** refers to the lungs.
- * **pneumonia** (nu-MO-nyah) is inflammation of the lungs.
- * **meninges** (meh-NIN-jeez) are the membranes that enclose and protect the brain and the spinal cord.
- * **spores** are a temporarily inactive form of a germ enclosed in a protective shell.

Friendly Bacteria

Naturally occurring “friendly” bacteria and fungi live side by side in the human body. Some bacteria help keep fungi in check by preventing them from reproducing uncontrollably and causing disease. From time to time, however, doctors need to prescribe antibiotics to combat not-so-friendly bacteria that cause illness. Most antibiotics kill many types of bacteria, both good and bad, and using them for long periods can destroy too many friendly bacteria, allowing fungi to grow unchecked and eventually cause infection. To preserve the bacteria humans need, it is important to use antibiotics only when necessary and prescribed by a doctor.

* **feces** (FEE-seez) is the excreted waste from the gastrointestinal tract.

* **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.

* **spleen** is an organ in the upper left part of the abdomen that stores and filters blood. As part of the immune system, the spleen also plays a role in fighting infection.

* **boils** are skin abscesses, or collections of pus in the skin.

* **ulcerate** means to become eroded by infection, inflammation, or irritation.

* **endemic** (en-DEH-mik) describes a disease or condition that is present in a population or geographic area at all times.

and central United States in soil that contains bird and bat feces*. When the soil is disturbed, the fungal spores may be inhaled. Histoplasmosis can cause flu-like symptoms, including body aches, fever, and cough. Most people who become infected do not experience symptoms, but as with other fungal infections, people with weak immune systems are at risk for severe disease. In those cases, the infection affects the lungs and may spread to the liver*, spleen*, bones, and brain.

Mucormycosis (mu-cor-my-KO-sis) is caused by a fungus found on decaying plants. Most people do not get sick from exposure to this fungus. However, people with weakened immune systems or uncontrolled diabetes are susceptible to becoming sick. Mucormycosis often starts with a sinus infection. Infection then spreads to the brain and sometimes to the lungs, skin, digestive system, and kidneys. The death rate for this fungal infection ranges from 30 to 70 percent, depending on where the infection is located.

Sporotrichosis (spo-ro-trih-KO-sis) is a skin infection caused by the *Sporothrix schenckii* fungus, which is found in soil, thorny plants, hay, sphagnum (SFAG-num) moss, and other plant materials. It enters the skin through a small cut or puncture, such as a thorn might make. Soon, small reddish bumps resembling boils* form around the cut and often ulcerate*. In some cases, infection can spread to other parts of the body, such as the lungs or joints.

How Common Are Fungal Infections?

Superficial fungal infections, such as athlete’s foot and candidiasis, are common. Systemic infections, by contrast, are rare, appearing in less than one to two people in every 100,000 in the United States, according to the Centers for Disease Control and Prevention. They are more common in certain populations, such as people with AIDS or those who have had organ transplants.

With the so-called endemic* mycoses, rates of disease are higher in specific geographic areas. For example, coccidioidomycosis occurs in about 15 of every 100,000 people in parts of the southwestern United States (with 10 to 50 percent of the population testing positive for exposure to the fungus). In areas where histoplasmosis is found, up to 80 percent of the population test positive for exposure to *Histoplasma capsulatum*, but the disease develops only in people with weak immune systems.

Are Fungal Infections Contagious?

Some fungal infections, such as candidiasis and ringworm, can spread from person to person through contact with the infected area. Most infections, however, develop from fungi found naturally on the human body or in the environment. Many fungi that cause systemic respiratory disease are found in soil or in the droppings of animals or birds. Usually they are inhaled after the soil or droppings are disturbed, sending dust and fungal spores into the air.

How Do Doctors Make the Diagnosis?

Most superficial fungal infections are diagnosed based on their appearance and location. A doctor may also take a skin scraping to examine under the microscope or to culture* in a laboratory. Some fungi glow with a particular color under ultraviolet* light, so a doctor may make the diagnosis by shining such a light on the affected area. Systemic infections can be diagnosed by collecting a sample of blood, urine, cerebrospinal fluid*, or sputum to culture.

Can Fungal Infections Be Treated?

Most superficial fungal infections are treated at home with antifungal creams or shampoos for one to two weeks. Oral (taken by mouth) antifungal medication also may be prescribed, if necessary. Some cases of fungal infection are more persistent and may need to be treated with medicine for two to four weeks or even longer. Systemic illnesses often require hospitalization so that the patient can receive intravenous* antifungal drugs and supportive care.

Can Fungal Infections Be Prevented?

Preventing fungal infections can be difficult, because fungi are everywhere. In general, people who are otherwise healthy rarely contract systemic fungal infections. Practicing good hygiene, keeping the skin dry, and changing socks and underwear every day can help prevent superficial skin infections.

G

Galactorrhea

Galactorrhea is the spontaneous flow of milk from the nipple at any time other than the expected nursing period right after a pregnancy.

What Is Galactorrhea?

Galactorrhea is the spontaneous flow of milk from the nipple at any time other than the expected nursing period right after a pregnancy. The word galactorrhea comes from the Greek “galaktos,” meaning “milk” and “rhein” meaning “to flow.” The sugar contained in breast milk is called galactose. Galactorrhea is also sometimes called witch milk, because it occurs at unexpected and unexplained times. Galactorrhea may occur in either females or males. Both females and males have mammary glands in their breasts. The mammary glands in a male are less developed than in a female, but under certain conditions may be stimulated to create milk. Galactorrhea may be intermittent or consistent, scant or abundant, and come from one or both breasts. Milk production is caused by the hormone prolactin, which is made by the pituitary gland.

What Causes Galactorrhea?

There are many different causes of galactorrhea. In both males and females, the most common cause of galactorrhea is a prolactin-secreting tumor called a prolactinoma that grows in the pituitary gland. Overproduction of prolactin and the development of galactorrhea may also be caused by specific drugs, including some drugs given for high blood pressure (especially methyl dopa); some narcotic pain killers; and birth control pills. Birth control pills may cause galactorrhea while a person is taking them and after a person stops taking them because resulting changes in estrogen levels have an effect on prolactin production. Some types of antipsychotic drugs* can cause galactorrhea because they act on a receptor for the neurotransmitter* dopamine*. Prolactin production is also regulated by dopamine. Dopamine inhibits (holds back) prolactin production at inappropriate times. Drugs that inhibit dopamine effectively remove inhibition of prolactin production, with galactorrhea as a result. Other causes of galactorrhea that do not involve high levels of prolactin include an underactive thyroid gland in a condition known as hypothyroidism*, chronic kidney failure, and some spinal cord injuries.

Galactorrhea in newborns Galactorrhea may temporarily occur in newborns of either gender. High levels of maternal estrogen in the

* **antipsychotic drugs** are medications that counteract or reduce the symptoms of a severe mental disorder such as schizophrenia.

* **neurotransmitter** (NUR-o-transmit-er) is a chemical produced in and released by a nerve cell that helps transmit a nerve impulse or message to another cell.

* **dopamine** (DOE-puh-meem) is a neurotransmitter in the brain that is involved in the brain structures that control motor activity (movement).

* **hypothyroidism** (hi-po-THY-royd-ih-zum) is an impairment of the functioning of the thyroid gland that causes too little thyroid hormone to be produced by the body. Symptoms of hypothyroidism can include tiredness, paleness, dry skin, and in children, delayed growth and mental and sexual development.

* **endocrine system** is a system of ductless glands, including the thyroid and pituitary among others, that secrete hormones and control many bodily functions.

* **MRI** short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

fetal circulation can result in temporary breast enlargement in newborn infants. Enlargement of the breast may also be associated with secretion of milk. This condition usually resolves on its own, as levels of maternal estrogen gradually fade after birth.

What Role Does the Pituitary Gland Play in Galactorrhea?

The pituitary gland is a pea-sized gland that sits at the base of the brain. It is part of the endocrine system*, which is the system responsible for hormonal regulation of bodily processes such as milk production. The pituitary gland secretes many different hormones that act on other parts of the endocrine system. One of the hormones produced by the pituitary gland is prolactin. The target of prolactin is the mammary glands of the breast.

How Do Prolactinomas Cause Galactorrhea?

Prolactinomas are very small tumors in the pituitary gland that affect the hormone prolactin and these tumors can cause galactorrhea. The tumors tend to be larger in men than in women when discovered, probably because they come to medical attention later. Individuals with prolactinomas are usually between 20 and 35 years of age.

How Is Galactorrhea Treated?

Treatment of galactorrhea is basically directed at the underlying cause of the problem. Self-manipulation of the breast to check for galactorrhea should be stopped, because it can prolong the condition of galactorrhea. Galactorrhea in infants does not require treatment and will stop on its own. Whether the prolactin level is elevated determines how galactorrhea is treated. Patients with isolated galactorrhea and normal prolactin levels do not require treatment if they are not bothered by the galactorrhea, do not wish to conceive, and do not have another physical abnormality or reduced bone density. Prolactin levels are still measured periodically in these patients.

In patients with elevated prolactin levels, an MRI* may be performed if a pituitary tumor is suspected. Treatment tries to reduce excess prolactin secretion and the symptoms it causes, reducing the size of the prolactinomas and preventing their recurrence. Medications that act on dopamine receptors inhibit further prolactin production, stop galactorrhea, and decrease the size of the prolactinomas. As of 2009, bromocriptine and cabergoline were the only dopamine receptor stimulators approved by the Food and Drug Administration for the treatment of elevated blood prolactin and galactorrhea. However, approximately 12 percent of patients cannot take bromocriptine. The side effects include nausea, vomiting, dizziness, headache, nasal congestion, fatigue, abdominal pain, leg cramps, anxiety, depression, confusion, and constipation. While cabergoline may be easier to take, it has serious side effects, too, and is expensive.

Surgery is usually not performed in patients with prolactinomas because the medication is effective. Surgery is only used in cases in which

other procedures have failed or in which the tumor's growth is causing a particular problem, for example when it presses on nerves of the eye necessary for vision. In such a case, the tumor is accessed directly through the sinuses or by radiation.

Gallstones

Gallstones are crystal-like particles that form in the gallbladder when certain substances separate out of bile. Gallstones can vary dramatically in size, and while some may cause no symptoms, others may lead to serious medical concerns, including inflammation and infection.*

What Does the Gallbladder Do?

The gallbladder is a small, pear-shaped organ that sits under the liver on the right side of the abdomen*. The gallbladder concentrates and stores the greenish-brown liquid called bile, a digestive juice that is made by the liver. When a person eats food, the gallbladder contracts and sends bile through tubes called bile ducts and into the small intestine, where it helps break down fats in the food.

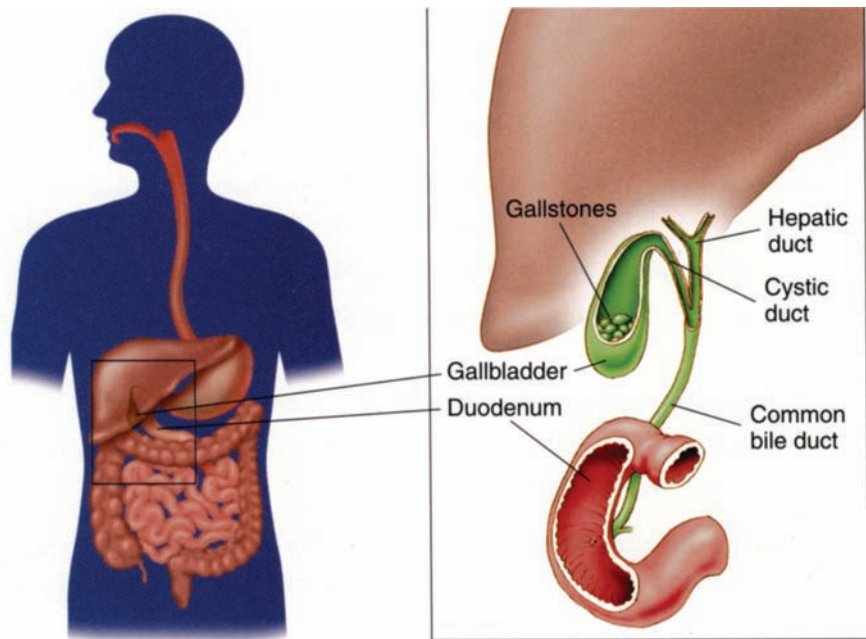

Bile has a number of ingredients, including water and dissolved bile salts. Bile salts act like detergent and help dissolve globules of fat. Bile also contains the following:

- cholesterol, a fat-like substance that is secreted by the liver as waste
- fats, including phospholipids, which are phosphorus-containing fatty substances
- bilirubin, which is a waste product secreted by the liver and formed by the breakdown of red blood cells

* **bile** is a greenish-brown fluid manufactured in the liver that is essential for digesting food. Bile is stored in the gallbladder, which contracts and discharges bile into the intestine to aid digestion of fats after a person eats.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

The gallbladder sits under the liver on the right side of the abdomen near the pancreas. When gallstones are formed, they can block the bile ducts, leading to pain and damage to the gallbladder, liver, and pancreas. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **pancreas** (PAN-kree-us) is a gland located behind the stomach that produces enzymes and hormones necessary for digestion and metabolism.

Like the bile salts, these substances are usually completely dissolved in the bile. When an imbalance exists, however, gallstones can develop. For instance, too much cholesterol can cause the bile to form crystals that drop out of the liquid. These crystals are gallstones.

What Are Gallstones?

Gallstones are pieces of solidified bile. The components of bile usually remain dissolved, but when something goes wrong that upsets the normal chemical balance, gallstones can form. Gallstones come in two main types: cholesterol stones, which account for about 80 percent of gallstones in the United States, and pigment stones, which form from bilirubin and calcium, a mineral that is also found in bile.

Gallstones can develop when a chemical imbalance exists in the bile, which causes it to contain more cholesterol (or bilirubin and calcium) than can be dissolved, or when the gallbladder does not contract enough to empty itself of bile on a regular basis. Gallstones can range in size from gravel-like particles to spheres the size of golf balls. Some people have single stones, whereas others develop many stones.

Although gallstones can result in little or no difficulties for many people, they can sometimes cause serious problems when they cause blockages, which can lead to inflammation and infection. When gallstones block the bile duct and trap bile inside the gallbladder, the gallbladder can become inflamed and sometimes develop a bacterial infection. This condition is called cholecystitis. Occasionally, the gallstones move farther down the bile duct to another small opening that is shared by the gallbladder and the pancreas*, a gland located near the stomach. Like the

gallbladder, the pancreas secretes digestive juices into the intestine. If the blockage occurs at this opening, damage to the gallbladder, liver, and pancreas can result. The resulting inflammation of the pancreas is known as gallstone pancreatitis.

Who Is at Risk for Gallstones?

One in every 10 people in the United States, or about 30 million people, have gallstones. Gallstones are rare in children and adolescents, but anyone can get them.

Cholesterol Diets high in cholesterol seem to be linked to gallstones, although some researchers believe that a high cholesterol diet must be accompanied by a genetic predisposition* toward gallstones. Anything that increases the cholesterol level in bile, including pregnancy, hormone therapy, and birth control pills, can increase a person's susceptibility to getting cholesterol stones.

Obesity and other health conditions Obese people also have a higher risk of gallstones, as do people who are fasting or on fad diets. Dieters may develop stones because lack of food means that the gallbladder does not regularly contract to release its bile, and the bile may sit in the gallbladder for a long time. People with liver diseases, infections of the bile ducts, and blood cell disorders (such as sickle-cell anemia*) are prone to developing pigment stones.

Other populations Groups of people who also seem to be at higher risk of developing gallstones include the following:

- women, especially those who have had several children (women are two to three times more likely than men to develop gallstones)
- people of Native American or Mexican ancestry
- people who are older than 60 years of age
- individuals with a family history of gallstones

What Happens When People Have Gallstones?

Most gallstones do not cause symptoms; only one in five people with gallstones experiences problems.

Symptoms Individuals who have symptoms usually feel them after a meal, when the gallbladder contracts to secrete bile. If a stone moves into the bile duct, a person will feel cramping pain in the abdomen and possibly also in the shoulder and back. In some cases, the pain can be severe. Individuals with cholecystitis may also experience nausea, vomiting, sweating, fever, chills, jaundice* (a yellowing of the skin and eyes), and chest pain. Symptoms of gallstone pancreatitis are similar to those of cholecystitis, but the pain may extend to the upper abdomen on the left side or to the back. Individuals who experience symptoms of cholecystitis or gallstone pancreatitis should contact a medical professional immediately.

* **genetic predisposition** is an inherited tendency to get a certain disease.

* **sickle-cell anemia** also called sickle-cell disease, is a hereditary condition in which the red blood cells, which are usually round, take on an abnormal crescent shape and have a decreased ability to carry oxygen throughout the body.

* **jaundice** (JON-dis) is a yellowing of the skin, and sometimes the whites of the eyes, caused by a buildup in the body of bilirubin, a chemical produced in and released by the liver. An increase in bilirubin may indicate disease of the liver or certain blood disorders.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **contagious** (kon-TAY-jus) means transmittable from one person to another, usually referring to an infection.

Diagnosis Medical professionals usually only diagnose gallstones if they are causing problems. To look for gallstones, doctors may use x-rays and ultrasound*, a painless procedure in which sound waves passing through the body create images on a computer screen.

Treatment The standard treatment for gallstones, and the only one guaranteed to cure gallstones permanently, is surgical removal of the gallbladder, usually through laparoscopic surgery (surgery performed through tubes that are inserted into the abdomen through small incisions). Doctors perform more than 500,000 of these operations every year in the United States. If a person cannot have laparoscopic surgery, the doctor may remove the gallbladder through an open incision 5 to 8 inches long in the abdomen.

People who cannot have surgery or do not want to have surgery can take medication to help dissolve gallstones, although this process can take months or even years. They may also undergo lithotripsy (LITH-o-trip-see). In this procedure, shock waves pass through the skin to shatter the stone into tiny particles that may be able to pass out of the gallbladder on their own.

Gangrene

Gangrene (GANG-green) is the decay or death of tissue caused by a lack of oxygen supply to the tissue and/or bacterial infection of the tissue.

What Is Gangrene?

Gangrene is not a contagious* disease. It is a condition in which living tissue (e.g., skin, muscle, or bone) begins to decay and eventually dies because blood flow (and oxygen) to an area is blocked or because harmful

bacteria invade the body's tissues after entering through a wound or sore. Gangrene most commonly affects the feet, toes, hands, and fingers. Gangrene can also occur inside the body in abdominal organs such as the intestines.

Doctors recognize three major forms of gangrene: dry, wet, and gas gangrene.

Dry gangrene Dry gangrene is the most common form of gangrene, and it occurs most frequently in the feet of people with diabetes*. Dry gangrene results from the gradual loss of blood supply to a part of the body. The tissue slowly dies because it receives little or no oxygen and nutrients from the blood, but it does not become infected. The first symptoms of dry gangrene are often numbness and tingling in the affected area. These symptoms are usually followed by severe pain as the condition progresses and the tissue begins to die; the skin temperature drops, and the color of the tissue changes, eventually turning black.

Dry gangrene is most often a complication of diabetes, arteriosclerosis*, or frostbite*. Because this condition usually develops gradually, it may go unnoticed for weeks or months, especially in elderly people. Dry gangrene usually is not life threatening, but it needs to be treated promptly.

Wet gangrene Wet gangrene is caused by a bacterial infection from severe wounds or burns or by a crushing injury that causes blood to stop flowing to a certain part of the body. When blood flow stops, bacteria begin to invade the damaged tissue. In wet gangrene, there is pain, swelling, and blistering of the skin, and the wound gives off a foul smell. Organisms that are commonly involved in wet gangrene include *Streptococcus* (strep-tuh-KAH-kus) and *Staphylococcus* (stah-fih-lo-KAH-kus) bacteria. Without treatment, wet gangrene can be fatal.

Gas gangrene Gas gangrene, which is a form of wet gangrene, involves infection of body tissue by certain types of bacteria (such as *Clostridium perfringens*, klah-STRIH-de-um per-FRING-enz) that are capable of thriving in anaerobic (ah-nuh-RO-bik) conditions (in which there is little or no oxygen). Once present in the tissue, these bacteria release toxins* and gas. Gas gangrene is marked by a high fever, brownish pus*, gas bubbles under the skin, skin discoloration, and a foul odor. It is the rarest form of gangrene, and only 1,000 to 3,000 cases occur in the United States each year. Like wet gangrene, gas gangrene can be fatal if not treated immediately.

How Do Doctors Diagnose and Treat Gangrene?

A doctor makes the diagnosis of gangrene based on a physical examination, the patient's medical history, and the results of blood and other laboratory tests. Cultures from the gangrenous area may be taken and laboratory tests performed to identify the type of bacterial infection and determine the extent to which an infection has spread.

▲ People with poor circulation may experience dry gangrene from loss of oxygen and nutrients carried by blood to the extremities. If the tissue turns black and dies, it must be removed surgically. SPL/Photo Researchers, Inc.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **arteriosclerosis** (ar-teer-e-oslav-RO-sis) is a condition in which arteries of the body have become narrowed and hardened from the buildup of calcium, cholesterol, and other substances, causing decreased blood flow through these vessels.

* **frostbite** is damage to tissues resulting from exposure to low environmental temperatures. It is also called congelation (kon-jeh-LAY-shun).

* **toxins** are substances that cause harm to the body.

* **pus** is a thick, creamy fluid, usually yellow or greenish in color, that forms at the site of an infection. Pus contains infection-fighting white cells and other substances.

* **amputation** (am-pyoo-TAY-shun) is the removal of a limb or other appendage or outgrowth of the body.

* **shock** is a serious condition in which blood pressure is very low and not enough blood flows to the body's organs and tissues. Untreated, shock may result in death.

Dead gangrenous tissue must be removed surgically by a procedure called debridement (deh-BREED-ment) so that the wound can heal and healthy new tissue can grow. People with gangrene caused by bacterial infections are treated with antibiotics. In more severe cases, amputation* of a finger, toe, or part of a limb may be necessary. Sometimes patients with gangrene are treated in a hyperbaric chamber, where they are exposed to oxygen at a high pressure to help the affected tissue heal.

The outcome for gangrene is usually favorable if the condition is recognized and treated early. Full recovery and new tissue growth can take several weeks to months. Sepsis, a potentially serious spread of infection through the bloodstream and body, can result from wet and gas gangrene. If left untreated, sepsis can result in shock* or death.

Can Gangrene Be Prevented?

Carefully cleaning and watching wounds for signs of infection can help prevent gangrene. It is wise to seek medical attention for any wounds that are not healing well or look infected. People who are susceptible to dry gangrene, such as those with decreased circulation in their legs and feet from diabetes or arteriosclerosis, are advised to pay attention to any skin infection in those areas (because such infections can lead to the development of wet gangrene) and to avoid smoking (because smoking constricts the blood vessels, further decreasing circulation). Daily foot care and hygiene is very important in people with advanced diabetes. Treatment with antibiotics before and after abdominal surgery has been shown to reduce the rate of infection and the possibility of developing wet or gas gangrene.

Gastroenteritis

Gastroenteritis (gas-tro-en-ter-I-tis) is a disease in which the lining of the stomach and intestines becomes inflamed, resulting in what is sometimes referred to as an upset stomach or stomach flu.

What Is Gastroenteritis?

Gastroenteritis is a general term for inflammation* of the gastrointestinal (gas-tro-in-TES-ti-nal) tract, the part of the digestive system consisting of the stomach, small intestine, and large intestine. Loss of appetite, vomiting, cramps, nausea*, and diarrhea* are the most common symptoms of gastroenteritis. In the United States, gastroenteritis usually is a mild disease. In countries in which water supplies are dirty, sewage treatment is poor, or medical facilities are scarce, it sometimes leads to death.

What Causes Gastroenteritis?

There are many different causes of gastroenteritis. Viral infections are the most common cause in the United States. Certain bacteria and parasites that can get into food or water supplies also can lead to the disease. In addition, gastroenteritis can result from food allergies or sensitivities, side effects of certain medications, and alcohol or toxic (poisonous) substances.

How Is Gastroenteritis Treated?

Mild gastroenteritis usually lasts just two or three days. Often, the only treatment needed is rest and drinking lots of clear fluids. However, gastroenteritis can be serious if vomiting and diarrhea cause dehydration (de-hy-DRAY-shun), a condition that results when a person loses fluid and body salts faster than they can be replaced by drinking. If a person becomes dehydrated, hospitalization may be needed to deliver intravenous (in-tra-VEE-nus) fluid replacement therapy. Intravenous (IV) therapy replaces lost fluid by dripping liquids and salts directly into the bloodstream through a small needle inserted into a vein.

How Can Gastroenteritis Be Prevented?

Washing the hands thoroughly after using the toilet and before handling food and before eating are important ways to prevent infectious gastroenteritis. Preparing and storing food properly also are important. For people who plan to visit developing countries, vaccines* are available against some of the diseases that cause gastroenteritis.

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

* **nausea** (NAW-zha) refers to a feeling of being sick to one's stomach or needing to vomit.

* **diarrhea** (di-ah-RE-a) refers to frequent, watery stools (bowel movements).

* **vaccines** (vak-SEENS) are preparations of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.

- * **bisexual** (bi-SEK-shoo-al) means being sexually attracted to both sexes.
- * **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).
- * **genitals** (JEH-nih-tul) refers to the external sexual organs.
- * **androgynous** (an-DRAW-gin-us) having characteristics of both sexes.
- * **transgendered** a person who identifies with and expresses a gender identity that differs from the one which corresponds to the person's sex at birth.

Gay, Lesbian, Bisexual, and Transgender Health

The gay, lesbian, bisexual, and transgender (GLBT) community in the United States consists of a diverse group of people of all ages, races, cultures, genders, and socio-economic backgrounds. Generally, the health concerns of GLBT people are no different than those of heterosexuals. Some health concerns are of specific concern to GLBT communities, however. For instance, gay men are at a higher risk of contracting HIV*/AIDS*. GLBT are also subject to societal bias, violence, and discrimination that can lead to mental health problems such as depression and anxiety.*

What Is Gender?

In its simplest form, the word “gender” refers to a person’s sex (male or female). For many reasons, however, people identify with gender and gender roles differently. Gender can be defined in many different ways, including physiologic gender, emotional gender, and social gender.

Physiologic gender Before the twentieth century, a person’s sex was determined solely based on his or her external genitals.*. Advances in technology have allowed for a fuller understanding of chromosomes and their effect upon gender identity. Generally, human beings are considered either male (with XY chromosomes) or female (with XX chromosomes). In some cases, though, there are combinations of chromosomes and genitalia that do not comply with the traditional definitions of male and female gender. For example, a person born with male or female genitalia may exhibit physical characteristics that are traditionally attributed to the opposite sex. These androgynous* attributes include body shape, body and facial hair, and tone of voice. In addition, some studies suggest that homosexuality itself is genetically determined.

Emotional gender Some individuals emotionally identify more with the opposite gender. There is an apparent conflict between the person’s physical sex and what his or her brain believes to be the essential or true identity, and this inner sense of identify may not comply with socially mandated roles. In some cases, this apparent conflict is resolved by social or professional choices that are fulfilling to individuals. However, profound confusion or contradiction between the physical and emotional identities may cause some individuals to be diagnosed with gender identity disorder. Some people who experience gender identity issues opt to undergo surgical procedures (gender reassignment) to change their sexual characteristics. These people are transgendered*. Gender reassignment surgery strives to create in the body of an individual the sexual physical traits of the opposite sex. This kind of surgery might include either the

removal of a person's breasts, testicles*, or penis, or the addition of breasts or female or male sex organs.

Social gender Social gender refers to the traditional roles that men and women are expected to conform to, based on their physiological gender. In every society, males and females are typically assigned certain gender roles that are widely considered acceptable. For example, in the United States, girls are encouraged to choose toys that are perceived to be feminine, such as dolls, dress-up clothes, kitchen toys, and play cosmetics. Boys are encouraged to choose toys that are perceived as masculine, such as cars, trucks, sports equipment, tools, and play weapons. When children grow up, these social norms predict the girls will become nurturers in roles such as nurses, grade-school teachers, and social workers, and boys will be masterful and dominant in roles such as doctors, scientists, and soldiers. As adults, while there is a majority of one sex in a given role, the opposite sex is represented, too. Men are nurses; women can be truck drivers and soldiers. Thus, stereotypical expectations, which condition children to accept gender-specific roles, do not suit everyone.

What Are GLBT Healthcare Concerns?

Many people feel a level of embarrassment or inhibition that prevents them from seeking medical assistance. If the problem that draws them into the medical setting is assumed to trigger prejudice in the care giver, people may be reluctant to seek medical help. Like other minorities, GLBT people may face bias and discrimination in healthcare settings. For that and other reasons, some people may be reluctant to seek routine medical treatment. Regarding sexual issues, people may feel uneasy discussing their concerns. A young woman who is pregnant but unmarried may feel this hesitancy in seeking help. In the same way, members of the GLBT community may feel hesitant in instance in which the problem is personal and sexual in nature and about which the patient fears the medical provider may have strong opinions. Many medical professionals are not sensitized to treat their patients in a neutral and nonjudgmental way. Plus some controversial federal legislation proposed in 2008 suggested the medical professionals do not have to provide services if they have moral objections to them. GLBT individuals, like others seeking certain services, may be inclined to fear prejudice and criticism among the medical professionals they seek help. In addition, because people in same-sex relationships may not have domestic partner benefits, these individuals are at risk for being uninsured, further compounding the problem of seeking medical help.

What Illnesses and Diseases Affect the GLBT Community

For the most part, GLBT people have the same health concerns that heterosexual* people do, and they live as healthy or unhealthy lives as the rest of the population does. All people can get cancer, heart disease, and HIV/AIDS. All sexually active people ought to be concerned about diseases

* **testicles** (TES-tih-kulz) are the paired male reproductive glands that produce sperm.

* **heterosexual** (he-te-ro-SEK-shoo-al) refers to a tendency to be sexually attracted to the opposite sex.

- * **sexually transmitted disease** is an infection, such as the human immunodeficiency virus (HIV) or herpes, that can be passed from person to person by sexual contact.
- * **anal** refers to the anus, the opening at the end of the digestive system through which waste leaves the body.
- * **herpes simplex** (HER-pee-z SIM-plex) is a virus that can cause infections of the skin, mouth, genitals, and other parts of the body.
- * **syphilis** (SIH-fih-lis) is a sexually transmitted disease that, if untreated, can lead to serious life-long problems throughout the body, including blindness and paralysis.
- * **chlamydia** (kla-MIH-dee-uh) are microorganisms that can infect the urinary tract, genitals, eye, and respiratory tract, including the lungs.
- * **gonorrhea** (gah-nuh-REE-uh) is a sexually transmitted disease (STD) spread through all forms of sexual intercourse. The bacteria can also be passed from an infected mother to her baby during childbirth. Gonorrhea can affect the genitals, urethra, rectum, eyes, throat, joints, and other tissues of the body.
- * **contraception** (kon-tra-SEP-shun) is the deliberate prevention of conception or impregnation.
- * **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

that can spread through sexual activity and need to take precautions regarding them. However, many individuals are uninformed or deny being at risk, and so they engage in activities that may hurt them and their sexual partners.

A sexually transmitted disease* is one that is transmitted between humans through sexual contact, which includes vaginal or anal* intercourse and oral sex. STDs are caused by bacteria, parasites, and viruses. There are more than 20 STDs, including the following:

- HIV and AIDS
- Herpes simplex*
- Syphilis*
- Chlamydia*
- Gonorrhea*

STDs are prevalent among individuals who take sexual health risks and have multiple partners. HIV/AIDS is also a risk for drug users who share infected needles.

Lesbian health As a group lesbians have fewer pregnancies and use less oral contraception*. Those who do not use contraception or get pregnant face neither the risks nor the benefits of these choices. Lesbians who do not have health insurance may visit healthcare providers less frequently than insured individuals, which is also true for the general population. Individuals who use tobacco, have high alcohol consumption, poor nutrition, and are obese* have physical concerns apart from their sexual orientation.

Gay men's health Gay men (clinically referred to as men who have sex with men, or MSM), along with drug-addicted men who share needles, are at risk for contracting HIV/AIDS. When AIDS first appeared in the United States in the early 1980s, the disease was noted specifically among homosexual men. While the disease is contracted by heterosexual men too and by both heterosexual and homosexual women, it has had particularly high rates among American gay men. During the late twentieth century and into the early 2000s, knowledge about the risks of HIV/AIDS spread in the United States. Gay men, along with other men, need to take precautions to help protect themselves from this disease. As of 2009, testing for HIV was more routinely performed, and information was increasingly distributed about this infectious disease. MSM are also at risk of contracting STDs, just as other people are who engage in risky sexual behavior, as in not using condoms consistently, or who have multiple partners.

Transgender health There is limited statistical health information about transgendered individuals, perhaps because they represent such a small minority. Among this group, individuals who act as prostitutes are at particular risk for STDs, just as heterosexual prostitutes are. Risky behaviors such as having multiple sexual partners, sharing needles among IV drug users, and inconsistent use of condoms place these individuals

at risk, as it does all others who engage in these behaviors. Some transgendered individuals may have less access to health care because they are underinsured or uninsured, discriminated against, or afraid of discussing their health and orientation with mainstream medical professionals.

What Mental Health Issues Confront the GLBT Community?

Every human being is susceptible to becoming overwhelmed by stress and pressure, which can lead to mental health issues such as depression, anxiety, substance abuse, and suicide. Because of discrimination, bias, stigma, social pressure, and hate crimes, GLBT persons are at particular risk of having psychological problems. Minority status and laws that underscore it potentially add stress for all individuals who feel like or are outsiders to the dominant culture. This pattern of increased stress can be noted among foreign speakers, illegal aliens, racial minorities, the poor and/or homeless, along with sex-linked minorities.

How Does the GLBT Community Engage in Family Planning

Just like many heterosexual individuals, many GLBT people choose to start their own families and raise children. However, same-sex couples who wish to have children must select alternative paths, which infertile heterosexual couples who want children may explore as well. Some adopt children, and others use various methods to conceive and give birth. Several options are available to same-sex couples and to infertile heterosexual couples:

- In vitro fertilization (IVF) is a process by which a woman's eggs are fertilized outside the body (in vitro). The fertilized egg is then implanted in the uterus, where it can develop into a fetus.
- Artificial insemination involves mechanically placing sperm directly into a woman's uterus in the hopes of fertilization.
- Surrogacy is an arrangement in which one person gestates for another person to adopt. A woman agrees to become pregnant for the sole purpose of carrying a fetus to term for another person who is unable or unwilling to do so. The surrogate agrees to give up the child and all rights regarding the child to the adoptive parent.
- Adoption allows a child to become the legal dependent and responsibility of someone other than its biological parents. The child is permanently placed in a home of the adoptive parent or parents, who agree to raise the child in the same way a biological offspring would be raised.

What Are Hate Crimes?

Hate crimes are illegal acts committed against persons due to race, ethnicity, gender, or sexual orientation and against individuals who sympathize or stand with members of these groups. Hate crimes may involve assault, battery, rape, torture, and murder. Sometimes these crimes have specific

* **incidence** means rate of occurrence.

HIGH PROFILE HATE CRIMES

Numerous high profile hate crimes have brought national attention to the issue of violence against GLBT people.

In 1993, 21-year-old Teena Renae Brandon, an androgynous female who acted and dressed like a male and called herself Brandon Teena, was raped and later murdered in Lincoln, Nebraska, after her physical sexual identity was discovered. The documentary, *The Brandon Teena Story*, served as the basis for the 1999 Academy Award winning film *Boys Don't Cry*, starring Hilary Swank.

In 1998, 21-year-old Matthew Shepard was kidnapped, beaten, and left to die near Laramie, Wyoming. Shepard's death brought national attention to hate crimes, and it spurred state and federal governments to enact hate crime legislation. There have been various films, plays, books, and songs written about Shepard and his murder.

In 2002, 17-year-old Gwen Araujo was beaten and murdered. Araujo was born male but passed as a female and wished to have a sex-change operation. In 2008, 15-year-old Lawrence King, a gay teen, was shot in the head by a fellow student as he sat at his desk in the computer lab of E.O. Green School in Oxnard, California.

These infamous murders made hate crimes more visible and helped to create awareness and legislation to prevent hate crimes and protect people at risk of victimization.

religious, political, or cultural motivations, but other times there seems to be no motivation besides hate. Hate crimes may be perpetrated by individuals or groups, but in some countries, governments torture and execute minority individuals, including those suspected or accused of being gay, lesbian, bisexual, or transgender.

In 2007 the National Coalition of Anti-Violence Programs reported a 24-percent increase in reported hate crimes against GLBT people from the previous year. These included a 61-percent increase in sexual assaults, and the highest murder rate in ten years. In that same period, the number of hate crimes grew by 5 percent.

Domestic violence Domestic violence is a serious problem among both heterosexual and homosexual people, and the incidence* is about the same for the two populations. Many kinds of abuse occur in intimate relationships, including physical violence, emotional and verbal abuse, sexual abuse, and financial intimidation. Many victims of domestic abuse are afraid or ashamed and do not seek help in dealing with their abusive partners.

What Legal Issues Confront the GLBT Community

GLBT people face many legal difficulties that heterosexual people do not face.

Same-sex marriage In the early 2000s, there were six countries that recognized same-sex marriages: Spain, Netherlands, Belgium, Norway, Canada, and South Africa. In 1996 the U.S. Congress passed the Defense of Marriage Act (DOMA), which stated that individual states were not obliged to treat same-sex unions the same as heterosexual marriage and that the federal government would not treat them as the same. Twenty-six states passed amendments that banned recognition of same-sex marriage. As of 2008, only Massachusetts and California recognized same-sex marriages, and the law in California was being contested. New Jersey, Vermont, Connecticut, and New Hampshire allowed civil unions, which provided same-sex couples with benefits and rights similar to those enjoyed by married couples. Domestic partnerships, which grant couples some or all of the rights of marriage, were available in California, Washington, Oregon, Maine, and the District of Columbia.

Estate planning All people need to protect their estates with legal documents, but same-sex couples face certain hurdles that married couples do not. The estates of people who do not prepare for serious illness, injury, or death with advanced legal directives may end up in the hands of the state. Rights of survivorship for married individuals direct the state to disperse an estate to the surviving spouse, whereas laws against same-sex marriage may prevent the state from dispersing an estate to a surviving same-sex partner. For instance, if a gay man dies without a will, his assets may be divided among immediate family members but exclude his legally unrecognized long-term partner. Proper advanced planning can prevent this scenario. Because their intimate relationships are typically not recognized by state law, GLBT individuals need to secure legally their wishes regarding the dispersal of their estates. They can protect themselves by drawing up a will or trust, establishing medical power of attorney, drafting a living will, and designating power of attorney.

Another issue for same-sex couples concerns retirement benefits. In the event of a retired married person's death, the surviving spouse receives the retirement and social security benefits. However, that is not the case for the survivor of a same-sex couple. The prohibition that excludes the surviving member of a same-sex union causes some individuals to set up individual retirement plans for the survivor's protection.

What Family Therapy Resources Are Available to the GLBT Community?

Supporting gay, lesbian, bisexual, or transgendered loved ones can be difficult, given the dominant social prejudice against them. Many people benefit from counseling, therapy, or support groups that help them to understand the problems that their loved ones may face, including discrimination; abuse; and work, family, and relationship difficulties. Such groups as Parents, Families, and Friends of Lesbians and Gays (PFLAG) teach tolerance and acceptance and work to normalize people's attitudes toward sexual differences.

Gender Identity Disorder

Gender identity disorder (GID) is a medical diagnosis for someone who feels a strong sense of discontent with the biological (physical) gender that he or she has been assigned. These individuals often feel a strong desire or need to belong to the sex opposite their own and will dress and behave in ways traditionally ascribed to the opposite gender. People with this condition are generally referred to as transsexuals.

What Is Gender Identity Disorder?

Gender Identity Disorder is a complex condition in which individuals strongly identify with the gender opposite their own and feels trapped or stuck in the wrong body. To better understand this condition, a few terms must be defined:

- **Gender** is the category (male or female) a person is assigned to on the basis of biological sex. The term is used in discussing the different roles, identities, and expectations that the dominant society traditionally associates with males and females.
- **Gender identity** refers to individuals's own perception of their maleness or femaleness.

- **Feminine and masculine** are often used to describe behaviors generally associated with females or males. For example, boys are encouraged to choose toys and activities that are traditionally associated with masculinity, such as cars, sports, tools, and play weapons. By contrast, girls are encouraged to choose dolls, play cosmetics, and dress-up clothes, which are typically considered feminine.
- **Sex** usually refers to the biological (physical) differences between females and males. Specifically, these characteristics are the sex chromosomes* and certain anatomical features, for example, the penis or the vulva*.

Many people identify with, or conform to, traditional roles and expectations that the culture assigns to males and females. Sometimes, individuals may enjoy activities that are most often associated with the opposite sex. For example, someone who is biologically female may like to play football, and someone who is biologically male may like to do embroidery. Generally, this does not interfere with a person's sense that she or he is female or male, and it does not mean that she or he has gender identity disorder. GID should not be confused with nonconformity to traditional or typical gender roles. People who do not conform with all aspects of traditional gender roles seldom have any desire to be the opposite sex.

What Is Cross-Gender Identification?

GID goes beyond a failure or reluctance to identify with traditional roles or expectations about being female or male. There is nothing unusual about girls who prefer football to piano or boys who needlepoint to tools. A person with GID who is biologically female has a strong sense that she is a male. Likewise, a person with GID who is biologically male has a strong belief that he is a female. Cross-gender identification often causes an incredible amount of distress and can impair a person's ability to function. When that occurs, a person is said to have GID.

Mental health Most people realize that they have GID before adolescence. Children with GID may suffer from mental health issues such as depression, anxiety, and low self esteem. This may result in a child's refusal to attend school or social events where feminine or masculine clothing or behavior is expected, because they fear teasing or rejection by their peers. Because these children may choose behaviors and an outward appearance that are traditionally attributed to members of the opposite sex, they may feel isolated from other children. Children with gender identity disorder often express wishes to be the other sex or beliefs that they will "grow up to be" the opposite sex. Young children with this condition may be unhappy about their assigned sex. Older children may fail to develop age-appropriate same-sex relationships with their peers. For adolescents, GID can be very difficult, because these individuals may struggle with feelings of uncertainty about the opposite gender identification or be concerned about being unacceptable to their own family or peers.

Stigma

Boys with GID seem to suffer more than girls, perhaps because of culturally influenced rejection by their peers. In some studies, five times as many boys as girls saw a doctor for GID. Among adults, two or three times as many men as women sought help for GID. This difference probably is due to the greater social difficulties experienced by males who have Gender Identity Disorder.

* **chromosomes** (KRO-mo-somz) are threadlike chemical structures inside cells on which the genes are located. There are 46 (23 pairs) of chromosomes in normal human cells. Genes on the X and Y chromosomes (known as the sex chromosomes) help determine whether a person is male or female. Females have two X chromosomes; males have one X and one Y chromosome.

* **vulva** (VUL-vuh) refers to the organs of the female genitals that are located on the outside of the body.

- * **genitals** (JEH-nih-tuls) are the external sexual organs.
- * **genetically** (je-NE-ti-klee) means due to heredity and stemming from genes. Genes are located on the chromosomes in cells of the human body that help determine physical and mental characteristics, such as hair and eye color. The X and Y chromosomes contain genetic information that determines sex.
- * **bisexual** (bi-SEK-shoo-al) means being sexually attracted to both sexes.
- * **heterosexual** (he-te-ro-SEK-shoo-al) refers to a tendency to be sexually attracted to the opposite sex.
- * **hormone** is a chemical substance that is produced by a gland and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

Intersex conditions GID is not the same as intersexuality, or intersex conditions. Intersex conditions may be marked, for example, by genitals* that are not completely male or female. The person with this condition may be genetically* male but physically female (or the opposite). For example, a male with an intersex condition would have the XY sex chromosomes of males, but his genitals might appear female. Whereas there are many variations and degrees of intersexuality, about 1 in 1,500 to 1 in 2,000 children are born with noticeably atypical genitalia.

Cross-dressing There also is a difference between GID and transvestitism. A cross dresser or a transvestite becomes sexually excited by dressing in the clothes of the opposite sex. Often, the term transvestite is applied to gay or bisexual* men who dress in women's clothing, and the term cross dresser is applied to heterosexual* men who dress in women's clothing. Transvestites and cross dressers should not be confused with transsexuals (people with GID) who cross-dress to gain a sense of physical and emotional completeness rather than sexual excitement.

Gender Reassignment

The causes of GID are uncertain. Some researchers think that biological factors play a role, and others think that environmental factors, such as the lack of a bond with a parent or caregiver during childhood, are involved. The more important question may be how to resolve the problems that GID may create.

The emotional strain GID causes is real, and, for some adults, the only effective relief for this distress is a gender reassignment procedure, which usually involves sex-change surgical operations that remove and create physical genitalia. Because of the irreversible nature of these procedures, candidates must undergo extensive psychological screening and physical preparation that can take several years to complete.

Screening Gender reassignment procedures begin with lengthy and detailed screenings, as well as psychological evaluations. These interviews determine the existence and severity of GID. The person then is instructed about adopting a lifestyle that agrees with his or her gender identity, which is called real life experience (RLE). If people successfully adjust to this lifestyle change over a period of several months to a year, they often then begin hormone* therapy to develop more of the physical traits of the desired sex. Female patients transitioning to males take androgens, and males transitioning to females take testosterone blocking agents, estrogen, and progesterone.

Surgery After patients successfully complete screening, psychological evaluation, RLE, and hormone therapy, they are ready to undergo gender reassignment surgery. For males wishing to become females, hormone treatments may produce satisfactory breast development, although some people choose later to have breast enlargement surgery. Many people also

elect to have a bilateral orchiectomy, or removal of the testicles, rendering the person infertile and without testosterone. In male to female reassignment, a tracheal shave may be performed in which the Adam's apple is made to appear smaller by removing part of the trachea*. Body and facial hair growth is reduced by the hormone treatments and hair may also be removed by electrolysis*. Males who have gender reassignment surgery to become females undergo vaginoplasty, or the construction of a vagina from the penis, and are able to have sexual intercourse.

Females wishing to become males usually elect to have surgery to remove the breasts (bilateral mastectomy), the uterus*, and the ovaries* and to seal off the vagina*. The operation to construct a penis is extremely complicated, and the resulting penis is not capable of a natural erection. There are, however, artificial devices, such as erectile implants, which can be used to help the person achieve erection and successfully engage in sexual intercourse.

Life after Gender Reassignment Surgery There have been several worldwide studies conducted to assess the outcomes of sex-change surgery. These studies have shown that 9 in 10 transsexuals who undergo hormonal and surgical sex-reassignment procedures experience a satisfactory result. One of the studies found that 94 percent of the people who underwent the surgery and answered questionnaires stated that if they had it to do over again, they would make the same choice.

Genetic Diseases

Genetic diseases are disorders that are inherited from one's biological parents or are acquired as a result of a spontaneous genetic change.

What Is Heredity?

Individuals develop under the influence of a mix of genes* inherited from their biological parents. These genes, or small parts of chromosomes*, determine the architecture and activity of the entire body. They determine visible characteristics, such as eye color, skin color, and height, as well as traits that cannot be seen, such as the risk of certain diseases, the chemicals made by the body, and the functioning of body systems.

Normally, each cell in the body contains two copies of each gene: one that originally came from the egg of the mother and one from the sperm of the father. In many instances, these two copies are slightly different from each other. The result is a child who has some characteristics from the mother and some from the father, but who is never identical to either parent.

Because the cells have two copies, a gene that works normally can usually make up for one that has a defect. For example, a gene with a defect that causes a particular disease may pass down through generations of a family without causing illness. That is because the normal gene in the pair may work well enough to mask the defect of the other gene. However, if a child inherits two genes with the defect, the child will develop the illness, which explains how a child with a genetic disease can be born to parents without it.

What Causes Genetic Diseases?

Individuals can inherit genetic disorders, in which case they are born with the diseases, although some diseases have no symptoms at first. In some instances, however, individuals do not inherit the genetic diseases,

but instead they develop genetic diseases that occur spontaneously when disease-causing mutations* occur during cell division* occur. Since these spontaneous diseases involve changes in the genes, they are also known as genetic disorders.

Some inherited genetic disorders, such as cystic fibrosis* and phenylketonuria* (PKU), result simply from the inheritance of genes that do not work properly. In other disorders, however, genetic and environmental factors seem to work together to cause changes in otherwise normal genes. For example, some forms of radiation or chemicals can cause cancer in people who are prone to be affected due to their genetic makeup.

How Are Diseases Inherited?

How modern genetics began Gregor Mendel (1822–1884) is considered the father of modern genetics*. Mendel was an Austrian monk. While growing peas in the monastery garden, Mendel noted that certain traits appeared in offspring in predictable patterns, and he began to understand the basic rules of inheritance. These rules are called Mendelian (men-DEL-ee-an) laws.

Dominant and recessive genes Under Mendelian laws, each person normally has two copies of every gene, one from the mother and one from the father. A physical feature or a disorder carried by genes can be either a dominant (**G**) or a recessive (**g**) trait. An individual can therefore have one of three combinations: two dominant genes (**GG**), two recessive genes (**gg**), or one of each (**Gg**). If a person has two dominant genes, the dominant trait will appear. If the individual has two recessive genes, the recessive trait will appear. If the individual has one dominant gene and one recessive gene, only the dominant trait will appear because it is the “stronger” of the two. In Mendel’s peas, the trait for smooth peas was dominant over the trait for wrinkled peas. Thus, if a pea plant contains two genes for “smooth”, or one gene for “smooth” and one for “wrinkled,” the seed will be smooth. The pea is only wrinkled when it has two genes for “wrinkled.”

This pattern is also work in the way genetic diseases are inherited. If the disease-related gene is recessive, only individuals with the two copies of the recessive gene will develop the disorder. Therefore, a person with the pattern (**gg**) will be affected, but (**GG**) and (**Gg**) will not be affected by the disorder. If the disease-related gene is dominant, by contrast, a person with the patterns (**GG**) or (**Gg**) will be affected, but (**gg**) will not be affected by the disorder. Two copies of a dominant gene produce a much more serious form of the disorder.

Autosomal and sex-linked traits Of the 23 pairs of chromosomes in human cells, one pair are sex chromosomes, which determine a person’s gender. Sex chromosomes are called X and Y chromosomes. Females have two X chromosomes (**XX**), and males have one X and one Y chromosome (**XY**). The reproductive cells (egg and sperm) each have only one set of

A Genetic Glossary

- **Cells:** The units that comprise living beings. The human body is made of about 60 trillion cells.
- **Nucleus:** A membrane-bound structure inside cells that contains DNA.
- **Chromosomes:** DNA is packaged into units called chromosomes. Humans have 23 pairs of chromosomes, for a total of 46.
- **DNA (deoxyribonucleic acid):** A double-stranded molecule, made of chemical bases called nucleotides, that contains the genetic code necessary to build a living being.
- **Genes:** Segments of DNA located on the chromosomes. Genes are the units of heredity. They help determine a person’s characteristics, from eye color to how various chemicals work in the body.
- **Genome:** An animal’s entire collection of genes. The human genome contains approximately 25,000 genes.

* **mutations** (mu-TAY-shuns) are changes in a chromosome or a gene.

* **cell division** is the process by which a cell divides to form two daughter cells, each of which contains the same genetic material as the original cell.

* **cystic fibrosis** (SIS-tik fy-BRO-sis) is a disease that causes the body to produce thick mucus that clogs passages in many of the body’s organs, including the lungs.

* **phenylketonuria** (fen-ul-ke-ton-U-ree-a), or PKU for short, is a genetic disorder of body chemistry that, if left untreated, causes mental retardation.

▲
Three common inheritance patterns.
Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.

* **genetics** (juh-NEH-tiks) is the branch of science that deals with heredity and the ways in which genes control the development and maintenance of organisms.

23 chromosomes. While an egg always carries an X chromosome, a sperm cell can carry either an X or a Y, so it is the sperm that determines gender in the offspring. Inherited genetic disorders that are carried on the sex chromosomes are referred to as sex-linked. Sex-linked disorders usually affect males more often than females, because a female has two copies of the X chromosome, each of which carries a set of genes. In contrast, a male has only one X chromosome, so he has only one set of these genes. If his copy is damaged or defective, he has no normal copy to override or mask the defective one. Depending on the problem with the gene, the result can be an X-linked disorder.

Besides the sex chromosomes, human cells have 22 other pairs of chromosomes. These are called autosomes (AW-to-somes), or non-sex chromosomes, and disorders carried on these chromosomes, which are numbered 1 through 22, are referred to as autosomal (aw-to-SOME-al). In general, autosomal disorders are likely to affect males and females equally.

What Are the Common Inheritance Patterns of Genetic Diseases?

Single-gene autosomal diseases Most genetic disorders are caused by defective genes on the autosomes. If a single gene is responsible, then the following rules of inheritance usually apply. Exceptions exist, but these rules are useful guidelines for understanding inheritance. In an autosomal dominant disorder, the following applies:

- Only one copy of the gene is necessary to cause the disorder. So if a child inherits the disease, at least one of the parents has the disease as well.
- It is possible for the gene to change by itself in the affected person. This change is called a mutation. In this case, the disease is not passed down from a parent.
- Unaffected children of a parent with the disorder have unaffected children and grandchildren.

In an autosomal recessive disorder, the following applies:

- If two people without the disorder have a child with the disorder, both parents carry one copy of the abnormal recessive gene. Both parents' genetic pattern is therefore **Gg**. The parents are called "carriers."
- If a person with the disorder (**gg**) and a carrier* (**Gg**) have a child, that child has a fifty-fifty chance of having the disorder. Any child without the disorder will be a carrier.
- If a person with the disorder (**gg**) and a non-carrier (**GG**) have children, all of the children will be carriers (**Gg**), but none will have the disorder.
- If two people with the disorder (**gg**) have children, all of the children will have the disorder (**gg**).

Single-gene sex-linked diseases More than 150 disease traits are carried on the X chromosome. X-linked dominant disorders are rare. In an X-linked recessive disorder, the following applies:

- Nearly all people with sex-linked disorders are male. The disorder is transmitted through the female, because a son's X chromosome always comes from his mother. (The other sex chromosome, the Y chromosome, always comes from the father. A female, by contrast, receives two X chromosomes—one from her mother and one from her father—and no Y chromosome.) The mother is unaffected, however, because she has a second X chromosome that usually contains a normal gene for the trait.
- A male with the disorder never transmits it to his sons, because a father passes only his Y chromosome to his sons. Only his daughters receive his X chromosome.
- A son born to a female carrier (**Gg**) has a fifty-fifty chance of having the disorder, because he may receive the affected X chromosome, rather than the unaffected one.
- All daughters of affected males will be carriers, because they will all receive the father's affected X chromosome.

Multiple-gene diseases Many disorders are exceptions to the Mendelian laws of inheritance. One reason is that numerous genetic disorders result from a combination of many genes, rather than a single affected gene. These genetic disorders are known as multifactorial (mul-tee-fak-TOR-e-al) disorders. In addition, some disorders show reduced penetrance (PEN-e-trance), which means that a gene is not wholly dominant or recessive. For example, a person who has one recessive gene for a disorder might show milder symptoms of the disorder, but someone with two copies will have the full-blown disorder.

Chromosome disorders Other genetic disorders result from extra or missing chromosomes. In Down syndrome*, a person has three copies

* **carrier** is a person who has in his body a bacterium or virus or gene for a disease that he can transmit to other people without getting sick himself.

* **Down syndrome** is a genetic disorder that can cause mental retardation, shortness, and distinctive facial characteristics, as well as many other features.

- * **cri du chat** (kree-doo-SHA), French for cat's cry, is a genetic disorder that can cause mental retardation, a small head, and a cat-like whine.
- * **Turner syndrome** is a genetic disorder that can cause several physical abnormalities, including shortness, and lack of sexual development.
- * **embryo** (EM-bree-o), in humans, is the developing organism from the end of the second week after fertilization to the end of the eighth week.
- * **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.
- * **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.

of chromosome 21, rather than the usual two copies. In cri du chat*, a piece of chromosome 5 is missing. In Turner syndrome*, which affects only girls, all or part of an X chromosome is missing.

In most cases, chromosome disorders are not inherited. Instead, the problems occur for unknown reasons when the egg and sperm meet to form the embryo*.

Spontaneous (new) genetic mutations Sometimes, a child may be born with a dominant inherited disorder even though neither parent has the disorder. The cause is usually a spontaneous (or new) mutation in a gene or genes. The mutation may occur in a parent's egg or sperm cell, or it may occur after the egg has been fertilized and begins to develop into an embryo. This is frequently the case in achondroplasia (a-kon-dro-PLAY-zha), a form of dwarfism in which 90 percent of children born with the condition have unaffected parents. When this child grows up, the child will pass the gene on to his or her children according to the autosomal dominant inheritance pattern described above.

The Past and Future of Genetic Diseases

Mendel figured out the basic concepts of inheritance in the 1800s, before people knew that genes are the units of inheritance. It was not until 1953 that scientists described the structure of DNA. From the 1980s into the 21st century, scientists' understanding of genes and how they work grew at an incredibly rapid pace. They identified many disease-causing genes, opening the door to research on ways to fix genetic defects. This field of science is referred to as gene therapy.

Gene therapy A number of treatments for genetic disorders are available. For some disorders, the treatment is a special diet to prevent the buildup in the body of compounds that are toxic to patients. In other disorders, the treatment involves blocking or rerouting chemical pathways and essentially short-circuiting the disease. A third kind of treatment actually replaces defective genetic material with normal genetic material inside the cells. As of 2009 researchers were considering a variety of methods to perform this procedure. These include the use of microscopic "bullets" consisting of genetic material and viruses to deliver normal genes to cells.

Prenatal testing Medical professionals can test a fetus* for many genetic disorders before it is born. They conduct tests for prenatal (before birth) diagnosis on samples taken from the tissue or fluid surrounding a fetus. They then study the fetus's chromosomes using a karyotype (KAR-e-o-type), which is a visual display of the chromosomes from cells viewed under a microscope. Other techniques enable scientists and doctors to look directly at the DNA that makes up the genes contained in the chromosomes. Common prenatal tests include the following:

- **Amniocentesis** (am-nee-o-sen-TEE-sis): In amniocentesis, a needle passes through the mother's belly into her uterus* to collect some

of the fluid in which the fetus lives. This fluid, called amniotic fluid, contains cells from the fetus.

- Chorionic villus (kor-e-ON-ik VIL-us) sampling (CVS): CVS collects cells from the fetus with a needle. In this case, medical professionals remove the cells from the chorionic villi, which are structures in the uterus that are part of the placenta (the organ in the uterus that delivers nutrients and oxygen to the fetus).
- Percutaneous umbilical (per-ku-TAY-ne-us um-BIL-i-kal) blood sampling (PUBS): In PUBS, fetal blood from the umbilical cord*.

Genetic testing and counseling Geneticists believe that each person probably carries about 5 to 10 defective recessive genes. Thus, both potential parents may be worried about having a child with birth defects. If relatives have genetic disorders—or if ethnic or other background factors increase the risk of certain genetic diseases—parents-to-be may be even more concerned. For this reason, some adults seek genetic testing of themselves or their relatives to determine if they are carriers and whether their future children are susceptible to certain genetic disorders. Medical experts recommend that genetic testing is followed by counseling, which advises clients of the nature of the disorders, their options in family planning, and any steps they can take to increase the likelihood of having a healthy child.

Ethical concerns Increasingly in the 21st century, people will have the option to be tested to find out if they carry genes for genetic disorders. For example, women can find out if their unborn children have certain genetic defects or if they themselves have genes that make them more likely to develop certain disorders, such as breast cancer. This advance led to controversy about how this information should be used. Genetic testing can have far-reaching social, financial, and ethical effects. For example, a woman who thinks she will develop breast cancer might decide against having children or might decide to have her breast tissue removed before cancer cells develop. In addition, her insurance company might decide not to insure her because she is a high-risk client. With knowledge comes responsibility, and genetic testing surely will be at the forefront of debates about medical ethics for many years to come.

Inheritance Patterns of Some Genetic Diseases

The following are autosomal dominant disorders:

- Achondroplasia
- Huntington's disease
- Neurofibromatosis

The following are autosomal recessive disorders:

- Albinism
- Cystic fibrosis
- Phenylketonuria (PKU)
- Sickle-cell anemia
- Tay-Sachs disease

The following is a X-linked dominant disorder:

- Diabetes insipidus (one form)

The following are X-linked recessive disorders:

- Color blindness
- Hemophilia
- Hunter's syndrome
- Muscular dystrophy (Duchenne type)

The following are multiple genes disorders:

- Alzheimer's disease
- Some cancers (breast, colon, lung)
- Gout
- Rheumatoid arthritis

* **umbilical cord** (um-BIH-lih-kul) is the flexible cord that connects a baby to the placenta, the organ that unites the unborn child to the mother's uterus, the organ in which the baby develops.

* **contagious** (kon-TAY-jus) means transmittable from one person to another, usually referring to an infection.

Genital Warts

Genital warts are small fleshy growths of skin on or near the sexual organs that are caused by the human papillomavirus and are usually spread by sexual contact.

What Are Genital Warts?

Genital warts may be dome shaped or nearly flat, but most commonly they grow on stalks in clumps that look like small heads of cauliflower. Warts of this shape are called condylomata acuminata (kon-dil-o-MAT-a a-koo-min-NAT-a). Genital warts are highly contagious*, and sexually active individuals have approximately a 60 percent chance of getting them after a single sexual contact with an infected person. Genital warts usually cause no pain, but they can be bothersome or uncomfortable depending on their location.

Human papillomavirus The human papillomavirus (pap-i-LO-ma vi-rus) (HPV) is common and has many subtypes. Genital warts usually are caused by HPV-6 or HPV-11. Many people may become infected with HPV at some point during their lives but not know it because they do not have the visible warts. Among sexually active people in the United States, about 1 percent (1.4 million people) have genital warts and another 14 percent (19 million) have HPV infection without warts.

Cervical cancer Other kinds of HPV (mainly HPV-16 or HPV-18) can cause cancer of the cervix*, part of the female reproductive tract. Even though visible genital warts usually do not contain cancer-causing forms of the virus, women who have warts should be sure to get the yearly test for cervical cancer, called the Pap smear*, that is recommended for all women.

Removing genital warts Genital warts can be removed in a number of ways: by surgery, laser surgery* treatment, freezing (cryotherapy), or repeated treatment with chemicals that the doctor paints directly on the warts. They often recur after being removed. If untreated, they may grow, remain the same, or disappear on their own.

Preventing genital warts The surest protection is sexual abstinence, that is, not having sex at all. Those who have sex with multiple partners have a higher chance of getting infected (although all it takes is having sex with one partner with an HPV infection to become infected), and should always use condoms. Condoms offer protection against infection, although the exact degree of that protection is not known. Medical professionals do not know whether the removal of visible genital warts makes a person's infection less contagious. Even after removal, a person's chance of getting warts again is almost 50 percent.

In 2006, the Food and Drug Administration approved an HPV vaccine, known as Gardasil, for use in girls and women ages 9 to 26. The National Cancer Institute stated that widespread vaccination* had “the potential to reduce cervical cancer deaths around the world by as much as two-thirds, if all women were to take the vaccine and if protection turns out to be long-term.” It also noted that the vaccines can “reduce the need for medical care, including biopsies*, and invasive procedures associated with the follow-up from abnormal Pap tests, thus helping to reduce health care costs and anxieties related to abnormal Pap tests and follow-up procedures.”

Giardiasis

Giardiasis is an infection of the small intestine by the Giardia lamblia parasite. It is spread from person to person or by contact with contaminated water or food. Its major symptom is diarrhea.

What Is Giardiasis?

Giardiasis (je-ar-DY-a-sis) is a common infection caused by the *Giardia lamblia* (je-AR-de-a LAM-bli-a) protozoan, which is a one-celled organism that lives as a parasite*. *Giardia* contamination can occur in any water source, from clear mountain streams to poorly filtered city water supplies. The most common carriers of giardiasis are dogs, beavers, and humans. Giardiasis is easily passed from person to person through poor hygiene.

Giardiasis occurs worldwide in both developed and developing countries and in both temperate and tropical climates. In developing nations, infection rates from 20 to 50 percent may occur. In the United States, the disease is estimated to affect up to 20 percent of the population, with toddlers in diapers at busy day-care centers at particular risk. Giardiasis is the most commonly diagnosed parasitic infection in the United States, and although most cases are relatively mild or asymptomatic, it nonetheless results in thousands of hospitalizations each year.

What Are the Signs and Symptoms of Giardiasis?

It is estimated that more than 50 percent of people with giardiasis have no symptoms or only mild symptoms. When symptoms of giardiasis do occur, they may start gradually or suddenly, usually within one to three weeks after exposure to the parasite. The illness usually begins with frequent watery diarrhea* without blood or mucus. Because giardiasis affects the body's ability to absorb fats and carbohydrates from ingested foods (malabsorption), giardiasis often produces foul-smelling, oily stools that float. Symptoms may also include abdominal* cramps, a swollen or large abdomen, excessive gas, nausea and vomiting, loss of appetite, and sometimes a low-grade fever. Persistent symptoms can lead to weight loss and dehydration*. Severe symptoms may require hospital care.

How Do Doctors Diagnose Giardiasis?

Giardiasis is diagnosed by examination of stool samples under a microscope. Doctors look for evidence of trophozoites (tro-fo-ZO-ites), which are active *Giardia* protozoa inside the body, or for evidence of cysts, which are *Giardia* surrounded by a protective wall, the form of the protozoan during the resting stage of its life cycle. Detecting *Giardia* is difficult, so doctors often need to repeat the stool sample tests several times before they can confirm or rule out *Giardia* infection. Diagnostic tests may sometimes take as long as four or five weeks.

How Do Doctors Treat Giardiasis?

Several drugs are used to treat giardiasis, and some of them work well with a single dose. Sometimes a second round of drug treatment is required. There is some controversy among doctors about whether to treat people who carry the parasite but who do not have symptoms of giardiasis. Treatment is sometimes considered because these individuals may transmit the infection to others and may eventually show symptoms themselves.

How Do People Prevent Giardiasis?

There is no vaccine or prophylactic (disease-preventing) drug for giardiasis. Preventing giardiasis depends on maintenance of safe supplies of drinking water, the sanitary disposal of human and animal waste, washing of fruits and vegetables before eating or cooking, and proper hygiene, which includes thorough washing of hands after going to the bathroom and before eating.

The *Giardia* protozoan can be filtered from water but is otherwise difficult to destroy. It can survive in cold water for as long as two months, and it is resistant to chlorine levels used to purify municipal water supplies. When municipal water supplies have been approved by local health departments, the water may be considered safe to drink. However, when people are camping or traveling, they need to make sure that drinking water, cooking water, and ice come only from safe sources. Clear cold mountain streams may look safe and inviting, but they may also carry the *Giardia* parasite.

* **diarrhea** (di-ah-RE-a) refers to frequent, watery stools (bowel movements).

* **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

Glaucoma

Glaucoma (glaw-KO-ma) is a group of disorders that cause fluid pressure to increase inside the eye, which may result in vision loss.

What is Glaucoma?

If a balloon is slowly filled with water, eventually it bursts. But if the same balloon has several pin-sized holes at one end, then it becomes possible to continue adding water to the balloon to maintain its round shape, without

Anatomy of the eye. The arrows show the flow of aqueous humor from behind the iris, through the pupil, to the front of the eye, where it drains through the canal of Schlemm. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

breaking the balloon, as long as the amount of water being added is equal to the amount escaping through the pinholes.

The eye has a similar system of liquid that continuously flows in and out of a small chamber at the front of the eyeball. The problem for people with glaucoma is that the drainage out of the eye is blocked or not working properly. It is similar to the balloon that is filling with water. Without a way to make room for more liquid, pressure builds up. Although a pressure buildup will not cause the eye to burst, it may damage nerves at the rear of the eyeball that carry images to the brain.

Glaucoma is one of the leading causes of blindness in the United States. It affects more than 3 million people, especially the elderly and people of African ancestry. The disease is also hard to diagnose. Pressure can grow in the eye for years before the effects on vision are noticed. By then, often the damage has been done.

How Does Glaucoma Affect the Eye?

The eye is about the same size as a ping-pong ball and is divided into two compartments. The larger compartment at the rear of the eye contains a gel-like substance called vitreous (VIT-re-us) humor, which helps to maintain the eyeball's shape and to transmit light. The front compartment, or anterior chamber, is smaller and is filled with a watery liquid called aqueous (AY-kwee-us) humor. This clear liquid brings in nutrients vital to the eye's health and carries out waste that can damage it.

The aqueous humor flows from behind the front colored portion of the eye, which is called the iris. It moves through the pupil, the opening in the center of the iris, into the front chamber of the eye. The liquid flows through the chamber and out a tiny drainage canal that has a fine, mesh-like covering. The small hole on the canal rests at an angle where the colored iris meets the cornea, the clear cup-shaped disc at the front of the eyeball.

About 90 to 95 percent of people with glaucoma have a problem with this drainage system. The cause is unknown, as there is no visible blockage. It appears that the cells in the mesh covering the drainage canal do not do their job properly or that they lose their ability to allow proper drainage over time. Glaucoma develops gradually, but there is a rarer acute* form of glaucoma that develops suddenly when the iris closes off the drainage canal. This painful condition constitutes a medical emergency and requires immediate treatment.

The cause of most cases of glaucoma is not understood, although people of African ancestry, people who have diabetes or other family members with glaucoma, or those who have suffered eye injuries are at greater risk. Aging is another risk factor for glaucoma.

How Is Glaucoma Diagnosed?

Except for the rare cases of acute glaucoma that develop suddenly, most people do not realize they have glaucoma. As pressure is building in the eye, many of the millions of nerve cells at the rear of the eye are destroyed. The nerves that die first affect peripheral (pe-RIF-er-al) vision, the ability

* **acute** describes an infection or other illness that comes on suddenly and usually does not last very long.

No Mountain Too High

Glaucoma rarely occurs in young people, but Erik Weilenmayer was born with an eye disease that caused glaucoma. By age 13, he was totally blind. Erik did not let glaucoma prevent him from becoming a teacher and a mountain climber. He has scaled some of the toughest peaks, including Alaska's Mt. McKinley, the highest in the United States.

"When I first went blind, I wondered what I could do," Weilenmayer said in 1998. "It's really a kick to do extreme activities and do them well—and no more dangerously than anyone else."

Erik's accomplishments are a reminder that physical challenges and differences do not have to prevent people from participating in life's most difficult and demanding activities.

to see the sides of a normal field of vision. When the loss of vision becomes severe enough for a person to notice, the damage is so great that little can be done.

The best way to diagnose glaucoma is through an eye exam that uses an instrument called a tonometer (to-NOM-e-ter) to measure the pressure in the eye. One type of tonometer registers eye pressure by lightly touching the eye's surface. Eye drops are used to make this procedure painless. Another tonometer uses a puff of air to measure eye pressure. The doctor or eye specialist (ophthalmologist or optometrist) may also use a scope that shines light in the eye to look for damage to the optic nerve. Peripheral vision can be checked as part of the eye exam.

Why Are Early Diagnosis and Treatment Important?

Diagnosis Early diagnosis of glaucoma is the key to preventing vision loss. If glaucoma is discovered before the increased eye pressure has destroyed many nerves, vision can be saved in many cases. Routine eye exams, including tests for glaucoma, are important, especially for adults older than 35. Such eye exams are especially important for people at greatest risk for glaucoma, including people of African ancestry, people with relatives who have glaucoma, people with diabetes, and people with previous eye injuries.

Treatment The most common treatment involves eye drops that reduce pressure. Sometimes surgery is necessary either to open the drainage canal or to create a new one.

Glomerulonephritis

Glomerulonephritis refers to a group of diseases that damage the filtering ability of the kidney in a way that prevents the body from getting rid of metabolic waste and excess water.

Polly's Sore Throat

Polly will always remember fifth grade because she missed so much of it. She missed one week of school because she had strep throat, a sore throat caused by streptococcal bacteria. Several weeks later, Polly felt very tired, she lost her appetite, her abdomen and back hurt, and her face looked puffy. She rarely had to urinate, and when she did, her urine* was dark like cola. Polly's doctor suspected that she had a case of acute* (sudden) glomerulonephritis that was caused by her strep throat. Her doctor explained that Polly's kidneys were not working properly and that waste products from the cells were building up inside her body. Polly's condition got worse. She spent several days in the hospital, then she recuperated at home for several weeks.

What Are the Kidneys?

The kidneys are a pair of bean-shaped organs located in the back of the abdominal cavity right above the waist. There is one on each side of the spinal column. The kidneys perform a number of functions, chiefly filtering about 400 quarts of blood per day to remove cellular waste products and extra water to create urine, adjusting the chemical and fluid balance

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

* **acute** describes an infection or other illness that comes on suddenly and usually does not last very long.

◀ The kidneys are located on both sides of the spinal column just above the waist.

▲
Kidney glomerulus seen under a microscope. *Image copyright Jubal Harshaw, 2008. Used under license from Shutterstock.com.*

* **glomerulus** (glom-ER-you-lus) is from a Greek word meaning filter. The glomerulus is a knot of blood vessels that have the job of filtering the blood.

* **ions** are positively or negatively charged elements or compounds, such as hydrogen, sodium, potassium, and phosphate, which are necessary for cellular metabolism.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

in the body by controlling the concentration of urine, and participating in the control of blood pressure. The kidneys also are involved in regulating the effects of vitamin D on the body and in stimulating bone marrow to create new red blood cells. When the kidneys are damaged by disease, some or all of these functions can be impaired. When the kidneys do not function properly, a person can become very ill; when they fail to function at all, a person will die without treatment.

Each kidney is made up of about one million units called nephrons (NEF-rons). Each nephron consists of a collecting tubule that eventually takes wastes to the bladder, and a filtering unit called a glomerulus*.

What Is Glomerulonephritis?

In a person with glomerulonephritis, the glomeruli (plural of glomerulus) do not function properly. When the glomeruli are damaged, the filtering mechanism does not work properly. Instead of keeping proteins in the blood, while allowing excess water, ions*, and wastes to pass through the filter into collecting tubules where they become urine, the glomeruli filters leak. This leakage allows proteins to move out of the bloodstream with the water and wastes and to be excreted in the urine. Loss of large amounts of protein from the blood then causes fluid to leak out of the bloodstream into the body's tissues. The retention of fluid gives the body, especially the face and legs, a puffy and bloated appearance.

Although there are many causes of glomerulonephritis, scientists think that they are all related to a problem caused by immune system* proteins called immunoglobulins. Some event that is not completely understood stimulates these proteins to collect in glomerular cells. This causes inflammation* in cells that results in damage to the glomeruli.

Acute Glomerulonephritis

Acute glomerulonephritis most often occurs in children between 2 and 15 years of age and is uncommon in adults over age 40. Post-streptococcal glomerulonephritis is the most common kind of acute

RICHARD BRIGHT'S CONTRIBUTIONS

Richard Bright (1789–1858), a British physician, was the first to describe the kidney disorder known later as Bright's disease, a type of glomerulonephritis. Bright studied kidney function and was meticulous in his clinical observations. He worked with kidney patients, studying their symptoms, and then he correlated symptoms with the kidney defects he observed during autopsies (dissecting examinations after death).

The results of Bright's research first appeared in *Reports of Medical Cases* in 1827. Bright also contributed to the study of lung disease, heart disease, various fevers, and tumors.

glomerulonephritis. It usually develops two to three weeks after a streptococcal infection in the throat or (rarely) on the skin. In some people, the streptococcal infection triggers an inappropriate response in the immune system that results in immune system proteins being deposited in the glomeruli. Post-streptococcal glomerulonephritis is decreasing in developed countries such as the United States, probably due to the prompt treatment of streptococcal infections with antibiotics. Other infections, such as bacterial endocarditis*, a heart infection, can also trigger acute glomerulonephritis.

Symptoms of acute glomerulonephritis include blood in the urine, which turns it a brownish color, a decreased volume of urine, and puffiness in the face and ankles from fluid retention. Eventually fluid may accumulate in the lungs making breathing difficult. Blood and urine tests are done to determine the extent of the kidney damage.

In treating acute glomerulonephritis, the physician corrects any chemical imbalances in the blood caused by loss of proteins and other molecules in the urine. Diuretic drugs are used to help eliminate excess fluid from the body. Antibiotics and corticosteroid* drugs are given to control infection and inflammation. In serious cases, dialysis may be temporarily necessary to remove waste products that have built up in the blood. Most people recover completely from acute glomerulonephritis, but in about 10 percent of people, the condition becomes chronic*.

Chronic Glomerulonephritis

Chronic glomerulonephritis may develop without symptoms for many years. The disease can be triggered or associated with many diseases and conditions, including the autoimmune diseases systemic lupus* erythematosus, HIV*/AIDS* infection, and Goodpasture's syndrome* (a rare condition). Chronic glomerulonephritis also can develop from diabetes* and severe high blood pressure (hypertension).

Symptoms of chronic glomerulonephritis often go unrecognized for a long time and include protein in the urine, foamy urine, high blood pressure, swelling in the face and ankles, and frequent urination. Often the first indication of chronic glomerulonephritis comes from an abnormal urinalysis during a routine physical examination. As kidney failure progresses, fatigue, nausea and vomiting, difficulty sleeping and nighttime muscle cramps develop.

Diagnostic blood, urine, and imaging tests are done to determine the underlying cause of the disease and to assess how far kidney failure has progressed. A kidney biopsy* is sometimes performed.

Chronic glomerulonephritis cannot be cured, but it can be treated. If an underlying disease such as diabetes or lupus is causing the kidney damage, that disease is treated. Chronic glomerulonephritis tends to worsen with time, eventually ending in complete kidney failure. When the kidneys fail people either need kidney dialysis several times per week or a kidney transplant in order to survive.

What Is Kidney Dialysis?

When the kidneys stop filtering blood properly due to injury or disease, hemodialysis ("hemo" means "blood") is the most common treatment. A dialysis machine acts as an artificial kidney. People undergoing dialysis are hooked up to the machine via needles and tubes so that blood is pumped out of their body and through the filters in the machine. The machine does the job of the kidney in removing wastes and excess water, then the cleaned blood is returned to the body through a vein. Some people need dialysis temporarily while their kidneys heal, but many more depend on it permanently to stay alive. The only alternative to dialysis for these people is a kidney transplant.

* **endocarditis** (en-do-kar-DYE-tis) is an inflammation of the valves and internal lining of the heart, known as the endocardium (en-doh-KAR-dee-um), usually caused by an infection.

* **corticosteroid** (KOR-ti-ko-STER-oid) is one of several medications that are prescribed to reduce inflammation and sometimes to suppress the body's immune response.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **lupus** (LOO-pus) is a chronic, or long-lasting, disease that causes inflammation of connective tissue, the material that holds together the various structures of the body.

* **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).

- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).
- * **Goodpasture's syndrome** is an autoimmune disorder of unknown cause, characterized by circulating antibodies in the blood that attack the membrane of the kidney's glomeruli and the lung's alveoli.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.
- * **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.
- * **metabolic** (meh-tuh-BALL-ik) pertains to the process in the body (metabolism) that converts food into energy and waste products.
- * **enzymes** (EN-zimes) are proteins that help speed up a chemical reaction in a cell or organism.
- * **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.
- * **hypoglycemia** (hi-po-gly-SEE-mee-uh) is a condition that occurs when the amount of glucose, or sugar, in the blood becomes too low. Symptoms can include dizziness, trembling, sweating, and confusion.

Glycogen Storage Diseases

Glycogen storage diseases (GSD) are a group of inherited metabolic diseases in which there is a deficiency of one of the enzymes* involved in glycogen metabolism.*

What Is a Glycogen Storage Disease?

The major energy reserve of the body is glycogen stored in the liver* and muscles. Glycogen is formed from glucose, and glycogen is broken down into glucose, a multiple step process requiring proper functioning of several enzymes, which are deficient in GSD. As a result, blood glucose levels are low (hypoglycemia*), and there is excess storage of glycogen in the liver and muscles. There are several types of GSD, with symptoms ranging from mild (muscle cramps) to life-threatening (liver or kidney failure and death).

What Is a Metabolic Disorder?

Human bodies convert food into energy, a process called metabolism. In metabolic disorders, a defective metabolism leads to energy failure. Glucose is the major energy source in the body, especially for brain, heart, and muscle function, and it is obtained directly from food in the digestion process that breaks down protein and fat. Excess blood glucose present after a meal is converted into glycogen, which is stored in the liver and muscle. In between meals or after strenuous exercise, glucose demand is met by breaking down stored glycogen into glucose. In GSD, one of several enzymes involved in glycogen metabolism is defective, which leads to either too much or too little glycogen stores in tissue or results in an

abnormal form of glycogen storage. Normal glucose and glycogen metabolism are so essential to the functioning of every cell in the body that any abnormality in this process can result in catastrophic illness or death.

How Do People Get a Glycogen Storage Disease?

Glycogen storage diseases are inherited or sex-linked*. The information about the structure and function of the body is stored in chromosomes* in the form of DNA* clusters called genes*. There are two copies of each gene, and a person gets one copy from each parent. If one or both copies of the gene are defective, there is a change in genetic information inherited by the child which results in abnormal structure and/or function in the child's body. Most forms of GSD occur when both parents have one abnormal copy of a gene responsible for a particular enzyme and both parents pass on this abnormal copy to the child. In such parents, each pregnancy has a 25 percent chance of producing a normal child, a 25 percent chance of producing a child with GSD, and a 50 percent chance of having a child with one defective gene copy. People who have the gene but not the disease are called carriers.

How Common Are Glycogen Storage Diseases?

These are rare diseases, with an overall incidence of 1 in 20,000 births. Four of the twelve types of GSD are more common, accounting for more than 90 percent of all cases. Accurate statistics are unavailable for the other types of GSD. Certain ethnic groups are more likely to develop the disease, such as North African Jews. The age of onset varies from birth to childhood.

What Are Common Symptoms of Glycogen Storage Diseases?

Although each type of GSD has slightly different symptoms depending on the affected organ(s), common symptoms include the following:

- Hypoglycemia due to the body's inability to provide sufficient glucose from glycogen
- Enlarged liver due to excess glycogen storage
- Muscle cramps, pain, fatigue, and muscle breakdown after exercise due to lack of readily available glucose for muscle function
- Protein and fat deficiency from break down to produce glucose, leading to growth retardation, weak bones, and muscle wasting

How Are Glycogen Storage Diseases Diagnosed?

Milder cases of GSD may not ever be diagnosed or may go undiagnosed into adulthood, whereas more severe cases are seen in infancy or childhood. The important symptoms are hypoglycemia, liver damage, growth retardation, muscle cramps, and abnormal blood chemistry profile (abnormally high levels of protein and fat breakdown products such as lactic acid, uric acid, and cholesterol).

* **sex-linked** genetic traits involve the chromosomes that determine whether a person is male or female. They usually affect boys, who have only one X chromosome.

* **chromosomes** (KRO-mo-somz) are threadlike chemical structures inside cells on which the genes are located. There are 46 (23 pairs) of chromosomes in normal human cells. Genes on the X and Y chromosomes (known as the sex chromosomes) help determine whether a person is male or female. Females have two X chromosomes; males have one X and one Y chromosome.

* **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

- * **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.
- * **echocardiogram** (eh-ko-KAR-dee-uh-gram) is a diagnostic test that uses sound waves to produce images of the heart's chambers and valves and blood flow through the heart.
- * **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.
- * **placenta** (pluh-SEN-ta) is an organ that provides nutrients and oxygen to a developing baby; it is located within the womb during pregnancy.
- * **amniocentesis** (am-nee-o-sen-TEE-sis) is a test in which a long, thin needle is inserted in the mother's uterus to obtain a sample of the amniotic fluid from the sac that surrounds the fetus. The fetal cells in the fluid are then examined for genetic defects.
- * **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

In cases of excess liver glycogen deposition, an ultrasound* shows an abnormally enlarged liver. In types of GSD which involve the heart, the heart is enlarged, which can be seen by an echocardiogram*. X-rays may show fractured bones.

More definitive tests include liver or muscle biopsy* and microscopic examination for glycogen deposition and for levels of enzyme activity. If a fetus is suspected of having the disease, a small piece of the placenta* can be removed for genetic testing. With amniocentesis*, GSD can be detected prior to birth. In some cases, genetic testing can be done from skin and/or blood samples. Before undergoing such testing, the prospective parents should meet with a genetic counselor in order to make an informed decision about whether to have children.

How Are Glycogen Storage Diseases Treated?

Treatment depends on the type of GSD, the organ affected, and the predominant symptom. In most cases, a team of doctors, including specialists in the heart, nervous system, respiration, and genetics, are needed, as GSD are rare and complex diseases. Hypoglycemia is avoided by modifying the diet. Avoiding strenuous exercise and avoiding fasting is important in all GSD. Treatment approaches involving gene therapy and genetic engineering were as of 2009 areas of continuing research.

What Are the Different Types of Glycogen Storage Disease?

There are twelve types of GSD that are numbered in the order in which the deficient enzyme was discovered, given the name of the person who first described the disease, or identified by the deficient enzyme. Another common way of categorizing GSD is by the organ system that is most affected, which depends on which tissue shows the enzyme deficiency.

Glycogen storage diseases affecting the liver Eight types of GSD affect the liver. Two of these are severe and show up in early infancy or childhood. Common features include hypoglycemia, liver and/or kidney enlargement, growth retardation, and motor delay. Diagnosis is usually by liver ultrasound, liver biopsy, analysis of enzyme activity, and genetic testing. Treatment includes frequent carbohydrate-rich meals either by mouth, intravenously*, or by a tube in the stomach in order to maintain a consistent blood glucose level. In older children, cornstarch can be given orally at night to prevent hypoglycemia. Cornstarch is a complex compound of glucose that is broken down in the body over several hours to maintain a steady supply of glucose. To maintain healthy bones and to promote growth, a high protein diet with multivitamin and calcium supplements is recommended.

Type I Type I (also called von Gierke's disease or hepatorenal glycogenosis) is the most common GSD, accounting for 25 percent of all cases with an incidence of 1 in 50,000 to 100,000 births. Within hours of birth,

affected babies become hypoglycemic when glucose derived from the mother is exhausted. They are lethargic and may have convulsions*, may stop breathing, or go into a coma*. Later characteristics in the young child include irritability, difficulty waking from sleep, tremors, and overwhelming hunger. Affected children have delayed puberty*, growth retardation, a characteristic doll-like face (due to fat deposits in the cheeks), skinny limbs, and a bulging belly due to the enlarged liver. Glycogen depositis in the kidneys leads to kidney failure. Nosebleeds occur due to non-sticky platelets*. In later life, benign* or cancerous tumors* can occur in the liver and kidney. This GSD is usually diagnosed in individuals between 4 and 10 months of age. No prenatal* testing was available as of 2009. Besides hypoglycemia, blood tests show abnormally high levels of lactic acid, cholesterol, and uric acid.

Hypoglycemia is avoided by frequent modified meals and by using cornstarch. Children are advised to avoid contact sports due to the likelihood of bleeding and liver injury. Infections should be avoided and promptly treated when they occur. Treatment may include organ transplantation, which has been performed with some measure of success. As of 2009, no genetic therapy was available for enzyme replacement.

Type III Type III (also called Cori or Forbes disease, Debrancher deficiency, or limit dextrinosis) affects about 1 in 100,000 births with increased incidence among the Inuit of North America and the Sephardic Jews of North Africa. Symptoms first appear in babies about three to four months of age, yet many patients may live in their 60s. The symptoms are similar to Type I in infancy. Over time, the liver shrinks and becomes scarred. Muscle wasting, heart enlargement, and bone fractures are common. Hypoglycemia is not as severe as in Type I. A carbohydrate and protein rich diet is advised.

Type VI Type VI (also called Hers' disease or liver phosphorylase deficiency) accounts for up to 30 percent of all GSD cases, and most cases are X-linked. The enzyme called phosphorylase, which is involved in the first step of glycogen breakdown in the liver, is deficient. Type VI is a milder disease than Type I, with symptoms beginning between one and five years of age with hypoglycemia, growth retardation, and liver enlargement. Liver size becomes normal after puberty. Several symptoms normalize or become milder as patients grow older. A carbohydrate and protein rich diet is advised.

Type VIII and XI These are rare disorders caused by defects of the enzymes in the liver and have symptoms similar to Type VI.

Type IX Type IX (also called Phosphorylase kinase deficiency) is due to deficiency of liver glycogen phosphorylase kinase, which is an enzyme made up of four different subunits. Overall, this disease is very similar to Type VI in terms of the symptoms, but it is much milder, with symptoms

- * **convulsions** (kon-VUL-shuns), also called seizures, are involuntary muscle contractions caused by electrical discharges within the brain and are usually accompanied by changes in consciousness.
- * **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.
- * **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.
- * **platelets** (PLATE-lets) are tiny disk-shaped particles within the blood that play an important role in clotting.
- * **benign** (be-NINE) means a condition is not cancerous or serious and will probably improve, go away, or not get worse.
- * **tumors** (TOO-morz) are abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.
- * **prenatal** (pre-NAY-tal) means existing or occurring before birth, with reference to the fetus.

* **ketones** (KEE-tones) are the chemicals produced when the body breaks down fat for energy.

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

improving after puberty. Most patients reach their full potential height and weight in adulthood. Some patients also have exercise-related muscle pain and cramps. A carbohydrate and protein rich diet is advised.

Type X Type X is caused by a defect in an enzyme and causes symptoms similar to Types VI and IX.

Type 0 Type 0 (also called glycogen synthetase deficiency) is a rare disease in which the problem is not with breakdown of glycogen but deficient glycogen synthesis from amino acid and fat. In this disease, the liver has limited glycogen stores, and patients become hypoglycemic quickly with fasting. After a meal, blood sugar rises quickly as the body is unable to shunt all the excess glucose into glycogen. When glucose is demanded by the body between meals, the liver is unable to provide enough. Hypoglycemia is seen in infants and children as early morning fatigue or convulsions. Long-term complications are short stature and weak bones. Type 0 is usually diagnosed by blood tests that show fasting hypoglycemia and excess ketones*. Liver biopsy shows low glycogen content and low or no enzyme activity. Consumption of frequent protein-rich meals and taking cornstarch at night in order to slowly release glucose are recommended.

Glycogen storage diseases that predominantly affect the muscle GSD that affect the muscle are Types II, IV, V, and VII. Of these, Type II affects the heart and skeletal muscle; Type IV affects muscle and liver; and Type V and VII affect only the skeletal muscle. Hypoglycemia usually does not occur. Muscle weakness in infants is detected in delayed motor milestones such as rolling over and sitting up. Children have difficulty running and climbing stairs. Respiratory muscle weakness leads to progressive respiratory failure. In adolescents and adults, muscle weakness is detected after strenuous exercise. With severe muscle breakdown, the urine* may become burgundy-colored due to the presence of a muscle protein. Enlarged heart and heart failure may occur. Avoiding strenuous exercise is essential. A high protein diet is advocated. Some patients may need walkers or wheelchairs along with physical and occupational therapy. Respiratory difficulty is most pronounced at night, and patients may need to be on breathing machines. In some conditions, enzyme replacement or liver transplant is performed.

Type II Type II (also called Pompe's disease, acid maltase deficiency, or lysosomal storage disorder) occurs in about 1 in 40,000 births and highest rates occur among African Americans. The acid alpha-hydrolase (acid maltase) enzyme is deficient in the lysosomes of the heart and skeletal muscles. Lysosomes are small compartments inside the cell that function as recycling centers for substances such as glycogen. When this does not happen, as in Type II, glycogen accumulates in the heart and muscle lysosomes leading to injury.

There are three types based on the age of onset: infantile, juvenile, and adult. In the infantile form, infants appear normal at birth. Around four to six months of age, they develop muscle weakness leading to floppy limbs and delayed motor milestones. They also develop breathing difficulty, an enlarged heart, and heart failure. Despite best medical treatment, death usually occurs by one to two years of age. The juvenile form is characterized by skeletal and respiratory muscle weakness, which progresses slowly into the second to third decades, resulting in death due to respiratory failure. The adult onset form has slowly progressing respiratory and skeletal muscle weakness leading to sleep apnea, respiratory failure, and death. Hypoglycemia is not a symptom.

Treatment attempts to handle the symptoms only. Diet modifications are not of much use in these cases. Enzyme replacement can be done. Treatment of respiratory and heart failure can be performed but does not prolong life. Importantly, parents of an affected child need counseling regarding the chance of having another affected child in subsequent pregnancies.

Type IV Type IV (also called Andersen's disease, brancher deficiency, amylopectinosis, or adult polyglucosan body disease [APBD]) accounts for only 3 percent of all GSD and is more common in the Ashkenazi Jews. In this disease, the branching enzyme that is responsible for normal branching of glycogen is deficient and leads to deposition of abnormal glycogen with long branches in the liver and muscle. A foreign-body like reaction ensues that activates the immune system to attack these tissues, leading to scarring of the liver and muscle.

There are several forms of the disease. Typically, in the first year of life the afflicted person has an enlarged liver and spleen and general failure to thrive. Children usually die due to progressive liver failure and cirrhosis by about five years of age. Hypoglycemia is not common. The milder forms have non-progressive liver dysfunction, and these individuals tend to survive into adulthood. Other forms of disease cause skeletal, respiratory, and cardiac muscle weakness. In the perinatal* form, the individual shows nerve and muscle symptoms before birth or immediately after birth. The polyglucosan form causes brain and nerve injury.

Liver biopsy is helpful in detecting scarring and determining enzyme activity. Liver transplant is the only solution for progressive liver failure.

Type V Type V (also called McArdle's disease, muscle phosphorylase, or myophosphorylase deficiency) is caused by glycogen phosphorylase deficiency in skeletal muscles. It is a rare disease with only a few hundred known cases. Symptoms can be mild, and they usually appear in the second to third decade. Patients complain of severe muscle cramps and tenderness after exercise with muscle breakdown and red-colored urine in severe cases. Following some rest, patients experience a second-wind phenomenon and can continue their exercise. Some patients develop

* **perinatal** (per-ee-NAY-tal) means existing or occurring around the time of birth, with reference to the fetus.

* **jaundice** (JON-dis) is a yellowing of the skin, and sometimes the whites of the eyes, caused by a buildup in the body of bilirubin, a chemical produced in and released by the liver. An increase in bilirubin may indicate disease of the liver or certain blood disorders.

sustained muscle weakness especially in the large thigh muscles. Patients are normal in stature, and the muscles themselves look normal. A variant of this disease leads to a fatal infantile form with death from rapidly progressive respiratory muscle failure. Avoiding strenuous exercise, taking breaks during exercise in order to take advantage of the second-wind phenomenon, and a high-protein diet are the main treatments.

Type VII Type VII (also called muscle phosphofructokinase deficiency or tarui disease) is the least common GSD, and worldwide only about 50 patients with the disease had been identified as of 2008. The disease is very similar to Type V and is characterized by exercise intolerance. However, the symptoms occur earlier in childhood and are more severe. Patients also have anemia and develop jaundice*. Kidney stones develop and may block the urinary tract. There is no treatment other than restricting high carbohydrate diet and avoiding vigorous exercise.

What Is the Long-term Prognosis for Patients with Glycogen Storage Diseases?

The long-term prognosis depends on the severity of the disease and how effectively symptoms are managed. Maintenance of a healthy blood glucose level can reverse all signs in a milder types (e.g., VI, IX and X) and a normal healthy lifespan can be expected. In other types (e.g., II and IV), death occurs in infancy. Death is usually due to severe hypoglycemic coma, liver failure, respiratory failure, and infections.

Gonorrhea

Gonorrhea (gah-nuh-REE-uh) is a sexually transmitted disease (STD) and is spread through all forms of sexual intercourse. It can also be passed from an infected mother to her baby during childbirth. Gonorrhea primarily affects the mucous membranes of the genital and urinary tracts (including the urethra). Non-genital sites of infection include the rectum*, eyes, throat, other organs and tissues of the body, and (in cases of gonococcal arthritis) joints.*

What Is Gonorrhea?

Gonorrhea is an infection caused by the bacterium *Neisseria gonorrhoeae* (nye-SEER-e-uh gah-no-REE-eye), which can colonize and multiply in the body's mucous membranes, especially the mucous membranes of the male and female genital* tracts. It affects primarily the cervix and the male urethra. There are non-genital sites of infection: The bacterium can also affect the mucous membranes of the rectum, eyes (the conjunctiva), and throat. In the female, the cervix is the most common site of infection and the vagina is generally spared. In gonorrhea infection there may be a discharge from the penis or vagina and pain during urination.

In women, the first site of infection is usually the cervix*; if untreated, infection can spread to the uterus* and the fallopian tubes* and result in pelvic inflammatory disease (PID), a severe infection of a woman's reproductive organs, including the fallopian tubes, uterus, and ovaries*, sometimes with spread of the infection to other body tissues near these organs. Babies born to mothers who have gonorrhea can develop an eye infection that can lead to blindness and other complications if it is not treated.

How Common Is Gonorrhea?

Gonorrhea is the second most commonly reported STD in the United States, according to the Centers for Disease Control and Prevention (CDC); chlamydial infection* is number one. The CDC states that after a period of several years in which the annual number of cases of gonorrhea declined, the number began to increase again in 2005. There were 358,366 cases of gonorrhea reported in the United States in 2006; however, many more went unreported. Some experts estimate that as many as 2 million cases occur per year.

Gonorrhea is most common in highly populated urban areas and in people who have more than one sexual partner; however, anyone who has sexual relations with an infected person can contract gonorrhea. Most infected men are between the ages of 20 and 24; most infected women are between the ages of 15 and 19. After 2000 the incidence of gonorrhea was higher among women than among men. Gonorrhea in children almost always points to sexual abuse.

- * **urethra** (yoo-REE-thra) is the tube through which urine passes from the bladder to the outside of the body.
- * **rectum** is the final portion of the colon that terminates at the anus.
- * **genital** (JEH-nih-tul) refers to the external sexual organs.
- * **cervix** (SIR-viks) is the lower, narrow end of the uterus that opens into the vagina.
- * **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.
- * **fallopian tubes** (fa-LO-pee-an tubes) are the two slender tubes that connect the ovaries and the uterus in females. They carry the ova, or eggs, from the ovaries to the uterus.
- * **ovaries** (O-vuh-reez) are the female reproductive organs from which ova, or eggs, are released in women.

* **chlamydial infection** (kla-MIH-dee-ul) infection is infection by bacteria of the genus *Chlamydia*. The microorganisms can occur in various forms in which the bacteria can invade the urinary and genital systems of the body, as well as the eyes and lungs. One of its most common forms is a sexually transmitted disease (STD), usually passed from one person to another through unprotected sexual intercourse.

* **semen** (SEE-men) is the sperm cell-containing whitish fluid that is produced by the testes, travels in the male reproductive tract, and is discharged from the penis during ejaculation.

* **lymph (LIMF) nodes** are small bean-shaped masses of tissue that contain immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **abdominal** (ab-DAH-mih-nul) refers to the body cavity below the ribs and above the hips that contains the stomach, intestines, and other organs.

Is Gonorrhea Contagious?

Gonorrhea is highly contagious. The risk of contracting the disease is increased in sexually active people who do not use condoms during sexual activity and in people who have multiple sexual partners. A person who has gonorrhea even in the absence of symptoms can transmit the disease to others starting at the time of initial infection.

The bacteria that cause gonorrhea are transmitted via direct contact (mucous membrane-to-mucous membrane and mucous membrane-to-skin) during all types of sexual activity. The bacteria are also carried in vaginal fluids and semen*, and transmission as a result of contact with these fluids is also possible. Infected women can pass the infection to their babies during childbirth.

People can infect themselves if they touch an infected body part of another person and then rub or scratch their eyes. Gonorrhea can also be spread through kissing; however, this method of transmission is rare.

How Do People Know They Have Gonorrhea?

Many people who contract gonorrhea have only mild symptoms or even none at all. Males are much more likely than females to know they have gonorrhea, but up to 20 percent of males do not experience any symptoms. Within two weeks after being infected, males often have a burning sensation during urination. They may have pain in or a greenish discharge from the penis. The lymph nodes* in the groin may swell, and the urethral meatus (the external opening of the urinary tract at the head of the penis) may become irritated and red.

Between 30 and 60 percent of infected women may not have any noticeable symptoms of infection. Those who develop symptoms usually begin to experience them within two to three weeks after contact with the bacterium. Symptoms may include a bloody or greenish-yellow discharge from the vagina; pain during urination and/or sexual intercourse; and itching, soreness, or redness in the genital area. Other symptoms, including abdominal* pain, bleeding during or after intercourse, and bleeding between periods may mean a woman has PID.

How Do Doctors Diagnose and Treat Gonorrhea?

Because the symptoms of gonorrhea are similar to those of chlamydial infection, doctors usually test a person experiencing symptoms that point to gonorrhea for both of these STDs. In addition, doctors usually test a patient who has suspected gonorrhea or chlamydial infection for syphilis and ask him or her to be tested for HIV infection. In September 2006 the CDC revised its recommendations for HIV testing to include yearly HIV screening for people at high risk of infection—which includes those diagnosed with other STDs—unless the patient refuses testing.

Diagnosis A sample of fluid or discharge obtained from the vagina, cervix, tip of the penis, or rectum can be cultured and tested for *Neisseria*

gonorrhoeae bacteria. Results are usually known within 48 hours. Another test, the polymerase (pah-LIM-er-ace) chain reaction (PCR), can be used to look for the presence of the bacterium's DNA* from the bacteria in urine, fluid from the cervix, or from fluid discharge from the urethra. This test gives faster and more accurate results.

Pharyngeal (fair-un-JEE-ul), or throat, gonorrheal infection can be established by doing a throat culture. In newborns at risk for gonorrheal eye infection, doctors swab the baby's eye discharge and do a culture to confirm the diagnosis. Gonorrheal eye infection is uncommon in U.S. infants because newborns routinely receive antibiotic eye drops or ointment at birth to prevent infection.

Treatment Gonorrhea is curable when treated with antibiotics, although some strains* of the bacteria are increasingly resistant to medication. In April 2007 the CDC added gonorrhea to the list of so-called superbugs; that is, diseases that are resistant to most antibiotics in common use.

It is important for individuals who are diagnosed with gonorrhea to discontinue all sexual activity during the period of illness. All sexual partners should be made aware of the diagnosis and should undergo testing, even if they do not have symptoms. If they have the disease they should also be treated with antibiotics. People who have both gonorrhea and chlamydial infection are treated with a combination of antibiotics; people diagnosed with gonorrhea alone are often treated for chlamydial infection as well, since gonorrhea has a shorter incubation* period and its symptoms typically start a week or so earlier than those of chlamydial infection. Newborns infected with gonorrheal conjunctivitis are given antibiotics intravenously (directly into a vein).

With appropriate antibiotic treatment, gonorrhea usually clears up within two weeks. It is important to take all of the medication even if the symptoms improve prior to completion of the full course, and to contact the doctor if they do not. When treated early, patients do not usually have any long-term complications.

Complications If a person has had gonorrhea before, he or she can become infected again. In fact, the reinfection increases the likelihood of complications. In women, untreated gonorrhea can lead to PID, which can cause ectopic pregnancy* and sometimes it can lead to infertility (the inability to become pregnant). Women have a 15 percent likelihood of becoming infertile after a single episode of PID; if they have another episode, the likelihood rises to 50 percent. Ectopic pregnancies require emergency surgery; an ectopic pregnancy in which the fallopian tube bursts can cause massive bleeding and even death.

Without treatment, the bacteria can spread throughout the body, to the blood, and via the bloodstream and to the joints, heart, and brain, although these complications rarely occur in young people who are in good health. Newborns that are not treated for gonorrheal eye infection are at risk for blindness. People with untreated gonorrhea are more

* **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

* **strains** are various subtypes of organisms, such as viruses or bacteria.

* **incubation** (ing-kyoo-BAY-shun) is the period of time between infection by a germ and when symptoms first appear. Depending on the germ, this period can be from hours to months.

* **ectopic (ek-TAH-pik) pregnancy** is an abnormal pregnancy in which the fertilized egg lodges and grows outside the uterus, usually within one of the fallopian tubes.

* **HIV** or human immunodeficiency (HYOO-mun ih-myoo-no-dih-FIH-shen-see) virus, is the virus that causes AIDS (acquired immunodeficiency syndrome).

likely to contract HIV* if they have unprotected sex with someone who is HIV-positive.

Can Gonorrhea Be Prevented?

Unfortunately, there is no vaccine against gonorrhea as of 2009. The best way to avoid contracting gonorrhea is to suspend or discontinue all forms of sexual activity. For those persons who are sexually active, the proper use of latex condoms during all forms of intercourse is important. Doctors advise women who are sexually active to have a yearly gynecological exam with STD screening. They also recommend that people with any symptoms of gonorrhea or who are at risk for STDs see a doctor. If a person is found to have gonorrhea, all their sexual partners must also be tested and treated. Doctors in the United States are required by law to report cases of gonorrhea to the CDC and to local public health departments.

Gout

Gout (GOWT) is a painful, inflammatory disease of the joints caused by deposits of crystals of uric (YUR-ik) acid.

Gout

Gout risk factors

- Family history of the disease
- Male
- Overweight
- Excessive alcohol
- Purine-rich diet
- Enzyme defect that makes it difficult for the body to break down purines
- Exposure to lead in the environment
- Organ transplant recipient
- Use of medicines such as diuretics, aspirin, cyclosporine, or levodopa
- Take niacin (vitamin)

Signs of gout

- Hyperuricemia
- Presence of uric acid crystals in joint fluid
- More than one attack of acute arthritis
- Arthritis that develops in a day, producing a swollen, red, and warm joint
- Attack of arthritis in only one joint, often the toe, ankle, or knee

What Is Gout?

Gout is a disease that causes painful inflammation in joints. Gout falls under the broad category “arthritis,” which means inflammation of the joints. While it can affect any joint, gout commonly afflicts the joints of the big toe, and this foot-related gout is sometimes called podagra (po-DAH-grah). The inflammation results from deposits of thin, sharp crystals of uric acid. Uric acid is a product in the metabolism of foods and of DNA in the nuclei of cells. Foods and DNA break down into nitrogen-containing chemicals called purines, and the enzyme xanthine oxidase continues the process by metabolizing the purines to uric acid. The uric acid that results typically dissolves in the blood and, after passing through the kidneys, flushes from the body in the urine*. In a patient with gout, however, the body either produces too much uric acid or excretes too little, and the excess crystallizes and accumulates in the joints and other tissues, causing inflammation and pain.

Gout comes in two types: primary and secondary. Primary gout results from excess uric acid that accumulates in the system of people with a genetic background of gout and strikes mainly men 40 years of age and older. Secondary gout occurs in situations in which the body is

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

* **leukemia** (loo-KEE-me-uh) is a form of cancer characterized by the body's uncontrolled production of abnormal white blood cells.

A VIVID DESCRIPTION

Gout has an unusually long written history. The Greek physician Hippocrates (c. 470–410 B.C.E.) described this painful form of joint inflammation, or arthritis. One of the best known early accounts of the disease comes from English physician Thomas Sydenham (1624–1689), who also suffered from acute attacks of gout. In 1683, he wrote “Tractatus de podagra et hydrope”, in which he attempted to put down on paper the symptoms of such an attack:

The victim goes to bed and sleeps in good health. About 2 o'clock in the morning, he is awakened by a severe pain in the great toe; more rarely in the heel, ankle, or instep. This pain is like that of a dislocation, and yet the parts feel as if cold water were poured over them. Then follow chills and shiver and a little fever.

The pain which [is] at first moderate becomes more intense. With its intensity the chills and shivers increase. After a time this comes to a full height, accommodating itself to the bones and ligaments of the tarsus and metatarsus [the ankle and feet]. Now it is a violent stretching and tearing of the ligaments—now it is a gnawing pain, and now a pressure and tightening. So exquisite and lively meanwhile is the feeling of the part affected, that it cannot bear the weight of bedclothes nor the jar of a person walking in the room.

presented with large amounts of nuclear purines to metabolize because billions of excessive cells are turning over. This happens most frequently in acute leukemia*. When the leukemia responds to treatment, the uric acid concentrations subside and gout treatments can be stopped. Besides primary and secondary gout, doctors sometimes describe a patient's condition as tophaceous gout, a chronic form of the disease in which the uric acid crystals form hard masses, called tophi, around the joints.

Overall, according to the Arthritis Foundation, gout affects about 2.1 million Americans.

How Is Gout Diagnosed and Treated?

Usually, a doctor's first suspicion of gout is based on a patient's report of his or her symptoms. These may include swelling, redness, tenderness, heat, and a sudden onset of pain—usually severe—in a joint. For many patients, the first gout attacks occur in the big toe. Typically, these attacks last about a week with the most severe pain occurring for one or two days. Cases vary, however, and some people may have attacks that last from several hours to several weeks, whereas others may experience constant and milder joint pain. To make a definite diagnosis, medical professionals will test for the presence of uric acid crystals in the fluid—called synovial fluid—around an arthritic joint. After using a needle to extract the fluid, lab technicians examine it for the crystals, which are a characteristic sign

of gout. A doctor may also recommend a blood test to check uric acid concentrations in the blood serum. A high concentration, called hyperuricemia, may indicate gout. However, some people with high concentrations may not develop gout, whereas others with low, even normal levels, may get the disease.

Because gout can be caused by the excess production of uric acid, by the inability to adequately excrete it in the urine, or by both, treatments vary. One commonly prescribed medication is allopurinol. The development of this medication, which led in part to a 1988 Nobel Prize in Physiology or Medicine for collaborating researchers Gertrude Elion (1918–1999) and George Hitchings (1905–1998), inhibits xanthine oxidase and, therefore, blocks the production of uric acid. Medications known as uricosuric drugs, including probenecid, work by boosting the excretion of uric acid in the urine. To quell intense inflammation, doctors may recommend anti-inflammatory agents, such as colchicine, ibuprofen, and other nonsteroidal anti-inflammatory drugs (NSAIDs). In addition, medical professionals typically caution patients to reduce or eliminate alcohol intake, and the consumption of certain fish and red meat—especially organ meats such as liver, pancreas, brain, and other types of meat rich in cell nuclei and, therefore, purines.

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

Growth and Growth Disorders

Growth is the normal development of children and teens as they increase in height, skeletal durability, and muscular strength. Normal growth is determined based on an average measure with a wide range of variance. Growth disorders are conditions of abnormal growth in children. The disorders may be caused by poor nutrition, abnormal levels of certain hormones involved in growth, genetic disorders of bone growth, and other diseases.

Daniel and Jeremy's Story

When Daniel turned eight, he was the smallest child in his class. Many younger children were bigger. He was worried that something was wrong with him.

His parents took him to see a pediatric endocrinologist*. The doctor took Daniel's medical history and performed blood tests, x-rays, and measurements. The doctor found nothing abnormal in Daniel's health. The doctor concluded that Daniel was normal for his age. Most children with short stature do not have a medical condition. There is a wide range of normal heights at any age in childhood.

While at the doctor's office, Daniel met Jeremy who was the same age but shorter. Jeremy felt like he was trapped inside the body of a four-year-old. "My friends teased me and called me 'Shorty,'" he said. "I felt terrible being so much shorter than my brother who was three years younger." Jeremy's parents were told that his body was not making enough growth hormone*. Daily shots of human growth hormone helped Jeremy, who grew to be taller than his brother.

Concerns about what is normal are different for boys and girls, particularly during adolescence. Girls begin puberty* and have a growth spurt before boys do. For several years many normal adolescent girls are taller than the boys in their peer group. However, many girls grow taller than they really want to be. Many adolescent girls do not want to be tall and are uncomfortable with their height even though it is within normal range. With each successive generation growing taller than the previous one, an adolescent girl can expect to be taller than her mother or aunts. While being tall may not feel good to teen girls, most tall women enjoy their height as mature women.

What Is Normal Growth?

Everyone has a different size and shape, and there is a wide range of what doctors consider normal growth. In order to monitor growth, doctors use an established range of normal heights and weights for different age groups. From the time a child first goes to the doctor, measurements of height and weight are taken. The doctor uses a growth chart to compare a child's height and weight growth rate with those of others the same age.

As a newborn, everyone starts out at about the same size. Yet, some end up short and some tall.

When developing a standard growth chart, researchers take a large number of children of different ages and make a graph of their heights and weights. The height at the fiftieth percentile means the height at which half of the children of that age are taller and half are shorter. The twenty-fifth percentile means that three-fourths (75%) of the children are taller at that age, and one-fourth (25%) are shorter. The seventy-fifth percentile means that three-fourths of the children (75%) are shorter and one-fourth (25%) are taller.

People vary greatly, and if children are between the third and ninety-seventh percentile, and if they are growing at a normal rate, they usually are regarded as normal. If children are outside these ranges (over ninety-seventh percentile or under the third percentile), doctors may look for some explanation. Most often, these children simply have inherited “short” or “tall” genes* from their parents, and they will continue to grow at a normal pace. While adult height is related to the height of a person’s parents, there is still much variation among siblings.

How Are Growth and Puberty Related?

During adolescence, a growth spurt normally occurs. Generally, growth spurts for girls start about two years earlier than growth spurts for boys. Rates of growth and change during puberty vary with the individual. Parents’ growth and puberty patterns often are passed on through their genes to their children: If one or both parents had a late puberty, then their children are more likely to reach puberty later and to experience a later growth spurt. The medical term for this “late bloomer” pattern is constitutional growth delay.

Children with precocious puberty experience early growth spurts due to the abnormally early rise in sex hormone levels in their bodies. Although initially this causes these children to grow taller than others their age, their skeletons mature more rapidly as well, often causing them to stop growing at an early age. Therefore, if precocious puberty is left untreated, it may lead to a decrease in a child’s ultimate height.

As would be expected, children with delayed puberty do not experience growth spurts at the usual age, so they lag behind in height as their peers grow rapidly and mature sexually. When puberty finally occurs for these children, on its own or as a result of treatment, they “catch up”: They may continue to grow into their late teens and may even exceed the final adult heights of some of their peers.

How Does Growth Take Place?

Growth occurs when bones of the arms, legs, and back increase in size. The long bones of the limbs have a growth plate at the end. The growth plate is made of cartilage, which is a tough, elastic tissue. Cartilage cells in the growth plate multiply and move down the bone to produce a matrix

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person’s body structure and physical characteristics. Inherited from a person’s parents, genes are contained in the chromosomes found in the body’s cells.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **sickle-cell disease** is a hereditary condition in which the red blood cells, which are usually round, take on an abnormal crescent shape and have a decreased ability to carry oxygen throughout the body.

* **cystic fibrosis** (SIS-tik fy-BRO-sis) is a disease that causes the body to produce thick mucus that clogs passages in many of the body's organs, including the lungs.

* **dysplasia** (dis-PLAY-zha) means abnormal growth or development.

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

(tissue from which new bone is formed). These cartilage cells then die, leaving spaces. Special cells called osteoblasts (OS-tee-o-blasts), meaning bone beginners, then produce bone (by laying down the minerals calcium and phosphorus) to fill the spaces and replace the matrix. Once all the cartilage in the growth plate has been turned to bone, growth stops, which usually occurs before ages 16 to 18. An x-ray of the hand or knee can show the doctor the bone age (maturity of the bone) and how much potential growth remains.

Why Do Some Children Not Grow Normally?

Nutrition Children with poor nutrition may have poor growth. A balanced diet with adequate protein is essential for normal growth. Some parts of the world have serious problems with malnutrition, and the growth of children may be affected in these areas.

Chronic diseases Chronic diseases that may impair growth include diabetes*, congenital heart disorders, sickle-cell disease*, chronic kidney failure, and cystic fibrosis*.

Furthermore, intercurrent illnesses can bring a slowdown or stop in height increments. These involve two or more illnesses that would have little effect alone but cause serious problems when occurring together. These illnesses may be recognizable or may be too subtle for recognition.

Bone disorders One form of extreme short stature is caused by abnormal formation and growth of cartilage and bone. Children with skeletal dysplasia* are short and have abnormal body proportions. Their intelligence levels usually are normal. Most of these conditions are inherited or occur due to genetic abnormalities.

Intrauterine growth retardation If growth in the uterus is interrupted while a fetus* is forming or developing, the condition is called intrauterine (meaning within the uterus) growth retardation (IUGR). IUGR is not the same as when a baby is born prematurely. The small size of a premature infant usually is normal according to the gestational (jes-TAY-shun-al) age (or the age from conception).

Failure to grow normally in the uterus may result from a problem with the placenta (the organ that supplies nutrients and oxygen to the baby). Growth of the fetus can be affected by the mother smoking cigarettes or drinking alcohol during the pregnancy. Infections, such as German measles, may cause the problem, but sometimes the cause cannot be determined.

Failure to thrive Failure to thrive (FTT), or inadequate weight gain any time after birth, occurs frequently in infants. There are many possible causes, and the doctor must examine the child carefully. Often, the baby or child simply is not getting enough to eat. Sometimes other illnesses are

interfering with weight gain that must be treated. Severe social deprivation such as occurs in an inadequate orphanage or institution can also lead to a slowdown or stoppage in height gains.

Genetic conditions Disorders of certain chromosomes* also can cause short stature. For example, Down syndrome, a condition that occurs when a person has three copies of chromosome 21, results in arms and legs that are shorter than usual. Another genetic condition, Turner syndrome, is caused by a missing or partially missing X chromosome. The average height of adult women with Turner syndrome is between 4 feet 6 inches and 4 feet 8 inches without treatment. Adolescent girls with Turner syndrome have underdeveloped ovaries.

Marfan syndrome is a hereditary condition affecting connective tissue and is associated with tall stature. People with Marfan syndrome have very long arms and legs, eye problems, and differences in facial features. Other physical problems, such as aortic aneurysms and other heart abnormalities, also may be present. It is commonly believed that Abraham Lincoln had Marfan syndrome.

Achondroplasia

Achondroplasia (a-kon-dro-PLAY-zee-a) is a genetic condition that affects the skeletal system and causes people to be unusually short. Gene mutations (changes) that cause achondroplasia can be spontaneous (not carried by the parents), and most people with achondroplasia are born to average-sized parents. In some cases, however, achondroplasia is inherited. The most common form of short stature, achondroplasia affects about 1 in 25,000 people. The average adult height of people with achondroplasia is little more than four feet.

Unusually short stature and very short legs and arms are the most visible signs of achondroplasia. Some people are also affected by other problems, which may include the following:

- Late development of motor skills
- Increased susceptibility to middle ear infections
- Pressure on the brain and spinal cord, resulting in nerve and breathing problems
- Hydrocephalus (hy-dro-SEF-a-lus), excess fluid in the brain
- Crowding of teeth in the jaw
- Disproportionately large head with a bulging forehead
- Curvature of the spine and bowed legs
- Problems with joints

Once achondroplasia is suspected in a developing child (for instance because of outward appearance, failure to grow, or how bones look in x-rays), doctors look for the genes that cause achondroplasia. As of 2009 there was no cure for achondroplasia. Treatments involved resolving accompanying medical problems, such as surgery to alleviate joint discomfort.

* **chromosomes** (KRO-mo-somz) are threadlike chemical structures inside cells on which the genes are located. There are 46 (23 pairs) of chromosomes in normal human cells. Genes on the X and Y chromosomes (known as the sex chromosomes) help determine whether a person is male or female. Females have two X chromosomes; males have one X and one Y chromosome.

Sometimes, people with achondroplasia opt for an experimental surgical procedure that lengthens the arms and legs. It involves cutting a bone, inserting a scaffold between the bone segments, and allowing new bone to grow and fill in the gaps. Limb-lengthening surgery is not a common treatment because it is controversial, painful, requires repeated surgeries, and can lead to complications, such as nerve damage.

How Do Hormones Cause Growth Disorders?

Growth is controlled by hormones (chemical messengers) from various glands. An important growth hormone is secreted by the pituitary gland. The gland looks like a peanut sitting at the base of the brain. Other hormones are also essential for growth. The thyroid gland in the neck secretes thyroxine (thy-ROX-in), a hormone required for normal bone growth. Sex hormones from the ovaries (estrogen) and testicles (testosterone) are essential for the growth spurt and other body changes that occur during puberty.

Pituitary hormones The pituitary gland is attached by a stalk to the hypothalamus, an area of the brain that controls the function of the pituitary. The anterior or front part of the pituitary gland secretes the following hormones that can affect growth:

- Growth hormone to regulate bone growth
- Thyroid-stimulating hormone to control the production and secretion of thyroid hormones
- Gonad-stimulating hormones for development of the sex glands (gonads) and secretion of sex hormones
- Adrenal-stimulating hormone to regulate the secretion of adrenal gland hormones

Too little growth hormone Sometimes the pituitary gland does not make enough growth hormone (hypopituitarism), which usually slows a child's growth rate to less than two inches per year. The deficiency may appear at any time during infancy or childhood. When doctors have ruled out other causes of growth failure, they may recommend special tests for growth hormone (GH) deficiency. Children with growth hormone deficiency are treated with daily injections of the hormone, often for several years. With early diagnosis and treatment, these children usually increase their rate of growth and may catch up to achieve average or near-average height as adults.

In pituitary dwarfism, caused by low amounts of growth hormone, the person is short but has normal body proportions. This is different from other forms of dwarfism due to genetic skeletal dysplasia. In these cases, the person with dwarfism is short, and the growth of the arms, legs, torso, and head often is out of proportion. For example, the person's arms and legs may appear relatively smaller than the head or torso.

Acromegaly results from excessive secretion of growth hormone and causes enlargement of many parts of the body, including the hands (left), fingers, toes, ears, nose, and jaw. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

Too much growth hormone Two conditions arise from excessive amounts of growth hormone (hyperpituitarism) in the body: acromegaly and gigantism. The cause usually is a benign* pituitary tumor*.

Acromegaly, a condition caused by increased secretion of growth hormone after normal growth has been completed, occurs in adults. The condition is rare, occurring in 6 out of 100,000 people. Because the adult cannot grow taller, the excess growth hormone in acromegaly causes adult bones to thicken and other structures and organs to grow larger. Usually, it does not appear until middle age, when the person notes a tightening of a ring on the finger or an increase in shoe size. Tests at that time may reveal a pituitary tumor.

Gigantism occurs when excessive secretion of growth hormone occurs in children before normal growth has stopped, which results in the overgrowth of long bones. The vertical growth in height is accompanied by growth in muscle and organs. The result is a person who is very tall, with a large jaw, large face, large skull, and very large hands and feet. Many health problems may be associated with gigantism, including heart disease and vision problems. Untreated gigantism may lead to acromegaly. Delayed puberty also may occur in this condition. Surgery or radiation can correct the problem. Hormone replacement may be necessary if there is pituitary damage from this treatment.

Too little thyroid hormone The thyroid gland looks like a butterfly at the base of the neck. One wing is on one side of the windpipe or trachea, and the other is on the other side. The wings are joined by a thin strip of thyroid tissue. The thyroid gland makes the hormone thyroxine (thy-ROX-een).

* **benign** (be-NINE) means a condition is not cancerous or serious and will probably improve, go away, or not get worse.

* **tumor** (TOO-mor) is an abnormal growth of body tissue that has no known cause or physiologic purpose. A tumor may or may not be cancerous.

The thyroid is controlled by the pituitary gland, which makes thyroid-stimulating hormone. The hormone thyroxine controls the rate of chemical reactions (or metabolism) in the body. Too much thyroxine, or hyperthyroidism, speeds up metabolism.

The opposite condition is hypothyroidism, which is caused by the body's underproduction of thyroid hormone, and this condition affects many different body processes. A child with thyroid hormone deficiency has slow growth and is physically and mentally sluggish. The lack of this hormone may be present at birth, if the thyroid gland did not develop properly in the fetus. Or the problem may develop during childhood or later in life as a result of certain diseases of the thyroid.

In most states, babies are tested for hypothyroidism at birth. Blood tests can detect the problem, and treatment usually is a daily pill that replaces the missing thyroid hormone. Early diagnosis and continuing treatment help these children grow and develop normally.

Too much cortisol The adrenal glands, which are located on top of the kidneys in the abdomen, secrete the hormone cortisol. If too much cortisol is made by the child's adrenals, or if large doses of the hormone are given to the child to treat certain diseases, Cushing's syndrome may develop. Children with this syndrome grow slowly, gain weight excessively, and may experience delayed puberty due to the effects of the abnormally large amounts of cortisol in the body.

A Complex Problem

There are many causes for growth problems. In order to detect these disorders early, it is important for doctors to track growth carefully in infants and children. Many of these conditions can be treated effectively, resulting in more normal adult heights for children with growth disorders.

Gum Disease

Gum disease is an infection caused by bacteria that affect the tissues surrounding and supporting the teeth.

What Is Gum Disease?

Like getting gray hair and wrinkles, losing teeth once seemed to be an inevitable part of growing old, and gum disease was a primary reason for the tooth loss. In the early 2000s, the number one cause of tooth

Gum disease causes the gums to become red, swollen, and inflamed. Compare the healthy gums on the left to the diseased gums on the right. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

loss in adults is still gum disease, also known as periodontal (per-ee-o-DON-tel) disease. This infection is caused by bacteria that affect the tissues surrounding and supporting the teeth. Tooth loss, however, does not occur until the disease is advanced. Fortunately, people can often prevent it by taking good care of the teeth and gums and seeing a dentist regularly.

The mildest form of gum disease is known as gingivitis (gin-gi-VY-tus). It causes the gums to become red and swollen and to bleed easily. At this stage, gum disease is still easily treatable. If gingivitis is left untreated, though, it can turn into periodontitis (per-ee-o-don-TY-tis), a more serious gum disease. In advanced periodontitis, the gums and the bone that supports the teeth can be badly damaged. The teeth may become loose and fall out, or a dentist may have to pull them out.

What Causes Gum Disease?

The cause of gum disease is plaque, a sticky film on the teeth that comes from bacteria living in the mouth. If an individual does not remove plaque each day by brushing and flossing, it will harden into a rough substance called calculus, also known as tartar. The bacteria in plaque produce chemicals that irritate the gums and cause infection. Left in place, these chemicals cause the gums to pull away from the teeth and create pockets of space between the teeth and the gums. The pockets are prime locations for infection. As the infection gets worse, the pockets get deeper, which can result in destruction of the bones in the jaw that hold the teeth in place.

Teenagers may get gingivitis, but they rarely develop periodontitis. Gum disease becomes more common as a person ages. In the United States, about half of adults 35 to 44 years old have gingivitis, and about half of people aged 55 years old and older have periodontitis. Individuals who smoke or chew tobacco, have uncontrolled diabetes, eat poorly, or have too much stress are all at greater risk for developing gum disease. Female hormones can play a part, too, and girls who are going through puberty* and pregnant women are at risk.

What Happens When People Have Gum Disease?

Symptoms Gum disease is usually painless in the early stage, but some signs do exist. These may include the following:

- Gums that bleed easily during tooth brushing or flossing
- Red, swollen, or tender gums
- Gums that have pulled away from the teeth
- Bad breath that does not go away
- Pus between the teeth and gums
- Loose teeth

- A change in the way the teeth fit together when the person bites
- A change in the fit of a partial set of false teeth

Diagnosis A dentist can check the gums for signs of disease. Besides carefully looking at the gums, the dentist can use a probe with a special rounded tip to check them. The dentist gently moves this probe around the gum line to search for pockets in the gums.

Treatment Treatment depends on the type of gum disease and how far along it is. For gingivitis, the dentist typically performs a deep cleaning of the tooth surface to remove plaque and tartar. For people with periodontitis, the cleaning usually also includes root planing, which smooths out any rough spots on the root. These rough spots are havens for bacteria. This two-part cleaning helps the gum tissue heal and reattach to the tooth surfaces.

If the pockets are too deep to clean inside, the dentist may need to perform surgery to shrink the pockets. If part of the bone supporting the teeth has been destroyed, the person may need further surgery. Such surgery can reshape or rebuild the bone that has been lost. Dentists also have other ways of treating gum disease. A dentist may recommend that patients with severe gum disease—and sometimes those with gingivitis—rinse with a solution called chlorhexidine gluconate. This solution curbs swelling and redness of the gums and reduces the number of bacteria in the mouth. Another drug for treating severe gum disease doxycycline hyclate, which is usually taken in tablet form, helps prevent the destruction of the teeth and gums.

How Can Gum Disease Be Prevented?

Brushing and flossing the teeth helps remove plaque, and in the early stage of gum disease, brushing twice a day and flossing every day usually cures the problem. Guidelines include the following:

- Using a soft-bristled toothbrush
- Picking a brush that feels comfortable and will reach all the teeth, even those in back
- Replacing the brush when the bristles show signs of wear
- Brushing with a short, gentle, back-and-forth motion
- Remembering to brush the inside surfaces, the back teeth, and the tongue
- Flossing to reach plaque between the teeth and under the gum line, where a brush cannot get.

In addition, individuals should see a dentist regularly for checkups and professional cleanings.

Gynecomastia

Normally, women have breasts and men do not. However, when the breast tissues, or mammary glands, of men overdevelop, along with (sometimes) the swelling of the nipples, the condition is called gynecomastia. When gynecomastia does occur, it usually happens in male babies, teenage males, and older men. Such abnormally large breasts often secrete milk from the nipples. The cause of gynecomastia was not fully understood as of 2009. However, one of the prime causes is an imbalance of sex hormones.*

What Are Possible Causes of Gynecomastia?

Gynecomastia is caused primarily by an overabundance of the female hormone estrogen or an undersupply of the male hormone testosterone. However, in 25 percent of the cases, the cause is unknown. More than one-half of male newborn babies have the condition for two to three weeks after being born. Excess estrogen in the blood system of their mothers causes this temporary problem. About one in three adolescent boys around the age of thirteen or fourteen years is temporarily afflicted with gynecomastia because of hormonal changes due to puberty*. Very tall or obese boys are more likely to have gynecomastia. For nine out of ten boys, breast size reduces partially within months and disappears totally within a few years.

Elderly men, especially those who are overweight or obese, sometimes have gynecomastia due to complications from cancers of the liver, kidney,

lung, pituitary gland, adrenal glands*, or testicles*. Older men can get the condition due to chronic conditions such as cirrhosis* of the liver or an overactive thyroid. Other causes include spinal cord injuries, chest wall injuries and, even, starvation.

Males of any age can acquire gynecomastia due to excessive use of alcohol, medications, and illicit drugs. Medicines that can cause gynecomastia include steroids such as prednisone; ulcer medicines such as cimetidine; heart medicines such as digitalis; and AIDS* (acquired immune deficiency syndrome) medications such as those used with highly active antiretroviral therapy. Other medicines that may cause the problem are ulcer medicines such as cimetidine; epilepsy* medicines such as phenytoin; antiandrogen drugs such as flutamide; anti-anxiety and anti-depressant medicines such as diazepam (Valium); and various chemotherapy* drugs.

Illicit drugs, which can possibly contribute to the disorder, include marijuana, amphetamines, anabolic steroids/androgens, and heroin. Obesity can also bring on gynecomastia because being overweight increases production of the female hormone estrogen. Males can get the condition when using large amounts of lotions and oils containing tea tree oil or lavender.

What Are the Symptoms and How Is Gynecomastia Diagnosed?

Breast enlargement is the obvious symptom. The breasts can also feel hard or rubbery. Young males may notice a small breast bud on either side, or both sides, of the breast. These usually disappear within a year or so.

Gynecomastia is diagnosed with a physical examination that pays attention to the breast tissue, abdomen, and genitals. In addition, the physician will compile a medical history. Sometimes the doctor orders chest x-rays, testicular ultrasound* scans, computerized tomography* scans, or magnetic resonance imaging* scans. Physicians often perform a biopsy with the presence of a large breast lump, which is tender or firm, especially if breast cancer has occurred within the family.

How Is Gynecomastia Treated?

Gynecomastia is normally not treated for males younger than their early twenties because it generally goes away on its own. However, if it does not, hormonal treatments may be necessary to lower estrogen levels, raise testosterone levels, or both. Surgery is an elective cosmetic (although not medically necessary) option, which includes either liposuction to remove breast fat (but not breast tissue) or mastectomy* to remove breast tissue. If certain medicines have caused gynecomastia, then the individual is advised to discontinue using them. In most cases, gynecomastia is not life threatening or physically harmful, but it can be an early indicator of a serious medical condition. Emotional problems (such as embarrassment) can sometimes result, especially for teenage boys who may be teased by the appearance of enlarged breasts.

Reducing the risk of Gynecomastia

To minimize the chance of contracting gynecomastia, males should maintain a healthy lifestyle. Doing so entails avoiding the use of illicit drugs; stopping, or at least minimizing, the intake of alcohol; maintaining a healthy weight; and reviewing all medications, both pre-scribed and over-the-counter, with their family doctor.

- * **adrenal glands** (a-DREEN-al glands) are the pair of endocrine organs located near the kidneys.
- * **testicles** (TES-tih-kulz) are the paired male reproductive glands that produce sperm.
- * **cirrhosis** (sir-O-sis) is a condition that affects the liver, involving long-term inflammation and scarring, which can lead to problems with liver function.
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).
- * **epilepsy** (EP-i-lep-see) is a condition of the nervous system characterized by recurrent seizures that temporarily affect a person's awareness, movements, or sensations. Seizures occur when powerful, rapid bursts of electrical energy interrupt the normal electrical patterns of the brain.
- * **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.
- * **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **computerized tomography** (kom-PYOO-fer-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

* **mastectomy** (mas-TEK-to-mee) is the surgical removal of the breast.

H

Hair and Hair Loss

Hair loss refers to the partial or total loss of hair from part of the body where normally it grows.

Hair Today, Gone Tomorrow

Hair is said to be a person's crowning glory. Most of the hair on a person's head is growing constantly. Scalp hair grows about half an inch per month, although this growth rate slows as people age. For each individual hair, the growth stage lasts for two to six years. It is followed by a resting stage, lasting two to three months, during which the hair still is attached but no longer grows. After the resting stage, the hair falls out, and a new hair starts to form. Hair loss occurs when people lose more hairs than normal or when new hairs do not grow to replace the lost ones.

How Does Hair Grow?

Hair is made of keratin (KER-a-tin), the same protein that makes up nails and the outer layer of skin. The part of a hair that shows is called the hair shaft. Below the skin is the hair root, which is enclosed in the follicle (FOL-i-kul), a tiny, bulb-shaped structure. The root is alive, but the shaft is composed of dead tissue made by the follicle.

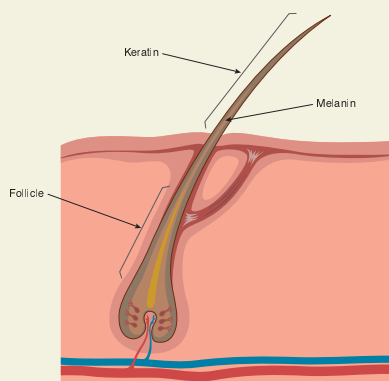

Hair color is inherited and is determined by multiple genes. The color comes from two types of pigment in the hair: pheomelanin (feo-MEL-an-in) and eumelanin (u-MEL-an-in). Pheomelanin ranges from yellowish reddish in color. Eumelanin is either brown or black. The relative amounts of these two pigments determine hair color.

What Is Hair Loss?

Hair loss refers to the partial or total loss of hair from part of the body where it normally grows, especially the scalp. Alopecia (AL-o-PEE-sha) is the medical term for baldness, which is the loss of all or a significant part of the scalp hair. Hair for humans is mostly decorative. Losing hair is not a medical problem in itself, although in some cases, it can be a sign of illness. Many people are perfectly comfortable being bald. However, others feel that hair loss makes them less attractive.

What Causes Hair Loss?

Hair loss is extremely common. About half of all men and one-fourth of all women over age forty experience some thinning of the hair on the

▲ A strand of hair showing the follicle, melanin, and keratin. *Illustration by Bryon Thompson. Reproduced by permission of Gale, a part of Cengage Learning.*

- * **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.
- * **menopause** (MEN-o-pawz) is the end of menstruation.
- * **immune system** is the body system that fights disease.
- * **thyroid gland** (THY-roid GLAND) is located in the lower part of the front of the neck. The thyroid produces hormones that regulate the body's metabolism (me-TAB-o-LIZ-um), the processes the body uses to produce energy, to grow, and to maintain body tissues.
- * **fungus** (FUN-gus) is any organism belonging to the kingdom Fungi (FUN-ji), which includes mushrooms, yeasts, and molds.
- * **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.
- * **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

head. This is normal and is not related to any medical problem. However, hair loss also can occur for other reasons. Following are some specific hair loss conditions and their causes.

Common baldness At least 95 percent of scalp hair loss is caused by a combination of age, genetics, and changes in the level of hormones* called androgens (AN-dro-jenz). This type of hair loss is called androge-netic (AN-dro-je-NET-ik) alopecia. In men, the condition usually starts with a hairline that keeps moving higher, followed by a thin or bald spot that appears on top of the head. Eventually, all that may be left is a horse-shoe-shaped fringe of hair around the sides and back of the head, which is known as male-pattern baldness. In women, the condition usually leads to thinning of the hair over the whole head, which is especially common after menopause*. It is known as female-pattern baldness.

Alopecia areata Alopecia areata (ar-ee-AY-ta) can develop in people of any age, including children. This condition leads to sudden hair loss, often in round patches on the scalp about the size of a coin or larger. In severe cases, the hair may fall out from the whole head, including the eyebrows and beard, or the whole body. Alopecia areata is thought to be caused by a problem with the immune system* in which immune cells attack the body's own follicles, for reasons that are not clear. People who develop alopecia areata are usually otherwise in good health. The hair often grows back on its own within 6 to 24 months.

Medical conditions and hair loss Several medical conditions and treatments can cause hair loss in people of all ages and both sexes. Sometimes, people notice a lot of hair falling out within one to three months after having a high fever, a severe infection, or a major operation. Some women also lose a large amount of hair within a few months after giving birth due to changing hormone levels following pregnancy. Changing hormone levels are also why babies lose a great deal of their hair during the first six months of life. In addition, an overactive or underactive thyroid gland* can cause hair loss, as can ringworm (a fungal* infection) of the scalp.

People with cancer often lose their hair during chemotherapy*. Other medications may cause hair loss as well, including blood thinners, birth control pills, and medicines for depression* and high blood pressure. Fortunately, this kind of hair loss usually is temporary. Typically, the hair grows back once the body adjusts, the disease is treated, or the medicine is stopped.

Trichotillomania Trichotillomania (trik-o-til-o-MAY-nee-a) is a psychological* disorder in which people pull out their own hair, leading to noticeable hair loss. The most commonly affected spots are the scalp, eyebrows, and eyelashes. This nervous habit may be a reaction to emotional stress or anxiety. It often begins in childhood, although it occurs in adults, too. The hair grows back once the hair pulling is stopped.

Poor diet When people do not get enough protein from their diet, the body may try to save protein by shifting hairs from the growing stage to the resting stage. As a result, a large number of hairs may fall out two to three months later, when the resting stage ends. Lack of iron also can lead to hair loss. Eating a healthy diet or taking iron pills can prevent or reverse this problem.

Improper hair care Chemicals such as dyes, bleaches, straighteners, and permanents can damage the hair if used too often or left on too long. Even shampooing, brushing, and combing can harm the hair if done too roughly. Hairstyles that pull the hair, such as tight ponytails and braids, also put a lot of stress on it. Mistreating the hair in any of these ways can lead to temporary hair loss.

How Is the Cause of Hair Loss Identified?

People who experience sudden, fast, or unusual hair loss should see a physician, who can identify the cause. In some cases, doctors may decide that the baldness is simply due to aging. In other cases, doctors may check the scalp and take samples from it to look for signs of disease. In addition, doctors may pluck several hairs from one spot on the head. These hairs then are examined under a microscope to see whether they are in the growing or resting stage. The percentage of hairs in each stage can provide another clue to the cause of the hair loss.

How Is Baldness Treated?

Hair loss due to alopecia areata usually clears up on its own with time. In the meantime, the condition sometimes is treated with corticosteroid* medicines that are rubbed onto the skin or taken by mouth or in an injection.

Common baldness due to aging does not need treatment for medical reasons. However, some people seek help, because they are concerned about the way their appearance. There are several treatment options.

Hairstyles, wigs, and hair additions Simply getting the right haircut and styling the hair in a flattering way can make a big difference with thinning hair or scattered hair loss. For more widespread hair loss, wigs are an easy solution. Several kinds of partial wigs, known as hair additions, are available as well. They can be attached to the remaining hair or anchored to the scalp with special glues or fasteners.

Medication Two medications are approved in the United States for regrowing lost hair or preventing further hair loss: minoxidil (mi-NOK-si-dil) and finasteride (fi-NAS-ter-ide). Minoxidil (Rogaine) can be bought without a prescription. It is a liquid that is rubbed onto the scalp. Only about one-fourth of men and one-fifth of women who use regular-strength minoxidil regrow a significant amount of hair, and it may take several months before these results are noticeable. The new hair

* **psychological** (SI-ko-LOJ-i-kal) refers to mental processes, including thoughts, feelings, and emotions.

* **corticosteroid** (KOR-ti-ko-STER-oid) is one of several medications that are prescribed to reduce inflammation and sometimes to suppress the body's immune response.

Hair-Raising Facts

- Natural blondes have about 140,000 hairs on their head, on average. Brunettes have about 105,000 hairs, and redheads have about 90,000 hairs.
- At any given time, about 90 percent of the hairs on a person's head are growing. About 10 percent of the hairs are resting, getting ready to fall out.

A Hairy Situation

Some people worry about having too little hair. Others worry about having too much. Hirsutism (HIR-soot-iz-uhm) is the medical term for excessive hair growth on the body and face, especially in women. Many women, particularly those of southern European and Middle Eastern descent, develop quite a bit of body and facial hair when they reach puberty. This is perfectly normal, and in both women and men, the amount of body and facial hair often increases slowly with age.

If a person does not like the way the hair looks, it can be bleached or removed in a variety of ways. However, sometimes there is an increase in the growth of coarse, dark facial and body hair over a period of weeks or months. This can be a sign of a medical problem in which the level of androgens in the blood is abnormally high, as in certain disorders of the ovaries and adrenal glands.

Some medicines, such as steroids and certain blood pressure drugs, also may cause the growth of body and facial hair. In addition, anorexia nervosa (AN-o-REK-se-a ner-VO-sa), an eating disorder that involves self-starvation and often occurs in teenage girls, may cause an increase in fine body hair.

often is thinner and lighter in color than the original hair. Also, any hair growth that occurs ceases once the treatment is stopped.

Finasteride (Propecia) is a pill sold by prescription. This drug is approved for sale only to men, because it has not been shown to work in women, and it can cause birth defects if used by pregnant women. More than four out of five men who use finasteride have slowing of their hair loss, and more than three out of five have some hair regrowth. As with minoxidil, positive effects can take months to see.

Surgery Hair transplantation (trans-plan-TAY-shun) surgery is a lasting but expensive and often painful solution to hair loss. When done for cosmetic reasons, it normally is not covered by medical insurance. The operation involves cutting tiny plugs of hair-bearing scalp from parts of the head where hair still grows, and then reattaching the plugs to bald parts of the head. No new hair is added. Existing hair simply is moved from one spot to another. Because hundreds or even thousands of the tiny plugs must be moved to get good results, the procedure usually is done in several surgery sessions that are months apart. Sometimes, a larger flap of skin is moved instead of many tiny plugs.

Scalp reduction surgery is another procedure, which may be combined with hair transplantation. It involves removing a bald area of scalp from the top of the head and then stretching the hair-bearing scalp to cover the area. Hair surgery is performed by dermatologists and cosmetic and plastic surgeons.

Coping with Hair Loss

Hair loss can be upsetting, even when it is temporary. Hairstyles, wigs, hair additions, hats, and bandannas can help hide hair loss if it makes a person uncomfortable. For many people, hair loss simply does not matter. Others wear their baldness with pride. Many even shave any remaining hair if the hair loss is patchy.

Halitosis

Halitosis is bad breath.

What Causes Halitosis?

Halitosis is the medical name for bad breath. Often people with halitosis do not know that they have it. Halitosis can be caused by many factors:

- Eating certain strong smelling foods, such as garlic and onion, which have odors that are absorbed into the bloodstream, transferred into the lungs, and then released when a person exhales
- Having poor oral hygiene habits, which leave food particles in the mouth to collect odor-causing bacteria
- Tooth decay
- Gum disease*
- Smoking
- Sinus or respiratory infections
- Unusual dryness of the mouth, a condition called xerostomia (ze-ro-STO-me-a)
- Medical disorders, such as liver disease, kidney disease, or diabetes
- Certain medications
- Dieting and ketone* build-up in the body

How Is Halitosis Treated and Prevented?

Treatment for halitosis depends on its cause. Dentists can identify oral causes, which account for most cases of halitosis, and develop an appropriate treatment plan. For halitosis due to gum disease, dentists may refer people to periodontists (gum specialists). If a person has a healthy mouth but still has halitosis, a dentist may also recommend a visit to a doctor. The doctor can then try to determine the cause of the bad breath and select treatment options.

Good dental hygiene is essential for preventing halitosis. Good dental hygiene includes the following steps:

- Brushing teeth at least twice every day
- Brushing the tongue

* **gum disease** is an infection caused by bacteria that affect the tissues surrounding and supporting the teeth.

* **ketones** (KEE-tones) are the chemicals produced when the body breaks down fat for energy.

* **stimulus** (STIM-yoo-lus) is an agent in the environment that excites a response or reaction. A stimulus might cause a person to function, become active, or respond. The plural form is stimuli.

- Using dental floss every day to remove pieces of food that remain caught between teeth even after brushing and cause an accumulation of bad-smelling bacteria.
- Visiting a dentist's office for a regular check-up and cleaning

Some dentists also recommend that their patients scrape the tongue as part of their regular cleaning routine. In this quick, painless procedure, an individual drags a metal or plastic scraper over the tongue to mechanically remove bacteria that might cause odor.

People who wear dentures must take precautions, too. They should take out their dentures every night and clean them well before putting them in again.

Hallucination

A hallucination (ha-LOO-sin-A-shun) is something that a person, while awake, perceives as real but that is not actually caused by an outside stimulus.*

Is It All in Their Heads?

A good magician can make audience members think that they are seeing something they really are not, such as an animal disappearing into thin air or a bouquet appearing from under a handkerchief. These tricks are often referred to as illusions. The magician knows how to perform the illusion so that the viewer's eyes and brain are likely to misinterpret what is really happening.

Hallucinations are different from illusions. Illusions are mistaken perceptions of real events. During an hallucination, the person is not reacting to something real in the outside world. The brain creates its own stimulation instead of relying on input from the five senses. In other words, the entire experience, its cause and its response, takes place inside the brain.

Hallucinations occur when a person is conscious or awake, so although dreams may cause people to think that what they are dreaming is real, these are not true hallucinations. However, a large percentage of the population reports having brief hallucinations when they are just at

the edge of consciousness while falling asleep or waking up. These are true hallucinations, and they are considered normal and harmless.

Hallucinations can involve any of the five senses: sight, hearing, taste, smell, and touch. They can appear in the form of seeing visions, hearing voices or music, smelling odors that are not really present in the environment, distorting the taste of food, or feeling as if something is crawling over or touching either the skin or the interior of the body. These sensations can be brief or extended. Often they are quite vivid and seem absolutely real to the person who experiences them. In people with mental illness, hallucinations often are accompanied by delusions. A delusion is a strong belief about something that is clearly false. For example, a delusional person might believe that the television is sending out signals that control his brain and cause him to hear voices.

What Triggers Hallucinations?

Hallucinations can occur when a person is mentally ill, uses certain drugs, is under prolonged stress, is exhausted or sleep deprived for a long time, experiences extremely high fever, or has certain nervous system diseases. People who are blind or deaf may also have hallucinations due to lack of sensory input from the eyes or ears. Scientists are not exactly sure why some people hallucinate, but they do know that nerves in specific areas of the brain responsible for interpreting sensory information are activated on their own without outside stimuli when a person hallucinates.

The most common hallucinations are those that accompany psychotic (sy-KOT-ik) disorders*, such as schizophrenia*. About three-fourths of people who are treated for schizophrenia experience hallucinations. These hallucinations can reach the point where the sense of reality is so impaired that a person cannot function normally. Along with hallucinations, people with psychotic disorders may experience delusions, incoherent speech, and agitated behavior, but they usually are not aware of their altered mental state. They lose touch with aspects of reality, which affects their thinking and behavior. They often report hearing voices that tell them that they are bad or that they should act in a certain way. For example, the serial murderer Son of Sam (David Berkowitz) claimed to have repeatedly heard voices in his head telling him to kill. People with schizophrenia also tend to see disturbing visions. Medications can help with hallucinations caused by schizophrenia, and in some cases, people can be trained to recognize and even control their hallucinations. This level of improvement usually requires intensive therapy.

Anxiety* disorders and intense emotions or a highly traumatic experience also can generate hallucinations. For example, people who experience the death of a loved one often report hallucinations in which they see that person or hear the person's voice. Similarly, people who undergo extreme abuse sometimes report later visions of their abuser. Soldiers or others with post-traumatic stress disorder*

Phantom Limb Syndrome: A Tactile Hallucination

People who have undergone amputation of a limb or other appendage help researchers understand what may happen in the brain when it hallucinates. Many of these patients report that they feel like the missing body part is still there, even though they know the arm, leg, hand, or other body part is gone. For example, it is common for people who lose a leg to try to stand up and walk after their surgery. Feeling like an amputated limb is still present is called phantom limb syndrome, and there are two main theories about why it happens. It may be that the nerve cells in the brain area that used to receive signals from that limb go into overdrive and stimulate themselves because that input has disappeared. Another theory is that the brain is programmed for a body that is whole and intact and in the right place so that when certain signals are missing, spontaneous nerve cell activity takes over. In either case, the brain is compensating for the lack of sensory input.

* **psychotic (sy-KOT-ik) disorders** are mental disorders, such as schizophrenia, in which the sense of reality is so impaired that a person can not function normally. People with psychotic disorders may experience delusions, hallucinations, incoherent speech, and agitated behavior, but they usually are not aware of their altered mental state.

* **schizophrenia** (skit-so-FREE-nee-ah) is a serious mental disorder that causes people to experience hallucinations, delusions, and other confusing thoughts and behaviors, which distort their view of reality.

- * **anxiety** (ang-ZY-e-tee) can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person's physical or mental well-being.
- * **post-traumatic stress disorder** (post-traw-MAT-ik STRES dis-OR-der) is a mental disorder that interferes with everyday living and occurs in people who survive a terrifying event, such as school violence, military combat, or a natural disaster.
- * **flashbacks** are intensely vivid, recurring mental images of a past traumatic event. People may feel or act as if they were reliving the experience.
- * **hallucinogenic drugs** are substances that cause a person to have hallucinations.
- * **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.
- * **Alzheimer's (ALTS-hy-merz) disease** is a condition that leads to gradually worsening loss of mental abilities, including memory, judgment, and abstract thinking, as well as changes in personality.
- * **lesions** (LEE-zhuns) is a general term referring to a sore or a damaged or irregular area of tissue.

may also experience hallucinations as flashbacks* to especially traumatic events.

Hallucinogenic drugs* such as the street drugs ecstasy, LSD, mescaline, peyote, and psilocybin (magic mushrooms) are artificial sources of brain overstimulation. They excite the central nervous system* so much that certain areas of the brain produce visions, sounds, and feelings that are not based in reality. Some hallucinogenic drug users continue to experience bizarre visions and sounds even long after they stop using the drug. Some prescription drugs also can produce hallucinations as an unwanted side effect.

That the brain may compensate for a lack of sensory input helps to explain why people who are deaf or blind or who are placed in extended solitary confinement often experience hallucinations. Under such circumstances, the different areas of the brain that were used to receiving signals through the senses start to stimulate themselves. Reduced sensory input also may explain why people tend to “see” ghosts at night instead of during the day; the brain is more likely to create the vision of ghosts when other visual stimuli are absent.

Some nervous system diseases such as Alzheimer's (ALTS-hy-merz) disease* may also cause hallucinations. Brain damage, brain tumors, or lesions* in the brain also may stimulate the production of hallucinations.

Hangover

A hangover, also known as veisalgia (vy-SAL-gee-uh), occurs after a person becomes intoxicated due to drinking too much alcohol. Hangovers may have several unpleasant symptoms, including headache, sensitivity to sound, jitteriness, tiredness, and nausea.

What Is a Hangover?

When individuals drink too much alcohol, they may wake up the next morning with a hangover. Generally, the more alcohol they drink, the worse their hangover is. The amount of alcohol that brings on a hangover varies from person to person. Frequently an amount of alcohol that causes a hangover in a person who is a light drinker may not cause one in a person who is a frequent, heavy drinker. Frequent and heavy drinkers develop a tolerance to alcohol.

However, heavy alcohol consumption can lead to many serious health problems. In the near term, alcohol poisoning is a drug overdose, which can lead to persistent vomiting, changes in mental status, coma*, and death. Over the long term, heavy drinking can lead to cirrhosis* of the liver, which can be fatal.

Regular consumption of alcohol can also lead to alcoholism, a progressive long-lasting dependency on alcohol. Alcoholics have a physical craving for alcohol. Chronic alcohol consumption can lead to many health and other problems. Alcohol consumption can affect people's work life, their finances, and their relationships with family and friends. Habitual drinkers who drive are likely to experience legal problems with traffic tickets or accidents. They may lose their license to drive. The court can order them to attend driver responsibility sessions or attend meetings of Alcoholics Anonymous. The best way to prevent alcoholism is to avoid drinking alcohol or to drink infrequently and then only small amounts. Restricting alcohol consumption avoids a lot of potential problems, and it prevents having a hangover the morning after.

What Are the Symptoms of Hangover?

Typically, hangover symptoms begin a few hours after individuals stop drinking, often beginning the following morning and continuing for several hours. Symptoms may include one or more of the following:

- Mild to severe headache
- Jitteriness
- Sensitivity to sound and sometimes to light
- General feeling of being sick
- Tiredness
- Dry mouth and eyes, and a desire to drink water
- Poor coordination
- Drowsiness
- Trouble sleeping and/or concentrating
- Loss of appetite
- Stomachache, nausea, and/or vomiting
- Muscle aches
- Diarrhea

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

* **cirrhosis** (sir-O-sis) is a condition that affects the liver, involving long-term inflammation and scarring, which can lead to problems with liver function.

- Increased blood pressure and a higher heart rate
- Feelings of anxiousness
- Heightened irritability
- Sweating
- Dizziness and/or vertigo
- Trembling or shaking

Many people with a hangover also feel strongly repulsed by a mere thought of alcohol.

A study in 2003 showed that women appear to get much more severe hangover symptoms than men do. The study suggested that because in general women weigh less than men, women are more easily intoxicated and have more troublesome hangovers.

What Causes a Hangover?

The hangover is related to do the hormone vasopressin (vay-zo-PRESS-in). Drinking alcohol puts alcohol into the bloodstream. The alcohol the release of antidiuretic hormone from the posterior pituitary gland. Normally, vasopressin signals the kidneys to send water back into the body where it can be used. When alcohol blocks vasopressin production, however, the kidneys send most of the water to the bladder, which then releases it as urine. This water comes from the body itself as well as from the alcoholic beverage. In fact, drinkers' bodies release up to four times more water than is present in the beverages they consume. For this reason, people who are drinking alcoholic beverages urinate frequently.

The water imbalance causes many of the symptoms of a hangover. Some of these occur because urine releases both sodium and potassium, along with water. When the body loses too much sodium and potassium, its muscles and nerves do not function correctly. This dysfunction results in headaches, tiredness, and nausea. In addition, alcohol-induced water loss can cause a dry mouth.

Besides its effects on vasopressin and the subsequent water loss, alcohol also affects the liver. The liver regulates blood sugar, the body's primary fuel. Blood sugar is also known as glucose (GLUE-cose). The liver regulates glucose by storing some of it in a slightly different form, called glycogen (GLY-co-jen). When individuals drink alcohol, the alcohol breaks down the glycogen in the liver and converts in into glucose, but instead of moving the glucose into the bloodstream for the body's cells to use, the glucose goes into the urine and then leaves the body. This reduces the amount of energy available to the body and causes hangover symptoms such as fatigue, general weakness, and poor coordination.

In addition, most alcoholic beverages contain congeners, which are substances that are generally added for flavor or color. Certain types of alcohol contain higher amounts of congeners, which may contribute to hangover symptoms. Dark liquors, such as brandy and whisky, have more congeners than clear ones, such as vodka and gin.

Can Hangovers Be Prevented?

Avoiding alcohol is the surest way to prevent hangovers. People who do drink can also avert hangovers by taking certain steps. One way is to drink only on a full stomach, to drink slowly, and to consume moderate amounts of alcohol. Drinking several eight-ounce glasses of water prior to going to sleep may help relieve the dry mouth and dehydration*. The National Institute on Alcohol Abuse and Alcoholism recommends a maximum of one drink per day for women and two per day for men. The institute defines one drink as a 12-ounce beer, a 4-ounce glass of wine, or a mixed drink with 1.5-ounces of liquor (80-proof distilled spirits). Another suggestion is to drink a glass of water after every alcoholic beverage. Doing so helps to replace some water loss, to reduce dehydration, and to limit the amount of alcohol consumed by exchanging some of those alcoholic drinks with glasses of water. Finally, choosing alcohol with lower congener content may also help to prevent hangover.

How Is Hangover Treated?

Frequently recommended hangover treatments include the following:

- Staying in bed and getting some rest
- Eating fruits or honey, and drinking fruit juice. These contain a type of sugar called fructose (FROOK-tose), which some studies indicate may help to remove the alcohol from the body more quickly.
- Eating salty foods to replace the body's lost minerals

When treating hangover, some people take aspirin for headache. They should not, however, take acetaminophen*, which appears in many over-the-counter pain medications and which in the presence of alcohol can be harmful to the liver. People who are frequent, heavy drinkers should avoid acetaminophen at all times. The National Institute on Alcohol Abuse and Alcoholism also cautions that people who are taking any medications should talk to a doctor or pharmacist before drinking alcohol, because many medications interact harmfully with alcohol and can result in increased risk of illness, injury, or death. The institute also notes that many medications can make a person more susceptible to the effects of alcohol, so drinking while taking these drugs may be dangerous.

Hansen's Disease *See Leprosy (Hansen's Disease).*

Hantavirus Pulmonary Syndrome

Hantavirus pulmonary syndrome (HAN-tub-vy-rus PUL-mo-nar-ee SIN-drome) is a lung disease that causes respiratory distress (breathing difficulty) and, in some cases, death. Hantavirus, the virus that causes the disease, is carried by rodents.

What is Hantavirus Pulmonary Syndrome?

Hantavirus pulmonary syndrome, or HPS, is a potentially deadly disease that attacks the lungs. A family of viruses* called hantavirus causes HPS. These viruses live in rodents but do not make them sick. The Sin Nombre virus (SNV) hantavirus causes most HPS in the United States, but some cases have come from the Bayou, the New York, and the Black Creek Canal viruses.

Rodents, usually mice and rats, shed hantavirus in their saliva, urine, and droppings. Humans catch the virus when they disturb dried droppings (by sweeping, for example) and inhale the particles that are sent into the air. People can also contract hantavirus by touching an infected animal or its droppings and then touching their nose or mouth. Eating food or drinking water contaminated by rodent droppings is another way to contract the infection. Rodent bites, although rare, can also spread the disease.

The most common carriers of hantavirus are deer mice (found almost everywhere in North America), cotton rats and rice rats (found in the southeastern United States and Central and South America), and white-footed mice (found in most parts of the United States and Mexico). Cats and dogs do not carry hantavirus, and they cannot catch it from rodents. However, cats and dogs can spread hantavirus to humans if they bring an infected rodent into a home or other buildings where people live or work.

Is Hantavirus Pulmonary Syndrome Common?

HPS is rare. Health authorities first recognized the disease in the United States in 1993, and the Centers for Disease Control and Prevention (CDC) recorded only 465 reported cases through early 2007. Although HPS occurs in people throughout North and South America, most cases in the United States appear in the Southwest and in places that have large rodent populations.

People of every age, sex, and race can contract HPS, but it is not contagious and cannot be spread by sneezing, coughing, kissing, or having other bodily contact.

What Are the Symptoms of Hantavirus Pulmonary Syndrome?

The first symptoms of HPS usually appear one to five weeks after a person has been exposed to the virus. HPS can be difficult to diagnose because the early signs, such as fever, tiredness, and body aches, are similar to those of the flu. About half of the people who catch HPS may also experience dizziness, chills, nausea, vomiting, abdominal* pain, or headaches.

From two to five days after the first symptoms, a person infected with hantavirus starts coughing and experiences shortness of breath. The disease quickly becomes more severe, and people who do not receive immediate treatment may become extremely ill and go into shock*, needing intensive care in a hospital.

How Do Doctors Diagnose Hantavirus Pulmonary Syndrome?

A doctor may suspect HPS if a person with flu-like symptoms complains about difficulty breathing, especially if the person has been exposed to rodents or rodent droppings. To confirm the diagnosis, the doctor uses blood tests to see if the person has developed antibodies* to a strain* of hantavirus. Chest x-rays or ultrasound* images can help the doctor check the condition of a person's heart and lungs.

How Is Hantavirus Pulmonary Syndrome Treated?

HPS is a serious disease, and someone who has it needs treatment in a hospital's intensive care unit. There the patient might be given fluids, have his or her blood pressure monitored, and have a tube inserted in the throat to make it easier to breathe. Because a virus causes HPS, antibiotics do not work against it, although an antiviral drug may help some patients. According to the CDC, as of the early 2000s, 38 percent of reported cases of HPS have been fatal.

Doctors know more about the disease and are quicker to get patients into treatment. The earlier people with HPS receive help, the better their chances of survival. Recovery from HPS is fairly fast, although patients may feel worn out for several months.

Camp with Care

The great outdoors is home for most rodents, and many of them carry hantavirus. Campers can help keep camping and hiking trips safe by following a few simple precautions:

- using a tent with a built-in floor and pitching it away from woodpiles or any rodent nests or burrows
- sleeping on a raised surface, at least 12 inches off the floor
- airing out cabins that have not been used for a half hour or more, then checking for rodent droppings
- using water and disinfectant to wipe out the area (without sweeping)
- keeping all food in rodent-proof containers
- burying or burning trash
- using bottled water for drinking, cooking, and all washing
- staying away from mice, rats, chipmunks, and all other rodents.

* **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.

* **shock** is a serious condition in which blood pressure is very low and not enough blood flows to the body's organs and tissues. Untreated, shock may result in death.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **strain** is a subtype of an organism, such as a virus or bacterium.

Symptoms of hay fever

Symptoms

Sneezing
Runny nose
Watery eyes
Postnasal drip
Sore throat and roof of mouth
Head congestion
Ear pressure
Sleep disturbances
Nasal discharge
Swollen, blue-colored skin under the eyes
(allergic shiners)
Fatigue
Irritability

▲

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.

* **allergies** (AL-uhr-jeez) are immune system-related sensitivities to certain substances, for example, cat dander or the pollen of certain plants, that cause various reactions, such as sneezing, runny nose, wheezing, or swollen, itchy patches on the skin, called hives.

* **atopy** (AT-uh-pee) is an allergic hypersensitivity that affects parts of the body not in direct contact with the allergen, as hay fever, asthma, or eczema.

Can Hantavirus Pulmonary Syndrome Be Prevented?

There is no vaccination* available for HPS. The best way to avoid contracting the virus is to get rid of possible sources of infection, which means avoiding woodpiles and other places where rodents live outdoors and keeping homes and workplaces free of mice and rats. Experts also recommend sealing holes where rodents can enter (they can squeeze through spaces as small as 0.25 inch in diameter) and wearing a mask and gloves when cleaning out areas with rodent droppings.

Hay Fever

Hay fever is an allergic reaction to plant pollen, in the United States most commonly ragweed, tree, or grass pollen. Hay fever may be either seasonal, meaning that the person has a runny nose and other symptoms only during certain periods of the year, or perennial, which means that the person has symptoms all year long.

What Is Hay Fever?

Hay fever is one of several allergies* that are called atopy* or atopic (a-TOP-ik) allergies because they affect parts of the body that are not in direct contact with the allergens*. About 20 percent of people with hay fever eventually develop asthma, and some develop eczema* as well. Doctors refer to hay fever as allergic rhinitis* because it involves irritation

and inflammation of the nasal passages. Other names for hay fever are grass fever and rose fever.

How Common Is Hay Fever?

Hay fever is very common in the United States. The National Institutes of Health estimates that between 20 and 25 percent of Americans have some form of hay fever, although the specific pollens that trigger the symptoms vary from region to region across the United States. In general, the hay fever season is shorter in the northern states and longer in the South, particularly along the East Coast. From mid-spring to early summer the pollen count is highest in most parts of the country.

The most common sources of the pollens that trigger hay fever are plants or trees that are pollinated by the wind rather than by bees or other insects. Such trees and other plants include birch, alder, willow, and horse chestnut trees; ryegrass, Kentucky bluegrass, timothy, and Bermuda grass; and ragweed, sorrel, and sagebrush.

Hay fever affects children more often than adults. About 80 percent of people with hay fever develop it before age 20, with the average age at the time of the first episode being between 8 and 11 years of age. Some doctors think that as many as 40 percent of children may suffer from hay fever at some point in childhood. The symptoms typically become less severe in adulthood and may go away completely.

Is Hay Fever Contagious?

The most noticeable symptoms of hay fever are a stuffy or runny nose, sneezing, and teary or watery eyes. Some people also have coughing, headaches, fatigue, and drowsiness. These symptoms are easily confused with the symptoms of a cold. Unlike colds, hay fever is not contagious. It does, however, appear to run in families. It is possible for several members of a family to be affected by hay fever at the same time if they are all allergic to the same type of weed or tree pollen, but this fact does not mean that the disorder can be spread from one person to another like a cold does.

How Do People Know They Have Hay Fever?

Many people who get the runny nose, watery eyes, and other symptoms of hay fever think at first that they just have a cold. One way to tell the difference is that colds usually clear up in about a week. Another difference is that hay fever is usually worse during certain months of the year or at certain times of day during pollen season. Hot, dry, and windy days are more likely to trigger the symptoms of hay fever than cool or rainy days. The pollen count is also likelier to be higher early in the morning than later in the day.

The symptoms of hay fever are not caused by viruses like those that cause colds. They develop when plant or weed pollen enters the person's airway and the tissues that line the eyelids. Then white blood cells in the immune system* produce antibodies* to the plant allergens. These antibodies are stored in special cells in the mucous membranes lining the nose and eyelids known as mast cells. When the allergen comes in contact

* **allergens** are substances that provoke a response by the body's immune system or cause a hypersensitive reaction.

* **eczema** (EG-ze-mah) an inflammatory skin condition characterized by redness, itchiness, and oozing blisters that become crusty and hard.

* **rhinitis** (rye-NYE-tis) is the medical term for inflammation of the tissues inside the nose.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **histamine** (HIS-tuh-meen) is a substance released by the body during inflammation. It causes blood vessels to expand and makes it easier for fluid and other substances to pass through vessel walls.

* **antihistamines** (an-tie-HIS-tuh-meens) are drugs used to combat allergic reactions and relieve itching.

* **corticosteroids** (kor-tih-ko-STIR-oyds) are chemical substances made by the adrenal glands that have several functions in the body, including maintaining blood pressure during stress and controlling inflammation. They can also be given to people as medication to treat certain illnesses.

* **anticholinergics** (AN-ti-koll-in-ER-giks) are medications given to counteract a chemical in the central nervous system that controls muscles, sweat glands, and some glands that secrete mucus.

with the mast cells, a compound called histamine* is released. Histamine is responsible for the runny nose, itchy and watery eyes, and sneezing of hay fever.

How Do Doctors Diagnose and Treat Hay Fever?

Diagnosis The first step in diagnosing hay fever is to take a history of the patient's symptoms. The doctor will ask when the symptoms began; whether they appear during the same time of year every year; whether the symptoms are continuous or come and go; and whether they are worse at specific times of day. In most cases the doctor will ask whether there is a family history of allergies and whether the patient also has asthma or eczema.

The next step is a series of skin tests to find out which specific pollens are causing the patient's runny nose and other symptoms. The doctor takes a small amount of material extracted from a specific type of pollen and injects it under the patient's skin or applies it to a tiny scratch on the arm or upper back. If the patient is allergic to the material, the skin will develop a wheal, or flat-topped reddish swelling.

Treatment There are three parts to treating hay fever: avoiding the specific trigger(s); using medications to relieve such symptoms as itching eyes and a runny nose; and taking allergy shots to reduce one's sensitivity to triggers.

The doctor may recommend one or more of the following types of medications in treating hay fever:

- **antihistamines***. These drugs counteract the effects of histamine in causing the watery eyes and runny nose associated with hay fever. Some are available over the counter whereas others require a prescription. The older antihistamines often make people drowsy; patients who use these medications should not drive or operate machinery while taking them. The later antihistamines are more expensive but do not make people drowsy as a side effect.
- **Decongestants**. These are nasal sprays or tablets taken by mouth that clear up stuffiness in the nose. People with high blood pressure, however, should avoid oral decongestants because they can raise blood pressure.
- **Nasal corticosteroids***. These sprays reduce the inflammation of the tissues lining the nose and eyes. They may take about a week to start to work but are safe for long-term use.
- **Anticholinergics***. These prescription drugs work by drying up secretions from the glands that line the nasal passages. They are used as nasal sprays two or three times per day. These sprays may, however, dry out the nose too much and lead to nosebleeds.
- **Gargling and rinsing out the nasal passages with salt water**. Patients can purchase premixed sprays or make their own rinse by adding one-fourth teaspoon of salt to two cups of warm water.

Can Hay Fever Be Prevented?

The most common strategy for preventing hay fever is avoiding the plants that trigger the patient's symptoms. Staying indoors when the pollen count is high, filtering the air inside the house, avoiding grassy fields or large forested areas, or moving to a part of the country with a dry desert climate are some ways people lower their exposure to airborne pollens.

Another approach is desensitization*, also called immunotherapy (im-you-no-THER-a-pee). In desensitization therapy, individuals are given a series of injections of their specific allergen under the skin, with the concentration of pollen in the shots being gradually increased. It takes an average of 8 to 12 months for people to see benefits, however, and the shots must be taken for at least three years and sometimes closer to five years.

A later possibility for preventing hay fever is a vaccine* that was first tested in patients in Canada, Europe, and the United States in the summer of 2007. If the vaccine were to pass all its safety tests and be approved for use, people with hay fever would have to have only four shots—one per week for one month.

Headache

Headache is a pain or discomfort felt in the head. It is not a disease but a symptom of some other problem in the body, and there are many possible causes. When someone gets a headache it usually is temporary, and only very rarely is it a sign of serious illness.

* **desensitization** (de-sens-ih-tih-ZAY-shun) a method for reducing a person's reaction to an allergen.

* **vaccine** (vak-SEEN) is a preparation of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.

- * **menstrual cycle** (MEN-stroo-al SYkul) culminates in menstruation (men-stroo-AY-shun), the discharging through the vagina of blood, secretions, and tissue debris from the uterus that recurs at approximately monthly intervals in females of reproductive age.
- * **chronic** (KRAH-nik) lasting a long time or recurring frequently.
- * **glaucoma** is a group of disorders that cause pressure to build in the eye, which may result in vision loss.
- * **sinusitis** (sy-nyoo-SY-tis) is an infection in the sinuses, which are hollow cavities in the facial bones near the nose.
- * **withdrawal** a group of symptoms that occurs when a drug that causes physical or psychological dependence is regularly used for a long time and then suddenly discontinued or decreased in dosage.

What Are Headaches?

Headaches are one of the most frequent local pain complaints; most people experience a headache at least once in their lives. Although there are dozens of causes of headaches, most headaches are due to tension or stress. About 12 percent of people in the United States at some point in their lives may have a recurrent, often severe type of headache known as migraine.

Up to 50 million people in the United States annually seek medical help for migraine and other severe headaches. Every 10 seconds, someone in the United States goes to the emergency room with a migraine or other type of headache. The lost work hours due to migraine and other headaches costs an estimated \$13 billion every year in the United States. It has been estimated that more than \$1 billion are spent each year for over-the-counter remedies to relieve headaches.

A large percentage of women's headaches are related to their menstrual cycle*. Chronic* headaches may accompany emotional disturbances such as depression. Many times, headaches are just one of a number of symptoms, such as fever or dizziness, that are brought on by various diseases or injuries. Migraine headaches frequently are accompanied by nausea and other symptoms that are characteristic of it.

What Are the Causes and Types of Headaches?

The pain of headache may be mild, extremely severe, or anywhere in between. It may involve the entire head, one side only, the forehead, the base of the skull, or it may seem to move around. The pain may be sharp, a dull ache, or throbbing. A headache may last a few minutes or hours. It may recur from time to time, or it may become chronic, coming back many times over an extended period.

Many people believe that the brain itself is involved in headaches, but neither the brain nor the skull has nerves that register pain. The sources of head pain are the nerve endings in the blood vessels and muscles in and around the head. Pain may be felt when these tissues become stretched, inflamed, or damaged. Headaches can arise in blood vessels within the brain, as well as in the meninges (me-NIN-jeez), which are the sensitive membranes that cover the brain.

Mild headaches may arise from a change in the weather and from hunger. Common causes of mild to severe headache pain include disorders of the eyes, ears, and sinuses. For example, eyestrain and diseases such as glaucoma* can produce pain in the front of the head and around the eye. Mastoiditis, an inflammation of the bone behind the ear, can cause severe pain on the affected side of the head. Sinusitis* can cause sharp headaches in the front of the head (often called sinus headaches). A jaw or bite that does not close properly can also cause headache.

Many types of infection with fever, such as influenza (flu), cause headache. Other causes include drinking too much alcohol, heavy smoking, withdrawal* from caffeine, or inhaling a noxious gas, such as carbon

AN ANCIENT, AND DRASTIC, TREATMENT

Prehistoric people are known to have surgically cut holes in the skull of living persons, presumably to relieve some ailment. This procedure is called trephining (tre-FAN-ing). The purpose of this operation is not known with certainty. Perhaps it was carried out to relieve the pressure of a blood clot* under the skull caused by a blow to the head. However, it is believed that in some instances it may have been done in an attempt to cure headaches by releasing evil spirits. Stone Age patients who underwent this surgery apparently often survived, because many of the skulls found by scientists showed new growth of bone around the holes.

* **blood clot** is a thickening of the blood into a jelly-like substance that helps stop bleeding. Clotting of the blood within a blood vessel can lead to blockage of blood flow.

* **tumors** (TOO-morz) are abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.

* **vascular** refers to veins and arteries (the blood vessels).

monoxide. Contrary to popular belief, high blood pressure rarely is a direct cause of headache.

Headache is one of the symptoms of concussion and sometimes becomes chronic following this injury.

Rarely, headaches may be caused by brain abscesses, brain tumors*, bleeding into the brain, and meningitis (an inflammation of the membranes covering the brain).

Physicians often classify headaches as those caused by disease or injury (described above); tension headaches; and vascular* headaches. Vascular headaches include migraine and a type called cluster headaches. Tension and migraine headaches are very common.

What Are Tension Headaches?

Headaches that are associated with emotional stress or muscular tension are called tension headaches. The muscular tension may be in the neck, face, or scalp. It may be the result of poor posture or of constantly bending over one's work. These headaches are extremely common, and almost everyone has them at one time or another. A person may have one after working on the computer too long or bending over while doing homework.

Pressures from school, friends, or family may play a role. Adults may develop tension headaches because of stress at work. Tension headaches may be mild to moderate and occur in various parts of the head. The feeling has been described as a steady ache or as a tight sensation.

The pain of tension headaches can be chronic or recurrent, sometimes coming on every day. Muscles near the site of the pain, such as at the back of the neck or on the sides of the head, are often tense and tender. Sometimes chronic tension headache is a symptom of depression.

What Are Migraine Headaches?

Migraine is a moderate to severe headache that can interfere with a person's activities. The pain is typically, although not always, in one side of the head, at least at the beginning, and may last from hours to days.

Migraine headaches occur every so often, usually beginning in adolescence or early adulthood. They tend to become less frequent with age and tend to be rare or absent after the age of 40 to 50.

Migraine is one of the most common types of headaches, affecting about 20 million people in the United States alone. Women are four times more likely to experience migraine than men. People in all walks of life have been afflicted, including Sigmund Freud (psychologist), Thomas Jefferson (U.S. president), Charles Darwin (geologist and evolutionary biologist), and Lewis Carroll, the author of *Alice in Wonderland*. Modern sufferers include Princess Diana of Great Britain and basketball player Kareem Abdul-Jabbar.

The cause of migraine headaches was not known as of 2009. They are classified as vascular headaches because blood vessels in the head dilate (expand) during an attack. It is believed that certain chemical substances in the nerve cells surrounding the vessels are involved in the attack. The precise mechanism was not fully understood.

Migraine headaches tend to run in families. However, one does not catch this type of headache from someone else.

Most migraine attacks begin without warning. Typically, the pain is throbbing, often growing in intensity. It usually is accompanied by nausea and sometimes vomiting. The slightest noise or movement can make it worse. Ordinary light coming through a window may be unbearable.

The aura In about 15 percent of people who get migraines, the headaches are preceded by a distinctive type of warning called an aura (OR-uh). An aura can be a blank spot in the vision bordered by zigzag and flashing lights or numbness or weakness in parts of the body. After several minutes, the aura goes away and the pain of the headache begins. Migraine preceded by an aura has been called a classic migraine or migraine with aura.

Triggers In a number of individuals, certain factors, or triggers, can bring on a migraine attack. Common examples include red wine and foods such as cheese, nuts, chocolate, and citrus fruits. Nitrites, which are used as meat preservatives in products such as bacon or cold cuts, are

HOW DID MIGRAINE GET ITS NAME?

Aretaeus of Cappadocia, a medical writer in Greece in the 2nd century C.E., is believed to have been the first to recognize migraine as a one-sided headache with stomach and visual disturbances. Galen, a contemporary of Aretaeus, gave this affliction the name *hemikrania*, meaning “half of the head,” referring to the way it typically affects people. In Old English, the term became *megrin*, and that evolved over the centuries to “migraine.”

another recognized trigger. Other triggers include excessive sleep, relaxation after exercise, fatigue, and stress. Still others are related to hormonal changes, such as those that occur at the onset of menstruation. Sometimes the trigger is not known.

What Are Cluster Headaches?

Intensely painful headaches that occur one or more times daily are called cluster headaches. These headaches may recur for weeks or months, then not return for years. The pain is centered on one side of the head around the eye. Besides pain, the symptoms include a watery eye on the affected side and a runny nose.

Cluster headaches occur in men more often than in women and usually first appear when people are about 40 years of age. The cause was unknown as of 2009.

Should People with Headache See a Doctor?

Most headaches, although unpleasant, are not signs of serious health problems. A person should see a doctor if the headaches are unusually persistent or severe, if there are any changes in vision or speech, or if there is weakness or numbness in any body part. A doctor or other medical professional should be consulted whenever a headache is accompanied by neck stiffness, a high fever, loss of consciousness, or confusion. Treatment should not be delayed for any headache that is sudden and severe or that occurs after a head or neck injury. Children that experience recurrent headaches should be seen by a doctor. People with established chronic headaches that experience any sudden change in headache pattern or intensity should consult with a doctor. These changes are a cause for concern and should be investigated.

How Are Headaches Treated?

Over-the-counter pain-relieving drugs, such as acetaminophen* or ibuprofen*, may ease mild headaches. Relief also may come from such simple measures as getting some fresh air, taking a hot bath, getting a muscle massage, or lying down for a while. Tension headaches can be dealt with by addressing the cause of the emotional or physical stress.

For severe headaches, such as migraine, the best approach is prevention, that is, avoiding the factors that the individual knows are most likely to trigger an attack. Once an attack begins, pain-relieving drugs may help to ease symptoms. The doctor can also prescribe medicines that will narrow the blood vessels in the brain that have dilated during an attack. If migraine attacks occur frequently, the doctor can prescribe medications to prevent the migraine. Biofeedback, a relaxation technique, has proven helpful in relieving and avoiding some headaches.

Cluster headache attacks may be over before pain-relieving drugs can take effect. However, some prescription medicines may be useful in prevention.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

* **ibuprofen** (eye-bew-PRO-fin) is a nonsteroidal anti-inflammatory drug (NISAD) used to reduce fever and relieve pain or inflammation.

Many common headaches can, of course, be prevented by maintaining a healthy lifestyle, including regular eating and sleeping habits, not using any products containing tobacco, and avoiding excess alcohol and caffeine intake.

Hearing Loss See *Aging; Deafness and Hearing Loss.*

Heart Disease

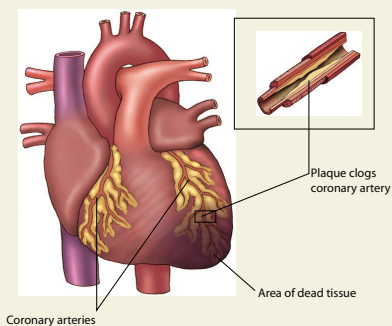

Heart disease is a broad term covering many conditions that prevent the heart from working properly and prevent it from pumping blood throughout the body.

Max's Story

Fourteen-year-old Max and his grandfather, Harry, often shared a Saturday morning ritual: breakfast at their favorite diner, followed by a brisk game of tennis. On this occasion, they both ordered the special: two fried eggs, four strips of bacon, hotcakes, and a side of hash browns. Plates cleared, they hit the tennis courts, but only ten minutes into their game, Harry, breathing hard and sweating heavily, stopped and complained of a squeezing pain in his chest. Although his grandfather protested that it was most likely indigestion, Max went for help. At the emergency room, his grandfather was given aspirin and placed on a heart monitor that showed

During a heart attack, the flow of blood to the heart is blocked by atherosclerotic plaque or clots, causing tissue death in the areas deprived of oxygen. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

The United States and the World

According to the American Heart Association (AHA), cardiovascular disease was the leading cause of death in the United States every year between 1900 and 2008, except the year 1918. The following statistics come from the AHA *2008 Heart and Stroke Statistical Update*:

- 80 million Americans have some form of cardiovascular disease. The most common condition is high blood pressure, which affects 73 million Americans.
- About 38 million of these people are 60 years old and older.
- Heart disease killed 869,700 people in the United States in 2004, making it the leading cause of death. It accounts for nearly 40 percent of all deaths each year.

he had experienced a heart attack. A nurse told Max that his quick action had probably saved his grandfather's life.

What Is Heart Disease?

Heart disease includes a group of diseases that prevent the heart from working as well as it should. It is the leading cause of death in developed countries, including the United States.

Only a little larger than a fist, a normal, healthy heart is at the center of the body's cardiovascular system*. Each day the average heart beats, or expands and contracts, about 100,000 times. In a 70-year lifetime, an average human heart beats more than 2.5 billion times.

The circulatory system* is responsible for providing nourishment to the body's cells and removing wastes from them. The arteries take oxygenated blood from the heart to the cells; the veins take blood from right side of the heart where it is pumped through the pulmonary arteries to the the cells to the lungs for reoxygenation and recirculation by the left side of the heart.

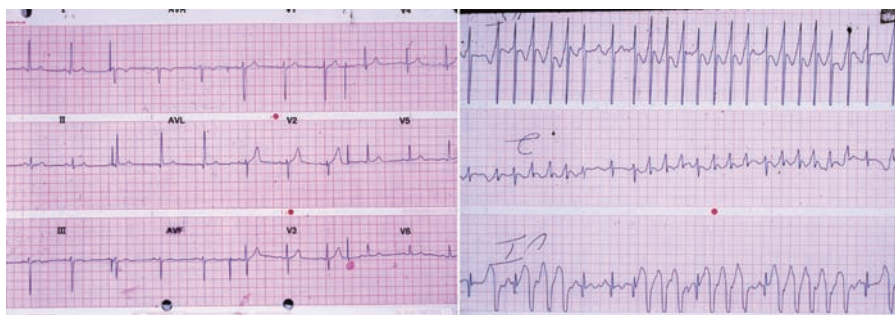

The coronary arteries supply the heart muscle itself with oxygenated blood. At birth, these coronary arteries are usually healthy, open, and clear, permitting a maximum flow of blood to the heart, but as people age, these vessels can become clogged with a thick combination of lipids (fats), including cholesterol, calcium, and other substances. As these layers accumulate inside the arteries, they can lead to arteriosclerosis (ar-teer-e-o-skle-RO-sis), a condition also known as "hardening of the arteries," since this buildup eventually stiffens the inner artery walls. Arteriosclerosis (ath-er-o-skle-RO-sis), a buildup of plaque* on the innermost portion of the vessel, is the most common cause of arteriosclerosis. Over time, plaque continues to accumulate inside the blood vessels, much like grease that clogs a kitchen drainpipe. The result is a narrowing of the inside diameter of the vessel.

What Are the Different Types of Heart Disease?

Coronary arteries affected by atherosclerosis will eventually develop coronary artery disease, a condition in which the vessels are so narrow that they can no longer provide adequate nutrients or oxygen to nourish the heart. Blood flow is blocked either partially or totally.

Heart attacks are injuries to the heart muscle that occur when blood flow through a coronary artery is interrupted, cutting off the vital supply of oxygen to the heart. Blood can be kept from the heart by narrowing of the arteries from atherosclerotic plaque, by a blood clot* blocking the narrowed vessel, or by a contraction (spasm) of the artery in response to a lack of oxygen or blood. The part of the heart muscle affected by the blockage is usually slowly starved of oxygen. The longer the heart muscle goes without nourishment, the more muscle tissue deteriorates or dies. Quick action, like that taken by Max, is essential. Healthcare workers use the phrase "time is muscle" to illustrate how crucial it is to seek immediate medical attention in the case of a suspected heart attack.

Whereas blocked arteries are the most common cause of heart attacks, there are many factors that contribute to this dangerous condition, such

Doctors use electrocardiograms to monitor heart rhythms. Compare the healthy heart rhythm (left) to heart rhythm during a heart attack (right).

Martin M. Rotker/Photo Researchers, Inc.

as high blood pressure. Pumping blood against high pressures inside the blood vessels (as occurs in people with uncontrolled hypertension) can put too much strain on the heart. Abuse of alcohol, viral infections, tuberculosis, parasites, or other vascular (blood vessel) diseases can also lead to heart disease.

Diseased valves can also put abnormal strain on the heart. There are two valves between the atria (upper chambers) and ventricles (lower chambers) of the heart, and two valves between the ventricles and their outflow tracts. These valves open and close like tiny camera shutters to make sure that blood flows in the right amount and in the right direction. If a valve is scarred and cannot open completely, the heart has to work harder to pump enough blood through the obstruction. A valve that does not close completely can allow blood to go backward through the heart chambers, making the heart work harder by having to pump the same blood twice.

Bacterial endocarditis*, or inflammation of the endocardium (the inner surface of the heart), is an infection that can cause the heart valves to malfunction. Such an infection may rarely occur following oral surgery or dental work, when the normally harmless bacteria are released into the bloodstream. This problem generally affects valves that were previously damaged from rheumatic heart disease or other conditions.

Heart failure occurs when the heart can no longer sufficiently pump blood throughout the body. While the heart is still working, it cannot do its job properly. While heart failure can affect any part of the heart, the problem usually occurs on the left side. When the left side of the heart fails, the chambers cannot keep up with the amount of oxygenated blood that is coming in, and blood can back up in the lungs, making it difficult for the person to breathe. In right-sided heart failure, the deoxygenated blood backs up in the veins, causing swelling in the legs, fatigue, and sometimes, difficulty breathing. Heart failure can often be treated through diet, exercise, smoking cessation, medication, and sometimes, surgery.

Various forms of heart disease can also cause dysrhythmias (dis-RITH-me-as), or disturbances in the normal heartbeat pattern. Although some dysrhythmias are harmless, many may cause severe problems. For example, ventricular fibrillation (ven-TRIK-yoo-lar fib-rill-AY-shun) is a type of heart rhythm in which pumping is uncoordinated and ineffective and can cause sudden death.

* **cardiovascular system** (kar-dee-o-VAS-ku-lur) is made up of heart and blood vessels.

* **circulatory system** (SIR-ku-la-tor-ee) is made up of the heart, arteries, veins, capillaries, and circulating blood.

* **plaque** (PLAK) is a raised patch or swelling on a body surface. Arterial plaque occurs on the inner surface of an artery and is produced by fatty deposits.

* **blood clot** is a thickening of the blood into a jelly-like substance that helps stop bleeding. Clotting of the blood within a blood vessel can lead to blockage of blood flow.

* **endocarditis** (en-do-kar-DYE-tis) is an inflammation of the valves and internal lining of the heart, known as the endocardium (en-doh-KAR-dee-um), usually caused by an infection.

* **risk factors** are any factors that increase the chance of developing a disease.

* **menopause** (MEN-o-pawz) is the end of menstruation.

* **aerobic exercise** (air-O-bik) is exercise designed to increase oxygen consumption by the body; it helps keep the heart and lungs in shape.

What Causes Heart Disease?

Risk factors Heart disease is not contagious and, to a large extent, can be prevented, controlled, and, in some cases, even reversed. When looking at what causes heart disease, researchers divide the risk factors* into those that people can control and those that they cannot. Among the factors that cannot be changed are the following:

- **Age.** As people age, their cholesterol levels usually increase and hardening of the arteries appears and progresses in many people.
- **Gender.** Men have higher cholesterol levels than women until around age 45. Women catch up after menopause*.
- **Heredity.** People with a family history of heart disease are at an increased risk.

The good news is that some risk factors can be controlled. These include the following:

- **Smoking.** Smokers' risk of heart attack is almost twice that of nonsmokers, and their risk of sudden cardiac death is two to four times that of nonsmokers. Quitting (or never starting) is definitely a heart-healthy decision.
- **High blood pressure.** Hypertension puts extra stress on the heart. Taking medication to lower high blood pressure, maintaining healthy body weight, avoiding salt, and increasing exercise can help people reduce blood pressure.
- **Blood lipids.** Lowering fats in the blood, such as cholesterol, can reduce the risk of heart disease. Individuals who come from a family with heart disease; who have other risk factors such as smoking, diabetes, hypertension, obesity, or physical inactivity; or who have a parent with a high cholesterol level should have their lipid levels monitored by a doctor.
- **Diabetes.** Many people with diabetes have high blood pressure or are obese. Diabetes can also increase lipid levels and accelerate the development of atherosclerosis, heart attack, and stroke.
- **Obesity.** Obesity is generally defined as having an adult body mass index greater than 30. About one-third of American adults are obese, even though maintaining a healthy weight throughout life seems to be one of the best ways of living longer and healthier. In a famous 30-year study of 5,127 adults in Framingham, Massachusetts, between 1948 and 1978, those who maintained their weight from age 25 on had a lower risk of heart disease. Those who lowered their weight over this time reduced their risk even further.
- **Physical activity.** People who frequently exercise have a lower rate of cardiovascular disease; those who are inactive have a higher rate. Aerobic exercise* lowers the heart rate, lipid levels, and blood pressure and decreases body fat. Such activities include brisk walking, running,

swimming, rowing, and jumping rope for at least 10 to 15 minutes. It is estimated that 59 percent of American adults get no aerobic exercise.

Heart disease is also a leading cause of death worldwide. The World Health Organization (WHO) reported that in 1998, for example, 32 percent of all deaths (16.7 million) resulted from heart disease. It was the number one cause of death in all regions of the world, except Africa (where it was ninth) and the western Pacific (where it was third).

WHO predicted that worldwide heart disease death rates would climb from 2008 until 2028, if developing nations continued their trend toward increased smoking and more westernized diets.

Other risk factors that can be controlled include drinking too much alcohol too often and having too much stress.

The fat connection Cholesterol (ko-LES-ter-ol) is a soft, waxy substance that circulates in the blood and is found in every cell of the body. It is an important building material for cells and nerves and is used for the production of certain hormones. Cholesterol is used by the liver to make bile acids, which help digest food. Triglycerides (try-GLIS-er-ides) are fats in the blood that, like cholesterol, can come from either the diet or can be produced by the liver. Triglycerides are different from cholesterol, but like

Body Mass Index

The body mass index (BMI) has been used since the early 1980s as a medical standard for obesity measurement. The steps for calculating BMI are as follows:

1. Multiply weight in pounds by 703
2. Divide that number by height in inches
3. Divide that number by height in inches again

The recommended BMI for adults is 18.5 to 25. The overweight range is 25 to 30. Any adult with a BMI over 30 is considered obese. While these guidelines are accurate, they are not definite indicators of overall health.

Did You Know?

- Coronary heart disease is the most frequent killer of American men and women. Every 26 seconds someone suffers a coronary problem; every minute someone dies from one.
- In 2008, it was estimated that heart disease costs about 448 billion dollars annually in the United States alone.
- About 2,500 heart transplants are performed each year, with thousands of other patients waiting in line.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

cholesterol, they are normally present in the blood. Elevated triglycerides may be associated with certain illnesses.

The body makes all the cholesterol it needs, but people also get cholesterol from their diets, particularly when they eat foods made from animal and dairy products. High blood cholesterol levels can have many causes, including genes* (heredity) and lifestyle choices (diet). Too much cholesterol can lead to coronary heart disease. Hyperlipid disorders, in which there is too much cholesterol or too much triglyceride in the blood, are some of the most common inherited conditions, affecting one in every 500 people. In people with such disorders, risk factors such as obesity, cigarette smoking, and high blood pressure can increase the chance of coronary heart disease even further.

How Do People Know They Have Heart Disease?

Heart disease is the number one killer in developed countries, and heart attacks are recognized as the most obvious sign of heart disease. Each year, 1.2 million Americans have heart attacks. But one problem with heart disease is that in 20 to 40 percent of people (like Max's grandfather), a heart attack is the first symptom of the disease. By then, plaque may have narrowed one or more arteries, limiting their ability to supply an area of the heart muscle with the oxygen and nutrients it needs.

Veins in the circulatory system.
 Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.

Because a heart attack can cause severe damage by robbing the heart of oxygen, a quick reaction to the earliest signs of a heart attack is essential. Angina pectoris (an-JY-na PEK-to-ris), a squeezing, tightness, or heaviness in the chest that can extend to the left arm, neck, jaw, or shoulder blade, is often the first sign that someone with atherosclerosis is at risk for a heart attack. Physical exercise, a heavy meal, strong emotions, or extreme temperatures can bring it on. If angina occurs when a person is at rest, this means that the heart is starving for oxygen even when it is not working hard. Besides chest pain, weakness, fainting, profuse sweating, nausea, and vomiting can accompany a heart attack, although a heart attack that arrives without angina—a “silent” heart attack—may not be revealed until a patient shows up in the physician’s office for an unrelated condition.

Valve disease can cause related symptoms of dizziness, fatigue, weakness, shortness of breath, and chest pain when exercising. These same signs, along with edema (e-DEE-ma), an accumulation of fluid that occurs when the heart cannot keep the circulation moving properly, can indicate heart failure*. Gravity often pulls the fluid downward, causing swelling in the feet, ankles, and legs.

Diagnosis

Depending on the type of heart disease, a physician can use a number of different tests to help pinpoint heart problems. They are divided into invasive tests done internally and noninvasive tests that can be performed externally.

Noninvasive procedures include the following:

- **Electrocardiogram** (ECG or EKG). A recording of the heart’s electrical activity to help a doctor diagnose and monitor irregular heart rhythms, heart attacks, or other abnormalities. A portable ECG machine worn by a patient called a Holter monitor can also test the effectiveness of drug therapy for dysrhythmias and monitor pacemaker* functions for 12, 24, or 48 hours.
- **Stress test.** An ECG performed during exercise to determine the cause of chest pain and other symptoms related to physical activity.
- **Echocardiogram.** Ultrasonic waves, or high-frequency inaudible sound waves, are bounced off the surfaces of the heart and converted into an image that can be displayed on a monitor to diagnose congenital* heart disease, valve disease, congestive* heart failure, and other conditions.
- **Ultra-fast computed tomography.** Scanning that employs electron beams to detect calcium deposits in the coronary arteries.

Invasive procedures include cardiac catheterization, which is used to evaluate coronary artery disease, causes of angina, complications following a heart attack, heart defects, and other internal disorders. A catheter, or long, thin tube, is inserted into the cardiovascular system, usually through an arm or leg artery. A contrast solution (a dye that will show up on film) is then injected to visualize the blood vessels on film (angiography). Depending on

Common Symptoms of a Heart Attack

Common symptoms of a heart attack include (but are not limited to):

- uncomfortable pressure, fullness, or a squeezing sensation in the center of the chest that lasts more than a few minutes or reoccurs
- chest discomfort that spreads to the shoulders, neck, jaw, arms, or back
- chest discomfort with fatigue, dizziness, nausea, clammy skin, anxiety, and breathlessness

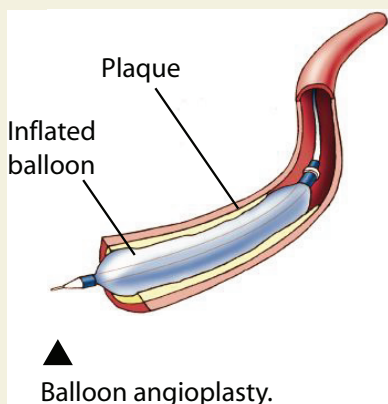

Interestingly, some people never feel chest pain with a heart attack.

* **heart failure** is a medical term used to describe a condition in which a damaged heart cannot pump enough blood to meet the oxygen and nutrient demands of the body. People with heart failure may find it hard to exercise due to the insufficient blood flow, but many people live a long time with heart failure.

* **pacemaker** a device whose function is to send electrical signals that control the heartbeat. The heart’s natural pacemaker is the sinoatrial node, a special group of cells. Sometimes it is necessary to implant a battery-powered pacemaker that sends small electrical charges through an electrode placed next to the wall of the heart.

* **congenital** (kon-JEH-nih-tul) means present at birth.

* **congestive** (kon-JES-tiv) means characterized by accumulation of too much fluid.

▲ Balloon angioplasty. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

Microwave Ovens

Convenience stores, cafeterias, and snack bars used to post warnings near their microwave ovens for people with pacemakers. Electromagnetic radiation emitted from the microwave ovens sometimes caused current variations in the pacemakers. Pacemakers in the early 2000s are shielded from stray electromagnetic forces and have a backup mode in case of disruption of the main circuit's programming.

* **aorta** (ay-OR-ta) is the major large artery that carries blood from the heart to the rest of the body.

its position, the catheter can help doctors diagnose the extent of coronary artery plaque buildup or abnormalities of the aorta* and valves.

How Is Heart Disease Treated?

Although many heart conditions cannot be cured, they can be controlled with lifestyle changes, medication, or surgery, or a combination of these strategies.

Medications Irregular heartbeats, heart failure, and angina are often treated with a combination of changes to create a healthier lifestyle and medications. One of the most common medications used is nitroglycerine (ny-tro-GLIS-er-in), in the form of a tiny pill dissolved under the tongue, which acts to open the heart's blood vessels and permit more oxygen to flow to the heart muscle. Beta-blockers decrease the heart's demand for oxygen by slowing down the heart rate. Studies have shown that aspirin can help to prevent recurring heart attacks by thinning the blood, which can prevent clots and make it easier for the blood to travel through narrowed vessels. At the time of a heart attack, patients may be given special clot-dissolving medications intravenously (injected into a vein) to help unclog the diseased coronary arteries. Medications are also used to control high blood pressure.

Surgical procedures Angioplasty (AN-je-o-plas-tee), also called balloon angioplasty, opens up vessels blocked by plaque buildup. A specially designed balloon is threaded through an artery. Once positioned, the balloon is set at the narrowest portion of the blocked artery and inflated, pumping up and widening the channel. After the artery is opened, the balloon is withdrawn.

One problem is that coronary arteries opened by angioplasty often close within three to six months. To prevent this closing, surgeons often place a stent, a one-inch tube of wire-like stainless steel shaped like a tiny coiled spring, into the vessel, where it is expanded. The stent props the vessel open like scaffolding supporting a tunnel. Stents can also be life-saving for patients whose arteries suddenly collapse or become spastic (contracts) and close during angioplasty, setting off a heart attack.

A pacemaker is a device that can be inserted under the skin in the chest or abdomen to restore a regular heartbeat. Advanced devices can sense and respond to changes in body movement, temperature, and breathing rate.

Bypass surgery is a procedure in which a segment of vein taken from the leg or an artery from the chest is grafted to an opening in the side of the normal coronary artery above the obstructed (blocked) segment and then to the normal portion of the artery below the obstruction. Blood then "bypasses" the obstructed segment, much like a road that serves as a route around a construction site.

Damaged valves can be replaced with mechanical valves made of plastic or Dacron or a biological valve taken from a pig, cow, or human donor.

Cardiac transplantation is the most dramatic means of treating patients with severe heart failure. Although still filled with challenges, the surgical

FROGS' LEGS AND GALVANOMETERS

The sophisticated electrocardiograph (ECG or EKG) used in the early 2000s began with the study of frogs' legs.

During the 1700s, scientists Luigi Galvani (1737–1798) and Alessandro Volta (1745–1827) used frogs to study muscle action. Their work led to development of the galvanometer (gal-va-NOM-e-ter), which measures current by electromagnetic action.

In 1903, William Einthoven (1860–1927) introduced the string galvanometer. Einthoven's galvanometer evolved into the modern EKG machine, one of the fundamental tools that cardiologists use to monitor the heart's rhythms.

procedure is well accepted around the world and is being performed more often. However, not enough human hearts are available from organ donors.

Living with Heart Disease

Heart disease often represents a turning point in a person's life. People who formerly led unhealthy, mainly inactive lives may be inspired to change the way they live by eating more healthy foods, exercising regularly, and quitting smoking.

In the case of a heart attack, full recovery generally takes about four to six weeks, depending on the extent of the injury, the patient's overall health, and the condition of the rest of the heart. Most people are able to resume regular activities within a few weeks or months. Like all patients with heart disease or damage, those who have had heart attacks need to adopt a healthier lifestyle, including eating a low-fat diet. Most go on to recover and enjoy many more productive years of life.

Wise Modifications in Diet

Experts suggest that it is a good idea for all healthy Americans above the age of two years to modify their diets. Among specific suggestions are the following:

- Reduce total dietary fat to no more than 30 percent of total daily calories.
- Eat a variety of fruits, vegetables, and whole grains.
- Reduce dietary saturated fat and cholesterol: switch from whole to skim milk; reduce the number of egg yolks eaten; avoid solid cooking fats such as lard; give up foods containing certain vegetable oils such as palm, coconut, and partially hydrogenated oils; and substitute frozen yogurt, sherbet, or ice milk for ice cream.

* **congenital** (kon-JEH-nih-tul) means present at birth.

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

Heart Disease, Congenital

Congenital heart disease refers to various conditions present at birth that prevent the heart from working properly. Most of these are malformations that prevent the heart from pumping blood throughout the body.

David's Story

Six-year-old David liked everything about the first grade. He especially liked his gym class, even though he always ended up feeling tired and worn out after only a few minutes of dodge ball or relays. One day after a game of dodge ball, David collapsed on his way back to the bench. After he was rushed to the hospital, a doctor discovered that he had a hole in his heart.

The doctor explained to David and his parents that the small hole located between the two chambers of David's heart was called a septal defect and that oxygenated blood was mixing with deoxygenated blood. This condition deprived David's organs of the oxygen that they need, which caused his collapse.

What Is Congenital Heart Disease?

Congenital heart disease refers to congenital* (present at birth) heart defects that affect the ability of a person's heart to function properly. Congenital heart defects occur while a fetus* is still developing and can be attributed to many causes. About 36,000 infants are born with heart defects every year. It is the most common congenital cause of infant death.

To understand the different types of congenital heart defects, one needs to understand how the heart works to pump blood through the body. The heart is a muscle made of four chambers. There is a left side and a right side. Two atria sit on top of two ventricles. The atria and ventricles are separated by one-way valves that keep blood flowing in one direction so it can get to the places in the body that need it. Each vein that carries blood to the heart and each artery that carries blood from the heart has a specific job.

Every time the heart contracts, all of these parts work together to keep the blood flowing throughout the body. The following statements describe the direction of blood flow through the heart:

- Deoxygenated blood returns to the right atrium through the superior and inferior vena cava.
- The blood goes down through the tricuspid valve into the right ventricle.

- Blood passes through the pulmonary valve and artery to the lungs, where it is reoxygenated.
- Reoxygenated blood returns to the left atrium by way of the pulmonary veins.
- Blood goes down through the mitral valve to the left ventricle.
- The blood leaves the left ventricle through the aortic valve and is pumped throughout the body via the aorta.

It is very important that all of these parts work properly. When one or more of these important parts of the heart has a defect, the heart cannot do its job.

What Are the Different Types of Heart Defects?

There are various types of defects that can be present at birth. Sometimes, a doctor, nurse, or technician will notice during a routine exam that the infant's heartbeat sounds abnormal. This abnormal sound is called a murmur. At other times, the condition may not be detected until the child is much older. Some congenital heart defects are more common than others. These include the following.

Septal defects Septal defects, sometimes called a “hole in the heart,” are the most common types of congenital heart defects. When the septum (the muscular wall that separates the right and left sides of the heart) has a defect, proper blood flow is interrupted, causing a number of problems. The symptoms of septal defects vary depending on how much blood goes through the septal defect and, therefore, to the wrong chamber of the heart. Sometimes, minor holes close spontaneously. Other times, a doctor must repair them surgically. Depending on the type and severity, unrepaired septal defects may result in malnourishment, cyanosis (a bluish discoloration of the lips and skin), hypertension (high blood pressure), hypertrophy (enlarged heart), pulmonary edema (fluid in the lungs), congestive heart failure (CHF), and infections.

There are several types of septal defects:

- Atrial septal defect is an opening between the upper chambers of the heart. This defect allows oxygenated blood to flow from the left atrium back into the right atrium (a left-to-right shunt) instead of through the aorta and to the body. Most septal defects cause left-to-right shunts because the pressure on the left side of the heart is usually higher than on the right. This condition dilutes the oxygenated blood and puts a strain on the heart and lungs because more blood must be pumped through the lungs and back around the body.
- Ventricular septal defect is an opening between the bottom chambers of the heart, which allows oxygenated blood to flow from the left back into the right ventricle. When this happens, the heart needs to work harder to pump enough blood through the body. The

* **cyanosis** (syeh-uh-NO-sis) is a bluish or purplish discoloration of the skin and mucous membranes due to a lack of oxygen in the blood.

added work may cause the heart to enlarge (hypertrophy). Some cases result in pulmonary hypertension (high blood pressure in the lungs). This condition may cause a reversal in the direction of blood flow with a right-to-left shunt, a combination called Eisenmenger's complex.

- **Atrioventricular septal defect** is a large hole that involves the atria and ventricles, as well as improperly formed valves. This defect sends the oxygenated blood back to the lungs to be oxygenated again and creates too much blood volume in the lungs.

Patent ductus arteriosus Patent ductus arteriosus is similar to a septal defect in that it involves a “hole” in the heart. The fetus receives oxygen from its mother, not from its lungs. To make this process possible, there is an artery (ductus arteriosus) in the heart that bypasses the lungs and sends oxygenated blood directly to the body. Normally, this ductus closes soon after the baby is born. Certain problems may cause it to remain open. Medicine may be given to the baby to close the ductus, but in some cases, surgery is required.

Patent foramen ovale A patent foramen ovale (PFO) happens when the septum between the two upper chambers of the heart develops normally in the uterus but the flap does not completely seal after birth. All people have a PFO before birth, but it seals correctly in 80 percent of people. If PFO is diagnosed by a cardiologist (heart specialist), a patient may be given medication to correct the problem.

Transposition of the great arteries Transposition of the great arteries makes up 10 to 11 percent of all congenital heart defects. In this condition the position of the two major vessels that carry blood away from the heart—the aorta and the pulmonary artery—is switched (transposed). When this happens, the aorta is connected to the incorrect (right) ventricle, and the blood that it pumps to the body has not yet passed through the lungs for oxygenation; the pulmonary artery is connected to the left ventricle, so the blood that is sent to the lungs has already been oxygenated. As a result, the baby develops cyanosis* (the skin and mucous membranes take on a bluish tint due to hypoxia, or inadequate oxygen). Unless surgery is performed soon after birth, infants who are born with this defect do not survive.

Tetralogy of Fallot Tetralogy of Fallot (fal-LOW) (TOF) is a combination of four different problems and occurs in 9 to 14 percent of all congenital heart defects. TOF results in the following:

- **Pulmonary stenosis** is narrowing of the pulmonary artery, which impedes the passage of blood from the right ventricle to the lungs. When this happens, it is difficult for the blood to get to the lungs, and the right ventricle must work much harder to try to push it through. As a result, the muscular walls of the right ventricle get

too thick (hypertrophy), and there may not be enough oxygen in the blood that is pumped to the body, causing cyanosis (a bluish tint to the skin).

- **Right ventricular hypertrophy** is enlargement of the lower right chamber of the heart. It occurs when defects in the heart cause the chamber to work much harder than normal, making the muscular walls grow bigger.
- **Ventricular septal defect** (a hole between the lower heart chambers) allows oxygenated blood from the left ventricle to flow into the right ventricle. When this happens, the extra (already oxygenated) blood “backs up” in the lungs and can cause pulmonary hypertension. It also puts additional strain on the heart, which can lead to an enlarged heart (hypertrophy).
- A **misplaced aorta** is positioned just above the ventricular septal defect and, therefore, is connected to both the right and left ventricles. When this happens, the heart receives and pumps deoxygenated blood to other organs in the body.

TOF is usually repaired surgically during infancy.

Coarctation of the aorta Coarctation of the aorta accounts for 9 to 11 percent of all congenital defects. The aorta is one of the major vessels of the heart and is responsible for delivering the oxygenated blood

HELEN B. TAUSSIG: A PIONEER IN PEDIATRIC CARDIOLOGY

Helen B. Taussig (1898–1986) was a brilliant physician who made many discoveries in the field of congenital heart defects, especially cyanotic congenital heart disease. She founded the field of pediatric cardiology. Taussig wrote *Congenital Malformations of the Heart* (1947) and received the 1954 Albert Lasker Award for Clinical Medical Research for her work. Taussig was instrumental in developing the Blalock-Taussig shunt, the cardiac surgery that is used to treat conditions such as tetralogy of Fallot and hypoplastic left heart syndrome. In 1944 Taussig and Alfred Blalock performed the first shunt operation on an 11-month-old baby.

Taussig was the first female president of the American Heart Association, and in 1959 she was promoted to full professor at Johns Hopkins University. She also played a large role in preventing thalidomide, a drug known to cause birth defects, from reaching U.S. markets. In 1964, President Lyndon Johnson awarded Taussig the Medal of Freedom. Johns Hopkins University named the Helen B. Taussig Children’s Pediatric Cardiac Center in her honor, and in 2005 the School of Medicine named one of its four colleges after her as well.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

from the heart to the rest of the body. Sometimes, babies are born with a defect that leaves part of their aorta very narrow. When this happens, the heart has to work much harder to pump the blood through the narrowed opening. This defect can be mild or severe, and it can be repaired surgically. There are a few options for repairing coarctation of the aorta. Doctors can replace the narrowed section entirely. They can also cut out the section and sew the normal sized ends together, or they can try to widen the vessel with a balloon (angioplasty).

Hypoplastic left heart syndrome Hypoplastic left heart syndrome occurs in 4 to 8 percent of all congenital heart defects. It is a complex condition in which the left side of the heart, which is responsible for pumping oxygenated blood throughout the body, has not developed properly. The structures that are affected include the left ventricle, the mitral valve, the aorta, and the aortic valve. In babies with this condition, the left ventricle of the heart is so small that the heart cannot pump blood needed by the body. The mitral and aortic valves are very narrow or closed, and the aorta is also very narrow. This creates a situation in which the right side of the heart has two jobs, instead of one. First, it must send the blood to the lungs to be oxygenated. Second, it must pump blood to the rest of the body via a patent ductus arteriosus, which typically closes soon after birth. This condition is often fatal if not treated shortly after birth.

THE DELAYED DIAGNOSIS AND TREATMENT OF HEART DEFECT

In 2008, 23-year-old Louise Banks of the United Kingdom made headlines when she underwent surgery for a massive congenital septal defect that had gone undetected until that year. Although Banks had various symptoms during her childhood and early adulthood, doctors missed identifying the congenital heart problem that was the underlying cause.

As a child, Banks suffered from episodes of fainting, but her condition was misdiagnosed. As a teenager, a gym trainer grew concerned about her low heart rate during exercise and encouraged her to see a doctor. Again, her problem was misdiagnosed. Even when her heart rate became erratic during the birth of her son, the underlying condition was still undetected.

At the age of 23, Banks consulted another doctor who performed an ultrasound* on her heart, and it was only then that the one-and-a-half inch hole was discovered.

Banks underwent surgery to have the hole repaired, which was completely successful. Thereafter her heart functioned normally.

What Are the Symptoms of Congenital Heart Disease?

Babies who are born with heart disease may or may not show symptoms of the defect right away. Sometimes, children may not show symptoms until they are much older. In very few cases, individuals may not learn of their condition until adulthood. Specific symptoms depend on the severity of the defect. These may include an odd skin color (gray or cyanotic, commonly called blue baby syndrome); swelling (edema) in the legs, feet, or abdomen; shortness of breath; difficulty feeding; and immediate fatigue during play or sports.

What Causes Congenital Heart Disease?

As of 2009, causes for congenital heart defects were not fully understood. Researchers believed that both environmental and genetic factors played a role. Several specific gene mutations were identified between 1985 and the early 2000s.

Scientists also suspected that viral infections may play a key role in the development of congenital heart defects. These infections include rubella (German measles) and the flu. Pregnant women should make certain that they are vaccinated against rubella and the flu; they should avoid coming in contact with people who are sick; and they should avoid all forms of alcohol, tobacco, drugs (both legal and illegal), and toxic chemicals.

According to the March of Dimes, researchers identified certain medications as potential causes of congenital heart defects. These include some anti-seizure medications, the acne medication Isotretinoin, and Thalidomide.

Is Congenital Heart Disease Preventable?

Many congenital heart defects, such as those attributed to heredity, are not preventable. Still, there are several precautions that women can take that may prevent certain complications during pregnancy. There are specific steps that women can take in preparation for and during pregnancy. Women should do the following:

- Take a folic acid supplement of at least 400 micrograms. Folic acid is a B vitamin that has been shown to prevent many major birth defects, especially those that affect the brain and spine. Folic acid supplements need to be taken before pregnancy to be effective.
- Avoid contact with toxic chemicals, including many cleaners, paints, and solvents.
- Have their doctor ensure that they are vaccinated and immune to rubella (German measles), a viral infection, and the flu.
- Discuss all medications and supplements that they are taking with their doctor.
- Avoid alcohol, tobacco, and drugs (both legal and illegal), during pregnancy.

Congenital Heart Disease Deaths Decrease

According to the American Heart Association, the death rate among those born with congenital heart defects has declined by 39 percent since 1979. In fact, from 1994 to 2004, the death rate declined more than 31 percent.

* **electrocardiogram** (e-lek-tro-KAR-dee-o-gram), also known as an EKG, is a test that records and displays the electrical activity of the heart.

* **echocardiogram** (eh-ko-KAR-dee-uh-gram) is a diagnostic test that uses sound waves to produce images of the heart's chambers and valves and blood flow through the heart.

* **catheter** (KAH-thuh-ter) is a small plastic tube placed through a body opening into an organ (such as the bladder) or through the skin directly into a blood vessel. It is used to give fluids to or drain fluids from a person.

How Is Congenital Heart Disease Diagnosed?

In most cases, congenital heart defects are diagnosed in early infancy after a baby shows outward signs of problems. These may include shortness of breath, difficulty eating, or ashen or cyanotic skin tones. Other times, problems may not arise until childhood, as in David's case. More rarely, defects are discovered during routine examinations before birth or during adulthood.

In all of these cases, doctors will conduct further testing to identify and treat whatever problem is present. These routine tests include:

- An x-ray that reveals the appearance of the heart and lungs. It can reveal if the heart is too large or small, in the wrong position, or whether there is a problem with the lungs.
- An electrocardiogram* (EKG or ECG) involves the placement of electrodes on the chest. It tells doctors about the electrical activity of the heart and whether it is beating properly.
- An echocardiogram* is an ultrasound of the heart. Physicians can watch the heart working in real-time. This helps them to assess whether the heart is working properly.
- Blood and urine tests can tell the doctor if the proper measures of oxygen, gases, and enzymes are present in the body. Sometimes, certain variations indicate potential cardiac problems.
- Cardiac catheterization is a more invasive test that doctors can perform to assess cardiac problems. A long catheter* is inserted into the heart, usually through the femoral artery or vein in the groin. This allows doctors to insert a special dye that helps reveal any blockage or defect.

What Are the Treatment Options?

Most congenital heart defects can be repaired or improved surgically. Because of advances in cardiology over the last century, children who are born with serious cardiac defects can go on to live happy, healthy lives.

Often babies who are born with heart defects undergo surgery immediately, and the defects that they were born with never interfere with their lives. Other times, the surgery may only provide temporary improvement, not a solution. These are cases in which the defect is so severe that the only way to completely fix the problem is through a heart transplant. According to the United Network for Organ Sharing, 2,536 children age 17 and under received heart transplants in 2007.

Heart Murmur

A heart murmur is an extra sound that occurs during a heartbeat and is caused by turbulence in blood flow through the heart. Most heart murmurs are innocent, which means they do not cause health problems and may disappear with age. But some heart murmurs require medical treatment because they are a sign of a problem in the heart's walls, lining, or valves, or are indications of other diseases or conditions.

◀ Anatomy of the heart showing heart valves and sinus node. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

- * **endocarditis** (en-do-kar-DYE-tis) is an inflammation of the valves and internal lining of the heart, known as the endocardium (en-doh-KAR-dee-um), usually caused by an infection.
- * **rheumatic fever** (roo-MAH-tik) is a condition associated with fever, joint pain, and inflammation affecting many parts of the body, including the heart. It occurs following infection with certain types of strep bacteria.
- * **prophylactic** (pro-fih-LAK-tik) refers to something that is used to prevent an illness or other condition, such as an infection or pregnancy.
- * **heart failure** is a medical term used to describe a condition in which a damaged heart cannot pump enough blood to meet the oxygen and nutrient demands of the body. People with heart failure may find it hard to exercise due to the insufficient blood flow, but many people live a long time with heart failure.

Is a Heart Murmur Always a Problem?

The sound of a heart murmur may occur as the heart is filling with blood or as it is contracting to send blood to other parts of the body. Sometimes the murmur indicates a defect in the heart or in one of its valves. Many times doctors also find “innocent” heart murmurs, which do not require any special treatment. Innocent murmurs are common in babies and children. The murmurs often disappear as a child gets older, and they are not a sign of heart disease.

Heart murmurs may also occur when one or more of the heart’s four valves is operating abnormally. Sometimes the valves do not close completely, which may allow blood to leak back from one chamber to another, which should not occur. Valves also might not open completely, which causes blood to rush through a smaller opening than normal. The murmur can result from a hole, usually in the wall between the left and right sides of the heart.

Consequences of a Heart Murmur

Some people are born with valve defects or with holes that cause heart murmurs. Others develop a heart murmur after bouts with endocarditis* or rheumatic fever*. Both of these infections may damage heart valves. For these patients, doctors may advise prophylactic* (preventative) antibiotic treatment to be taken before a surgical or dental procedure because bacteria entering the bloodstream during the procedure may adhere to abnormal or damage heart valves, causing infection inside of the heart.

Anemia and other medical conditions such as an irregular heartbeat (arrhythmia) may be associated with murmurs even when the heart valves are perfectly normal. A heart murmur may be found in individuals who have heart failure*. If the heart becomes enlarged (a condition called cardiomegaly), a murmur may be heard as the blood flow throughout the heart decreases.

What Does the Doctor Hear and Do?

Diagnosis A doctor listens to a patient’s heart as part of the physical exam. That is how murmurs usually are detected. Certain defects cause particular sounds, which help doctors make their diagnosis. For example, if a valve fails to close properly between the upper and lower chambers on the heart’s left side, doctors may hear a distinctive murmur that aids in diagnosing the problem.

Doctors can also use an echocardiogram to examine the heart and determine a murmur’s cause. This test is done with a device that uses sound waves to create an image of the heart. It is similar to the ultrasound machine that creates images of the fetus (unborn developing baby) inside a pregnant woman.

Treatment If the murmur is innocent, nothing special needs to be done. People with innocent heart murmurs can play sports, eat the same foods, and engage in all the same activities as their schoolmates.

Murmurs that indicate valve disease may need to be treated with medication or surgery. Such surgery may involve either replacing the valves or closing a hole in the wall in the heart. Although it is important to find and treat those murmurs caused by valve abnormalities or other medical conditions, most murmurs detected during childhood or adolescence are innocent.

Heartburn (Dyspepsia)

Dyspepsia (dis-PEP-see-a) is a broad term used to describe painful or otherwise uncomfortable feelings in the abdomen and sometimes extending into the chest and throat that occur after eating. Heartburn is one type of dyspepsia. Symptoms of heartburn may include a burning sensation in the chest that moves toward the back of the throat after eating. The burning chest pain may especially occur when lying down after eating or when bending forward. The burning pain may be accompanied by a bothersome feeling that food is stuck partway down the food pipe, or esophagus.

Does the Heart Burn When Someone Has Heartburn?

Sarah's grandfather always comes to her house for Sunday dinner. For several weeks in a row, he seemed uncomfortable after eating and did not lie down for his usual nap. Sarah heard him talking to her father about heartburn. This scared Sarah, who thought that her grandfather was having heart problems.

▲ Heartburn occurs when the contents of the stomach move backward through the muscular valve called the lower esophageal sphincter and up into the esophagus. The stomach's acid and digestive enzymes irritate the lining of the esophagus, causing a burning feeling in the chest and a bitter, sour taste in the throat and mouth. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

Before or After?

Antacids, acid blockers, and proton-pump inhibitors are three types of dyspepsia medications that individuals can buy without a doctor's prescription. These over-the-counter (OTC) medications work in different ways.

Antacids, which should be taken after a meal, neutralize the acids already present in the stomach. People usually feel better right away, but relief lasts only a few hours.

Histamine Type 2 receptor blockers interfere with the action of histamine that signal stomach cells to produce acid.

Proton-pump inhibitors are especially effective, because they destroy the enzyme that is responsible for making stomach acids in the first place. Because of action, they can prevent heartburn from developing. Individuals usually take proton-pump inhibitors daily.

* **enzymes** (EN-zimes) are proteins that help speed up a chemical reaction in a cell or organism.

When Sarah asked her grandfather what was wrong with his heart, he explained that people with heartburn, which is also called acid indigestion, often complain of a burning feeling in the chest, close to where the heart is located. Usually, however, heartburn has nothing to do with the heart. The discomfort in the chest and throat occurs when the stomach contents, which include acid and digestive enzymes*, move backward into the esophagus, or food pipe. This stomach juice escapes into the food pipe when the muscular valve between the stomach and esophagus relaxes. The acidic juice irritates the lining of the esophagus and results in a burning feeling in the chest. People sometimes mistake the feeling for a heart attack. The backup of stomach juice, which doctors call gastroesophageal reflux, can also cause a bitter, sour taste in the throat and mouth. Heartburn usually occurs after a meal and can last for several hours, often becoming worse when the individual is lying down.

What Is Dyspepsia?

Dyspepsia comes from the Greek words for “bad digestion,” and it covers a wide range of stomach-related symptoms, including a burning and/or aching in the upper abdomen, heartburn, bloating, nausea, and vomiting. Symptoms typically return again and again.

Stomach ailments are some of the most common reasons why people visit their doctors. Some estimates suggest that one of every 20 patients that enters a doctor's office is there for a stomach problem. In all, up to 40 percent of adults in the United States and other Western countries experience dyspepsia, and elderly people are especially prone to it. Pregnant women commonly experience heartburn because of the pressure that the developing fetus puts on the mother's stomach and intestines. This pressure can force stomach juices into the esophagus.

While dyspepsia is quite widespread among adults, children rarely get it. They might feel indigestion after overeating, but children usually do not have heartburn or other types of dyspepsia.

By itself, dyspepsia is not a disease. Instead, it is a collection of uncomfortable symptoms that may arise because a person eats or drinks too much or is feeling stressed, anxious, or depressed. Nonetheless, a person who has recurring or frequent bouts of dyspepsia should see a doctor, because this may be a sign of other disorders, including the following:

- **Appendicitis** is inflammation of the appendix, a small tube connected to the large intestine.
- **Peptic ulcer** is a sore in the lining of the stomach or small intestine.
- **Hiatal hernia** occurs when part of the stomach pushes up into the chest through an opening in the diaphragm, the muscle between the chest and the abdomen.
- **Lactose intolerance** is a problem in digesting lactose, a sugar found in milk and other dairy products.
- **Gallbladder disease** is inflammation or blockage in the gallbladder, a small organ of the digestive system.

- **Gastroesophageal (gas-tro-e-sof-a-JEE-al) reflux disease (GERD)** is a digestive condition in which the muscular valve (lower esophageal sphincter) between the esophagus (food pipe) and stomach does not work properly, allowing stomach acid to flow backward into the esophagus.
- **True heart pain**, which is also called angina pectoris (an-JY-na PEK-tor-is), is a symptom that suggests something is wrong with the heart.

How Is Dyspepsia Diagnosed, Treated, and Prevented?

Dyspepsia is diagnosed in part by the patient's history of discomfort after eating. Doctors also use various tests to confirm dyspepsia. Some of these help the doctor to rule out other possible conditions, while others test specifically for dyspepsia. With respect to heartburn and acid reflux*, x-ray studies may show the reflux of swallowed material from the stomach into the esophagus. A pH probe may be placed within the esophagus to directly demonstrate that gastric acid is entering into the esophagus. Also, a flexible endoscope* may be passed into the esophagus to observe the inflammation, or esophagitis, that has resulted.

Most people with heartburn find that over-the-counter antacid medications, dietary changes, and lifestyle changes can help them feel better. When heartburn is frequent or chronic, it can lead to an inflammation of the esophagus (esophagitis). In this case, a doctor may prescribe antibiotics or other medications to help treat the inflammation. These medications include histamine blockers because histamine stimulates specialized stomach cells to secrete acid, and an enzyme inhibitor, which keeps the acid secreting cells from making any acid at all.

Guidelines for preventing heartburn include the following:

- Avoiding chocolate, coffee, and alcohol
- Passing up greasy or spicy foods
- Quitting smoking
- Losing weight
- Avoiding eating right before bed
- Finding ways to deal with stress

Having a Heat Wave!

A heat wave is a long period of very high heat and humidity. The National Weather Service uses a heat index (HI) to indicate when people should be warned about such conditions. The HI, given in degrees Fahrenheit, is a measure of how hot it feels when the actual air temperature is combined with the relative humidity (which is a measure of the amount of moisture in the air compared to the greatest amount of moisture the air could hold at the same temperature). For example, if the air temperature is 95 degrees Fahrenheit and the relative humidity is 55 percent, the HI, or how hot it feels, is 110 degrees Fahrenheit. The National Weather Service issues alerts when the HI is expected to be greater than 105 to 110 degrees Fahrenheit for at least two days in a row.

Heat-Related Injuries

Heat-related injuries, including heat cramps, heat exhaustion, and heat stroke, are problems that occur when the body's cooling system is overloaded.

Too Hot to Handle

Texas was in the grip of a severe heat wave in August just as students were heading back to school after summer break. The extreme heat forced schools around the state to take action. Schools in Plano, for example, kept their children inside for recess on very hot days. In Irving, the football coach cut short afternoon practices and had the players take extra water breaks. In Arlington, some football scrimmages were canceled, and others were scheduled after 7 p.m.

School officials were trying to prevent heat-related injuries, which are health problems that occur when the body's cooling system is overloaded. The body normally cools itself by sweating. Under some conditions, though, this system can start to fail. In such cases, a person's body temperature may rise quickly. Very high body temperatures can damage the brain and other vital organs.

What Are Heat-Related Injuries?

Heat-related injuries are divided into three types:

- **Heat cramps.** These are painful muscle cramps, usually in the stomach, arms, or legs, that may occur during heavy activity. Heat cramps are the least serious type of heat-related injury. They can, however, be dangerous if ignored because they are an early warning sign that the body is having trouble with heat.
- **Heat exhaustion.** This is the body's response to losing too much water and salt in sweat. It often occurs in people who exercise heavily or work in a hot, humid place, which makes them sweat a lot. Elderly

people and those with high blood pressure are also prone to heat exhaustion. As the body overheats, blood flow to the skin increases, and this decreases blood flow to other organs. As a result, an individual can experience weakness and confusion and may collapse. If heat exhaustion is left untreated, the person may suffer heat stroke.

- **Heat stroke.** This is the most serious type of heat-related injury. Heat stroke, also known as sun stroke, occurs when the body becomes unable to cool down. The body's temperature may rise to 106 degrees Fahrenheit or higher within minutes. Unless heat stroke is treated quickly, brain damage or death can result.

Who Is at Risk?

Several factors affect the body's ability to cool itself during very hot weather. One of the main ways the body cools itself is by sweating. The evaporation of sweat from the skin cools the body. When humidity (the amount of moisture in the air) is high, the sweat does not evaporate from the skin. Other factors that can limit the body's ability to control its temperature include fever, heart disease, sunburn, alcohol or drug use, and dehydration*, which is excessive loss of water from the body due to illness or not drinking enough liquids.

Some people have a high risk of heat-related injuries:

- **Babies and children under four years of age.** Babies and young children are very sensitive to the effects of high temperatures. They become dehydrated quickly because of their small size. They are also unable to help themselves if they start to get overheated.
- **People age 65 or older.** An older person's body may not control its own temperature as well as a younger person's. Older people are also less likely to notice and respond to changes in temperature.
- **People who are overweight.** An overweight person's body may tend to hold onto more body heat than a the body of a person who has a more normal weight.
- **People who are ill or taking certain medicines.** Any illness or medicine that leads to dehydration raises the risk of heat-related injuries.

What Are the Symptoms?

Heat Cramps

- Painful muscle cramps, usually in the stomach, arms, or legs
- Heavy sweating

Heat Exhaustion

- Heavy sweating
- Cold, clammy skin
- Paleness
- Tiredness

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

When Heat Kills

An extreme heat wave settled on the city of Chicago in July 1995, bringing soaring high humidity paired with seven consecutive days of air temperatures of at least 90 degrees. On two of those days, the thermometer soared to 102 and 106 degrees Fahrenheit. The 106-degree mark was a record. On that day the humidity was also very high and made the temperature feel like at least 120 degrees Fahrenheit. For hundreds of residents, the extreme heat was fatal. Many of the victims were elderly individuals who either had no air conditioners in their homes or who were unable to afford the cost to run their air-conditioning systems. A power outage in parts of the city made the problem even worse. By the end of the heat wave, an estimated 500 to 700 local people had died from the heat.

- Weakness
- Dizziness
- Headache
- Fainting
- Muscle cramps
- Nausea
- Vomiting
- Fast, weak pulse
- Fast, shallow breathing

Heat Stroke

- Very high body temperature (above 103 degrees Fahrenheit as measured by mouth)
- No sweating
- Red, hot, dry skin
- Dizziness
- Headache
- Confusion
- Nausea
- Vomiting
- Fast, strong pulse
- Unconsciousness

What Is the Treatment?

Heat Cramps Heat cramps usually occur during heavy activity. Medical professionals advise a person experiencing heat cramps to stop activity, sit quietly in a cool place, and sip water, clear juice, or a sports drink. Firm pressure on the muscles or a gentle massage of them will help to relieve the muscle cramps. Even after the cramps have disappeared, the individual should avoid returning to heavy exercise for a few hours, because this level of activity might lead to heat exhaustion or heat stroke. An individual whose cramps have not gone away within an hour should call a doctor.

Heat Exhaustion If the symptoms are severe, or if the person has heart disease or high blood pressure, someone should call for medical help immediately and either move the victim to a shaded area and fan the person's body or, if possible, move the person into an air-conditioned room. The individual should lie down and remove heavy clothing. Sips of water and placing cool, wet cloths on the skin are helpful. A cool shower or bath may also be beneficial.

Heat Stroke Heat stroke is a serious medical emergency, and onlookers should summon medical help right away. While waiting for

assistance, caregivers can help the person cool off by getting him or her out of the sun and fanning the patient or by moving the person into an air-conditioned room. There, the person should lie down and remove clothing. Applying cool, wet cloths, or putting the person in a cool bath or shower will help. If the humidity is low, another solution is to wrap the person in a cool, wet sheet. If the person is outside, spraying the person lightly with a garden hose can be effective. Those providing first aid should take the person's temperature regularly and continue the cooling efforts until the person's temperature drops to 101 to 102 degrees Fahrenheit. Sometimes the person's muscles may start to twitch wildly as a result of heat stroke. If this happens, the caregiver's job is to keep the person from getting hurt. The caregiver should not, however, put anything in the person's mouth or give anything to the person to drink. If vomiting occurs, the caregiver should keep the airway open by turning the person onto his or her side.

How Can Heat Injury Be Prevented?

The best ways to prevent heat-related injuries are to keep cool and use common sense. The following tips may help on hot summer days:

- Consume plenty of fluids, regardless of thirst. During heavy exercise in hot weather, individuals should drink at least two to four glasses of cool fluid each hour. Water is always a good drink choice. Avoid very cold drinks, which can cause stomach cramps; salt tablets; and caffeine-containing drinks, such as iced teas and colas, that cause the body to lose more fluid.
- Slow down the pace. During hot weather, cut back on heavy exercise, or move it to the coolest time of day, usually early in the morning.
- Stay indoors if possible. An electric fan can make the inside space more comfortable, but a fan alone may not be enough during a severe heat wave. Air conditioning is much more effective, so remaining in an air-conditioned home or spending a few hours at an air-conditioned mall or public library can help.
- Wear lightweight, loose-fitting, preferably light-colored clothing. Light-colored fabrics reflect away some of the sun's energy.
- Eat smaller, more frequent meals to avoid generating the extra body heat associated with digesting large meals.

Helicobacter Pylori Infection

Helicobacter pylori (HEEL-ih-ko-bak-ter pie-LOR-eye) is a bacterium that can cause inflammation of the stomach and is associated with the development of peptic ulcers* and some types of stomach cancer.

What Is *H. pylori* Infection?

H. pylori is a spiral-shaped bacterium that has adapted to living in the stomach under the mucus gel. In order to survive, *H. pylori* burrows into the protective mucus lining the stomach. Once it gets into the mucus, it uses an enzyme to cause a chemical reaction that produces bicarbonate and ammonia. Both of these are strong bases that neutralize any stomach acid that reaches the bacterium. The immune system* responds to the presence of *H. pylori*. This can cause inflammation* of the lining of the stomach, a condition called gastritis (gah-STRY-tis). Some people go on to develop peptic ulcers. A peptic ulcer is a painful open sore that forms in the stomach or the duodenum. *H. pylori* infection is also associated with an increase in the likelihood of developing certain stomach cancers.

How Common Is *H. pylori* Infection?

In the United States, about 10 percent of children under the age of 12 are infected with *H. pylori*. This number increases with age until about half of all Americans over age 60 have the infection. The infection is much more common among African Americans, Hispanics, and Native Americans than among whites. The rate of infection is much higher in the developing world. Even though infection with *H. pylori* is associated with peptic ulcer, most people who are infected with the bacterium never experience any symptoms or develop a peptic ulcer.

Is *H. pylori* Infection Contagious?

H. pylori infection appears to be contagious, but as of 2009 it was not known how it spreads. Researchers suspected that the infection can be spread when an infected person passes the bacterium in feces (FEE-seez),

A VACATION LEADS TO A BREAKTHROUGH

In 1982 (John) Robin Warren (b. 1937), a biologist, and Barry J. Marshall (b. 1951), a physician, were the first researchers to discovered a link between stomach inflammation (gastritis), peptic ulcers, and a bacterium later known as *Helicobacter pylori*.

Originally, Warren and Marshall were unsuccessful in growing the bacterium Warren had found in stomach samples until cultures containing the bacterium were accidentally left to grow for an unusually long time because of a vacation break. It turned out that the *H. pylori* bacterium just took longer to grow than many other bacteria.

Warren and Marshall were able to show a connection between infection with *H. pylori* and peptic ulcers. For their work, they were awarded the Nobel Prize in Medicine and Physiology in 2005.

or bowel movements. When another person is exposed to the infected feces, whether by changing a diaper, cleaning a bathroom, or doing someone's laundry, that person could become infected with the bacterium. Mouth-to-mouth contact may also contribute to the spread of *H. pylori* infection. Some research has found *H. pylori* bacteria in saliva, leading researchers to suggest that kissing is one way that the bacteria spread. In addition, coming into contact with food, water, or vomited material that contains *H. pylori* bacteria may put a person at risk of infection.

What Are the Signs and Symptoms of *H. pylori* Infection?

H. pylori infection can cause a variety of symptoms, but the most common one is abdominal pain. About 90 percent of people with peptic ulcer disease are also infected with *H. pylori*. A person with peptic ulcer disease may feel a gnawing or burning pain below the ribs and above the navel. Abdominal pain from an ulcer usually occurs when the stomach is empty, typically several hours after eating or in the morning or evening hours. Eating food, drinking milk, or taking antacids may make the pain subside for a short time. Nonetheless, the vast majority of people infected with *H. pylori* have no symptoms.

Other symptoms of peptic ulcer disease are as follows:

- Frequently feeling sick to the stomach (nausea, NAW-zee-uh)
- Loss of appetite
- Frequent burping
- Sudden, sharp abdominal pain
- Weight loss
- Vomiting
- Bloody or black stools

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **antagonist** (an-TAG-oh-nist) a chemical that acts within the body to reduce or oppose the effects of another chemical.

Symptoms of stomach cancer are similar to those of peptic ulcer disease.

As of 2009, researchers did not fully understand the relationship between *H. pylori*, gastric inflammation, and peptic ulcers. For example, about 90 percent of people who have peptic ulcers are infected with *H. pylori*, but the vast majority of those infected do not develop an ulcer. About 10 percent of people with ulcers do not have *H. pylori* infections. Also, antibiotic treatment to rid the body of *H. pylori* does not, by itself, cure most ulcers.

How Is *H. pylori* Infection Diagnosed?

If a person has lasting abdominal pain or other symptoms of peptic ulcer disease, there are several methods a doctor can use to make a diagnosis. One of the most common ways to check for ulcers is with endoscopy (en-DOS-ko-pee). For this procedure, a person is given medication to relax and numb the throat. Then a doctor gently inserts an endoscope (a thin, flexible tube with a camera and light on the end) down the throat, through the esophagus, and into the stomach and intestines. The camera on the end of the endoscope allows the doctor to view the digestive system and take pictures of it. In addition, the doctor can perform a biopsy, removing a small amount of tissue for study. The biopsied tissue can be sent to a laboratory for further testing and to check for evidence of *H. pylori* infection.

A person suspected of having *H. pylori* infection might also undergo a breath test. During a breath test, a person drinks a liquid containing a carbon marker known as carbon-13 (^{13}C). The person then provides a breath sample by blowing up a balloon or blowing bubbles. The sample is checked for the presence of the ^{13}C marker. If the person has *H. pylori* infection, there will be traces of ^{13}C present in the carbon dioxide gas molecules of the person's breath.

A person's blood can also be checked for the presence of antibodies* to *H. pylori*, indicating infection.

How Is *H. pylori* Infection Treated?

People who are infected with *H. pylori* are treated for 10 to 14 days with what is called triple therapy. This approach consists of a combination of two or three antibiotic medicines that kill *H. pylori* bacteria and a drug that reduces acid production in the stomach. Two classes of drugs reduce acid production: histamine antagonists* and proton pump inhibitors. Patients may also take an antacid that temporarily helps coat the inside of the stomach. After treatment has been completed, tests sometimes are done to check that *H. pylori* infection has been eliminated. Reinfection is possible.

Although many people who are infected with *H. pylori* never have symptoms and never develop peptic ulcers, if left untreated ulcers can lead to serious problems. In some cases, the ulcer can make a hole all the way through the stomach or duodenum wall. In other cases, the ulcer or acid

breaks a blood vessel and causes serious internal bleeding. It is important to get medical help promptly for the following symptoms, which may signal a peptic ulcer or other serious problem:

- Sharp, sudden, or long-lasting stomach pain
- Bloody or black stools (bowel movements)
- Bloody vomit or vomit that looks like coffee grounds

Are There Complications of *H. pylori* Infection?

A person who has untreated *H. pylori* infection has an increased risk of developing stomach cancer later in life. Long-term loss of blood from the gastrointestinal tract due to ulcers can cause anemia*. Severe untreated ulcers can lead to a perforation, or a hole, when the sore erodes all the way through the lining of the stomach or intestine. Perforations can cause sudden severe bleeding and spread of infection into the abdominal cavity that can be fatal.

Can *H. pylori* Infection Be Prevented?

As of 2009, *H. pylori* infection could not be prevented. Researchers did not fully understand how *H. pylori* spreads or why some infected people develop ulcers and others do not. As a general precaution people should wash their hands thoroughly after going to the bathroom and before eating. They should eat food that has been properly cooked and drink water from a clean, safe source. As of 2009, there was no vaccine against *H. pylori* infection.

Hemochromatosis

Hemochromatosis (HE-mo-KRO-ma-TOE-sis), also called iron overload disease, is a disorder in which too much iron is absorbed from food and builds up in the body. Hemochromatosis is usually an inherited disorder.

What Is Hemochromatosis?

Iron is an essential mineral obtained from food. The human body normally absorbs about 10 percent of the iron in food. People with hemochromatosis absorb excess iron. Because the body does not have a mechanism for removing the excess iron, it is stored in tissues, particularly in the skin, liver*, heart, pancreas*, and joints*. The iron can damage these organs and, without treatment, eventually cause them to fail, possibly leading to death.

Iron metabolism Most of the iron in the body is contained in hemoglobin* molecules in red blood cells, where it is responsible for transporting oxygen* to body tissues. Iron is also required to store oxygen in muscles as myoglobin and to make DNA*. However, excess iron is a deadly poison. Therefore, the body has an elaborate system for ensuring that the only the correct amount of iron is absorbed.

In normal iron metabolism* about 90 percent of the iron in the diet is taken up by specific cells in the intestinal tract. When these cells are filled with iron, they die and are excreted in the feces*. The other 10 percent of iron is used by the body. Heme iron, the form of iron in hemoglobin and myoglobin, is readily absorbed by the body from dietary meat. However, most dietary iron is non-heme iron. Stomach acid converts non-heme iron into a form that is easily absorbed by the duodenum of the small intestine*. From there it is carried in the bloodstream by a protein called transferrin, which is normally 25 to 35 percent saturated (filled) with iron. If the transferrin is too heavily loaded, it loses its ability to bind iron, resulting in free iron in the blood. Reactions with free iron produce chemicals called free radicals that are very destructive to cells and tissues. In addition, free iron can nourish bacteria* that are normally harmless but that can cause life-threatening infections in people with high iron levels. Cancer* cells also thrive on iron.

Ferritin is a protein that stores unneeded iron in almost every cell of the body. One ferritin molecule can hold up to 4,500 atoms of iron. However, when ferritin is overloaded with iron, it turns into a substance called hemosiderin, which contains ferric oxide or rust. Large amounts of hemosiderin disrupt organ function. For example, if cells in the pancreas are overloaded with hemosiderin, they cannot produce insulin*, resulting in diabetes*.

In addition to transferrin, there are two other transporters of free iron: Divalent metal transporter 1 carries free iron from the bloodstream into cells and ferroportin carries iron out of cells into the bloodstream.

What Are the Types of Hemochromatosis?

Primary or hereditary hemochromatosis is caused by mutations* in genes* that code for the proteins involved in regulating the absorption, transport, and storage of iron in the body. Primary hemochromatosis is categorized according to the age of onset, the genetic* cause, and the mode of inheritance.

Type 1 Type 1 hemochromatosis is one of the most common inherited disorders in the United States, affecting about one million people. It generally affects men between the ages of 40 and 60 and post-menopausal women, probably because women lose iron through menstruation*, pregnancy, and breastfeeding, and, therefore, tend to develop iron-overload symptoms later than men.

Type 1 hemochromatosis is caused by mutations in the hemochromatosis gene—called HFE—which encodes a protein located on the surface of intestinal and liver cells, as well as some immune system* cells. This protein helps the cells regulate the absorption of iron into the small intestine. It also helps control the levels of the protein called hepcidin, which circulates in the blood and prevents excessive iron absorption by the small intestine. More than 20 different mutations that cause type 1 hemochromatosis have been identified in the HFE gene. The two most common mutations prevent the HFE protein from reaching the cell surface.

About 10 percent of the American population are believed to carry at least one of the genes that cause hemochromatosis. However, only people with two defective copies of HFE—one inherited from each parent—will develop type 1 hemochromatosis. In fact, it is estimated that no more than one-half of those with two defective HFE genes actually develop symptoms of hemochromatosis, although they will pass one defective gene on to all of their children.

Other primary hemochromatoses The other types of hemochromatosis are quite rare and had not been studied fully as of 2009.

The iron accumulation and symptoms of type 2 or juvenile-onset hemochromatosis begin in early childhood. They are caused by mutations in either the hepcidin antimicrobial peptide (HAMP) gene or the

* **cancer** is a condition characterized by abnormal overgrowth of certain cells, which may be fatal.

* **insulin** is a kind of hormone, or chemical produced in the body, that is crucial in controlling the level of glucose (sugar) in the blood and in helping the body use glucose to produce energy. When the body cannot produce or use insulin properly, a person must take insulin or other medications.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **mutations** (mu-TAY-shuns) are changes in a chromosome or a gene.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **menstruation** (men-stroo-AY-shun) is the discharge of the blood-enriched lining of the uterus. Menstruation normally occurs in females who are physically mature enough to bear children. Most girls have their first period between the age of 9 and 16. Menstruation ceases during pregnancy and with the onset of menopause. Because it usually occurs at about four-week intervals, it is often called the monthly period.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **infectious** means able to spread to others.

* **tuberculosis** (too-ber-kyoo-LO-sis) is a bacterial infection that primarily attacks the lungs but can spread to other parts of the body.

* **plague** (PLAYG) is a serious bacterial infection that is spread to humans by infected rodents and their fleas.

* **receptors** are cell structures that form a chemical bond with specific substances, such as neurotransmitters. This leads to a specific effect.

* **neonatal** (ne-o-NAY-tal) means pertaining to the first 4 weeks after birth.

WHY ARE HEMOCHROMATOSIS GENE MUTATIONS SO COMMON?

Type 1 hemochromatosis is very common in people of Northern European descent. In some parts of Europe as many as one in three may carry an HFE gene mutation. These people usually have a slightly increased level of iron in their bodies. Sharon Moalem and his colleagues at Mount Sinai School of Medicine in New York have hypothesized that hemochromatosis may confer protection against some deadly infectious* diseases, such as tuberculosis* and the Black Death or plague*. The bacteria responsible for these diseases sneak into the body in immune-system cells called macrophages where they thrive on iron. However, despite higher levels of iron in their blood and organs, people with hemochromatosis have much lower levels of iron in their macrophages. Thus, hemochromatosis may have conferred resistance to the pandemics of plague that swept through Europe from the 14th to the 18th centuries.

hemochromatosis type 2 (juvenile) gene called HFE2. The HAMP gene produces hepcidin, which was originally identified by its ability to fight bacterial infections. There are at least eight mutations in HAMP that lead to type 2 hemochromatosis. The HFE2 gene encodes a protein called hemojuvelin, which regulates the level of hepcidin. More than 20 mutations that cause type 2 hemochromatosis have been identified in HFE2. As with HFE, only those with two defective copies of HAMP or HFE2 develop hemochromatosis.

Symptoms of type 3 hemochromatosis are usually evident by age 30. They are caused by mutations in the TFR2 gene that produces transferrin receptors* on liver cells. This receptor binds transferrin for iron transport into cells. This receptor also helps control the levels of hepcidin. There are at least nine different mutations in TFR2 that cause type 3 hemochromatosis. Again, two defective TRF2 genes are required for the development of type 3 hemochromatosis.

Type 4 hemochromatosis, also called ferroportin disease, usually affects men between the ages of 40 and 60 and post-menopausal women. It is caused by mutations in the SLC40A1 gene that encodes ferroportin 1. These mutations produce abnormal ferroportin 1 proteins that do not correctly transport iron out of cells and release it to transferrin in the blood. About 15 mutations have been identified in SLC40A1 that cause type 4 hemochromatosis. Only one defective copy of SLC40A1 is sufficient to cause type 4 hemochromatosis.

Neonatal* hemochromatosis is a rare condition in which iron accumulation begins before birth. It progresses rapidly and liver damage is apparent at birth. The cause of neonatal hemochromatosis is unknown.

Secondary hemochromatosis Secondary hemochromatosis is iron overload caused by some other disease or condition. These include the following:

- Certain types of anemia*
- African iron overload, which is a combination of heredity and diet
- Other rare inherited disorders
- Chronic liver diseases, such as hepatitis*
- Overloading the body with iron via oral supplements or injected medication, blood transfusions*, or long-term kidney* dialysis*.

How Do People Know They Have Hemochromatosis?

Many people with hemochromatosis never experience symptoms or complications, despite having high levels of iron in their bodies. For example, people who frequently donate blood may be unwittingly treating themselves for hemochromatosis. Other people suffer from serious complications and may die of the disease.

Early symptoms of hemochromatosis are nonspecific and may include the following:

- Fatigue
- Weakness
- Joint pain
- Abdominal pain
- Weight loss
- Palpitations—a fluttering sensation in the chest
- Loss of sex drive

Later symptoms of hemochromatosis may include:

- Severe fatigue
- Skin discoloration
- Arthritis*
- Chronic abdominal* pain
- Heart abnormalities
- Liver disease, including liver enlargement, cirrhosis*, cancer, or liver failure
- Low hormone* production by the pituitary* and thyroid gland*
- Damage to the adrenal glands*
- Diabetes mellitus
- Reproductive organ failure, including shrinkage of the testicles*, infertility*, or early menopause*

The decreased secretion or absence of sex hormones caused by type 2 hemochromatosis becomes evident during adolescence. Females usually

What Is “Bronze Diabetes?”

Hemochromatosis was probably first identified in 1865 by the French physician Armand Trousseau (1801–1867). He called it bronze diabetes because his patients appeared tanned from iron deposits in the skin and had symptoms of diabetes due to pancreatic damage.

* **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.

* **hepatitis** (heh-puh-TIE-tis) is an inflammation of the liver. Hepatitis can be caused by viruses, bacteria, and a number of other noninfectious medical conditions.

* **blood transfusions** (trans-FYOO-zhunz) are procedures in which blood or certain parts of blood (such as specific cells) are given to a person who needs them due to illness or blood loss.

* **kidney** is one of the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.

* **dialysis** (dye-AL-uh-sis) is a process that removes waste, toxins (poisons), and extra fluid from the blood. Usually dialysis is done when a person’s kidneys are unable to perform these functions normally.

* **arthritis** (ar-THRY-tis) refers to any of several disorders characterized by inflammation of the joints.

* **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.

- * **cirrhosis** (sir-O-sis) is a condition that affects the liver, involving long-term inflammation and scarring, which can lead to problems with liver function.
- * **hormone** is a chemical substance that is produced by a gland and sent into the bloodstream carrying messages that have certain effects on other parts of the body.
- * **pituitary** (pih-TOO-ih-tare-e) is a small oval-shaped gland at the base of the skull that produces several hormones—substances that affect various body functions, including growth.
- * **thyroid gland** (THY-roid GLAND) is located in the lower part of the front of the neck. The thyroid produces hormones that regulate the body's metabolism (me-TAB-o-LIZ-um), the processes the body uses to produce energy, to grow, and to maintain body tissues.
- * **adrenal glands** (a-DREEN-al glands) are the pair of endocrine organs located near the kidneys.
- * **testicles** (TES-tih-kulz) are the paired male reproductive glands that produce sperm.
- * **infertility** (in-fer-TIH-lih-tee) is the inability of females to become pregnant or of males to cause pregnancy.
- * **menopause** (MEN-o-pawz) is the end of menstruation.
- * **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.
- * **impotence** (IM-po-tens) is failure of a man to achieve or to maintain an erection.
- * **heart disease** is a broad term that covers many conditions that prevent the heart from working properly to pump blood throughout the body.

begin menstruation normally, but menses stops after a few years. Male puberty* may be delayed or symptoms of sex-hormone deficiency, such as impotence*, become evident. Untreated, type 2 hemochromatosis leads to heart disease* by the age of 30.

How Do Doctors Diagnose and Treat Hemochromatosis?

Diagnosis Hemochromatosis is diagnosed by a physical exam, medical and family histories, and various tests. Dietary causes—such as iron supplements—must be ruled out. Excessive vitamin C supplements can cause symptoms of iron overload because vitamin C increases the amount of iron absorbed by the body. Genetic* tests can determine the presence of gene(s) responsible for hemochromatosis; however, genetic screening may overlook rarer mutations.

Diagnostic tests include the following:

- Transferrin saturation (TS) that measures the iron load of transferrin in the blood
- Serum ferritin that may indicate the buildup of iron in organs
- The total amount of iron in the blood, although this may be normal even with hemochromatosis

Quantitative phlebotomy—a series of measured blood withdrawals—should lower test results.

Liver damage from hemochromatosis may be determined by the following:

- Blood tests for liver function
- MRI* to visualize the amount of iron in the liver
- A superconducting quantum interference device that can measure the amount of iron in the liver
- A liver biopsy* to measure the iron level in the liver and diagnose liver damage.

Treatment Early diagnosis and treatment can prevent or delay—and sometimes reverse—the complications of hemochromatosis. The goals of treatment are to do the following:

- Reduce the iron in the body to normal levels and maintain these levels over the long term
- Prevent or delay organ damage
- Treat complications

The most common treatment for hemochromatosis is therapeutic phlebotomy, in which blood is periodically withdrawn through a vein*. Treatment usually begins shortly after diagnosis. One or two pints of blood are withdrawn once or twice per week for six months to three years. Once iron levels have returned to normal, phlebotomy may be reduced to about every three months.

People who cannot undergo periodic phlebotomy may be treated with iron chelation therapy. These are oral or injected medications that bind to iron and remove it from the body in the urine or feces.

Hemochromatosis is also treated with dietary measures including the following:

- Avoidance of any iron supplementation
- A limit of 200 milligrams per day of vitamin C supplements
- Limited red meat—the most readily absorbed form of iron
- Increased fiber, which inhibits iron absorption
- If not contraindicated, coffee or tea consumption with meals to inhibit iron absorption
- Abstinence or limited alcohol, because alcohol enhances iron absorption and can exacerbate liver damage
- Fresh fruits and vegetables, which contain antioxidants that help protect against free-radical damage caused by iron

Can Hemochromatosis Be Prevented?

Most people do not know that they have hemochromatosis until organ damage occurs. Genetic testing and counseling can advise parents on the likelihood that they will pass on hemochromatosis genes to their children. Although routine genetic screening can identify most people who are at high risk for hemochromatosis, the majority of these people will never develop the disease. However, close relatives of those diagnosed with hemochromatosis should have their iron levels tested before symptoms and possible organ damage occur.

Although there is no way to prevent hemochromatosis in genetically susceptible people, environmental and lifestyle factors can affect the onset and progression of symptoms. These factors include the following:

- The amount of iron in the diet
- Alcohol consumption
- Infections such as hepatitis, which can increase liver damage
- Uncooked fish or shellfish, which may contain bacteria that cause infection in people with hemochromatosis

Hemoglobinopathies

Hemoglobinopathies (he-muy-glo-bin-AH-path-ees) are inherited disorders caused by defects in the genes that code for hemoglobin* (Hb). Hemoglobinopathies are characterized by low levels of hemoglobin protein and/or low production and high turnover of red blood cells, resulting in anemia* and body tissues that are starved for oxygen*. The most common hemoglobinopathies are sickle-cell anemia* and thalassemia (thal-ab-SE-me-ah).*

Sophia's Story

Sophia was resting on the sofa when her teacher called her mother. Sophia had fallen asleep in class again. "I couldn't help it, Mom. I was just so tired and my legs hurt." Sophia's mother reached for the telephone to schedule a blood transfusion*. "No," cried Sophia. "I hate those. And there are other kids who need that blood a lot more than I do." Sophia's mother reminded her that all of their friends had donated blood so that it would be available for Sophia when she needed it.

Initially, her parents had thought Sophia was just small for her age. Then the doctor diagnosed Sophia as anemic and prescribed iron supplements to increase her red-blood-cell (RBC) count. The iron did not help. Sophia's growth was delayed and she tired very easily. Then her liver* and spleen* became enlarged and her skin yellowed with jaundice*.

Her parents were mystified when the specialist diagnosed Sophia with a genetic* disease—beta thalassemia or Mediterranean anemia. No one in either of their large Greek and Italian families had ever had anemia. And Sophia's older brother was perfectly healthy. But blood tests showed that both of Sophia's parents carried a beta thalassemia trait: They each had one normal gene coding for the beta-globin chain of hemoglobin and one abnormal thalassemia gene. Their normal gene made enough beta-globin

so their mild anemia had never been detected. However, Sophia had inherited an abnormal thalassemia gene from each of her parents. Her brother had inherited the two normal genes.

Immediately after her blood transfusion Sophia returned to school and resumed her normal activities. It could have been much worse. Sophia had beta thalassemia intermedia. Her body made enough beta-globin that, with occasional blood transfusions, she could remain healthy and live a normal life. Had she been diagnosed with beta thalassemia major, near-weekly transfusions would have been required to keep her alive.

What Are Hemoglobinopathies?

Hemoglobinopathies cause anemia—the blood does not contain enough properly functioning RBCs to carry enough oxygen to all the cells of the body. Hemoglobinopathies are autosomal dominant* recessive* genetic disorders. Autosomal genes are located on chromosomes other than the X or Y sex chromosomes*. Therefore, defects in these genes affect males and females equally. Recessive traits usually only cause serious problems if two or more of the recessive genes are present.

Hemoglobin Hemoglobin is the protein that is responsible for carrying oxygen from the lungs to cells throughout the body and transporting carbon dioxide* from the cells back to the lungs. RBCs or erythrocytes (e-RITH-ro-sites) are the most abundant cells in the blood, and each RBC contains about 300 hemoglobin molecules.

Normal RBCs survive about 120 days. Dying RBCs are engulfed by cells called macrophages (MAK-ro-fayj-ez) in the spleen. More than 2 million RBCs die every second and must be replaced at exactly the same rate by the bone marrow*.

Hemoglobin is made up of four protein chains called globins—two alpha-globins and two beta-globins. Hemoglobinopathies are caused by defects in the genes encoding these globins. These altered genes result in abnormal hemoglobin proteins that are inefficient at transporting oxygen. They may also slow down the rate of hemoglobin production in the bone marrow and speed up the destruction of RBCs by the spleen, a condition called hemolytic* anemia.

Sickle-cell anemia Sickle-cell anemia is the most familiar hemoglobinopathy. HbS makes the RBCs sickle- or crescent-shaped rather than disc-shaped. These cells carry less oxygen than normal RBCs. They are fragile and more easily destroyed than normal RBCs, with a lifespan of only 10 to 20 days. The destruction of RBCs causes accumulation of the hemoglobin breakdown product bilirubin*, resulting in jaundice. The bone marrow cannot replace the RBCs fast enough. In addition, their sickle shape prevents the RBCs from flowing easily. They tend to bunch up and clog small blood vessels. Oxygen starvation and blockage of blood vessels can cause severe inflammation*, pain, and tissue damage, precipitating sickle-cell crises.

* **jaundice** (JON-dis) is a yellowing of the skin, and sometimes the whites of the eyes, caused by a buildup in the body of bilirubin, a chemical produced in and released by the liver. An increase in bilirubin may indicate disease of the liver or certain blood disorders.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **autosomal dominant** mode of inheritance in which only one copy of an abnormal gene is necessary to cause disease.

* **recessive** describes a gene that is not dominant, one that requires a second identical recessive gene in order for the trait to show in the individual. When a recessive gene is paired with a dominant one, the individual is said to be a carrier of the trait.

* **chromosomes** (KRO-mo-somz) are threadlike chemical structures inside cells on which the genes are located. There are 46 (23 pairs) of chromosomes in normal human cells. Genes on the X and Y chromosomes (known as the sex chromosomes) help determine whether a person is male or female. Females have two X chromosomes; males have one X and one Y chromosome.

* **carbon dioxide** (CAR-bon dy-OK-side) is an odorless, colorless gas that is formed in the tissues and breathed out through the lungs.

* **bone marrow** is the soft tissue inside bones where blood cells are made.

* **hemolytic** (he-mo-LIT-ik) refers to destruction of red blood cells with the release of hemoglobin into the bloodstream.

- * **bilirubin** (bih-lih-ROO-bin) is a substance that the body produces when hemoglobin, an iron-containing component of the blood, is broken down.
- * **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.
- * **malaria** (mah-LAIR-e-uh) is a disease spread to humans by the bite of an infected mosquito.

WHAT ARE UNUSUAL HEMOGLOBINS?

Normal adult hemoglobin is designated HbA or AA. People with sickle-cell anemia have only hemoglobin S (HbS or SS). In the late 1940s, using a procedure called electrophoresis (e-lek-tro-fo-REE-sis), Linus Pauling and Harvey Itano showed that in an electric field HbS moves more slowly toward the positive electrode than HbA. They concluded that HbS was slightly less negatively charged than HbA. Later, Vernon Ingram demonstrated that HbS differs from HbA in a single amino acid of its beta-globin, with an uncharged amino acid replacing a negatively charged amino acid. Electrophoresis continued to be used in the early 2000s to identify different types of hemoglobin.

Hundreds of unusual hemoglobins are now known. The most common are:

- HbS (sickle)
- Hb β Thal (beta thalassemia)
- HbH
- HbC
- HbE
- HbD (Punjab)

Only those who inherit two *HbS* genes (SS), one from each parent, have sickle-cell anemia. Those with one *HbS* gene and one normal *HbA* gene (SA) have sickle-cell trait. Only about 45 percent of their hemoglobin is HbS and only about 1 percent of their RBCs undergo sickling. SA individuals are not only usually healthy, they have increased resistance to malaria*, an often fatal disease in Africa where *HbS* is common.

Thalassemias Whereas sickle-cell anemia is a well-defined disorder, thalassemias are a range of disorders in which the rate of Hb production in the bone marrow is low and the turnover of RBCs is excessive. Alpha thalassemias are caused by defects in genes encoding alpha-globins. Beta thalassemias are caused by defects in genes encoding beta-globins. Thalassemias are classified as minor or major, depending on the degree of deficiency in the affected globin and the resulting severity of the anemia.

Four genes, two inherited from each parent, are required to make sufficient alpha-globin. Therefore, there are multiple types of alpha thalassemias:

- *Silent carrier* is the alteration or absence of one alpha-globin gene. The reduction in hemoglobin is so small that it is not usually diagnosed unless the person has a child with thalassemia.
- *Alpha thalassemia trait, mild alpha thalassemia, or alpha thalassemia minor* is the presence of two defective alpha-globin genes. This condition can cause mild anemia.

- *Hemoglobin H disease* is caused by the presence of three defective alpha-globin genes. HbH is the abnormal hemoglobin formed by the remaining beta chains. It destroys RBCs, causing severe anemia and other health problems.
- *Alpha thalassemia major* or *hydrops fetalis* is the most severe thalassemia in which all four alpha-globin genes are defective. It usually causes death before or shortly after birth.

Beta thalassemia minor or beta thalassemia trait, with one defective beta-globin gene, can result in mild anemia. If both beta-globin genes are altered, the severity of the condition depends the specific genetic changes. It may be referred to as one of the following:

- Beta thalassemia intermedia
- Beta thalassemia major
- Cooley's anemia
- Mediterranean anemia
- Beta-zero thalassemia
- Beta-plus thalassemia

The distinction between beta thalassemias intermedia and major is usually based on the latter's requirement for regular life-sustaining blood transfusions.

Rare hemoglobinopathies Hemoglobin C and hemoglobin E diseases are rare hemoglobinopathies in which abnormally shaped RBCs are subject to excessive destruction, resulting in chronic* hemolytic anemia. Whereas hemoglobin C disease is similar to sickle-cell anemia, hemoglobin E disease rarely causes symptoms other than anemia. *HbE* is common among Southeast Asians.

Other hemoglobinopathies result from rare combinations of abnormal hemoglobins:

- HbE plus Hb β Thal causes hemoglobin E disease or E beta thalassemia, a moderately severe anemia.
- HbS plus Hb β Thal causes sickle beta thalassemia, a sickle-cell disease of varying severity, depending on the amount of beta-globin produced. It usually occurs in people of Mediterranean ancestry.
- HbS plus HbC causes hemoglobin S-C disease or sickle-hemoglobin C disease.
- HbS plus HbD causes a rare form of sickle-cell disease.

How Common Are Hemoglobinopathies?

Most hemoglobinopathies are relatively rare. However, sickle-cell disease affects millions of people worldwide. In West and Central Africa 25 percent of the population has sickle-cell trait and 1 to 2 percent of babies are born with sickle-cell disease. In the United States more than 70,000 people have sickle-cell disease and 2 million carry sickle-cell trait. One in every

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

* **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.

500 African Americans is born with the disease and one in 12 has sickle-cell trait.

Thalassemia affects about 1,000 Americans. Alpha thalassemias occur most often in Chinese and Southeast Asians. Beta thalassemias occurs most often in people of Mediterranean origin and, to a lesser extent, in Chinese and other Asians and in blacks.

Hemoglobin C disease is most common among blacks and about 2 to 3 percent of African Americans carry one copy of the *HbC* gene. However, hemoglobin S-C disease is more common than hemoglobin C disease.

What Are the Symptoms of Hemoglobinopathies?

The symptoms of serious hemoglobinopathies usually develop in infancy, as the bone marrow switches production from fetal to adult hemoglobin. Symptoms depend on the severity of the anemia caused by the specific genetic defect. Other symptoms, such as jaundice and enlargement of the spleen, reflect the excessive destruction of RBCs.

Common symptoms of sickle-cell disease include the following:

- Delayed growth and puberty*
- Paleness
- Shortness of breath
- Fatigue
- Rapid heart rate
- Fever
- Abdominal* pain
- Bone pain
- Ulcers on the lower legs
- Frequent infections

Thalassemia minor does not necessarily produce symptoms, although the RBCs are small. However, babies with hemoglobin H disease or beta thalassemia major develop severe anemia during the first year of life, resulting in slow growth, abnormal bone development, especially of the facial bones, and enlarged liver and spleen. Other symptoms may be similar to those of sickle-cell disease.

How Are Hemoglobinopathies Diagnosed and Treated?

Severe hemoglobinopathies are usually diagnosed in early childhood. The primary diagnostic is hemoglobin electrophoresis, which measures the amounts of the different types of hemoglobin in the blood. Other tests for hemoglobinopathies may include:

- Complete blood cell count (CBC)
- Peripheral blood smear for examining the size and shape of RBCs, since their appearance is often diagnostic for a specific hemoglobinopathy

- Serum hemoglobin to measure of the amount of hemoglobin in the blood outside of the RBCs, which may be elevated with hemoglobinopathy
- DNA testing to determine the specific genetic defect

Treatments Severe hemoglobinopathies require intensive lifelong medical care. Bone marrow transplants*, especially in children, can sometimes cure sickle-cell disease and thalassemias. However, it is often very difficult to find a suitable bone marrow donor. Other treatments for hemoglobinopathies include:

- Folic acid supplements to stimulate RBC production
- Antibiotics* and vaccines* to prevent infections
- Drugs to stimulate RBC production
- Blood transfusions
- Hydroxyurea, which can help prevent sickling and reduce the frequency of sickle-cell crises. It may also increase the amount of fetal hemoglobin that is produced, thereby reducing the need for blood transfusions to treat thalassemia.

Other treatments for sickle-cell and hemoglobin E diseases are directed at managing and controlling symptoms and preventing crises. These include:

- Medications for pain
- Intravenous fluids to offset dehydration* and help keep cells from sickling
- Oxygen therapy

Periodic RBC transfusions alleviate symptoms and improve the quality of life for those with beta thalassemia intermedia. Treatment of beta thalassemia major requires transfusions as often as every two to four weeks throughout life. Because frequent blood transfusions can lead to a dangerous accumulation of iron in the body, patients must undergo iron chelation therapy with chelating drugs that bind the iron and remove it from the body. In the past this procedure was difficult and painful, and many thalassemia patients shortened their lives significantly by failing to comply with the therapy. Fortunately, the use of oral chelating drugs replaced older chelation therapies.

Complications of sickle-cell disease Sickle-cell disease and other hemoglobinopathies render people very susceptible to infections. In the United States, babies are tested for HbS as part of routine newborn screening, regardless of their ethnic background. Before screening became commonplace, many infants with sickle-cell disease died from infections. The use of preventative antibiotics and a full immunization regimen significantly reduced this infant mortality.

In addition to the symptoms and complications of anemia, most people with sickle-cell disease experience critical illnesses called crises. These

* **transplants** (TRANS-plantz) are organs or tissues from another body used to replace a poorly functioning organ or tissue.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

* **vaccines** (vak-SEENS) are preparations of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

- * **gene therapy** is a treatment that works by altering genes.
- * **remission** is an easing of a disease or its symptoms for a prolonged period.
- * **gallstones** (GAWL-stonz) are hard masses that form in the gallbladder or bile duct.
- * **kidney** is one of the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.
- * **pulmonary** refers to the lungs.
- * **hypertension** (HI-per-ten-chen) is abnormally high arterial blood pressure.
- * **heart attack** is a general term that usually refers to a sudden, intense episode of heart injury. It is usually caused by a blockage of a coronary artery, which stops blood from supplying the heart muscle with oxygen.
- * **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

CAN GENE THERAPY CURE HEMOGLOBINOPATHIES?

In the late 20th century and early 2000s, scientists hoped to eventually cure hemoglobinopathies by replacing the defective genes with normal ones. Because they were among the best understood genetic disorders, sickle-cell disease and thalassemia were early targets of gene therapy* experiments. In 1980 Martin Cline, the California scientist who created the first transgenic mouse, performed unauthorized gene therapy experiments on two individuals with hemoglobinopathy. In addition to censure by the scientific community and public alarm over the consequences of genetic experimentation, Cline's attempts demonstrated that these diseases were not amenable to simple gene therapy cures.

begin suddenly when clumping of sickled RBCs obstructs the normal flow of blood, depriving tissues and organs of oxygen. Specific types of sickle-cell crises are as follows:

- Hemolytic crisis from the breakdown of damaged RBCs
- Splenic sequestration crisis due to enlargement of the spleen from trapping RBCs
- Aplastic crisis from an infection that prevents the bone marrow from producing new RBCs

Sickle-cell crises can last for hours or days. Many people experience long periods of remission* during which they may feel relatively well. Others experience pain on a daily basis and may be hospitalized with crises several times per year.

Sickle-cell crises can damage almost any part of the body. People with sickle-cell disease are particularly susceptible to the following:

- Gallstones*
- Liver problems
- Kidney* failure
- Bone disease
- Pulmonary* hypertension*
- Heart attack*
- Stroke*

In the past most people with sickle-cell disease died from organ failure between the ages of 20 and 40; however, with better treatment and disease management, their life expectancy in the United States rose to over 50 years.

Complications of thalassemia Beta thalassemia major has a great many potential complications, including the following:

- Impaired growth
- Delayed puberty
- Liver problems
- Gallstones
- Osteoporosis*

Iron accumulation from transfusions and increased iron absorption from food damages glands* and organs, especially the heart. Heart failure* at a young age is the leading cause of death among people with thalassemia. Infections are also a major cause of death. However, with improved medical treatments, children with beta thalassemia major are living well into adulthood.

Can Hemoglobinopathies Be Prevented?

Prospective parents who may be carrying a hemoglobinopathy gene can choose to be tested and receive genetic counseling before having children. Prenatal* screening is also available for fetuses at high-risk for hemoglobinopathies.

Couples at risk for these genetic diseases can also use preimplantation genetic diagnosis as a method for reproducing without transmitting their genetic disorder. Designed in the early 1990s, this technology is an established reproductive option worldwide at centers specializing in it. The process involves *in vitro** fertilization and *in vitro* embryo culture*. The fertilized egg goes through cell division over the next several days and when a blastocyst (a clump of cells destined to develop into a fetus) has formed, a biopsy* is performed to test it for the genetic condition. Unaffected embryos (not more than two) are transferred to the mother's uterus.

HOW ARE HEMOGLOBINOPATHIES INHERITED?

If "A" represents a normal hemoglobin gene and "X" represents a gene causing a hemoglobinopathy, normal adults are designated AA, with two normal hemoglobin genes. Carriers can be designated AX, with one gene encoding a normal hemoglobin and one gene encoding an abnormal hemoglobin. Carriers may have no symptoms and may be unaware that they have some abnormal hemoglobin. Among the children of an AA adult and an AX adult, 50 percent will be AA and 50 percent will be AX. Among the offspring of two AX adults, 25 percent will be AA, 50 percent will be AX, and 25 percent will be XX and have a serious hemoglobinopathy. All of the children of an AA adult and an XX adult will be AX carriers. All of the children of two XX adults will be XX and have a hemoglobinopathy.

* **osteoporosis** (os-te-o-por-O-sis) is the loss of material from the bone. This makes the bones weak and brittle.

* **glands** are organs that produce substances such as hormones and chemicals that regulate body functions.

* **heart failure** is a medical term used to describe a condition in which a damaged heart cannot pump enough blood to meet the oxygen and nutrient demands of the body. People with heart failure may find it hard to exercise due to the insufficient blood flow, but many people live a long time with heart failure.

* **prenatal** (pre-NAY-tal) means existing or occurring before birth, with reference to the fetus.

* **in vitro** in the laboratory or other artificial environment rather than in the living body.

* **culture** (KUL-chur) is a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **rectum** is the final portion of the large intestine, connecting the colon to the outside opening of the anus.

Hemorrhoids

Hemorrhoids (HEM-o-roids), sometimes called piles, are enlarged veins in the rectum, which is the lower portion of the digestive tract. They are similar to varicose veins of the legs. Hemorrhoids may bleed and cause pain.

Where Do People Get Hemorrhoids?

Hemorrhoids occur in two places. When they are located in the upper part of the rectum*, the hemorrhoids are called internal hemorrhoids. In the lower part of the rectum, they are called external hemorrhoids.

Hemorrhoids are said to be prolapsed if they have slipped down from their usual position and extend outside of the anal* opening.

What Causes Hemorrhoids?

Hemorrhoids have a number of different causes. They occur often in women who are pregnant or who have just given birth. People with chronic constipation are at risk for hemorrhoids because of added pressure to the anorectal (pertaining to the anus and rectum) area when they pass stools (solid waste matter, feces) that are hard and dry.

What Are the Symptoms of Hemorrhoids?

Pain during bowel movements and blood in the stool are the usual symptoms that accompany hemorrhoids. Sometimes there is a discharge of mucus, and there may also be itching, burning, or pain in the area. The enlarged vein in the rectum sometimes develops a clot, which can be very painful. People with hemorrhoids sometimes develop iron deficiency anemia* from the bleeding that occurs.

How Are Hemorrhoids Diagnosed and Treated?

The doctor first examines the anal area through a viewing tube called an anoscope to rule out other conditions that cause similar symptoms. For mild cases of hemorrhoids, doctors may recommend the following:

- a diet with adequate amounts of fiber (whole grains, vegetables, and fruit) to prevent constipation
- drinking lots of liquids to prevent constipation
- sitz baths, which are shallow baths of warm water
- medicines that soften stools and make them easy to pass
- creams that can be applied to the hemorrhoids to reduce pain, swelling, and itching.

When the hemorrhoids are internal, they can be removed in the doctor's office by a simple procedure. Tiny rubber bands are wrapped tightly around the hemorrhoids. Following this procedure, the hemorrhoids wither away and drop off without causing pain.

Internal hemorrhoids that stay prolapsed (outside the body), or external hemorrhoids that have clotted, are often removed surgically. This method of removal is usually done on an outpatient* basis with local anesthesia*.

Hepatitis

Hepatitis (hep-a-TY-tis) is inflammation of the liver*, an abnormal condition that harms liver cells. Hepatitis may be acute* or chronic*, mild or extremely serious. It has many causes. These include infection with the hepatitis A, B, or C viruses, or other germs and exposure to toxic chemicals, including alcohol and certain medications.*

What Is Hepatitis?

The liver, a red-brown, wedge-shaped organ in the upper abdomen, is the largest internal organ in the body. It has many jobs. It gets rid of harmful substances in food, disposes of old blood cells, helps digest fat, produces chemicals to make the blood clot, and makes sure the blood carries the right balance of fat, sugar, and amino (a-ME-no) acids (the building blocks of proteins) to all the cells of the body.

Hepatitis is a general term that means the liver is inflamed. Many conditions can cause hepatitis. These include:

- Excessive drinking of alcohol
- Overdoses or side effects of medication
- Inhalation of toxic chemicals
- Problems with the immune system*
- Infection with a range of microbes, including viruses

Hepatitis frequently results from infection with a hepatitis virus*, usually the hepatitis A, B, or C virus. Each one can cause acute viral hepatitis, a condition that usually lasts four to six weeks. Typically, people who have acute viral hepatitis feel exhausted and have jaundice (JAWN-dis), which is a yellowish tint to their skin and the whites of their eyes. In rare cases, acute viral hepatitis can develop into a life-threatening illness called fulminant* hepatitis. Usually, however, it is milder, and the person recovers without needing special care. Often, viral hepatitis causes no symptoms at all.

Hepatitis B and C can do long-term damage as well. About 75 to 85 percent of people infected with hepatitis C and 5 to 10 percent of those infected with hepatitis B cannot fight off the virus; they become infected chronically, meaning the virus remains active in their body for more than six months. In most cases, the infection lasts for decades.

Because the liver is large and resilient, it usually keeps working well despite the virus. In fact, most people with chronic hepatitis live a normal life

span and do not even realize that they have the infection. After 10, 20, 30, or more years, however, some people with chronic infections eventually have serious liver damage, such as cirrhosis*, or scarring of the liver, that is frequently fatal. Some people with chronic hepatitis require a liver transplant*, and hepatitis C is the leading reason people get such transplants. People who have chronic hepatitis also have a much greater than normal risk of developing a kind of liver cancer*, called hepatocellular carcinoma (hep-a-to-SEL-yoo-lar kar-si-NO-ma). Liver cancer is a serious, often fatal disease.

According to the World Health Organization, the hepatitis C virus (called HCV) infects about 3 percent of the worldwide population, and health officials fear it will cause major public health problems in the 21st century. Scientists are still learning about hepatitis C, which was not even identified until 1988. Research has shown that alcohol consumption is especially dangerous to people who have hepatitis C, because it makes the virus spread even faster.

In addition to the hepatitis A, B, and C viruses, scientists have identified two less-common hepatitis viruses, called D and E. Hepatitis D is only found in people who already have hepatitis B. Hepatitis D makes their illness worse. Hepatitis E occurs only in the developing world. It resembles hepatitis A in that it usually causes only a short-term illness, but it can be more dangerous, especially to pregnant women. It typically spreads through water that has been contaminated by sewage, often after flooding. At one time, researchers believed they had found two other hepatitis-causing viruses: F and G. As of 2009, however, other scientists had been unable to show that F and G lead to the illness.

Hepatitis A: How Does It Spread?

Every now and then, local news reports announce an outbreak of hepatitis. Often, the report states that people who ate in a certain restaurant or attended a certain nursery school in recent weeks should see their doctor about preventing infection. The culprit in these outbreaks is hepatitis A. Sometimes called infectious hepatitis, this type is highly contagious*, but it almost never does permanent damage, which means that it does not become chronic and lead to cirrhosis. On very rare occasions, however, it does cause fulminant hepatitis and death. In the United States, hepatitis A outbreaks are most common in daycare centers, where it typically spreads by eating food, drinking water, or putting something else into the mouth that has been contaminated with feces* from someone who is infected. This method of infection, called the “fecal-oral route,” occurs if caregivers fail to wash their hands after changing a diaper and then prepare or serve food, or if a toddler forgets to wash after using the toilet and then handles another child’s cup or pacifier. Hepatitis A can also spread when water supplies are contaminated with sewage or when people eat raw or undercooked shellfish from contaminated waters.

Once people have recovered from hepatitis A, it is over. They are not “carriers” of the virus and cannot infect anyone else.

* **cirrhosis** (sir-O-sis) is a condition that affects the liver, involving long-term inflammation and scarring, which can lead to problems with liver function.

* **transplants** (TRANS-plantz) are organs or tissues from another body used to replace a poorly functioning organ or tissue.

* **cancer** is a condition characterized by abnormal overgrowth of certain cells, which may be fatal.

* **contagious** (kon-TAY-jus) means transmittable from one person to another, usually referring to an infection.

* **feces** (FEE-seez) is the excreted waste from the gastrointestinal tract.

* **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.

Hepatitis A: How Is It Prevented?

Good hygiene, including washing hands after using the toilet and before handling food, can prevent hepatitis A.

Vaccination* against hepatitis A is available. Medical professionals recommend it for children and adults traveling to developing countries where sanitation is poor; for children in communities with high rates of hepatitis A; and for children who live in states with above-average levels of the disease.

A preventative measure is also available for people who have already been exposed to the virus. An injection of immune globulin (GLOB-yoo-lin), a substance that helps the immune system, can often prevent infection. For the globulin to be effective, the individual must receive it within two weeks of exposure to the virus.

Hepatitis B and C: How Do They Spread?

People with chronic hepatitis B and C are “carriers,” meaning their blood can transmit the virus to others even if they have no symptoms of illness. The chief method of spreading hepatitis B and C is through contact with infected blood. In the United States, these viruses spread most commonly when drug users share the needles that they use to inject their drugs. More than 80 percent of people who inject street drugs, for instance, are believed to be infected with hepatitis C.

The spread of these viruses can also occur when a healthcare worker is accidentally pricked with a needle used on a patient who has hepatitis,

HEPATITIS AT A GLANCE

Hepatitis A

- Spread by fecal-oral route
- Has a vaccine
- Cannot become chronic
- Spreads through food or water
- Does not spread through the air

Hepatitis B

- Spread by blood
- Has a vaccine
- Can become chronic
- Does not spread through food or water
- Does not spread through the air

Hepatitis C

- Spread by blood
- Does not have a vaccine

- Can become chronic
- Does not spread through food or water
- Does not spread through the air

Hepatitis D

- Spread by blood
- Does not have a vaccine
- Can become chronic
- Does not spread through food or water
- Does not spread through the air

Hepatitis E

- Spread by fecal-oral route
- Does not have a vaccine
- Cannot become chronic
- Spreads through food or water
- Does not spread through the air

when a person uses improperly sterilized equipment to perform a body piercing, tattooing, or circumcision*; and when two people share razors, toothbrushes, or other objects that may have small amounts of blood on them. An organ transplant can also be a source of hepatitis infection.

The transfusion* of infected blood was once the most common source of infection. People with hemophilia (he-mo-FIL-e-a), a blood-clotting problem, were at particular risk because they received frequent transfusions. After 1992, however, blood banks in the United States screened donated blood for hepatitis B and C viruses, and the risk of infection from a transfusion dropped sharply. Anyone who received a transfusion before July 1992, however, should see a medical professional to be tested for hepatitis.

Compared to hepatitis C, hepatitis B is more contagious and spreads much more readily through sexual contact. Individuals who have sex with many partners are at increased risk. Hepatitis C seldom spreads through sexual contact. Hepatitis B, and more rarely hepatitis C, can also spread from infected mothers to newborns. Occasionally, medical professionals can find no obvious source of infection with hepatitis C. They do know that a person cannot catch it by working, going to school, or swimming with infected people, or simply by being near or even hugging infected individuals.

How Is Hepatitis B Prevented?

A vaccine can prevent hepatitis B. After 1991, U.S. health officials recommended it for all newborns. Doctors also advise it for all children aged 11 or 12 if they did not get the shots as babies. In addition, medical professionals recommend the vaccine for everyone at high risk, including health-care workers, people who have had sex with multiple partners, and anyone who lives with, has sex with, or takes care of a person who has hepatitis B.

Once a person has been exposed to hepatitis B, speedy treatment with hepatitis B immune globulin (HBIG), coupled with vaccination, sometimes can prevent infection in adults. When mothers have hepatitis B, immediate treatment of their newborns can prevent the babies from developing chronic hepatitis.

People who have not been vaccinated can also prevent hepatitis B by refusing to have unprotected sex, by using condoms, and by staying away from illegal intravenous drugs. In addition, people should avoid contact with blood. They should not share razors, toothbrushes, or any items that might be contaminated with even the slightest amount of blood. Infected people should cover any wounds they may have and should dispose of or wash anything that may contain any of their blood.

Hepatitis C: How Is It Prevented?

As of 2009, no vaccine existed for hepatitis C, and no reliable treatment was available after a person is exposed. Prevention is like that for hepatitis B: refusing to share needles, avoiding contact with blood, limiting sexual contact, and using condoms.

The United States and the World

In the United States, an estimated 4 million people have chronic hepatitis C, and 8,000 to 10,000 people per year die from related liver disease. About 1 million to 1.5 million people have chronic hepatitis B, which results in about 5,000 deaths each year.

Worldwide, hepatitis B is more common, and at least 350 million people have the chronic infections. This disease is especially common in most of Asia, sub-Saharan Africa, and the Pacific, where 8 to 10 percent of all people are chronically infected. Many of these individuals also develop hepatocellular carcinoma, the liver cancer linked to chronic hepatitis. Worldwide, an estimated 180 million people have chronic hepatitis C.

In the United States, hepatitis B is most common in young adults, especially among intravenous drug users, health-care workers, prison inmates, and people who have sex with many partners. In developing countries, hepatitis B is most common in infants and young children, who get it from their mothers or within the family. When hepatitis B infects a child, the disease is much more likely to become chronic.

* **circumcision** is a surgical procedure in which the fold of skin covering the end of the penis is removed.

* **transfusion** (trans-FYOO-zhun) is a procedure in which blood or certain parts of blood, such as specific cells, is given to a person who needs it due to illness or blood loss.

- * **incubation** (ing-kyoo-BAY-shun) is the period of time between infection by a germ and when symptoms first appear. Depending on the germ, this period can be from hours to months.
- * **spleen** is an organ in the upper left part of the abdomen that stores and filters blood. As part of the immune system, the spleen also plays a role in fighting infection.
- * **esophagus** (eh-SAH-fuh-gus) is the soft tube that, with swallowing, carries food from the throat to the stomach.
- * **toxins** are substances that cause harm to the body.
- * **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

What Are the Symptoms of Hepatitis?

Depending on the virus, the time from infection to the appearance of symptoms can be two weeks to six months. The incubation* period is 15 to 45 days for hepatitis A, 15 to 150 days for hepatitis C, and 50 to 180 days for hepatitis B.

The symptoms for acute hepatitis include loss of appetite, nausea, vomiting, fatigue, fever, jaundice, darkening of the urine, abdominal pain, arthritis (ar-THRY-tis; joint pain), and skin rash. Bowel movements may look pale in color, and urine may become dark, so that it looks like tea. Often, however, symptoms are absent or so mild they go unnoticed.

Chronic hepatitis can cause loss of appetite, tiredness, low-grade fever, and a general sense of “not feeling well” that doctors call malaise (ma-LAZE). Like people with acute hepatitis, those with chronic hepatitis often experience no symptoms.

If the illness causes liver damage, additional symptoms can include weakness, weight loss, itching of the skin, enlargement of the spleen*, fluid in the abdomen, and a pattern of red blood vessels showing through the skin. In severe cases, massive bleeding can occur in the stomach and the esophagus*, and this condition requires emergency treatment. If the liver is no longer able to remove toxins* from food, the brain can feel the impact, causing the person to become drowsy or confused, and perhaps lapse into a coma*.

How Is Hepatitis Diagnosed?

In many cases, the first hint of hepatitis comes when a routine blood test shows signs of abnormalities in the liver. In other cases, individuals may try to donate blood and be rejected after their blood is tested.

Some individuals go to the doctor because they have one or more symptoms. Doctors will typically ask about medical history and whether these patients have had any exposure to infectious agents, alcohol and other toxins, or drugs. They will also do a physical examination, which may include taking the patient’s temperature, feeling for swollen glands, and checking for an enlarged spleen or liver.

To diagnose viral hepatitis, doctors may also perform several kinds of blood tests. Liver enzyme tests indicate whether the liver is inflamed. If it is, other blood tests can detect specific evidence of hepatitis B or C, and can help the doctor distinguish between acute and chronic cases.

How Is Hepatitis Treated?

Treatment for hepatitis depends on its cause and how sick the patient is.

Hepatitis A and E People with hepatitis A and E usually recover completely without needing hospitalization. They can take care of themselves at home by making sure they get enough rest and drink plenty of fluids. Doctors advise avoiding alcohol and drugs, because these substances can stress an already inflamed liver.

Hepatitis B and C Most of the time, doctors can monitor patients who have hepatitis B and C through blood tests that both evaluate liver inflammation and measure liver function. In severe cases especially when the liver is damaged and stops working well, a patient may need hospitalization. A doctor will typically only treat a person who has hepatitis B if the patient has active liver disease. The Food and Drug Administration (FDA) approved six drugs for use against hepatitis B. A commonly prescribed medication is alpha interferon, a naturally occurring substance that interferes with the viruses' ability to reproduce. The latest of the six drugs was telbivudine, which received FDA approval in 2006. Telbivudine not only curbs the virus but also fights liver inflammation.

As with hepatitis B, a doctor will decide if a particular patient who has hepatitis C is a good candidate for treatment. Treatment is usually a combination of an interferon drug called pegylated interferon alpha with another drug, ribavirin.

In addition, doctors often recommended that people who have chronic infectious hepatitis live a healthy lifestyle by avoiding alcohol, getting enough sleep, exercising regularly, and eating a nutritious diet. These measures reduce stress on the liver and can prevent or slow the progression of long-term liver disease.

Doctors typically closely monitor people who have chronic hepatitis and may want to see them at least once or twice per year. Doctors will do liver enzyme tests to see how well the liver is functioning and may order blood tests, sonograms*, or even liver biopsies* to check for cancer.

In cases of liver cancer or cirrhosis, sometimes the only treatment is a liver transplant, in which a person's damaged liver is replaced with a healthy organ taken from a newly deceased person. If the person can get a new liver in time, which is not always possible, such transplants usually are successful, although the virus eventually may damage the new liver as well.

Living with Chronic Hepatitis

Most people with chronic hepatitis do fine. They can go to school, engage in sports, work, have children, and live fully like anyone else. They need to make sure, however, that they do not put any extra stress on their liver. In the view of most experts, that means that they should never drink alcoholic beverages. They should not take any medicines, even common over-the-counter or herbal remedies, unless their doctors specifically approve them. They should not use illegal drugs. In many cases, they should be vaccinated against hepatitis A and against hepatitis B.

As with other chronic illnesses, people with hepatitis often struggle with feelings of grief, worry, and isolation. Some feel a stigma because their illness often is associated with drug abuse, even though it can result from many other causes. Because most people know little about hepatitis, friends and even family may have unrealistic fears about catching it and may avoid the infected person. Counseling for the entire family can sometimes help.

Hepatitis A Vaccine

The vaccine for hepatitis A is thought to provide protection for 15 to 20 years, possibly for life. Individuals receive a series of shots within a six-month period. Among those who may be candidates for the vaccine are the following:

- Military personnel
- Employees of daycare centers
- Institutional care workers
- Laboratory workers who handle live hepatitis A virus
- Handlers of primates who may harbor the hepatitis A virus
- Travelers to areas known to have hepatitis
- People living in, or relocating to, areas that have a high rate of infection or are experiencing a hepatitis A outbreak
- People who engage in high-risk sexual activity
- Users of injectable street drugs

* **sonograms** (SON-o-gramz) are images or records made on a computer using sound waves passing through the body.

* **biopsies** (BI-op-seez) are tests in which small samples of skin or other body tissue are removed and examined for signs of disease.

Hepatitis without a Virus

Not all hepatitis is caused by a virus. It can also be caused by toxic chemicals such as carbon tetrachloride, a solvent used in some dry-cleaning fluids, or by some medications. Many common medications, such as phenytoin for epilepsy and isoniazid (i-so-NY-a-zid) for tuberculosis (too-ber-ku-LO-sis), cause hepatitis in a small fraction of the people who take them. Once the person stops taking the drug, the liver recovers. Life-threatening hepatitis can result, however, if a person accidentally or intentionally takes an overdose of many medicines, including the common over-the-counter pain reliever acetaminophen (a-set-a-MEE-no-fen).

Finally, some people experience a chronic condition called autoimmune hepatitis. In such people, it appears, the body's immune system attacks its own liver cells. Although treatment with corticosteroids can improve the condition, it is often fatal unless a liver transplant is performed.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

The illness and sometimes the treatment can also cause fatigue and depression*. Infected people may need to get help from family and friends, seek treatment for depression, or modify their schedules to reduce stress. Many groups offer advice, support, and solidarity for people with chronic hepatitis.

Hernia, Gastrointestinal

A hernia is the protrusion of tissue or part of an organ through an opening in the tissue that normally encloses and contains it.

What Does Hernia Mean?

The word “hernia,” in Latin, means “rupture.” A hernia refers to an opening, or separation, in the muscle, tissue, or membrane that normally holds an organ or other tissues in place. This opening allows the normally contained tissues or parts of an organ to poke through the hole. Hernias can occur in many areas of the body, including the brain, but they

usually arise in the area of the body that is involved in digestion. These hernias are collectively known as gastrointestinal hernias, and they may result from muscular weakness, heavy lifting, straining, illness, obesity*, or pregnancy.

Gastrointestinal hernias come in several types:

- Inguinal (ING-gwi-nal) and femoral hernias that occur in the groin
- Hiatal (hi-AY-tal) hernia in the chest
- Umbilical hernia, which is in the naval
- Ventral, or incisional, hernia, which happens at the site of a scar from a previous surgical incision

Inguinal and femoral hernias The wall of the abdomen is made of thick muscle, but it has normally occurring holes in certain places, such as the groin, that provide places for structures, such as blood vessels, to pass. Hernias usually develop when the intestines push out against these built-in weaknesses. Inguinal and femoral hernias are similar, but femoral hernias occur lower in the groin near the upper thigh.

Hernias may develop at different locations in the body, although an individual is unlikely to develop all four kinds of hernia shown here. A hiatal hernia occurs when the stomach pokes above the diaphragm into the chest. An umbilical hernia occurs at the belly button (umbilicus) and is most commonly seen in infants. An inguinal hernia occurs in the groin, where the thigh meets the torso, and happens more often to men than to women. A femoral hernia occurs between the abdomen and the legs, and happens more often to women than to men. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

* **diaphragm** (DY-a-fram) is the muscle that separates the chest and abdominal cavities. It is the chief muscle used in breathing.

* **gangrene** (GANG-green) is the decay or death of living tissue caused by a lack of oxygen supply to the tissue and/or bacterial infection of the tissue.

Inguinal hernias are the most common type of gastrointestinal hernias. They frequently appear as large lumps that bulge just under the skin. Some people with inguinal hernias do not feel any pain from their hernias, but others experience severe pain especially when they cough, bend forward, or lift a heavy object. The only way to fix this type of hernia is to repair it surgically, using stitches or mesh to close the hole. Without surgery, an inguinal hernia usually keeps getting bigger.

Hiatal hernias Another common type of hernia is a hiatal hernia. The esophagus, or food pipe, passes to the stomach through a gap in the diaphragm* called the hiatus (hi-AY-tus). A hiatal hernia occurs when the stomach pokes above the diaphragm into the chest. This type of hernia results in no visible bulge, but people have other symptoms, such as heartburn. Hiatal hernias do not necessarily require surgery. Often, lifestyle changes such as losing weight, avoiding smoking, stopping alcohol consumption, and staying away from hot, spicy foods can make the symptoms go away.

Umbilical hernias Umbilical hernias are common in children. About 10 percent of babies have one, although they are more frequent among babies of certain ethnic groups. This type of hernia usually heals by itself.

Ventral hernias Ventral hernias happen when the intestine pokes through old scar tissue that has been stretched out, which may occur in people who are obese or in pregnant women.

Do Children Get Hernias?

Karen loved taking care of her baby brother. One day when she was changing his diaper, she noticed he had a plum-sized bump along the inside of his thigh where it met his torso (his groin). When he cried, it got bigger, like a small balloon being blown up. It looked pretty strange, but he did not seem to be in any pain. Karen's parents took him to the doctor, who said the baby had an inguinal hernia.

The doctor explained that up to 5 percent of healthy, full-term babies are born with inguinal hernias, and 80 to 90 percent of children with this type of hernia are boys. These hernias occur because certain openings do not close after birth the way they should, allowing the intestine to bulge out. The doctor scheduled an operation to surgically repair the baby's hernia and assured Karen's parents that the surgery was a safe and common procedure.

Are Hernias Dangerous?

In some cases, hernias can be dangerous if the protruding piece of intestine gets incarcerated (trapped) and strangulated (twisted). This condition can interfere with the flow of food and fluid through the intestine and sometimes stops the blood supply to that part of the intestine. When this happens, an individual will be in great pain and should immediately report to a hospital for emergency surgery. The trapped bit of intestine can develop infection and/or gangrene*, which if left untreated can be fatal.

Herpes Simplex Virus Infections

Herpes simplex viruses can cause several illnesses, the two most common being oral herpes, which cause lesions on the face, usually at the lip line, and the closely related genital herpes, which cause lesions in the genital region.*

What Are Herpes Simplex Virus Infections?

There are two types of herpes simplex virus (HSV): herpes simplex virus 1 (HSV-1) and herpes simplex virus 2 (HSV-2). They are members of the herpesvirus family. Genital herpes is a sexually transmitted disease* (STD). When an HSV infection causes blisters or sores, it is referred to as a herpes outbreak.

Oral herpes causes small, clear blisters on the skin. These are often called cold sores, fever blisters, or sun blisters. Small blisters may combine to form a larger sore. Although they usually occur on the face, especially around the mouth and nose, they can occur anywhere on the skin or mucous membranes*, either singly or in groups. Small HSV sores known as herpetic whitlow can appear on the fingers, especially in children who bite their nails or suck their fingers, thereby spreading the virus from their mouth to their hands. HSV skin infections can occur in other locations where the virus comes in contact with broken skin. The blisters may be painful, and they can break, bleed, and crust over, leaving red spots of healing skin.

Although HSV-1 often causes genital herpes, it is more often the case that HSV-2 is responsible for the sores on the penis in males and on the vulva*, vagina*, and cervix* in females. In genital herpes, both sexes can

Herpes simplex virus type 1 causes small, clear blisters to appear around the mouth and nose. Also called cold sores, fever blisters, or sun blisters, they typically unite to form a larger sore. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

* **lesions** (LEE-zhuns) is a general term referring to a sore or a damaged or irregular area of tissue.

* **sexually transmitted disease** is an infection, such as the human immunodeficiency virus (HIV) or herpes, that can be passed from person to person by sexual contact.

* **mucous membranes** are the thin layers of tissue found inside the nose, ears, cervix (SER-viks) and uterus, stomach, colon and rectum, on the vocal cords, and in other parts of the body.

* **vulva** (VUL-vuh) refers to the organs of the female genitals that are located on the outside of the body.

* **vagina** (vah-JY-nah) is the canal, or passageway, in a woman that leads from the uterus to the outside of the body.

* **cervix** (SIR-viks) is the lower, narrow end of the uterus that opens into the vagina.

- * **anus** (A-nus) is the opening at the end of the digestive system, through which waste leaves the body.
- * **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).
- * **menstruation** (men-stroo-AY-shun) is the discharge of the blood-enriched lining of the uterus. Menstruation normally occurs in females who are physically mature enough to bear children. Most girls have their first period between the age of 9 and 16. Menstruation ceases during pregnancy and with the onset of menopause. Because it usually occurs at about four-week intervals, it is often called the monthly period.
- * **contagious** (kon-TAY-jus) means transmittable from one person to another, usually referring to an infection.

develop herpes blisters around the anus* and on the buttocks. HSV-2 occasionally produces sores on other parts of the body, such as the mouth or throat. Having genital herpes increases the risk of contracting HIV* from unprotected sex with an HIV-positive individual. Infection with both genital herpes and HIV can also increase the likelihood that HIV will be transmitted to a sexual partner.

Primary HSV infection occurs when the virus first enters the body. After the initial infection, the virus particles migrate to sensory nerve cells, where they remain in an inactive or dormant state until they are reactivated (during a herpes outbreak). These outbreaks often occur at or near the same area as the primary infection. For example, repeated outbreaks of HSV-1 may cause cold sores in the same spot, along the outer border of the lips, but cold sores also can appear anywhere on the face in the vicinity of the mouth. Sometimes outbreaks, also called recurrent infections, occur for no apparent reason. Emotional and/or physical stresses that can trigger herpes outbreaks. The following are other times when outbreaks can occur:

- During menstruation*
- As a result of exposure to the sun (for oral herpes)
- From poor diet
- From exhaustion
- As a result of fever
- From illness
- As a result of steroidal medication

How Common Are Herpes Simplex Virus Infections?

Some 50 to 80 percent of Americans are infected with HSV-1 by age 30. In addition, at least 45 million Americans—about one in five adolescents and adults—are infected with HSV-2. About twice as many women as men have genital herpes—about one in four women compared with about one in eight men. This rate difference may be because, in cases of sexually transmitted herpes simplex illness, male-to-female transmission of HSV is more likely than female-to-male transmission. Over the decade ending in 2008, the percentage of Americans with HSV-2 infections decreased.

Is HSV Contagious?

HSV-1 and HSV-2 are both contagious* infections, which are spread very often through direct contact with infected skin or saliva. Children often contract HSV-1 through contact with an infected family member. Kissing or sharing dishes or eating utensils can spread HSV-1 infection.

High-school and college wrestlers sometimes develop a condition called herpes gladiatorum, caused by HSV-1, in which herpes blisters develop on the shoulders and back from contact with other wrestlers

and with virus-contaminated mats. Rugby players also transmit HSV-1 through physical contact, developing blisters that have been nicknamed “scrum pox.”

HSV-2 is most often spread via unprotected vaginal, oral, or anal sex. HSV-2 cannot be contracted from toilet seats or hot tubs. HSV-1 infection of the genitals can be transmitted through oral-genital or genital-genital contact with an infected person.

When a person has herpes simplex illness, active disease or a herpes outbreak is not necessary for the transmission of the herpes virus (either HSV-1 or HSV-2). Research suggests that at least 60 percent of new HSV infections are acquired from individuals with no noticeable blisters or sores. However, genital herpes is most easily spread through genital-genital or oral-genital contact during an active outbreak or in the few days preceding an outbreak.

How Do People Know They Have HSV Infection?

With HSV infection (either HSV-1 or HSV-2), most individuals have few or no symptoms of infection and often do not realize that they are infected. They may not become aware of symptoms for years after the primary infection.

HSV-infected individuals often experience itching, tingling, or pain in the area where recurrent lesions develop one or two days prior to the outbreak. These warning symptoms—called a prodrome—signal an early phase in the reactivation of the virus.

Symptoms of active HSV-1 or oral herpes infection include blisters or sores on the lips, face, neck, or shoulders. The blisters are often painful and may be accompanied by fever or other flu-like symptoms.

Symptoms of active HSV-2 or genital herpes infection can include the following:

- Blisters or sores on the genitals or rectum, which are often painful
- Fever or flu-like symptoms
- Swollen glands (lymph nodes*)
- Muscle aches
- A reddish rash
- A burning sensation during urination
- Discharge from the vagina or penis

The length and severity of HSV outbreaks vary greatly. The blisters of a primary infection break, leaving tender sores that may take two to four weeks to heal. Subsequent outbreaks are usually shorter. On average, people with genital herpes experience four to five outbreaks of genital herpes illness each year. Oral herpes outbreaks occur less frequently. Although both HSV-1 and HSV-2 remain in the body indefinitely, over time the frequency and severity of outbreaks of both types usually decrease.

Don't Confuse Canker Sores with Cold Sores

Canker sores are small, red sores inside the mouth. They later turn white. Unlike cold sores, canker sores are not caused by HSV, although they may be caused by stress. Canker sores and cold sores are both painful, but canker sores appear only inside the mouth, not on the face, lips, or neck as cold sores do.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

- * **cultured** (KUL-churd) means subjected to a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.
- * **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.
- * **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.
- * **intravenously** (in-tra-VEE-nus-lee) means given or injected directly through a vein.
- * **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).
- * **immunosuppressants** (im-yoo-no-su-PRES-ants) are substances that weaken the body's immune system.
- * **transplants** (TRANS-plantz) are organs or tissues from another body used to replace a poorly functioning organ or tissue.

How Is HSV Infection Diagnosed and Treated?

Diagnosis Doctors can often diagnose outbreaks of HSV-1 or HSV-2 based on the appearance and location of the sores. Sometimes, however, sores in the genital region can resemble signs of other STDs.

To diagnose HSV infection conclusively, a blister is scraped—preferably on the first day of an outbreak—and cultured* to see if HSV grows. For a quick diagnosis, a preparation from a blister can be examined under a microscope for signs of the virus. In the absence of active blisters, a blood sample can be tested for antibodies* against HSV or for HSV DNA*.

Treatment There is no cure for either HSV-1 or HSV-2. Some over-the-counter ointments or creams may help reduce the pain of cold sores, but they do not necessarily speed healing or prevent the sores from returning. Applying ice to the affected area, drinking cold liquids, or over-the-counter pain medications such as acetaminophen* can ease the discomfort of painful outbreaks. People with cold sores may want to avoid acidic foods—such as tomatoes, lemons, and oranges—that can irritate open sores on the lips or in the mouth. Antiviral medications are occasionally used to treat recurrent cold sores caused by HSV-1.

Antiviral medications such as acyclovir can significantly reduce the frequency, severity, duration, and pain of genital herpes outbreaks. Antiviral drugs can also reduce—but not eliminate—the risk of HSV transmission to sexual partners. Under some circumstances antiviral medications are administered intravenously*:

- Infections of the skin, nose, and mouth in people with a weakened immune system*
- Infections in newborn infants
- Rare—but severe or life-threatening—herpes infections in other parts of the body

Complications Although HSV infections usually are not dangerous, outbreaks of either oral or genital herpes can cause pain, embarrassment, and emotional stress. However, in people with weakened immune systems—such as those with cancer or AIDS* or who are on immunosuppressants* because of organ transplants*—HSV infection can cause serious illness or death:

- HSV can infect the skin surrounding the eye. From there, the virus can invade the cornea* of the eye, causing a condition known as herpes keratitis. If untreated, this condition can lead to scarring of the eye and blindness.
- The virus can spread throughout the body, causing life-threatening infection in the lungs, liver*, and other organs.
- HSV can infect the brain, causing encephalitis*.

A woman who has a primary HSV infection during pregnancy lacks antibodies against the virus and so can transmit HSV to her fetus*, possibly resulting in preterm birth and other complications, especially if the

infection occurs late in pregnancy. Infants born to women with active genital herpes are at risk for HSV infection, which they contract as they pass through the birth canal during delivery. In addition to facial and/or genital herpes, the newborn may have widespread HSV infection involving the eyes, lungs, liver, or brain. Although immediate treatment with antiviral medications may prevent or reduce the damage, severe neonatal* herpes is fatal in at least 50 percent of cases and as many as two-thirds of surviving infants have lifelong disabilities, including brain damage and mental retardation*.

Can HSV Infection Be Prevented?

It is difficult to prevent HSV-1 infection because the virus is so widespread in the human population and can be transmitted even when no visible sores are present. To reduce the risk of contracting oral herpes, people should not kiss anyone with active cold sores. Food, utensils, dishes, drinking glasses, lipstick, razors, and towels should not be shared with anyone, especially with someone who has ever had cold sores.

Using sunscreen, especially on areas prone to blisters, may reduce the likelihood of an oral herpes outbreak. People with active cold sores around the mouth should always wash their hands before touching their genitals or buttocks to reduce the risk of spreading HSV-1 to these areas.

The only way to absolutely ensure against genital herpes infection is to practice sexual abstinence. Because genital herpes is contagious even in the absence of active sores and since people often do not know that they are infected, a latex* condom should always be used during sexual activity. However, condoms do not protect all parts of the genital region. People with genital herpes should refrain from sex during active outbreaks.

Pregnant women with genital herpes may be treated with antiviral drugs to prevent an outbreak prior to delivery. A woman with active genital herpes should deliver by cesarean section* to reduce the risk of transmitting HSV to her infant.

Hiccups occur when the diaphragm and lungs suddenly contract during breathing. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

Hiccups

Hiccups occur when the diaphragm suddenly contracts during breathing. The vocal cords quickly close, and an odd sound comes from the throat. Hiccups are involuntary. Their cause is not known, and hiccups do not seem to serve any useful purpose.*

Are Hiccups Dangerous?

Most hiccups are not harmful. The frequency of most hiccups is usually from 4 to 60 hiccups a minute. Hiccups usually occur in people (even babies and fetuses) for a minute or two and then pass. There are, however, cases of prolonged hiccupping that can be dangerous, especially for people who are ill from other causes and who may become exhausted if they do not seek medical treatment.

What Are the Different Types of Hiccups?

Hiccups are classified into several categories. A hiccup bout can last from several seconds to several days. A persistent hiccup is one that lasts for several days or weeks. Hiccups lasting more than a month are called intractable. In rare cases, intractable hiccups may continue for years.

What Is the Treatment for Hiccups?

Everyone seems to have a favorite cure for hiccups, but usually the hiccups just go away by themselves. In severe cases of hiccups, doctors may try to block the hiccup process (also called the hiccup arc or pathway) by stimulating parts of the respiratory (breathing) system or by prescribing medications to relax the muscles involved. When all else fails, surgery is done to block the nerve signals from the phrenic (FREN-ik) nerve to the diaphragm. The purpose of this procedure is to paralyze part of the diaphragm.

High Blood Pressure *See Hypertension.*

Hirsutism

Most of the time women do not have noticeable hair on certain parts of their body and face where it is commonly found on men, such as the abdomen, mid-chest, chin, upper lip, inner thighs, and lower back. Such noticeable hair growth is also not normally found on women's*

What Are Various Home Cures for Hiccups?

Everyone seems to have a special way to stop hiccups even though none of these remedies has been proved to work consistently. Here are some of the most common home cures:

- Holding one's breath and then exhaling very slowly
- Holding the nose
- Breathing into a paper bag
- Sucking on ice cubes
- Sucking on hard candy
- Drinking water from the far side of a glass
- Gargling
- Pulling on the tongue
- Biting on a lemon
- Swallowing granulated sugar
- Swallowing hard crusts of bread
- Sneezing
- Peeling onions
- Bending over so that the head is lower than the chest
- Surprising or frightening the person with hiccups
- Slapping the person with hiccups on the back

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

- * **menopause** (MEN-o-pawz) is the end of menstruation.
- * **anxiety** (ang-ZY-e-tee) can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person's physical or mental well-being.
- * **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.
- * **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.
- * **ovaries** (O-vuh-reez) are the sexual glands from which ova, or eggs, are released in women.
- * **insulin** is a kind of hormone, or chemical produced in the body, that is crucial in controlling the level of glucose (sugar) in the blood and in helping the body use glucose to produce energy. When the body cannot produce or use insulin properly, a person must take insulin or other medications.
- * **cortisol** (KOR-ti-sol) is a hormone that helps control blood pressure and metabolism, the process of converting food into energy and waste products. It plays a part in the stress response.

breasts. However, when coarse, thick, dark hair appears in women in such typically masculine (male-pattern) places, the medical profession calls the problem hirsutism, or hypertrichosis. This condition signifies a hormonal imbalance that could be caused by a serious disease. It can be a serious cosmetic and psychological issue for women. Women suffering from this condition should be examined for presence of more serious medical problems.

How Many Women Develop Hirsutism?

Hirsutism occurs in about one out of ten women, but ethnicity can alter that percentage. Women of Mediterranean, South Asian, and Middle Eastern descent are more likely to get this condition. Also, as hormonal levels change after menopause*, about one out of four women have unwanted facial hair. Excessive male-pattern hair growth can become a psychological problem for women, who may feel less feminine and experience bouts of severe stress and anxiety* (or even depression*).

What Causes Hirsutism?

Generally, hirsutism is an inherited trait for women. It is usually caused by increased production of male hormones* (such as testosterone, which induces and maintains male secondary sex characteristics) or by abnormal sensitivity of hair follicles to male hormones. Although women produce primarily female hormones (such as estrogen, which promotes female secondary sex characteristics and the female reproductive system), they do produce small amounts of androgens (male hormones). However, when normal amounts increase drastically, hirsutism can occur.

A common cause of hirsutism is polycystic ovarian syndrome (PCOS), which is a condition that occurs when hormone levels become so erratic, especially during teenage and childbearing years, that cysts form in the ovaries*.

Another cause of hirsutism is high levels of insulin*, or what is called insulin resistance. This condition is observed in women who are exceptionally overweight because obesity forces higher levels of insulin to be produced, which then creates greater production of male hormones.

Other possible medical conditions that may increase the risk of hirsutism are Cushing's disease (excessive production of cortisol*); congenital adrenal hyperplasia (abnormal production of steroid hormones by the adrenal glands); hyperthecosis (abnormal thickening of the inner ovary layer); and cancerous ovarian or adrenal gland tumors.

Medicines (such as anabolic steroids, cyclosporine, danazol, and phenytoin) and testosterone can bring on the condition. Hirsutism can also result from age and pregnancy. In many cases, women first note more hair growth in their late teenage years, which gradually becomes more noticeable with time.

In rare cases, the condition occurs because of a serious problem. If hirsutism occurs along with the presence of acne, balding of the head, deepening of the voice, decreasing of breast size, enlarging of the clitoris, increasing muscle mass, or irregularity of menstrual periods, then a more serious disorder is possible. For instance, the more irregular the menstrual period, the more likely a woman is to develop hirsutism. If such symptoms occur, women ought to consult with their doctor.

How Is Hirsutism Diagnosed?

A common way to diagnose hirsutism is with the use of the Ferriman-Gallwey score, which provides a measurement of the amount of female hair growth at nine locations on the body (chin, upper lip, chest, upper back, lower back, upper abdomen, lower abdomen, upper arms, and thighs).

Diagnostic tests for the following substances are also used to identify hirsutism:

- Dihydroepiandrosterone sulfate (DHEA-S)
- Luteinizing hormone (LH), or lutropin
- Follicle-stimulating hormone (FSH)
- Androstenedione
- Prolactin (PRL) or luteotropic hormone (LTH)
- Free androgen index (FAI)
- Sex hormone-binding globulin (SHBG)
- Free (with total) testosterone
- 17-hydroxyprogesterone (17-OH progesterone, or 17OHP)

Additional tests may be recommended if a menstrual problem is present. If the doctor thinks a serious medical condition is at the root of hirsutism, then other tests may also be recommended, such as an ultrasound* (to detect tumors or cysts in the ovaries or adrenal glands) and a computerized tomography* (CT) scan (to analyze the adrenal

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

BEARDED LADIES AT THE CIRCUS

Circuses in the 19th century and well into the 20th century often featured a bearded lady (or bearded woman) advertised as one of the “freaks” of the big top. Even in the 21st century, Jennifer Miller (b. 1961) was featured as a bearded lady, juggler, and fire-eater in several circuses and at the Coney Island Sideshow. She was also a professor at Pratt Institute in Brooklyn, New York, and the founder of the New York City performance group Circus Amok. No longer advertised as a curiosity of the circus, these bearded ladies only have a hormonal imbalance: the condition known as hirsutism.

* **stimuli** (STIM-yoo-lie) are things in the environment that excite a person to function, become active, or respond. The singular form is stimulus.

glands). Tests to analyze levels of thyroid function, glucose, cortisol, or lipids (cholesterol and triglyceride) may also be used.

How Is Hirsutism Treated?

There is not a medical cure for hirsutism. Therefore, women oftentimes use temporary hair removal methods such as bleaching, depilatories (creams), electric hair removal, electrolysis and thermolysis, hair-retardant medicines, shaving, and waxing and plucking to eliminate excessive hair.

Permanent hair removal methods include anti-androgen drugs, birth control pills, and laser hair removal. Anti-androgen drugs, for instance, usually take at least three to six months to work. However, they should not be taken by women in their child-bearing years because they can harm unborn male fetuses.

In all cases, it is best to seek medical advice and counseling first from a doctor or medical specialist. They can conduct examinations and tests designed to detect the underlying cause of hirsutism.

HIV See *AIDS and HIV Infection*.

Hives

Hives are itchy wheals (welts) that erupt on the skin and are usually caused by an allergic reaction.

What Are Hives?

Hives, also known as urticaria (ur-ti-KARE-e-a), develop as a reaction to various stimuli*. Certain foods, food additives or dyes, drugs, alcohol, or viral infections can cause hives in susceptible people. Foods that commonly cause hives include milk, eggs, shellfish, strawberries, other fruits, and nuts.

Penicillin and aspirin cause hives in some people. Some viral infections that are known to cause hives are hepatitis (inflammation of the liver), infectious mononucleosis, and rubella (German measles).

Some people develop hives after vigorous exercise that causes them to sweat. Sometimes the sun or cold air can cause hives to appear on people's skin. In some people, diving into cold water can result in severe hives, a condition known as cold urticaria.

Symptoms

The first symptom of hives is itching, after which the wheals appear. Wheals usually are small, white welts with red, inflamed areas surrounding them; in some cases, however, they can be quite large. They usually erupt on the arms, legs, and trunk. Sometimes they develop into a ring, with the center clearing before the outer ring improves. Hives tend to come and go on different areas of the skin, and individual welts can last several hours.

What Is Angioedema?

Angioedema (an-jee-o-e-DEE-ma) also results in swelling, but it is not related to hives. In angioedema, swelling occurs in the deeper portion of the skin known as the dermis. It can occur in the hands, feet, eyelids, lips, genital area, and airway passages. Angioedema sometimes occurs at the same time as hives if the person is experiencing an allergic reaction. Angioedema can be serious, and when it affects the throat, it can be fatal if it is not treated promptly. In some cases, angioedema is a hereditary disorder, and a family history usually is present. In these cases, it is a chronic condition, which means that it recurs from time to time.

Treatment for Hives

Most cases of hives clear up by themselves in one to seven days. Some cases respond to medications such as antihistamines* or corticosteroids*. Antihistamines are used to combat the allergic reaction, and corticosteroids are used to fight the inflammation.

Can Hives Be Prevented?

The only way to prevent hives is to avoid a known trigger (the substance that sets off the reaction).

* **antihistamines** (an-tie-HIS-tuh-meens) are drugs used to combat allergic reactions and relieve itching.

* **corticosteroids** (kor-tih-ko-STIR-oyds) are chemical substances made by the adrenal glands that have several functions in the body, including maintaining blood pressure during stress and controlling inflammation. They can also be given to people as medication to treat certain illnesses.

Homeless Teens

Young people can become homeless. Some teenagers become homeless with their families when financial problems force them from their homes. Other young people become homeless when they run away from home because of abuse, neglect, or indifference on the part of their families.

- The average age of runaway children is between 14 and 17 years.
- About two million young people living in U.S. households report that they ran away during the previous year.
- Children make up about 40 percent of the overall homeless population, most of them accompanied by at least one parent. One of the fastest growing groups in the homeless population are families with children.
- In cities, about 5 percent of the homeless population consists of unaccompanied children.

Homelessness

Homelessness is the condition of having no fixed, adequate, or secure place to live. In many, although not all cases, homelessness may be a result of mental illness, abuse, or addiction. Even when no associated mental health problem exists, those who are homeless may suffer emotionally because of the lack of the most basic of human needs: safe shelter.

An Eye Opener

Jon and Ryan went for a bike ride one day and were astounded to discover a group of people living in cardboard boxes at the periphery of the county park. Before this, it had never occurred to them that at the edges of their suburban community were people who lived on the streets, dependent on social service agencies, charities, friends, and their own ingenuity to find shelter.

The number of people in the United States who are homeless is difficult to estimate because the population of homeless people is constantly changing as some people find housing and others are displaced. According to the 2006 annual report of the National Law Center on Homelessness and Poverty, 2.5 million to 3.5 million people experience homelessness over a one-year period, and nearly 40 percent of them are children. Homelessness strikes people who live in cities, as well as suburbs and rural areas.

Who Becomes Homeless?

Homelessness can be either temporary, lasting only a few days or weeks, or semi-permanent, lasting for several years. The number of people who

are without shelter is affected by many social factors, including the number of jobs available and how well those jobs pay; the cost of housing; the cost of basic necessities such as food; and the availability of social outreach and assistance programs. According to a fact sheet issued by the National Coalition for the Homeless in 2007, single men are three times as likely to be homeless as single women. The fact sheet also noted a racial disparity among the urban homeless population. Citing a 2004 study by the U.S. Conference of Mayors, it reported that 49 percent of the homeless population was African American, followed by 35 percent Caucasian, and 13 percent Hispanic.

In general, people are more likely to be homeless if they are between the ages of 25 and 54, have less than a high school education, have a history of mental illness, have served in the military, and/or have experienced domestic violence or abuse. Other factors that increase the risk of becoming homeless are time spent homeless, in foster care, or in a group home as a child; childhood physical or sexual abuse; experience as a child runaway; and a history of drug or alcohol abuse.

Health Problems Associated with Homelessness

Most people who are homeless have no health insurance and little access to medical care. In a study issued by the U.S. Department of Housing and Urban Development, almost half of homeless people surveyed had chronic (long-term) health problems such as diabetes*, cancer*, high blood pressure*, or arthritis*, but were not receiving treatment for these conditions. Another one-fourth of the homeless population had an infectious disease such as pneumonia*, tuberculosis, or AIDS*.

According to the U.S. National Center on Family Homelessness, when compared to children with homes, those who are homeless have the following:

- twice the number of ear infections
- four times as many asthma attacks
- five times the number of stomach problems

In addition, about half of school-aged children who are homeless experience anxiety, depression, or other emotional problems, and one in five homeless children require professional care to treat these problems.

In many cases, these health conditions are compounded by other problems that are a direct result of the lack of proper shelter and life on the streets. These may include frostbite, animal bites, insect infestations, leg ulcers, upper respiratory infections, and dietary deficiency. In addition, people who are homeless are sometimes the victims of violent acts that can leave behind both physical and emotional stress.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **cancer** is a condition characterized by abnormal overgrowth of certain cells, which may be fatal.

* **high blood pressure** also called hypertension, is a condition in which the pressure of the blood in the arteries is above normal.

* **arthritis** (ar-THRY-tis) refers to any of several disorders characterized by inflammation of the joints.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

Some people who are homeless experience difficulties with drug and alcohol abuse, or with mental illness, although many do not.

What Help Is Available to People Who Are Homeless?

The most common programs available to help people who are homeless are those that provide food (e.g., soup kitchens, food pantries) and emergency shelter. Although many people who are homeless are eligible for government programs such as Medicaid, food stamps, veterans' benefits, or welfare benefits, they often have difficulty claiming these benefits because they have no fixed address or lack the organizational skills necessary to follow through with the often-multiple steps involved in participating in the programs.

Nearly half of the people who are homeless work at least part time, but their income is too low to pay for permanent housing or other daily living expenses. Sometimes, they can find other sources of cash, including gifts from friends and families, and money collected from panhandling, although some resort to illegal activities such as drug dealing and prostitution to make money. Numerous agencies offer help by providing job training and assistance in finding steady sources of employment and income.

Reducing homelessness is the target of many social programs. Studies suggest that the most effective programs not only help people find places to live but also help people solve the underlying problems that led to their homelessness in the first place.

Hookworm

Hookworm is a type of parasitic roundworm that burrows through the skin, moves through the bloodstream to the lungs, and finally moves into the intestinal tract.

What Is Hookworm?

Hookworm is a type of parasitic* roundworm, known as a nematode (NEM-a-tode), that has hooked mouthparts. The worm uses these mouthparts to fasten itself onto the intestinal walls of various hosts*, including humans. Hookworm larvae (the stage between egg and adult) often enter the body through the skin between the toes in people who go barefoot. Hookworm affects about one-fourth of the world's population, most often in warm, moist areas and in places with poor sanitation.

How Do Hookworms Grow?

Adult hookworms live inside the small intestine of humans and other animals, where they attach to the intestinal wall and feed on the host's blood. Eggs are passed in the host's stools (feces). The eggs hatch into larvae in one to two days under warm, moist conditions out of direct sunlight. The larvae grow in the stools and/or soil for 5 to 10 days until they become filariform (fi-LARE-i-form), or threadlike. During this stage hookworm can cause infection.

Filariform larvae can survive for up to three to four weeks. When they make contact with the bare skin of a human or another animal, they burrow into the skin and enter the host's bloodstream. They then are carried

The United States and the World

- Approximately 3.5 billion people worldwide have some form of infection from intestinal parasites, with about 740 million people in rich and poor countries alike experiencing symptoms of illness.
- Roundworms, including hookworms and pinworms are among the most common intestinal parasites and are a major public health problem.
- Children living in poor regions with tropical climates are especially at risk for roundworm infections.
- Hookworm and other roundworm infections also occur in countries such as the United States, especially from contact with infected pets or their waste or from poor personal hygiene.
- Hookworms are responsible for about 50,000 deaths annually. The large roundworm *Ascaris lumbricoides* (which causes ascariasis) is responsible for another 20,000 deaths worldwide each year.
- Larva migrans is a condition in which larvae from animal hookworm penetrates human skin and causes an itchy rash where the larvae have penetrated. This condition occurs when people walk or lie on beaches where animals have passed infected feces.

◀ The parasitic hookworm *Ancylostoma caninum* uses its hooked mouthpart to attach to the intestinal wall. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

▲ Symptoms of late-stage hookworm infestation are an enlarged abdomen and diarrhea. Worms can live up to 15 years in the human body, and females can lay 10,000 to 25,000 eggs every day. In severe cases the number of parasites may grow so large that the intestines become blocked.

Jan Bradley/Photo Researchers, Inc.

* **parasitic** (pair-uh-SIH-tik) refers to organisms such as protozoa (one-celled animals), worms, or insects that can invade and live on or inside human beings and may cause illness. An animal or plant harboring a parasite is called its host.

* **hosts** are organisms that provide another organism (such as a parasite or virus) with a place to live and grow.

* **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.

* **diarrhea** (di-ah-RE-a) refers to frequent, watery stools (bowel movements).

“THE GERM OF LAZINESS”

In 1902 Dr. Charles W. Stiles (1867–1941) discovered a variety of hookworm indigenous to the United States. At the time, hookworm was a serious problem in the southern United States because of the warm, moist climate and poor sanitation conditions, combined with people’s habit of going barefoot. Hookworm was called the “germ of laziness” by the popular press of the day.

In 1909 oil magnate John D. Rockefeller (1839–1937) established the Rockefeller Sanitary Commission for the Eradication of Hookworm Disease with the gift of a \$1 million grant toward the cure and prevention of hookworm disease. Stiles’s work through the commission became a model used in hookworm eradication programs worldwide.

through the bloodstream to the lungs, where they burrow through the thin walls. Once inside the lungs, they move up the airways to the throat, where they are swallowed. They then pass down the digestive tract to the small intestine. Inside the small intestine, they attach to the intestinal wall, and the cycle begins again.

How Is Hookworm Diagnosed and Treated?

The most common symptom of hookworm is anemia* caused by a loss of iron due to blood loss. Other symptoms include lack of appetite, weight loss, diarrhea*, and vague abdominal pain. When the larvae are in the lungs, there may be a dry cough and mild fever. When the larvae burrow into the skin, there may be mild itching and a rash. It is not uncommon, however, for mild infections to show no symptoms at all.

An infection is confirmed in the laboratory by observing eggs in stool samples under a microscope. Medications can be prescribed to treat the infection. Anemia is treated with iron supplements.

Can Hookworm Be Prevented?

The most effective method of prevention is limiting direct contact between infected soil or sand and skin. In areas where hookworm is common or where human feces may be in the sand or soil, people should avoid walking barefoot or touching the soil or sand with their bare hands.

Hormone-Secreting Tumors

Hormone-secreting tumors are benign or malignant* abnormal cell masses that produce and release one or more hormones in an uncontrolled manner. The high levels of the hormone in the bloodstream cause various symptoms, depending on the hormone's effects on the body.*

What Are Hormone-Secreting Tumors?

Hormones are chemical messengers that control many bodily processes. They are produced and released into the bloodstream by specialized glands* of the endocrine* system, including the pituitary*, adrenal glands*, thyroid gland*, and pancreas*. Hormones stimulate responses in their target tissues: other endocrine glands, organs, or cells.

Most endocrine glands continuously secrete small amounts of their particular hormones, so that at any one time there may be minute quantities of more than 50 different hormones circulating in the blood. The human body has elaborate mechanisms for ensuring that enough—but not too much—of each hormone is released by each gland. Most hormones are regulated by negative-feedback mechanisms: Information about the amount of hormone or an affected substance is relayed from the target tissue to the secreting gland, which then adjusts the production and/or secretion of the hormone accordingly. Hormones can also be regulated by counter-regulatory hormones, which counteract or interfere with the hormone's effects.

Hormone-secreting tumors fail to respond to normal regulation and, therefore, produce and release excess hormone. There are almost as many types of hormone-secreting tumors as there are known hormones; the most common are tumors of the pituitary and pancreas.

Pituitary tumors The pituitary gland is located inside the skull above the nasal* passages. The size of a large pea, it is the master hormone-control gland, regulating hormone production of most other glands in

- * **benign** (be-NINE) refers to a condition that is not cancerous or serious and will probably improve, go away, or not get worse.
- * **malignant** (ma-LIG-nant) refers to a condition that is severe and progressively worsening.
- * **glands** are organs that produce substances such as hormones and chemicals that regulate body functions.
- * **endocrine** (EN-do-krin) refers to a group of glands, such as the thyroid, adrenal, and pituitary glands, and the hormones they produce. The endocrine glands secrete their hormones into the bloodstream, and the hormones travel to the cells that have receptors for them. Certain hormones have effects on mood and sometimes cause emotional swings.
- * **pituitary** (pih-TOO-ih-tare-e) is a small oval-shaped gland at the base of the skull that produces several hormones—substances that affect various body functions, including growth.
- * **adrenal glands** (a-DREEN-al glands) are the pair of endocrine organs located near the kidneys.
- * **thyroid gland** (THY-roid GLAND) is located in the lower part of the front of the neck. The thyroid produces hormones that regulate the body's metabolism (me-TAB-o-LIZ-um), the processes the body uses to produce energy, to grow, and to maintain body tissues.
- * **pancreas** (PAN-kree-us) is a gland located behind the stomach that produces enzymes and hormones necessary for digestion and metabolism.
- * **nasal** (NA-zal) of or relating to the nose.

- * **hypothalamus** (hy-po-THAL-uh-mus) is a brain structure located deep within the brain that regulates automatic body functions such as heart rate, blood pressure, temperature, respiration, and the release of hormones.
- * **growth hormone** is a chemical substance produced by the pituitary gland that regulates growth and other body functions.
- * **acromegaly** (akro-MEG-al-ee) is a disease in which the pituitary gland secretes too much growth hormone with the effect of gradual and permanent enlargement of flat bones, the hands and feet, abdominal organs, and some facial features.
- * **cortisol** (KOR-ti-sol) is a hormone that helps control blood pressure and metabolism, the process of converting food into energy and waste products. It plays a part in the stress response.
- * **menstruation** (men-stroo-AY-shun) is the discharge of the blood-enriched lining of the uterus. Menstruation normally occurs in females who are physically mature enough to bear children. Most girls have their first period between the age of 9 and 16. Menstruation ceases during pregnancy and with the onset of menopause. Because it usually occurs at about four-week intervals, it is often called the monthly period.
- * **hyperthyroidism** (h-per-THY-royd-ih-zum) is excessive activity of the thyroid gland, characterized by an enlarged thyroid gland, increased metabolic rate, rapid heartbeat, and high blood pressure.
- * **hyperglycemia** (h-per-gly-SEE-mee-uh) is an excess of blood sugar.

the body. The pituitary itself is regulated by the hypothalamus* of the brain, which releases chemicals that stimulate or inhibit pituitary-hormone production. There are five different types of cells in the anterior or front part of the pituitary, each of which makes one or two specific hormones.

Although only about 1,300 pituitary tumors are diagnosed in the United States each year, it is estimated that 15 to 20 percent of all people eventually develop tumors in their anterior pituitary. Of the diagnosed pituitary tumors, almost all are benign glandular tumors called adenomas. Although they do not usually grow beyond the pituitary, their effects can be profound. About 75 percent of pituitary adenomas are functional, meaning that they produce hormones and may not respond to normal feedback signals from the hypothalamus and other glands. Instead they release an excess amount of a specific hormone:

- About 43 percent of pituitary adenomas are prolactinomas. They secrete the hormone prolactin that stimulates milk production in females.
- About 17 percent are growth-hormone or somatotropin-secreting adenomas. These tumors cause gigantism in children. In adults—who normally produce only very small amounts of growth hormone*—somatotropin-secreting tumors cause acromegaly*, meaning “large extremities”—the growth of the bones of the face, hands, and feet.
- About 7 percent are adenomas that secrete adrenocorticotropic hormone (ACTH; corticotropin). ACTH causes the adrenal glands to grow and secrete steroid hormones such as cortisol*. Cushing’s disease is caused by ACTH-secreting tumors.
- About 5 percent are gonadotropin-secreting adenomas. Gonadotropins regulate ovulation and menstruation* in females and testosterone and sperm production in males.
- About 3 percent of anterior pituitary adenomas secrete thyroid-stimulating hormone (TSH), which causes the thyroid to grow and secrete thyroid hormones. TSH-secreting tumors result in hyperthyroidism*. Some pituitary tumors secrete more than one type of hormone, most commonly prolactin and growth hormone.

Pancreatic tumors The amount of glucose (sugar) in the blood is one of the most delicate balances maintained by the body. Too much blood glucose, or hyperglycemia*, can irreversibly damage organs. Too little glucose, or hypoglycemia*, can cause convulsions*, unconsciousness, and even death. When the blood-glucose level rises, beta cells in the islets of the pancreas are stimulated to increase insulin* secretion, which lowers blood glucose. As blood-glucose levels drop, alpha cells in the islets are stimulated to increase glucagon secretion, which raises the concentration of glucose in the blood. Thus insulin and glucagon secretion by the pancreas are both directly regulated by the concentration of

WHAT CAUSES HORMONE-SECRETING TUMORS?

Most hormone-secreting tumors probably result from acquired mutations* in an endocrine cell's DNA* that lead to the loss of a regulatory mechanism that prevents the cells from growing and producing hormones. The only known risk factor for hormone-secreting tumors is an inherited condition called multiple endocrine neoplasia type 1 (MEN1). People with MEN1 are at very high risk of developing pituitary, parathyroid, and pancreatic tumors. However, MEN1 accounts for only about 3 percent of pituitary tumors.

glucose in the blood. Insulin is also controlled by counter-regulatory hormones, including glucagon, growth hormone, adrenalin, and cortisol, which counteract the effects of insulin by raising blood-sugar levels.

There are three main types of hormone-secreting pancreatic tumors:

- Insulinomas are islet-cell adenomas that overproduce insulin, causing hypoglycemia. They are rare and usually occur as single, small tumors in adults. Only 5 to 10 percent are cancerous.
- Glucagonomas are islet-cell tumors that overproduce glucagon, causing glucose intolerance and hyperglycemia. About 60 percent of glucagonomas are cancerous and they commonly spread to the liver*. They also cause a distinctive skin lesion* called necrolytic migratory erythema.
- Zollinger-Ellison syndrome* (ZES) is caused by a single tumor or multiple small tumors called gastrinomas in the pancreas or small intestine*. These secrete high levels of the hormone gastrin, which causes the production of excess stomach acid. One-half to two-thirds of single gastrinomas are cancerous and commonly spread to nearby lymph nodes* and the liver.

What Are the Symptoms of Hormone-Secreting Tumors?

The symptoms of hormone-secreting tumors—as well as their diagnosis, treatment, and prognosis—depend on the physiological effects of the hormones that they secrete.

Pituitary-gland tumors Most pituitary adenomas are completely harmless and cause no symptoms. They are sometimes detected during MRI* brain scans for an unrelated problem. However, some pituitary-hormone-secreting tumors cause symptoms of hormone overproduction. Others may continue growing until they impinge on normal pituitary

* **hypoglycemia** (hi-po-gly-SEE-mee-uh) is a condition that occurs when the amount of glucose, or sugar, in the blood becomes too low. Symptoms can include dizziness, trembling, sweating, and confusion.

* **convulsions** (kon-VUL-shuns), also called seizures, are involuntary muscle contractions caused by electrical discharges within the brain and are usually accompanied by changes in consciousness.

* **insulin** is a kind of hormone, or chemical produced in the body, that is crucial in controlling the level of glucose (sugar) in the blood and in helping the body use glucose to produce energy. When the body cannot produce or use insulin properly, a person must take insulin or other medications.

* **mutations** (mu-TAY-shuns) are changes in a chromosome or a gene.

* **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

* **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.

* **lesion** (LEE-zhun) is a general term referring to a sore or a damaged or irregular area of tissue.

* **syndrome** is a group or pattern of symptoms or signs that occur together.

* **small intestine** is the part of the intestines—the system of muscular tubes that food passes through during digestion—that directly receives the food when it passes through the stomach.

Who Was Harvey Cushing?

Harvey Williams Cushing (1869–1939), a famous American neurosurgeon, developed many of the basic techniques for operating on the human brain. He first reported on “polyglandular syndrome,” which became known as Cushing’s syndrome, in 1912. In 1932 he published a landmark work on pituitary adenomas. Cushing also won a Pulitzer Prize for his biography of Sir William Osler, a father of modern medicine.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **MRI** short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

* **neurological** (nur-a-LAH-je-kal) refers to the nervous system, which includes the brain, spinal cord, and the nerves that control the senses, movement, and organ functions throughout the body.

* **impotence** (IM-po-tens) is failure of a man to achieve or to maintain an erection.

* **acromegaly** (akro-MEG-al-ee) is a disease in which the pituitary gland secretes too much growth hormone with the effect of gradual and permanent enlargement of flat bones, the hands and feet, abdominal organs, and some facial features.

* **joint** is the structure where two or more bones come together, allowing flexibility and motion of the skeleton.

cells, nerves, or neighboring parts of the brain, causing neurological* symptoms, including headaches and vision problems.

Prolactinomas are most common in young women and in older men. In women they can cause abnormal breast-milk production and the cessation of menstruation. In men they can cause loss of sexual interest or impotence*.

Growth-hormone-secreting tumors can cause children to grow very tall—sometimes over seven feet—in a very short time. Although the arm and leg bones of adults cannot grow, overproduction of growth hormone can cause the bones of the hands, feet, skull, jaws, and face to grow and become distorted. Other symptoms of acromegaly* include:

- Deepening of the voice
- Thickening of the tongue, roof of the mouth, and skin
- Increased body hair
- Headaches

Both gigantism and acromegaly can cause increased sweating and joint* pain. Acromegaly can lead to kidney stones*, diabetes* mellitus, and heart disease.

Cushing’s syndrome refers to symptoms caused by cortisol overproduction for any reason. Cushing’s disease is the overproduction of ACTH by a pituitary adenoma, which leads to excessive release of cortisol by the adrenal glands. Although symptoms of Cushing’s disease are similar to those of acromegaly, they appear much more rapidly and may include the following:

- Weight gain in the chest and abdomen*
- Fat deposits at the base of the neck
- Face swelling
- Easy bruising
- Irregular or absent menstruation
- high blood pressure*
- Moodiness or depression*
- Osteoporosis*

Symptoms of hyperthyroidism caused by TSH-secreting tumors include the following:

- Rapid heartbeat
- Tremors
- Anxiety
- Insomnia
- Increased appetite
- Weight loss
- Frequent bowel movements
- An enlarged thyroid

Pancreatic tumors Symptoms of hypoglycemia from insulinomas may be as mild as anxiety or hunger or as severe as seizures*, coma*, or death. Other symptoms include:

- Sweating
- Tremors
- Rapid heart rate
- Dizziness
- Headache
- Clouded vision
- Behavioral changes
- Confusion

Symptoms of glucagonoma include:

- Skin rashes
- An inflamed mouth and tongue
- Thirst
- Increased appetite
- Weight loss
- Frequent urination

Symptoms of gastrinomas include:

- Abdominal pain
- Diarrhea*
- Stomach or intestinal ulcers*
- Vomiting blood

How Are Hormone-Secreting Tumors Diagnosed and Treated?

Diagnosis Hormone-secreting tumors are diagnosed by measuring hormone levels in the blood and/or urine. A low blood-glucose level after fasting may indicate an insulinoma, whereas a high glucose level may indicate a glucagonoma. High blood levels of insulin or C-peptide, a byproduct of insulin production, may also indicate insulinoma. High glucagon levels in the blood or an abnormal glucose-tolerance test may suggest a glucagonoma. A high level of gastrin may indicate a gastrinoma.

Imaging techniques such as CT scans*, MRI, or ultrasound* are used to visualize hormone-secreting tumors. A biopsy* generally confirms the diagnosis of a tumor. However, hormone tests for some types of pituitary adenomas are accurate enough that a biopsy is not necessary.

Treatment of pituitary tumors Many hormone-secreting tumors can be successfully treated by surgical removal. More than 80 percent of small pituitary adenomas, called microadenomas, are cured by surgery. The cure rate is lower for larger macroadenomas.

* **kidney stones** are hard structures that form in the urinary tract.

These structures are composed of crystallized chemicals that have separated from the urine. They can obstruct the flow of urine and cause tissue damage and pain as the body attempts to pass the stones through the urinary tract and out of the body.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

* **high blood pressure** also called hypertension, is a condition in which the pressure of the blood in the arteries is above normal.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

* **osteoporosis** (os-te-o-por-O-sis) is the loss of material from the bone. This makes the bones weak and brittle.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

- * **diarrhea** (di-ah-RE-a) refers to frequent, watery stools (bowel movements).
- * **ulcers** are open sores on the skin or the lining of a hollow body organ, such as the stomach or intestine. They may or may not be painful.
- * **antibody** (AN-tih-bah-dee) is a protein molecule produced by the body's immune system to help fight a specific infection caused by a microorganism, such as a bacterium or virus.
- * **enzyme** (EN-zime) is a protein that helps speed up a chemical reaction in cells or organisms.
- * **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.
- * **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.
- * **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.
- * **radiation therapy** is a treatment that uses high-energy radiation from x-rays and other sources to kill cancer cells and shrink cancerous growths.
- * **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

HOW ARE HORMONE LEVELS MEASURED?

Most hormones are tiny molecules that are present at very low concentrations in the blood and urine. Until the 1960s no effective method for determining hormone levels existed. At the Bronx Veterans Administration Hospital in New York, Rosalyn Yalow (b. 1921), a nuclear physicist, and Dr. Solomon A. Berson (1918–1972) experimented with using radioactive isotopes to measure hormones. In 1960 they published their radioimmunoassay (RIA) for measuring the concentration of insulin in the blood of diabetes patients.

An RIA mixes a known amount of radioactively labeled hormone with an antibody* that specifically binds to that hormone. When human serum containing the hormone is added to the mixture, the hormone in the serum also binds to the antibody, displacing some of the radioactive hormone. By measuring the amount of radioactive hormone that remains bound to the antibody, the tiny amount of hormone in the serum can be determined.

Yalow and Berson applied RIAs to the measurement of other hormones, including corticotropin and growth hormone. Soon RIAs were measuring hundreds of substances, revolutionizing the study of hormones and hormone-secreting tumors. Despite its commercial potential, Yalow and Berson refused to patent their method. In 1977 five years after Berson's death, Yalow was awarded the Nobel Prize in Physiology or Medicine. Eventually the widespread use of RIAs was superseded by enzyme*-linked immunosorbent assays (ELISAs), which use fluorescence rather than radioactivity to measure hormone concentrations.

Medication that controls prolactin levels can successfully treat 80 to 90 percent of prolactinomas. Medications that reduce growth-hormone levels began in the early 2000s to replace surgery as the treatment-of-choice for somatotropin-secreting tumors.

ACTH-, gonadotropin-, and TSH-secreting adenomas are treated surgically. If the tumor persists or returns, a second surgery or radiation therapy* is used. If possible, stereotactic radiosurgery or proton-beam radiation therapy is used instead of conventional radiation. These techniques deliver an intense radiation beam directly at the tumor and have fewer potential undesirable effects. However, the benefits from radiation therapy may not be evident for months or even years. Medications are used if surgery and radiation both fail to control cortisol production caused by ACTH-secreting tumors. In severe cases the adrenal glands may be removed following pituitary radiation.

Treatment of pancreatic tumors Insulinomas are usually cured by surgery. Multiple tumors may require partial removal of the pancreas. If surgery is not possible or is ineffective, medication can be used to lower or suppress insulin secretion. Glucagonomas are usually surgically removed. Cancerous glucagonomas do not respond to chemotherapy*.

ZES is usually treated with medications called proton-pump inhibitors, which reduce stomach-acid production, promote ulcer healing, and relieve abdominal pain and diarrhea. Surgery may remove a single tumor if the cancer has not spread to other organs. Although the cure rate for ZES is relatively low, the tumors are slow-growing. Patients may live for many years following diagnosis and the medications are very effective at relieving symptoms.

HPV See *Human Papilloma Virus (HPV); Warts*.

Human Immunodeficiency Virus See *AIDS and HIV Infection*.

Human Papilloma Virus (HPV)

Human papilloma virus (HPV) is a group of more than 100 related viruses that can cause warts on the hands, feet, genitals, and other parts of the body.

* **viruses** (VY-rus-sez) are tiny infectious agents that can cause infectious diseases. Viruses can only reproduce within the cells they infect.

* **genital** (JEH-nih-tul) refers to the external sexual organs.

* **sexually transmitted disease** (STD) is an infection, such as the human immunodeficiency virus (HIV) or herpes, that can be passed from person to person by sexual contact.

* **vaginal** (VAH-jih-nul) refers to the canal in a woman that leads from the uterus to the outside of the body.

* **anal** refers to the anus, the opening at the end of the digestive system through which waste leaves the body.

Katy's Story

Katy was embarrassed. The warts on her fingers had gotten worse, and she hated the thought of anyone seeing them. At dinner that night, her mother asked her what was wrong with her hands.

"Nothing," Katy said. But at her mother's frown, she raised her right hand above the table. "They're gross," she said, bursting into tears.

"They're warts," her mother said. "That's no big deal. You've got a virus, that's all."

"You mean, a virus like one that gives you a cold?"

"Exactly. Although we'll need to take you to the dermatologist to take care of them," her mother said.

Katy sighed with relief. The warts weren't permanent, after all.

What Is Human Papilloma Virus?

Human papilloma virus (HPV) is the name of a group of more than 100 related viruses* that can cause warts on the hands, feet, genitals, and other parts of the body.

What Is a Wart?

A wart is an irregular but harmless growth of skin triggered by HPV. There are several different kinds of warts. Common warts, like Katy's, usually appear on the hands. Plantar warts grow on the soles of the feet. Periungual warts grow near the nails and can affect nail growth. Filiform warts appear on the face, as can flat warts, which also appear on the arms and legs. Common warts and periungual warts are rough; flat warts are flat, and plantar warts look like calluses. Filiform warts have thin, thread-like growths sticking out.

Genital* warts may take one of several shapes or may not be visible at all. Genital HPV is the most common sexually transmitted disease* and can affect both men and women. There are more than 40 types of genital HPV, which infects the skin and the mucous membranes.

How Is HPV Transmitted?

HPV thrives in warm, moist places, such as locker rooms, swimming pool areas, and showers. HPV is very contagious and can easily be spread from place to place on a person's body or between people. For example, sharing a razor can allow the virus to spread from one person to another. Or a person can spread the virus from one spot to another on his own body by scratching at a wart, picking up viruses, and then scratching another spot, which introduces the virus. Viruses enter the skin through a scratch, cut, or abrasion; swimmers often pick up the virus that causes plantar warts through a scrape caused by the concrete surfaces used around swimming pools. However, it may take two to nine months before the new wart grows.

People get HPV through genital contact, usually vaginal* or anal* sex. Because most people who have HPV do not realize they are infected, they can unknowingly pass the virus to their sex partners. About 20 million

Americans have HPV, and more than six million people get the virus each year.

How Are HPV and Warts Treated?

There are several methods of treating warts. One of them is to freeze the wart with liquid nitrogen (cryotherapy). Warts can also be removed surgically, with lasers, electricity, or cutting tools. Some people have success treating warts with home remedies, such as putting tape over the wart. Over-the-counter remedies containing salicylic acid are also useful.

No treatment is 100 percent effective. Most warts will go away on their own, although it may take years.

No treatment is available that can eliminate genital HPV. However, the body's natural defenses eliminate the infection; 70 percent of HPV infections are gone within a year, and after two years, 90 percent are eliminated. Nonetheless, some individuals with genital warts ask their doctor to remove them.

Medications Warts may be treated with the application of medication. Salicylic acid, sold under several brand names, works by softening the layers of skin that make up the wart. Once softened, the layers can be rubbed off. Because salicylic acid is both safe and effective (although it may take months to work), it is generally considered the most desirable first treatment for warts.

Prescription medications are also available for removing warts. Cantharidin blisters the skin under the wart, lifting it off. Bichloroacetic acid (BCA) destroys the proteins in the wart's cells. Both cantharidin and BCA must be applied by a health professional. The medication retinoid cream disrupts the cell growth in the wart; it can be applied by a patient at home.

Less commonly used in treating warts are the medications bleomycin, interferon, and the immunotherapy medications imiquimod and contact sensitizers. Each has drawbacks. Bleomycin is expensive, toxic, and painful upon injection; its effectiveness is questionable. Imiquimod is expensive and can cause skin irritation; little is known about its efficacy on non-genital warts. Interferon was an experimental treatment as of 2009. Contact sensitizers can cause severe allergic reactions and are considered dangerous for the health professionals administering them. Neither contact sensitizers nor bleomycin are recommended for pregnant women.

Cimetidine is a medication that may be taken by mouth or as an injection. Most medications are either injected or applied topically.

Cryosurgery If a wart does not respond to treatment with medication, the doctor may suggest surgery. Some patients opt for cryosurgery to remove their warts. For two weeks before the procedure, the patient applies a gel of salicylic acid. At the end of the two weeks, the wart will have turned white and taken on a cottony texture.

The doctor will then apply a small amount of liquid nitrogen, using a cotton swap, a spray, or a cry probe. The extreme cold destroys the root of

HPV VACCINE

A vaccine against the HPV strains most likely to cause cervical cancer is available, and the American Cancer Society recommends that women who are able to get the vaccine do so.

Studies have shown that the vaccine that targets four strains of HPV is 100 percent effective in preventing changes in cells in the cervix for four years. The Food and Drug Administration approved the vaccine for use in females between the ages of 9 and 26. However, it was less effective in women who had been previously exposed to two of the strains. Because the vaccine is less effective in women who have already been exposed to the virus, it is recommended that the virus be given before a woman becomes sexually active.

However, a woman should not get the vaccine if any of the following applies to her:

- Is pregnant, although the vaccine appears to be safe for mother and baby
- Has had a life-threatening allergic reaction to yeast
- Is allergic to the other components of the vaccine
- Has had a reaction to a previous dose of the vaccine

the wart. Common warts are usually treated with an open spray applied for 10 seconds. The procedure may be repeated at four-week intervals.

The advantages of cryosurgery for removal of warts include a short (two-week) preparation time, minimal wound care, and a low risk of infection.

Laser surgery By using an intense, focused beam of light, the doctor can burn the wart, destroying it. But laser surgery is not recommended for every case. This procedure is usually reserved for when a wart has not responded to medication, when warts are particularly widespread, when a wart is large, or when the patient is pregnant and needs the wart or warts removed. Local anesthetic is required for laser surgery.

Conventional surgery Warts may be removed with surgery. Usually surgery involves both burning the wart with an electric current (called electro-surgery), and curettage, cutting the wart off with a scalpel. Because this treatment tends to leave scars, it is considered less desirable than cryosurgery.

How are Plantar Warts Treated?

Plantar warts are found on the soles of the feet. The pressure of standing and walking can cause a layer of thickened skin to form over the wart itself. Unlike other kinds of warts, plantar warts can be painful.

To treat a plantar wart, the doctor scrapes the upper layer with a knife, in a procedure called paring. Because the upper layers of a plantar wart are dead and have no blood vessels, there is little to no pain or bleeding. Paring

may be used to distinguish a plantar wart from a callus; the doctor will look for evidence of blood vessels deep inside the structure, which indicate it is a plantar wart. Paring can also be used to remove skin layers and make the wart more accessible to other treatments, such as medication or cryosurgery.

How are Warts Treated with Home Remedies?

Some people have reported success in removing warts by applying duct tape. They cover the wart with tape and leave it on for six days. Then they remove the tape, soak the wart, and use an emery board on the wart. They repeat the process until the wart is gone. Doctors think that this may work because the tape removes some wart tissue (called debriding) every time it is removed.

Why Do Warts Recur?

No matter how they are treated, warts often recur. Treatments kill the wart itself but not the HPV that causes them. However, given time, the body's immune system can eliminate the viruses that cause warts.

To reduce the risk of warts recurring, individuals need to avoid walking barefoot in locker rooms, swimming pool areas, and showers. They should not touch existing warts, whether their own or someone else's. They should not share personal items, such as razors or towels, with a person who has warts.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

Huntington's Disease

Huntington's disease, formerly called Huntington's chorea (kor-EE-a), is a rare disease that causes part of the brain to deteriorate. A person with the disease has involuntary and strange movements. It is a genetic disorder, meaning that is inherited by the child from the parent's genes*.*

Who Is at Risk for Huntington's Disease?

In the United States, only about five out of 100,000 people develop Huntington's disease. Because it is transmitted from parent to child, only children of a parent who has the abnormal gene are at risk, and they have a 50 percent chance of developing the disease.

What Is Huntington's Disease?

Huntington's affects the basal ganglia (GANG-lee-a, nerve cell bodies in part of the white matter of the brain). This part of the brain acts as an important pathway for the central nervous system*. Huntington's disease causes erratic movements, usually first affecting the face and speech. Memory, reasoning, and speech become affected. Eventually, the abilities to walk, swallow, and take care of oneself are lost. Males and females are equally affected. A person with Huntington's disease usually first has symptoms between the ages of 35 and 50. A person with the disease may live for a period of 10 to 20 years, but the condition is progressive (becomes worse over time).

What Are the Symptoms of Huntington's Disease?

A person with Huntington's disease may first make unusual or strange facial grimaces and become clumsy. Also, the person may become irritable or forgetful. The person may appear to be drunk even without having consumed any alcohol. The awkwardness that comes from the disease

GEORGE HUNTINGTON

The word "chorea" comes from the Greek language, by way of Latin, and means "dance." During the Renaissance, the Swiss physician Paracelsus (1493–1541) wrote about the uncontrollable rhythmic movements characteristic of several different movement disorders.

In 1872, the American physician George Huntington (1850–1916) described an inherited choreatic disorder that began late in life. Because of that research the disorder was named Huntington's Chorea, later known as Huntington's disease.

WOODY GUTHRIE'S STORY

Woodrow Wilson (Woody) Guthrie (1912–1967) was a folk singer and song writer who was well known during the 1930s and 1940s for his songs about migrant workers and poor city people. Among his best known songs are “This Land Is Your Land” and “So Long, It’s Been Good to Know You.” Woody Guthrie died of Huntington’s disease.

When he first exhibited symptoms of the disease in the late 1940s, people thought he was drunk. Only after he was diagnosed as suffering from Huntington’s Chorea (as it was then known) in the 1950s was his behavior understood.

Although there is a predictive test for HD, Woody’s son, folk singer Arlo Guthrie (b. 1947), has opted not to be tested.

* **dopamine** (DOE-puh-meen) is a neurotransmitter in the brain that is involved in the brain structures that control motor activity (movement).

may put the person in danger, for example, by losing his balance while crossing the street.

What Is the Treatment for Huntington’s Disease?

There is no cure for Huntington’s disease, but there is medicine to control the erratic movements caused by the disease. This medicine blocks the production of dopamine* in the brain.

Offspring of someone with Huntington’s disease are advised to seek genetic counseling before deciding whether to have children of their own, as these children also could get the disease. A particular blood test can determine whether a person has the gene for Huntington’s disease.

Is There a Cure for Huntington’s Disease?

There is no cure for Huntington’s disease, but knowing if a person has the gene can influence that person’s decision about having children who might develop this disease later in their lives. The test shows whether the person has the gene that causes the disease. Sometimes people who are at risk may not want to know if they have the gene, and they take the chance of having children before the onset of the disease is noticed. They feel that knowing they have the gene will make it impossible for them to live a normal life.

Hydrocephalus

Hydrocephalus (hy-dro-SEF-a-lus) is an abnormal build-up of fluid inside the skull. This excess fluid often creates pressure on the brain and may result in mental and physical handicaps.

Why Is the Baby's Head So Big?

When Liz saw her baby brother in the hospital nursery, she was upset by his appearance. His head seemed huge. The doctor explained that John had hydrocephalus, or too much fluid within his skull. Because he was a newborn, the bones in his head had not yet grown together, which allowed his head to expand with the pressure caused by the extra fluid. The doctor warned Liz's family that the excess fluid may have squeezed and damaged John's brain, but it was too soon to tell for sure.

What Is Hydrocephalus?

Hydrocephalus refers to fluid buildup in and around the brain. The term comes from two Greek words: "hydro" meaning "water," and "cephalie" meaning "brain." Hydrocephalus often is called "water on the brain," but the brain and spinal cord are actually bathed in cerebrospinal fluid (CSF). Tissues lining the inside of the brain make CSF, which is a mixture of water, protein, sugar, and minerals, to cushion and protect the brain.

The brain contains four cavities, or spaces, called ventricles (VEN-tri-kuls). CSF normally flows into and around the ventricles, through tiny openings at the base of the brain, over the brain's surface, and around the spinal cord. Normally, the pressure exerted on the brain by CSF remains fairly constant because the body reabsorbs excess CSF into the bloodstream. In people who have hydrocephalus, however, either the flow of CSF is blocked (obstructive hydrocephalus) or the CSF cannot be reabsorbed (communicating hydrocephalus). In both cases, CSF accumulates and the extra pressure squeezes the brain and disrupts blood flow to the

brain. Without the oxygen and sugar that blood carries, the brain cannot function properly. Over time, blood vessels and nerve cells become damaged, which can result in problems with learning, thinking, and moving. The severity of hydrocephalus varies from person to person.

What Causes Hydrocephalus?

Often medical professionals cannot determine the cause of hydrocephalus, but sometimes they can. About one in 1,000 babies is born with the condition, which is known as congenital hydrocephalus. It may occur because the brain did not develop properly or because the fetus was infected with rubella (German measles), herpes, cytomegalovirus, or other viruses, or with microscopic organisms called protozoa. In addition, at least 80 percent of babies who have the congenital disorder spina bifida (a birth defect that leaves an opening in the spinal cord and spinal column) also develop some degree of hydrocephalus.

In infants, children, and adults, brain tumors* can cause hydrocephalus by blocking the flow of CSF. Hydrocephalus also can result from meningitis, an infection of the linings of the brain and spinal cord, and by bleeding in the brain due to a stroke* or a head injury. Infants born very prematurely frequently experience bleeding in the ventricles of the brain, which often leads to hydrocephalus. Hydrocephalus is less common in adults.

How Is Hydrocephalus Treated?

Babies suspected of having hydrocephalus receive careful monitoring. John's head kept getting bigger and ultimately his doctor used a CT scan* and an MRI* to examine his brain.

Some forms of hydrocephalus require no treatment, but most, like John's, require surgery. The surgeon placed a device called a shunt in John's brain to drain the excess CSF. Shunts are thin flexible tubes that pass through the skull and drain some of the excess CSF into the bloodstream or the abdomen where it is reabsorbed by the body. This procedure relieves pressure on the brain, but it does not cure the brain damage that has occurred already.

Most babies born with hydrocephalus live if they receive treatment, but about 60 percent have physical and/or mental handicaps. Liz's baby brother John was lucky. He was one of the children who did not have any mental or physical abilities because of hydrocephalus.

What Is Normal Pressure Hydrocephalus?

Normal pressure hydrocephalus (NPH) is a condition that typically affects older adults. Rather than having a consistently high level of CSF in the skull, individuals with NPH have a normal level of CSF most of the day, but experience occasional, short-lasting spikes in CSF. Eventually, those spikes cause brain damage, and patients may have symptoms such as dementia*, incontinence*, and walking problems. Sometimes, the symptoms lead to a mistaken diagnosis of Alzheimer's (ALTS-hy-merz) disease*. NPH can result from a stroke, meningitis, head trauma, brain tumor, or

* **tumors** (TOO-morz) are abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.

* **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **MRI** which is short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

* **dementia** (dih-MEN-sha) is a loss of mental abilities, including memory, understanding, and judgment.

* **incontinence** (in-KON-ti-nens) is loss of control of urination or bowel movement.

* **Alzheimer's (ALTS-hy-merz) disease** is a condition that leads to gradually worsening loss of mental abilities, including memory, judgment, and abstract thinking, as well as changes in personality.

Types of cholesterol

Types	Levels (mg/dl)
Total cholesterol:	
Desirable	<200
Borderline	200 to 240
Undesirable	>240
HDL cholesterol:	
Desirable	>45
Borderline	35 to 45
Undesirable	<35
LDL cholesterol:	
Desirable	<130
Borderline	130 to 160
Undesirable	>160
Ratio of total cholesterol to HDL cholesterol:	
Desirable	<3
Borderline	3 to 4
Undesirable	>4

Hyperlipidemias

Hyperlipidemias are abnormally high levels of fatty substances called lipids—primarily cholesterol and triglycerides—in the blood. They increase the risk for arteriosclerosis and heart disease.*

What Are Hyperlipidemias?

Hyperlipidemias are lipid metabolic* disorders that are sometimes called hyperlipoproteinemia or dyslipidemia. High levels of cholesterol or triglycerides may be referred to as hypercholesterolemia or hypertriglyceridemia, respectively.

Cholesterol and triglycerides Fats from food are absorbed in the intestines* and sent to the liver* where they are made into cholesterol and triglycerides. These lipids are also absorbed from food. Cholesterol is used to build cells and certain hormones*. Triglycerides are stored in fat cells until the body requires extra calories* for energy.

WHAT MAKES CHOLESTEROL “BAD” OR “GOOD”?

VLDL, LDL, and IDL are called “bad” cholesterol because special cells remove their cholesterol component and deposit it as plaque* on blood vessel walls. Plaque can clog or block arteries. A heart attack* occurs when an artery* supplying blood to the heart is blocked. A stroke* occurs from the blockage of an artery supplying the brain.

HDL is “good” cholesterol because it removes excess cholesterol from blood vessel walls and carries it to the liver where it is broken down and removed from the body. Thus high levels of HDL reduce the risk of atherosclerosis and heart disease.

Cholesterol and triglycerides are transported through the blood as part of molecules called lipoproteins:

- Very-low-density lipoprotein (VLDL) is formed in the liver and transports triglycerides to fat cells.
- Low-density lipoprotein (LDL) transports cholesterol and is formed from VLDL after VLDL delivers its triglycerides.
- Intermediate-density lipoprotein (IDL) transports cholesterol and triglycerides and is also formed from the breakdown of VLDL.
- High-density lipoprotein (HDL) removes LDL cholesterol from tissues and transports it back to the liver.
- Chylomicrons are large lipoproteins that transport triglycerides to muscle and fat cells.

High levels of triglycerides can also cause arteries to harden, thicken, and narrow. High blood triglycerides are associated with obesity* and metabolic syndrome*, both of which increase the risk of heart attack and stroke. Metabolic syndrome refers to the presence of several metabolic risk factors*, such as abdominal* fat, high blood pressure*, high blood sugar, and high cholesterol.

How Common Are Hyperlipidemias?

An estimated 106.7 million Americans have total blood cholesterol levels that are at least borderline high, defined as 200 to 239 milligrams per deciliter (mg/dL) of blood. Another 37.2 million have cholesterol levels above 239 mg/dL, putting them at high risk for coronary heart disease. Cholesterol levels tend to increase with age.

Hyperlipidemias are more common in men than in women, perhaps because women tend to have higher levels of HDL. Although most hyperlipidemias are acquired conditions, inherited familial hypertriglyceridemia occurs in about one out of every 500 Americans.

Triglyceride levels

Normal	Less than 150 mg/dL
Borderline-high	150–199 mg/dL
High	200–499 mg/dL
Very high	500 mg/dL or above

* **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

* **calories** (KAL-o-reez) are units of energy that are used to measure both the amount of energy in food and the amount of energy the body uses.

* **plaque** (PLAK) is a raised patch or swelling on a body surface. Arterial plaque occurs on the inner surface of an artery and is produced by fatty deposits.

* **heart attack** is a general term that usually refers to a sudden, intense episode of heart injury. It is usually caused by a blockage of a coronary artery, which stops blood from supplying the heart muscle with oxygen.

* **artery** An artery is a vessel that carries blood from the heart to tissues in the body.

* **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

- * **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.
- * **syndrome** is a group or pattern of symptoms or signs that occur together.
- * **risk factors** are any factors that increase the chance of developing a disease.
- * **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.
- * **high blood pressure** also called hypertension, is a condition in which the pressure of the blood in the arteries is above normal.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.
- * **hypothyroidism** (hi-po-THY-royd-ih-zum) is an impairment of the functioning of the thyroid gland that causes too little thyroid hormone to be produced by the body. Symptoms of hypothyroidism can include tiredness, paleness, dry skin, and in children, delayed growth and mental and sexual development.
- * **kidney** is one of the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.

What Causes Hyperlipidemias?

The primary cause of hyperlipidemias is a diet that is high in fat and cholesterol. Other factors that contribute to hyperlipidemias include the following:

- Obesity
- Lifestyle factors, including stress, lack of exercise, and regular excessive alcohol use
- Certain other disorders, including diabetes*, hypothyroidism*, Cushing's syndrome, and kidney* and liver disease
- Some medications, including birth control pills, estrogen, corticosteroids*, certain diuretics*, and beta blockers.

How Do People Know They Have Hyperlipidemia?

Because acquired hyperlipidemias may have no symptoms until complications develop, they are generally detected through regular blood screenings. A fasting lipoprotein profile is recommended every five years

WHAT ARE INHERITED HYPERLIPIDEMIAS?

Various hyperlipidemias can be inherited from one or both parents:

- Familial combined hyperlipidemia, causing high blood cholesterol and triglycerides, is the most common inherited blood fat disorder that leads to early heart attacks.
- Familial dysbetalipoproteinemia causes the buildup of large lipoprotein particles containing both cholesterol and triglycerides. It is often due to defects in the gene encoding apolipoprotein E.
- Familial hypercholesterolemia causes high levels of LDL from birth because of a genetic* defect that prevents the removal of LDL from the blood. This factor leads to atherosclerosis and heart attacks at an early age. Rare individuals who inherit the defective gene from each parent have severe treatment-resistant hypercholesterolemia.
- Familial triglyceridemia, in which the levels of triglycerides and VLDL—but not cholesterol—are high, is a common inherited disorder that usually becomes apparent during puberty* or early adulthood. It is often associated with obesity, high blood glucose levels, and high insulin* levels, which may further elevate triglycerides.
- Familial lipoprotein lipase deficiency is a group of very rare genetic disorders in which an enzyme* for breaking down fat is missing and chylomicrons build up in the blood.

beginning at age 20. Inherited hyperlipidemias and consequent heart disease usually develop at an earlier age than acquired hyperlipidemias.

How Are Hyperlipidemias Diagnosed and Treated?

Diagnosis A fasting lipoprotein profile measures total cholesterol, LDL cholesterol, HDL, triglycerides, and sometimes VLDL or VLDL cholesterol, and C-reactive protein that is suggestive of cardiovascular disease.

Treatment Treatment of hyperlipidemias aims to lower lipid levels in the blood to reduce the risk or slow the progression of atherosclerosis and heart disease and possibly reverse damage that has already occurred. A diet that is low in saturated fats and cholesterol and high in fruits and vegetables, along with regular exercise, is the frontline treatment. Losing weight and treating underlying diseases or conditions may also be imperative.

Various medications can lower LDL cholesterol or triglycerides or raise HDL cholesterol. Statins are the most common and most effective drugs for treating high cholesterol. They slow down the rate at which LDL is made and speed up the liver's destruction of LDL.

Other drugs for treating hyperlipidemias include the following:

- Bile acid sequestering resins
- Cholesterol absorption inhibitors
- Fibrates
- Nicotinic acid (niacin; vitamin B3), which—in very high doses under a doctor's supervision—can decrease LDL, raise HDL, and lower triglycerides

Can Hyperlipidemias Be Prevented?

A well-balanced low-fat diet and maintenance of healthy body weight are the best ways to prevent high cholesterol. Saturated (animal) fats, including egg yolks and whole-milk dairy products, increase LDL. Monounsaturated fats—such as olive, canola, or peanut oils—and fiber can lower cholesterol levels. Plant foods have no cholesterol, but some low-fat animal products, such as liver, are high in cholesterol.

To control cholesterol the daily diet should include no more than the following:

- 30 percent total calories from fat
- 8 to 10 percent total calories from saturated fat
- 300 mg cholesterol—the amount in one egg
- 2,400 mg sodium

Excess calories are converted into triglycerides. Sugar and refined foods such as white flour may cause a sudden increase in insulin, which can increase triglycerides. Even small amounts of alcohol can raise triglyceride levels. Trans fats—any food with partially hydrogenated oil listed

* **corticosteroids** (kor-tih-ko-STIR-oyds) are chemical substances made by the adrenal glands that have several functions in the body, including maintaining blood pressure during stress and controlling inflammation. They can also be given to people as medication to treat certain illnesses.

* **diuretics** (dye-yoor-EH-tiks) are medications that increase the body's output of urine.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

* **insulin** is a kind of hormone, or chemical produced in the body, that is crucial in controlling the level of glucose (sugar) in the blood and in helping the body use glucose to produce energy. When the body cannot produce or use insulin properly, a person must take insulin or other medications.

* **enzyme** (EN-zime) is a protein that helps speed up a chemical reaction in cells or organisms.

in its ingredients—should be eliminated from the diet. Finally, regular exercise—30 minutes most days of the week—raises HDL and lowers LDL and triglycerides.

Hypertension

Hypertension, or high blood pressure, is a condition in which the pressure of blood in the arteries is above normal.

What Is Hypertension?

Hypertension is the medical term for high blood pressure. Arteries are the blood vessels that carry the blood from the heart to organs and tissues throughout the entire body. High blood pressure results either when the output of the blood pumped by the heart increases or when there is an increased resistance to the flow of blood through the arteries or both. In terms of numbers, a resting blood pressure of 140/90 or greater in an adult is considered to be high. Normal blood pressure levels are lower in children and slowly increase with age.

Everyone’s blood pressure goes up in moments of excitement or stress, which is entirely normal. High blood pressure is considered to be a medical condition when it continues over an extended period of time. This condition can then become a serious threat to health; the higher the

pressure and the longer it is allowed to continue without treatment, the greater the risk becomes.

People who have hypertension are more likely to suffer a stroke*, heart attack*, or failure of the kidneys* or heart. For this reason, and because there usually are no symptoms until the damage is done, hypertension has been termed “the silent killer.”

Who Has High Blood Pressure?

Hypertension is not contagious and cannot be caught or passed from one person to another. Its causes are varied and complex: hereditary (genetic*) factors, medical conditions, or medications can play roles. In most cases, no single cause for a person’s hypertension can be found.

However, certain generalizations can be made about its prevalence* in the overall population. It has been estimated that one in three adults in the United States has high blood pressure. This prevalence is believed to be about the same in most industrialized Western countries. The prevalence of high blood pressure is relatively low in developing countries.

It is further estimated that about one-third to one-half of people with high blood pressure are unaware of their condition. Many people first find out when they go for a routine medical check-up.

The prevalence of hypertension is slightly higher in women than in men. Men and women of African descent are both more likely than others to develop the disorder. Hypertension usually begins after ages 20 to 30 and is uncommon in children and teenagers. In addition to age, gender, and race, other factors that have been linked to high blood pressure include obesity, smoking, a diet high in sodium (such as that found in table salt), excessive use of alcohol, and a family history of the disorder.

How Does the Body Control Blood Pressure?

As the heart pumps blood into the arteries, the blood is kept under constant pressure. Many times per day, blood pressure rises briefly when the heart beats faster to supply blood to the parts of the body that need it. For example, people’s legs will need more blood when they are running a race. After the effort has ended, blood pressure returns to its usual level.

Over time, when a person is at rest, the body controls blood pressure in two basic ways. One way is by constricting (narrowing) the arterioles (ar-TEE-re-olz), blood vessels that branch off larger arteries. The other way is by regulating the fluid volume of the blood.

The kidneys have a key role in both of these functions. By secreting the hormone renin, they cause the arterioles to constrict, thereby raising the blood pressure. In addition, the kidneys control the fluid volume of the blood either by retaining sodium or by excreting it into urine. Blood volume and blood pressure increase when sodium is retained in the body.

Did You Know?

- People almost never can tell whether they have high blood pressure by how they feel.
- About one-third to one-half of the people who have high blood pressure do not even know it.
- Hypertension is called “the silent killer” because it can cause a heart attack or stroke without warning symptoms.
- Many people with mild hypertension can be treated without the use of drugs.
- The guidelines for preventing high blood pressure are the same as the guidelines for leading a healthy life.

* **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

* **heart attack** is a general term that usually refers to a sudden, intense episode of heart injury. It is usually caused by a blockage of a coronary artery, which stops blood from supplying the heart muscle with oxygen.

* **kidneys** are the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **prevalence** of a disease or condition means how common it is in a population of people.

What Is a Sphygmomanometer?

A sphygmomanometer is the instrument that is used to measure blood pressure. It consists of an inflatable cuff, or wide band, that is wrapped around the upper arm, a rubber bulb to inflate the cuff, and a gauge that gives the pressure reading.

When measuring blood pressure, the cuff is inflated until it briefly stops the flow of blood in the arm (a painless process). The air pressure is then gradually released while a stethoscope (STETH-o-scope), a listening device, is placed on the artery of the arm just below the cuff. The pressure when the sound of the pulse is heard as the blood first begins to flow again is called the systolic pressure (the higher number). As more pressure is released, the sound of the pulse becomes muffled and disappears. The pressure at that point is called the diastolic pressure (the lower number).

The pressure is read on a gauge, which can be a glass column filled with mercury (the earliest type), a dial, or a digital readout. In some instruments, the blood pressure may be read directly, without the use of a stethoscope. The actual numbers in blood pressure readings represent millimeters of mercury (mm Hg), based upon the original glass column filled with mercury.

The word “sphygmomanometer” comes from the Greek word “sphygmos,” meaning “pulse,” plus “manometer,” a pressure gauge.

What Causes Hypertension?

Hypertension results when the body systems that keep the width of the arterioles and the fluid volume of the blood in a normal relationship become unbalanced. This disruption may occur due to disease or some other influence. Disease, such as disorders of the kidneys, certain tumors, or artery conditions, account for only about 10 percent of hypertension cases. In the great majority of cases, the precise cause remains unknown. In these instances, the disorder is referred to as “primary hypertension” or “essential hypertension.”

Certain factors are known to be influential in producing hypertension. Factors that may contribute to the development of hypertension include a fatty diet and lack of exercise (which can lead to obesity) and too much salt in the diet. Hypertension also occasionally occurs in women who are taking birth control pills. Other factors include diabetes*, smoking, and excessive alcohol consumption.

How Does Hypertension Affect the Body?

Hypertension rarely causes symptoms by itself. When it does, the blood pressure usually is extremely high. Symptoms may then include headache, nosebleeds, dizziness, confusion, and seizures*. A florid (reddish) complexion is not, as is often believed, a sign of hypertension.

Hypertension leads to or speeds up the process of atherosclerosis (ath-er-o-skle-RO-sis), or hardening of the arteries. In this process, cholesterol and other materials carried in the blood can build up in places along the artery walls damaged by years of high pressure. If a blockage should occur in the coronary arteries, which supply blood to the muscles of the heart, a heart attack can occur. If artery blockage occurs in the brain, the result is a stroke. Damage to arterioles can lead to brain hemorrhage (another kind of stroke), kidney failure, or blindness. Over a period of years, hypertension can bring about heart failure by overworking the heart.

If left untreated, the course of hypertension varies in different people. In most, the blood pressure tends to increase gradually as they age.

Hypertension during pregnancy A serious condition called preeclampsia (pree-ee-KLAMP-see-a) develops during the second half of pregnancy in about 7 percent of women. This disorder is characterized by a sudden rise in blood pressure, along with severe headaches, visual disturbances, and retention of fluids in the body. The condition is most common in first pregnancies and in women younger than 25 or older than 35 years. If left untreated, preeclampsia can lead to eclampsia, which is characterized by seizures and extremely high blood pressure that may be fatal to the mother or baby.

How Is Hypertension Is Defined by Numbers?

Blood pressure is expressed as two numbers: the systolic (sis-TOL-ik) pressure and the diastolic (dy-a-STOL-ik) pressure. The first (higher) number is the systolic pressure, which occurs during systole (SIS-to-lee), when the heart

contracts. The second (lower) number is the diastolic pressure, which occurs during diastole (dy-AS-to-lee), when the heart relaxes between beats.

These numbers are read from a special instrument, called a sphygmanometer (sfig-mo-ma-NOM-e-ter). Written down, the two numbers are separated by a slash. Normal pressure taken at rest in adults should be below 120/80, expressed as “120 over 80.” Healthy young adults typically will have a pressure of about 110/75, however, and normal blood pressures are even lower in young children. As previously mentioned, a pressure of 140/90 or higher (either number) in adults means stage 1 hypertension.

How Is Hypertension Diagnosed?

When assessing or diagnosing hypertension, a physician may take more than one reading, especially if the first reading is high. This is so because blood pressure varies over time. Moreover, some people have what is called “white coat hypertension,” which means that their blood pressure tends to go up when they are being examined by a doctor. To get an accurate reading, doctors try to have their patients feel as relaxed as possible. For people who have never had their blood pressure taken, it is important for a doctor to explain that the process is painless.

Diagnosing high blood pressure involves more than just numbers. A doctor has to try to determine the cause. The patient may be asked about eating and exercise habits. It is often important to know if someone else in the family has a history of high blood pressure. The doctor also may want to know about the patient’s salt intake, consumption of alcohol, smoking habits, use of medications such as birth control pills, and use of street drugs. Urine and blood samples may be taken to check kidney function and blood cholesterol levels.

It is commonly observed that blood pressure tends to go up with age. Although true statistically, this fact does not mean that it is acceptable from a health standpoint. Blood pressure that is equal to or more than 140/90 indicates Stage 1 hypertension and is a cause of concern at any age.

How Is Hypertension Treated?

For the small percentage of people whose hypertension is caused by particular disorders of the kidneys or certain tumors or artery conditions, surgery may be the chosen treatment and should provide a cure. For the great majority, however, the choice of treatment is likely to be changes in lifestyle or medication in addition to lifestyle changes.

Good health habits Many people with prehypertension can lower their blood pressure by making certain modifications in their lifestyle and diet, without the use of drugs. These changes may involve losing weight, getting more exercise, or modifying their diets in certain ways.

Excess weight, especially obesity, can be a factor in raising blood pressure. In losing weight, it is usually best to take a gradual approach and to emphasize reduction of fat in the diet. Any weight loss program should also include regular exercise such as walking briskly or jogging (with a

What the Numbers Mean

Blood pressure is measured in units called millimeters of mercury (mm Hg). It is written as two numbers, one over the other. The number on top is the systolic pressure (when the heart contracts). The bottom number is the diastolic pressure (when the heart relaxes between beats). When systolic and diastolic blood pressures fall into different categories, the higher category should be used to classify blood pressure level.

Blood pressure in adults falls into the following categories:

- **Normal:** systolic: <120 *and* diastolic: <80
- **Prehypertension:** systolic: 120–139 *or* diastolic: 80–89
- **Stage 1 hypertension:** systolic: 140–159 *or* diastolic: 90–99
- **Stage 2 hypertension:** systolic: >160 *or* diastolic: >100

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body’s pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

doctor's approval in adult patients). Many experts believe that it is almost impossible to lose weight permanently through diet alone.

Many people with hypertension can help to lower their blood pressure by adopting a low-sodium, or low-salt, diet. Studies have shown that people can get all the salt that they need in the foods they eat without adding any. Good rules to follow are to add less salt when cooking and at the table and to shop for foods that are low in sodium. Labels on cans or packages of processed food will indicate how much sodium is contained in each portion.

Another factor that may contribute to high blood pressure is stress. Although some stress is unavoidable in daily life, frequent unrelieved stress can be harmful. It is worthwhile to find ways, such as relaxation techniques, to lower stress levels. Physical exercise is an effective way for many people to decrease stress and blood pressure.

Common-sense rules about avoiding harmful substances apply to people with normal as well as high blood pressure. It is not advisable to smoke at any age or for adults to have more than one or two alcoholic drinks per day. The nicotine from cigarettes speeds up the heart and constricts blood vessels. Alcohol abuse has been associated with increased risk of developing hypertension, as well as many other health problems. Street drugs such as cocaine can have a direct adverse effect on the heart and increase blood pressure.

Medication When hypertension is present, or when prehypertension does not respond to diet, exercise, and other lifestyle changes, medicines may be prescribed. Several different types of drugs are available, the choice of which depends upon the particular needs of the patient.

Diuretic drugs are among the more commonly used pharmaceutical products. They act to increase the flow of urine and decrease the blood volume. Another group, called beta-blockers, alters the way the nervous system functions in the control of blood pressure. A third group of drugs, called vasodilators (va-zo-DY-layt-orz), act to relax the blood vessels, thereby decreasing the resistance to blood flow. Other types of drugs may be prescribed as well.

Prescription drugs for hypertension may have various side effects, depending upon the drug and the person taking it. All antihypertensive drugs may cause dizziness and fainting, however, if the blood pressure is lowered too much. It is extremely important not to stop taking medication without consulting a doctor.

Doctors treating hypertension may wish to have their patients monitor their blood pressure by taking readings at regular intervals. Devices for home use are available for this purpose.

Can Hypertension Be Prevented?

For teenagers and young adults, who are unlikely to have the condition early in life, hypertension may seem to be only a remote possibility for some time in the distant future. However, establishing a healthy lifestyle by keeping fit and trim through exercise and good eating habits and not

smoking can help prevent health problems such as hypertension from developing later. This is particularly important for people who have a family history of hypertension.

Last, it is important for people to get their blood pressure checked on a regular basis. Although doing so will not actually prevent hypertension, it can get someone who has the condition into treatment earlier, thereby keeping it under control and lessening the risk of developing serious health problems such as heart attack or stroke.

Hyperthyroidism See *Thyroid Disease*.

* **heart attack** is a general term that usually refers to a sudden, intense episode of heart injury. It is usually caused by a blockage of a coronary artery, which stops blood from supplying the heart muscle with oxygen.

Hypochondria

Hypochondria (hy-po-KON-dree-a) is a mental disorder in which people believe they are sick or have a serious disease, but their symptoms are not related to any physical illness and medical examination or tests show no sign of illness.

More than a Temporary Worry

Many people worried about their health from time to time. For example, a symptom such as chest pain can have many causes and may or may not be serious. But if individuals experiencing this symptom have just read a newspaper article about someone who experienced a heart attack*, they might worry that they are about to have one too. This temporary concern is not an example of hypochondria. With true hypochondria the worry is more lasting, and it interferes with one's daily life.

The prevalence of hypochondria among the general public is unknown, but studies have suggested that it accounts for between 4 and 9 percent of visits to doctors. Hypochondria occurs in all age groups and cultures and is about equally prevalent among males and females.

When Medical Reassurance Does Not Help

People with hypochondria may be overly concerned with a variety of symptoms and even with their normal bodily functions. Minor aches and pains, occasional coughing, dizziness, nausea, or small sores can convince people with hypochondria that they are seriously ill. They may also closely monitor normal bodily functions, such as heartbeat, breathing, sweating, and intestinal function, for signs of disease. The health worries of someone with hypochondria may be focused on a particular body organ, such as the heart, or on several parts of the body.

An important characteristic of people with hypochondria is that they are not fully reassured after a medical examination and tests have shown no physical basis for their complaints. Although their fears may be temporarily relieved, the belief that they are ill may still be so strong that they go from one physician to another seeking new tests and treatments.

What Causes Hypochondria?

People may wonder why some people are constantly worried about being sick. The cause or causes of hypochondria are not clearly understood, and experts have varying opinions.

One theory is that people who have hypochondria are excessively sensitive to their bodily sensations and may misinterpret their meaning. In some cases, hypochondria appears to be triggered by the death of a loved one. Researchers have also noted that hypochondria seems to be

more common in people who were seriously ill when they were children or who have spent a lot of time around sick relatives. Such past experiences may contribute to health worries.

Hypochondria may be one symptom of another mental disorder, such as depression* or anxiety*. For example, in some cases of obsessive-compulsive disorder*, a person may have extreme unfounded health worries and feel compelled to keep seeking reassurance from health professionals.

How Is Hypochondria Diagnosed and Treated?

The first step in diagnosing hypochondria is a thorough physical examination to make sure there is no medical disease or condition causing the patient's complaints. When the patient has been reassured that he or she is not ill, yet the intense health worries continue, the diagnosis of hypochondria may be made. The physician will need to take care not to confuse hypochondria with malingering*, or with such closely related mental conditions as conversion disorder* and Munchausen syndrome*.

Hypochondria can be difficult to treat because the beliefs about illness are usually very strong. Although reassurance that the person is in good health is necessary, it is likely to be helpful only for a short time. Psychotherapy can help individuals make gradual changes in the way they think about their bodily sensations and to cope with health anxiety. When hypochondria is a symptom of depression, anxiety, or obsessive-compulsive disorder, treatment focuses on the underlying disorder.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

* **hormone** is a chemical substance that is produced by a gland and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

* **pancreas** (PAN-kree-us) is a gland located behind the stomach that produces enzymes and hormones necessary for digestion and metabolism.

Hypoglycemia

Hypoglycemia (hy-po-gly-SEE-mee-a) is a condition that occurs when the amount of sugar in the blood gets too low.

Melinda's Story

Melinda was at the mall with friends when she started to feel weak and uncoordinated. She developed a pounding headache, began to shake and sweat, and could not see very well. Because Melinda has diabetes*, her doctor had warned her about these symptoms, and she knew they meant that her blood sugar had gotten too low. She carried candy in her backpack at all times for just such an occasion. Melinda told her friends that she should not have skipped lunch because a sensible diet and regular meals help prevent hypoglycemia in people being treated for diabetes. Melinda told them that hypoglycemia can cause coma* if not treated. After eating her candy bar, Melinda felt better within minutes.

What Is Hypoglycemia?

Hypoglycemia is a common medical emergency and means low (“hypo”) blood sugar (“glycemia”). Hypoglycemia is not a disease; it is a symptom of a problem the body has with regulating blood sugar. Its opposite, hyperglycemia (hy-per-gly-SEE-mee-a), means too much sugar in the blood, which is one of the features of diabetes.

Glucose is a sugar that represents an important source of energy for the body. The main dietary sources of glucose are carbohydrates found in foods such as rice, potatoes, bread, tortillas, cereal, milk, fruit, and sweets. After a meal, digestion breaks down food, and glucose molecules are absorbed into the bloodstream and carried to the cells, where they are used to produce energy. Insulin, a hormone* produced by the pancreas*, helps glucose enter cells. When the body takes in more glucose than needed, the extra glucose is stored in the liver and muscles in a form called *glycogen*, or the extra glucose is converted into fat for storage in fat cells. The body can use the stored glucose whenever it needs energy between meals. When the level of glucose in the blood begins to fall, *glucagon*, another hormone produced by the pancreas, signals the liver to break down glycogen and release glucose. This response increases the blood glucose levels to the normal level. When the level of glucose in the blood begins to rise, special cells, called beta cells, signal the pancreas to release insulin so that glucose can enter cells while also reducing glucose production by the liver. This response lowers the amount of glucose in the bloodstream. As the blood glucose level returns to normal, so does the secretion of insulin from the pancreas.

Insulin-Induced Hypoglycemia

The most frequent cause of hypoglycemia is the excessive effect of an incorrect dose of insulin in patients with diabetes who are being treated with insulin. Most people being treated with insulin for diabetes experience

hypoglycemia. Diabetes is characterized by high levels of sugar in the blood due to the body's inability to make enough insulin or to respond to insulin normally. People being treated with insulin for diabetes sometimes take too much insulin or may not eat enough, as happened to Melinda at the mall. In fact, 90 percent of people with insulin-dependent diabetes experience hypoglycemia; it is almost impossible for them to achieve normal blood glucose levels without having at least occasional episodes of hypoglycemia. The frequency of these episodes is also increased under unsteady conditions, such as infection, exercise, and irregular eating. Severe hypoglycemia is sometimes called "insulin shock," which can occur if diabetics take too much insulin, do not eat frequently enough, or do not eat sufficient amounts of sugar. Taking glucose or other sugar-containing (but not artificial sweetener-containing) beverages by mouth, or glucagon by injection, are effective treatments. Long periods of hypoglycaemia can lead to insulin coma, not to be confused with diabetic coma, resulting from hyperglycemia.

Non-Diabetic Hypoglycemia

In people who do not have diabetes, the three major forms are tumor-induced hypoglycaemia, reactive hypoglycaemia, and fasting hypoglycaemia.

Tumor-induced hypoglycemia Hypoglycemia can occasionally be caused by an insulinoma, a tumor* of the insulin-producing cells of the pancreas. Insulinomas secrete insulin and raise insulin levels too high in relation to the blood glucose level. These tumors are very rare and do not normally spread elsewhere in the body. Other non-islet-cell tumors occurring in the chest or abdomen also secrete insulin-like growth factors that may cause hypoglycaemia.

Reactive hypoglycemia Reactive hypoglycemia occurs after eating, especially after a meal containing lots of sugary or starchy foods. The sugar from the meal causes the body to rapidly produce a great deal of insulin to prevent blood sugar from rising too high. But the body makes so much insulin that the blood sugar level drops too low instead.

Fasting hypoglycemia Fasting hypoglycemia occurs several hours after a person's last meal. It can happen as a result of conditions such as anorexia nervosa*, or starvation.

Other possible causes of low blood sugar in people without diabetes are as follows:

- *Mistaken use of diabetes medication.* The accidental intake of another person's oral diabetes medication is a common cause of hypoglycemia.
- *Some medications.* Medications may cause hypoglycemia in children or in people with kidney failure. One medication known to have had this effect is quinine, used in the treatment of leg cramps and malaria.

* **tumor** (TOO-mor) is an abnormal growth of body tissue that has no known cause or physiologic purpose. A tumor may or may not be cancerous.

* **anorexia nervosa** (an-o-REK-se-a ner-VO-sa) is an emotional disorder characterized by dread of gaining weight, leading to self-starvation and dangerous loss of weight and malnutrition.

* **adrenal glands** (a-DREEN-ai glands) are the pair of endocrine organs located near the kidneys.

- *Alcohol.* Excessive alcohol intake in the absence of meals can block glucose production and deplete the body's stores of glycogen.
- *Some severe illnesses.* Liver disease, such as drug-induced hepatitis (liver inflammation), can cause hypoglycemia because the liver is a key glucose-producing organ. Kidney disease also affects glucose levels.
- *Hyperinsulinemia.* Hyperinsulinemia is characterized by excessively high blood insulin levels. It may be caused by a rare disorder of the beta cells of the pancreas that help release insulin.
- *Endocrine deficiencies.* The endocrine system consists of several glands that produce hormones to regulate all processes throughout the body. Some disorders of the adrenal glands* (Addison's disease) and the pituitary gland (hypopituitarism) can result in hypoglycemia because they cause a deficiency of the key hormones regulating glucose production.

How Is Hypoglycemia Diagnosed?

To find out if a person has hypoglycemia, doctors ask about symptoms and whether they go away when the person eats sugar. The doctor will also examine the patient and take a medical history to look for the specific features of disorders known to be associated with hypoglycemia. Blood tests performed when the person is having symptoms of hypoglycemia can confirm low levels of sugar in the blood, if present, and can measure the levels of insulin and other hormones and substances involved in the control of blood sugar levels. The tests can distinguish between the hypoglycemia symptoms due to adrenalin-related hormones and those due to a shortage of glucose being delivered to the brain ("neuroglycopenia").

Immune Deficiencies

Immune deficiencies (ih-MYOON dih-FIH-shen-seez) are conditions that impair the body's immune system so that it is less capable of fighting infection.

What Are Immune Deficiencies?

Immune deficiencies arise when one or more of the parts of the immune system are missing or not working correctly, leaving the body less able to fight disease-causing agents. There are two types of these deficiencies: primary (inherited) immune deficiencies and secondary (acquired) immune deficiencies.

◀ Primary and Secondary Immune Deficiencies. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

Organisms that typically do not cause problems in a person with a healthy immune system may produce an “opportunistic infection” in a person with an immune deficiency. A person particularly at risk for such infections might be placed in isolation in a sterile environment. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

- * **microorganisms** are tiny organisms that can only be seen using a microscope. Types of microorganisms include fungi, bacteria, and viruses.
- * **toxins** are substances that cause harm to the body.
- * **autoimmune diseases** (aw-toh-ih-MYOON) are diseases in which the body’s immune system attacks some of the body’s own normal tissues and cells.
- * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.
- * **tonsils** are paired clusters of lymphatic tissue in the throat that help protect the body from bacteria and viruses that enter through a person’s nose or mouth.
- * **appendix** (ah-PEN-diks) is the narrow, finger-shaped organ that branches off the part of the large intestine in the lower right side of the abdomen. Although the organ is not known to have any vital function, the tissue of the appendix is populated by cells of the immune system.

The immune system has many parts that work together to protect the body from foreign invaders, such as microorganisms* and toxins*. When any segment of the immune system is absent or breaks down, it can lead to an immune deficiency. With so many elements of the immune system, there are more than 80 different types of primary immune deficiencies. They range from those that have severe and sometimes fatal effects to mild diseases that cause people few, if any, problems. About half a million people in the United States have some type of primary immune deficiency, with more boys than girls affected by these conditions.

Secondary immune deficiencies are much more common than inherited deficiencies. Unlike patients with primary immune deficiencies, people with secondary immune deficiencies are born with a healthy immune system, but sometime later in life the system becomes weakened or damaged. Both primary and secondary deficiencies typically lead to frequent infections and sometimes to additional medical problems, including certain cancers. These people often experience a variety of skin, respiratory, and bone problems as well, and they are more likely to have autoimmune diseases*.

What Is the Immune System?

The immune system consists of a group of organs, cells, and a specialized system called the lymphatic (lim-FAH-tik) system that helps clear infectious agents from the body. Together, they guard the body against infectious diseases. The lymphatic system is a key part of the immune system: it consists of lymphatic vessels, lymph nodes*, and the thymus (THY-mus) and spleen. Lymph nodes and lymphatic vessels transport lymph, a clear fluid that contains white blood cells called lymphocytes (LIM-fo-sites), throughout the body. The lymphocytes mature in the thymus, a gland located behind the breastbone. The spleen, an organ that is the center of certain immune system activities, is found in the upper-left side of the abdomen. Lymphatic tissue is also found in other locations throughout the body, including the tonsils* and the appendix*.

When a foreign substance or microorganism enters the body, phagocytes (FAH-go-sites) often are the first cells at the site. These large scavenger white blood cells patrol the bloodstream, looking for possible invaders. When they find one, they engulf, digest, and destroy the intruder.

Other components of the immune response react when presented with specific antigens*. The most important players in this fight are two types of lymphocytes that learn to recognize and destroy the foreign invaders.

B cells, the first type, are white blood cells that produce antibodies*, which circulate in the blood and lymph streams. The first time B cells encounter a new foreign substance, they make antibodies in response to the intruder’s antigens. When the antibodies come across that specific antigen again, they attach themselves to it, marking it (and with it, the entire foreign substance or microorganism) for destruction by other

cells. Antibodies also summon phagocytes and body chemicals, such as complement proteins*, to the site of an infection and move them into action against the antigens.

T cells, the second type, are specialized white blood cells that have several roles. They monitor and coordinate the entire immune response, which includes recruiting many different cells to take part in that response. Some T cells, the T helper cells, signal the B cells to start making antibodies. Other T cells, the T killer cells, attack and destroy substances that they recognize as foreign. Once the foreign antigens have been defeated, cleanup crews of scavenger phagocytes called neutrophils (NU-tro-fils), a type of white blood cell that can surround and destroy invading organisms, and macrophages (MAH-kro-fay-jez), another form of engulf-and-destroy cell, arrive to clear up remains of the infection.

What Are Primary Immune Deficiencies?

A genetic* abnormality in any type of cell of the immune system can lead to a primary immune deficiency. Some of these deficiencies produce no symptoms, whereas others cause severe symptoms and may even be fatal. Although primary immune deficiencies are present at birth, some patients do not begin to show signs of the condition until later in childhood or even beyond childhood.

There are several well-known primary immune deficiencies. About 1 person in 600 is born with selective IgA deficiency, a mild disease that most often affects those of European ancestry. People with this condition lack immunoglobulin (ih-myoo-no-GLAH-byoo-lin) A (IgA), a class of antibodies that fight organisms that can infect the mucous membranes that line the mouth, airways, and digestive system*. Many patients with this disorder experience few symptoms, but some may have frequent infections.

The effects of common variable immunodeficiency, also known as hypogammaglobulinemia (hi-po-gah-muh-gloh-byoo-lih-NEE-me-uh), can range from mild to severe. Its symptoms occasionally affect infants but often do not appear until early adulthood. Those symptoms include frequent bacterial infections of the ears, sinuses*, bronchi*, or lungs brought on by low levels of various immunoglobulins, including IgA and IgG.

Caused by defective genes on the X chromosome*, X-linked agammaglobulinemia (a-gah-muh-gloh-byoo-lih-NEE-me-uh) is uncommon and affects only males. Patients have very low levels of mature B cells as well as low levels of immunoglobulins, which can result in pus* collections in the lungs, sinuses, and ears in addition to other infections.

SCID, also known as bubble boy disease, strikes about 1 in one million people. This group of immune disorders is marked by major deficiencies in B cells and T cells, low levels of white blood cells, and decreased levels of IgA, IgG, and IgM antibodies. Such massive defects in the immune

The SCID Mouse

To gain a better understanding of the human immune system, scientists developed a laboratory mouse that lacks an enzyme necessary for its immune system to function properly. Like people with severe combined immunodeficiency disease (SCID), these mice cannot fight infections.

Another very useful mouse model was developed in the 1980s, when scientists transplanted parts of the human immune system into the mouse. This gave an opportunity to researchers to study the workings of the human immune response more easily, as well as the impact of drugs and viruses on the immune system. This mouse has been described as a “living test tube.”

* **antigens** (AN-tih-jens) are substances that are recognized as a threat by the body's immune system, which triggers the formation of specific antibodies against the substance.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **complement proteins** are proteins that circulate in the blood and play a role in the immune system's response to infections. More than 20 complement proteins have been identified.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **digestive system** is the system that processes food. It includes the mouth, esophagus, stomach, intestines, colon, rectum, and other organs involved in digestion, including the liver and pancreas.

- * **sinuses** (SY-nuh-ses) are hollow, air-filled cavities in the facial bones.
- * **bronchi** (BRONG-kye) are the larger tube-like airways that carry air in and out of the lungs.
- * **chromosome** (KRO-mo-zom) is a unit or strand of DNA, the chemical substance that contains the genetic code to build and maintain a living being. Humans have 23 pairs of chromosomes, for a total of 46.
- * **pus** is a thick, creamy fluid, usually yellow or ivory in color, that forms at the site of an infection. Pus contains infection-fighting white cells and other substances.
- * **pneumonia** (nu-MO-nyah) is inflammation of the lungs.
- * **sepsis** is a potentially serious spreading of infection, usually bacterial, through the bloodstream and body.
- * **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.
- * **chronic** (KRAH-nik) lasting a long time or recurring frequently.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.
- * **cirrhosis** (sir-O-sis) is a condition that affects the liver, involving long-term inflammation and scarring, which can lead to problems with liver function.

system can leave patients open to many serious, even fatal infections, including the following:

- pneumonia*
- sepsis*
- meningitis*

Other primary immune deficiency diseases may involve other components of the immune system, including neutrophils and phagocytes. There may be fewer of these cells produced, as occurs in a condition known as neutropenia (nu-tro-PEE-nee-uh), which is marked by low levels of neutrophils in the blood. Chronic* granulomatous (gran-yoo-LO-muh-tus) disease is an immune disorder in which bacteria-fighting phagocytes are present but do not work properly. Genetic defects also can impair the complement system, a series of 20 or more proteins that come together during the body's immune response to complement (support) the work of antibodies. These conditions and defects in other parts of the complex immune system cause problems with the body's immune response, often making a person more susceptible to a variety of infections.

What Are Secondary Immune Deficiencies?

Secondary immune deficiencies are acquired, rather than inherited, disorders. Many chronic conditions, such as diabetes*, cancer, and cirrhosis* of the liver, make a person more likely to have infections. Patients who have had their spleens removed or whose spleens do not work properly, as occurs in sickle-cell disease*, for example, are especially vulnerable to infection by certain bacteria that the spleen normally fights. In addition, some medications, particularly corticosteroids* and drugs used to treat cancer, may limit the immune system. Malnutrition, especially when there is a lack of protein in the diet, also may weaken the immune response.

The human immunodeficiency virus (HIV*), a virus that attacks the immune system and is the cause of acquired immunodeficiency syndrome (AIDS*), is responsible for a sharp increase in the number of people with secondary immune deficiencies. HIV destroys T cells, which are crucial to the normal functioning of the human immune system. This condition can lead to overwhelming infections. People can contract the virus through contact with blood, semen*, vaginal* secretions, and breast milk.

What Are the Signs and Symptoms of Immune Deficiencies?

Immune deficiencies may be characterized by frequent, recurrent, or prolonged infections. In some cases, there may be an overwhelming or unusual infection. In others, organisms that typically do not cause problems in a person with a healthy immune system may produce an opportunistic infection* in a person with an immune deficiency. These infections are seen in people infected with HIV and often mark the onset of AIDS.

Other immune deficiencies are characterized by chronic opportunistic infections. Depending on the condition, patients may experience

recurrent lung and sinus infections, weakness, tiredness, a lingering cough, diarrhea (dye-uh-REE-uh), skin rashes, and hair loss. Many patients simply look sick. Signs of immune deficiencies also include poor response to treatments, incomplete or slow recovery from illness, fungal or yeast infections that keep coming back, and certain specific infections, such as pneumonia caused by *Pneumocystis carinii* (nu-mo-SIS-tis kah-RIH-nee-eye).

How Are Immune Deficiencies Diagnosed?

Although symptoms of opportunistic infections may suggest an immune deficiency, laboratory tests are needed to diagnose the specific deficiency. These include blood tests to measure levels of white blood cells, red blood cells, and platelets* and to measure the presence of specific types of cells, such as B cells and T cells. Other blood tests can measure the levels or function of antibodies (such as IgA, IgG, and IgM) and complement proteins. Skin tests may be done to check the responses of T cells. Other, more specific tests of the immune system's competency depend on the type of deficiency suspected.

How Are Immune Deficiencies Treated?

The primary goal in treating immune deficiencies is to prevent infections. Although it is a good idea for some people who have immune deficiencies to avoid contact with people who have infections, doing so is not always practical. Many patients take daily medication to prevent certain infections, and patients with antibody deficiencies may receive regular doses of the immunoglobulins they lack. People who have HIV or AIDS take combinations of drugs to keep the virus from making more copies of itself and destroying more T cells. Bone marrow* transplantation, to replace the absent or poorly functioning immune system cells of the affected person, is necessary for some patients with severe immune deficiencies, such as SCID. Prompt recognition and treatment of infections, including opportunistic infections, is essential.

- * **sickle-cell disease** is a hereditary condition in which the red blood cells, which are usually round, take on an abnormal crescent shape and have a decreased ability to carry oxygen throughout the body.
- * **corticosteroids** (kor-tih-ko-STIR-oyds) are chemical substances made by the adrenal glands that have several functions in the body, including maintaining blood pressure during stress and controlling inflammation. They can also be given to people as medication to treat certain illnesses.
- * **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).
- * **semen** (SEE-men) is the sperm-containing whitish fluid produced by the male reproductive tract.
- * **vaginal** (VAH-jih-nul) refers to the canal in a woman that leads from the uterus to the outside of the body.
- * **opportunistic infection** are infections caused by infectious agents that usually do not produce disease in people with healthy immune systems but can cause widespread and severe illness in patients with weak or faulty immune systems.
- * **platelets** (PLATE-lets) are tiny disk-shaped particles within the blood that play an important role in clotting.
- * **bone marrow** is the soft tissue inside bones where blood cells are made.

- * **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.
- * **fungi** (FUNG-eye) are microorganisms that can grow in or on the body, causing infections of internal organs or of the skin, hair, and nails.
- * **parasites** (PAIR-uh-sites) are organisms such as protozoa (one-celled animals), worms, or insects that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. Parasites live at the expense of the host and may cause illness.
- * **viruses** (VY-rus-sez) are tiny infectious agents that can cause infectious diseases. A virus can only reproduce within the cells it infects.
- * **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.
- * **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

Immune System and Other Body Defenses: Overview

The skin and the immune system help protect the body from infection and disease.

The First Line of Defense: Physical Barriers

The human body is constantly under the threat of attack from foreign invaders that can cause infection and disease. These invaders range from living microbes (MY-krobes), such as bacteria*, fungi*, parasites*, and viruses*, to non-living toxins, chemicals, and drugs. Fortunately, the body has a number of safeguards, located at the surface and internally, that prevent most foreign invaders from entering or causing harm. The physical barriers that keep these invaders at bay are often referred to as the body's first line of defense.

The skin is the largest organ in the body, and it provides both a physical and a chemical barrier against the outside world. The skin forms a protective layer that shields blood vessels, nerves, muscles, bones, and organs. Human skin serves also as a chemical shield; it produces peptide antibiotics* that it secretes in response to the skin's coming into contact with some microorganisms.

However, no organism is sealed completely against its environment. The human body has direct contact with the external environment in multiple places (not just at the skin's surface). The walls of the lungs' airways and the mucus-coated surfaces of the intestines are barriers between the human body and potentially harmful agents from the external environment.

The moist linings of the lungs' airways protectively secrete mucous (MYOO-kus), a sticky substance that traps microbes and other irritants that enter the body through the nose and throat. Tiny hairs, called cilia (SIH-lee-uh), are thread-like projections that line the trachea and the lungs and propel foreign particles and mucus out of the respiratory tract and away from the lungs to a place where they can be swallowed safely. The majority of harmful microbes that make it to the stomach are destroyed by stomach acids. In addition, tears and saliva both contain peptide antibiotics that destroy invaders.

Another important defense mechanism is the brain-blood barrier at the interface between circulating blood and the brain. The blood-brain barrier is a semi-permeable layer of cells that lines individual brain capillaries. It is a specialized "filter" that surrounds the brain and spinal cord and acts as a physical barrier to prevent proteins, toxins, and most microbes from entering brain cells while letting in glucose, the brain's principal nutrient.

The Second Line of Defense: The Immune System

A second line of defense is the intricate and complicated immune system*, whose function is to recognize and destroy foreign substances and microorganisms that enter the body. The properly functioning immune

Organs of the Immune System

The human body has several lines of defense against infection which work to prevent germs from invading the body or to destroy them once they find their way in. *National Institutes of Health. Reproduced by permission.*

- * **antigens** (AN-tih-jens) are substances that are recognized as a threat by the body's immune system, which triggers the formation of specific antibodies against the substance.
- * **histamine** (HIS-tuh-meen) is a substance released by the body during inflammation. It causes blood vessels to expand and makes it easier for fluid and other substances to pass through vessel walls.
- * **bone marrow** is the soft tissue inside bones where blood cells are made.
- * **lymphatic system** (lim-FAH-tik) is a system that contains lymph nodes and a network of channels that carry fluid and cells of the immune system through the body.

system can distinguish between the body's own tissues and foreign substances. It recognizes foreign entities by the presence of antigens*, usually located on the outside surfaces of these substances. (The body's cells have their own antigens, but these antigens are not recognized as foreign.) This ability to distinguish allows cells of the immune system to identify and destroy only those substances that carry harmful antigens. The immune system is also able to “remember” antigens that the body has been exposed to on a prior occasion, so that the body can mount a better and faster immune response the next time any of these antigens appears.

Inflammation Inflammation is one sign that the immune system is reacting to infection. Inflammation occurs when a tissue is injured. To the eye, inflamed skin may appear red and swollen, and the area may feel slightly warm to the touch. Indeed, inflammation is characterized by pain, redness, heat, and swelling. Inflammation also may cause a fever, which may help to kill bacteria or viruses at the site of the infection.

When bacteria, toxins, burns, or other culprits damage tissue, the injured tissues leak chemicals, including histamine* and other substances. This chemical mixture causes blood vessels around the damaged area to saturate injured tissues and make them swell. The increased flow of blood and fluid to the area also brings phagocytes and other infection-fighting cells to take care of any toxins or other antigens in the area. Pus, which is a whitish fluid containing dead body cells and tissue, dead bacteria, dead toxins, and dead and living phagocytes, sometimes forms at the site of inflammation.

Lymphocytes Lymphocytes (LIM-fo-sites), a kind of white blood cell that develops in bone marrow*, circulate throughout the body in the bloodstream and in the lymphatic system*. Lymphocytes are the part of the immune system that has the capacity to recognize and remember disease-causing agents.

Lymphocytes can be divided into two classes: B lymphocytes and T lymphocytes. B lymphocytes (or B cells) produce immunoglobulins (ih-myoo-no-GLAH-byoo-lins), also called antibodies. One particular B lymphocyte recognizes a specific antigen; its activity is triggered when it encounters its “matching” antigen. The activated B lymphocytes go to work, synthesizing and releasing rapidly large numbers of antibodies. The antibodies bind to specific antigens (and may in the act of binding neutralize the offending agent's capacity to do harm). Antibodies also stimulate the activity of phagocytic cells, which work with another type of white blood cell, called phagocytes (FAH-go-sites)—scavenger cells that surround and digest infected cells or microorganisms—and destroy the invaders.

T lymphocytes (or T cells) help to regulate the immune response. Several subsets of T cells have been discovered, each subset having a different function. Some T cells produce chemical messengers that communicate with and attract other kinds of white cells, whose assistance is needed. Some destroy virally infected cells and tumor cells. Some

T cells, like B cells, are antigen-specific and destroy foreign antigens or the substances that carry them.

Targeting antigens with antibodies Almost all activity of B cells and of some T cells targets specific antigens. That is, each time a new kind of foreign agent carrying a particular kind of foreign antigen invades the body, the immune system must produce a new round of B cells and T cells, which attack only that antigen. It is estimated that a healthy immune system can create more than 100 million types of antibodies. As some B cells and T cells mature, they begin to distinguish between the body's own cells and tissues that do not belong in the body. These immune cells become "memory" cells, because they remember a particular antigen, so that the next time it appears, the immune response can mobilize quickly.

In some cases, people acquire permanent immunity* to a disease; for example, people who contract chicken pox usually will not have it again, or, if they do, they have a much milder case.

When a B cell encounters a foreign invader, it starts to produce immunoglobulins or antibodies. An antibody is a very large protein molecule, and it has an antigen-binding site. Like a key designed to fit only a specific lock, an antibody "locks" onto a single type of antigen like an identifying marker. The combination of antigen and antibody (bound to each other) is known as an "antigen-antibody complex" or an "immune complex." There is also something called the "complement system." Immune complexes attract complement proteins, which normally circulate in the bloodstream in an inactive form. The complement proteins are a group of proteins that work to "complement," or amplify, the activities of antibodies.

T cells and cytokines Once the antibody binds to the antigen, a group of T cells known as helper T cells, which have become activated by the presence of the same antigen, secrete signaling molecules, small peptide molecules known as cytokines. These signaling molecules stimulate other white blood cells (or they induce white blood cells to stimulate yet another set of white blood cells) in such a way that the activity of the antibodies is enhanced, or they may draw white blood cells to the site of infection or injury. Some T cells, called killer T cells, are specialized to attack and destroy target cells. At the same time, millions of antibodies circulate in the bloodstream to bind to other "matching" antigens they encounter and so mount a larger attack.

Interferons are a group of cytokines that enhance and amplify immune response and are also used in medical therapies. The singular form, interferon, is used to refer to these therapies. Interferon has been effective in slowing the growth of some cancers. Among them are chemicals that alert phagocytes to the site of the infection. The complement system, a group of proteins that circulate in blood in inactive form, are activated by a large number of triggers, including the presence of antigen-antibody complexes at sites of infection. The proteins migrate to the site of an infection, where they amplify the already existing immune response and help to break up and dissolve microorganisms and foreign particles.

* **immunity** (ih-MYOOON-uh-tee) is the condition of being protected against an infectious disease. Immunity often develops after a germ has entered the body. One type of immunity occurs when the body makes special protein molecules called antibodies to fight the disease-causing germ. The next time that germ enters the body, the antibodies quickly attack it, usually preventing the germ from causing disease.

- * **rheumatoid arthritis** (ROO-mah-toyd ar-THRY-tis) is a chronic disease characterized by painful swelling, stiffness, and deformity of the joints.
- * **lupus** (LOO-pus) is a chronic, or long-lasting, disease that causes inflammation of connective tissue, the material that holds together the various structures of the body.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

Other Defenses

In addition to physical barriers (such as the skin and the mucous coating of inner membranes) and the immune system, the body has several other defense mechanisms that fight harmful invading agents. Coughing and sneezing are automatic reflexes that can rid the body of irritants. Tears serve a similar purpose.

Immune Response Effectiveness and Disease

Strong and healthy immune systems successfully ward off many diseases, particularly infections, but weakened immune systems are less able to do so. Thus, a weakened immune system gives various diseases an opportunity to develop. Age affects the immune system's effectiveness and can be a cause of immune deficiency. Newborns and the elderly may have weak or impaired immune responses to infectious disease. The immune systems of newborns are not fully developed at birth but typically become stronger during the first year of life. Breastfeeding strengthens the infant's developing immune system.

Autoimmune diseases A functioning immune system may be overactive and may mount an immune response against substances and tissues normally present in the body (i.e., the body attacks its own cells), giving rise to a number of immunological (ih-myoo-no-LAH-jih-kul) disorders, which are called autoimmune (aw-toh-ih-MYOON) diseases. In autoimmune diseases, the body cannot distinguish between itself and foreign particles: it may turn its disease-fighting powers on its own tissues, blood, and organs.

As of the early 2000s, more than 80 chronic autoimmune diseases had been identified. These diseases affect women more than men. According to the American Autoimmune Related Diseases Association, regarding the known chronic autoimmune diseases, about 75 percent of cases occur in women, and women appear to be most vulnerable to these diseases during their childbearing years when the levels of hormones are highest in their bodies.

Heredity seems to play a part as well. An individual may inherit a predisposition toward autoimmune diseases in general but may not have the same disease a close relative has. For example, a grandmother may have rheumatoid arthritis*, and the granddaughter may have lupus*. These diseases are related in many ways, but they are different diseases.

Medical conditions that increase risk of infectious disease

Some common medical conditions can put people at increased risk for infectious disease.

- People with diabetes* are especially prone to infection, in part because high blood sugar levels can interfere with white blood cell function.

- Individuals with chronic lung diseases are often at a high risk for pneumonia and bronchitis.
- Urinary tract infections tend to occur more frequently among people born with an abnormal urinary tract or among those who have experienced a urinary tract obstruction, such as a kidney stone*.
- People with certain types of heart disease, particularly diseases of the heart valves, are at greater risk for endocarditis (en-do-kar-DYE-tis), an inflammation of the inner lining of the heart, after dental procedures or surgery.
- Chronic malnutrition that includes a protein deficiency will result in immune problems, in part because immunoglobulins and other molecules are themselves proteins.

Compromised Immune Systems

Chronic diseases can wear down the immune system and make people more susceptible to infection. An immune system that is weakened in this way is said to be compromised. Following are major examples of compromised immune systems and the infectious diseases they can cause.

- Sickle-cell anemia* causes damage to the spleen*. Because the spleen helps to protect the body against bacterial infections, sickle-cell anemia leaves the body more vulnerable to them.
- Human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see) (HIV) infection badly damages and weakens the immune system, and persons with HIV are susceptible to life-threatening infections that take advantage of their failing immune system. In many cases, prompt diagnosis of such “opportunistic” infections and treatment of the underlying HIV with combinations of antiviral drugs have been shown to slow the immune system’s deterioration.
- Certain drugs and drug therapy regimens can also undermine the work of the immune system. Anti-cancer drugs, which usually target rapidly dividing cells, often kill vital beneficial white blood cells in the bone marrow.
- Patients who receive organ transplants are given high dosages of corticosteroid* drugs, which suppress the immune response, in an attempt to prevent their bodies from rejecting the transplanted tissue, which typically is recognized as “foreign.”
- Some people are born with immune system deficiencies, in whom some component of the immune system is missing or does not function adequately. These persons are said to have primary immunodeficiencies. Most primary immunodeficiencies are genetic disorders. They are often diagnosed in children under the age of one year.

* **kidney stone** is a hard structure that forms in the urinary tract. This structure is composed of crystallized chemicals that have separated from the urine. It can obstruct the flow of urine and cause tissue damage and pain as the body attempts to pass the stone through the urinary tract and out of the body.

* **sickle-cell anemia** also called sickle-cell disease, is a hereditary condition in which the red blood cells, which are usually round, take on an abnormal crescent shape and have a decreased ability to carry oxygen throughout the body.

* **spleen** is an organ in the upper left part of the abdomen that stores and filters blood. As part of the immune system, the spleen also plays a role in fighting infection.

* **corticosteroid** (KOR-ti-ko-STER-oid) is one of several medications that are prescribed to reduce inflammation and sometimes to suppress the body’s immune response.

- * **sepsis** is a potentially serious spreading of infection, usually bacterial, through the bloodstream and body.
- * **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.
- * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.
- * **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.
- * **allergies** (AL-uh-r-jeez) are immune system-related sensitivities to certain substances, for example, cat dander or the pollen of certain plants, that cause various reactions, such as sneezing, runny nose, wheezing, or swollen, itchy patches on the skin, called hives.
- * **asthma** (AZ-mah) is a condition in which the airways of the lungs repeatedly become narrowed and inflamed, causing breathing difficulty.
- * **placenta** (pluh-SEN-ta) is an organ that provides nutrients and oxygen to a developing baby; it is located within the womb during pregnancy.

- Hypogammaglobulinemias (hi-po-gah-muh-gloh-byoo-lih-NEE-me-uhs) are conditions in which the body has fewer antibodies than normal, which always means an increased risk of infection. Hypogammaglobulinemias frequently result in a greater number of bacterial respiratory illnesses.
- Agammaglobulinemias (a-gah-muh-gloh-byoo-lih-NEE-me-uhs) are conditions characterized by the absence of antibodies in the body and can cause severe, often fatal infections.

Other primary immune disorders include the following:

- Severe combined immune deficiency syndrome, in which an infant is born with a significant lack of both B cells and T cells, often leads to serious immunity problems; it occurs in one in one million births. During the first three months of life, babies with this condition can experience life-threatening infections and diseases, particularly sepsis*, pneumonia, and meningitis*. Common childhood diseases, such as chicken pox, can easily overwhelm these patients' immune systems.
- Chronic granulomatous (gran-yoo-LO-muh-tus) disease occurs in males when the body's phagocytes are ineffective against certain bacteria and fungi. Patients develop recurrent and unusual skin, lymph node*, and other infections. Repeated infections can lead to granulomas (gran-yoo-LO-muhs), masses that develop in the skin, lungs, liver*, lymph nodes, and bones. They can be slow to heal and drain.

Other Influences on Body Defenses

Many environmental factors can affect the health of the immune system. In environments in which cigarette smoking is rife, for example, people are more at risk for lung cancer and respiratory ailments, both of which can lead to various secondary infections, including bronchitis. Second-hand smoke, or passive smoking, increases the incidence of respiratory infections in both infants and children. Children who are exposed to second-hand smoke may be predisposed to pneumonia, allergies*, and asthma*, as well as repeated irritations of the eyes, nose, and mouth.

Nutrition, too, has an impact on the immune system. Diets deficient in a variety of nutrients, such as certain vitamins, minerals, or protein, can cause increased vulnerabilities to infection.

Medical Ways of Boosting the Immune System

In some instances, a patient will be given antibodies produced by another person to boost his or her own immunity, which is known as passive immunity. Infants are born with immature immune systems and receive important antibodies from their mothers prior to birth (across the mother's placenta*) and after birth from breast milk. These maternal antibodies usually disappear in the infant's system within 6 to 12 months, but until

that time they help to protect the infant against a range of infections, including pneumonia*, bronchitis*, influenza*, and ear infection.

Doctors can also give gamma globulin (GAH-muh GLAH-byoo-lin) to patients, antibody preparations that offer temporary immunity to individuals who might need this protection. When individuals receive an immunization or are given a vaccine*, their body's immune system is being primed to recognize the particular bacterium or virus that forms the basis of the vaccine. If, sometime later, these individuals are exposed to the same bacterium or virus, they will probably be able to fight off the infection again and not come down with the infectious disease.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

* **bronchitis** (brong-KYE-tis) is a disease that involves inflammation of the larger airways in the respiratory tract, which can result from infection or other causes.

* **influenza** (in-floo-EN-zuh), also known as the flu, is a contagious viral infection that attacks the respiratory tract, including the nose, throat, and lungs.

* **vaccine** (vak-SEEN) is a preparation of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.

- * **immunoglobulins** (im-mune-o-GLOB-u-linz) are types of antibodies.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.
- * **susceptibility** (su-sep-ti-BIL-i-tee) means having less resistance to and higher risk for infection or disease.
- * **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).
- * **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.
- * **bone marrow** is the soft tissue inside bones where blood cells are made.
- * **foreign** means coming from outside a person's body.
- * **antigen** (AN-tih-jen) is a substance that is recognized as a threat by the body's immune system, which triggers the formation of specific antibodies against the substance.
- * **virus** (VY-rus) is a tiny infectious agent that can cause infectious diseases. A virus can only reproduce within the cells it infects.
- * **bile** is a greenish-brown fluid manufactured in the liver that is essential for digesting food. Bile is stored in the gallbladder, which contracts and discharges bile into the intestine to aid digestion of fats after a person eats.
- * **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.
- * **respiratory** (RES-pi-ra-to-ree) refers to the breathing passages and lungs.

Immunoglobulin Deficiency Syndromes

Immunoglobulin deficiency syndromes (IDS) are immunodeficiencies in which some or all antibodies* are deficient or absent, resulting in susceptibility* to frequent, severe, and/or unusual infections.*

What Are Immunoglobulin Deficiency Syndromes?

There are many types of IDS, most of which are inherited or primary immunodeficiencies. Secondary immunodeficiencies are caused by an underlying disease or outside agent, such as HIV* or chemotherapy*.

The immune system B-cells or B-lymphocytes are the antibody-producing cells of the humoral or antibody-mediated immune response. Bone marrow* stem cells develop into precursor B-lymphocytes, which mature into B-cells. Each B-cell produces a specific antibody that recognizes and binds to a specific foreign* antigen*, such as a bacterium or virus*. When a B-cell encounters its antigen, it is stimulated to become a plasma cell and produces large amounts of antibodies that recognize that antigen.

Antibodies are protein molecules called immunoglobulins (Igs). There are five major classes of Igs:

- IgG is the most long-lasting and abundant antibody, present in large amounts in the bloodstream and tissues.
- IgM is the first type of antibody produced by B-cells. Later in the immune response IgM is replaced by a different Ig class with the same antigenic specificity.
- IgA antibodies are secreted in tears, bile*, saliva, and mucus*. They protect the respiratory* and gastrointestinal* tracts from infection.
- IgE antibodies are responsible for allergic reactions.
- IgD antibodies may help regulate B-cell function. They are present in only minute amounts.

Igs consist of four chains of amino acids*: two longer heavy chains and two shorter light chains that together form a "Y"-shaped protein. Each arm of the "Y" forms a binding site for the antibody's specific antigen.

T-cells or T-lymphocytes are part of the cellular or cell-mediated immune response:

- Killer or cytotoxic T-cells directly destroy antigens.
- Helper T-cells assist B-cells in producing antibodies and killer T-cells in attacking antigens.
- Regulatory T-cells suppress the actions of other T-cells.

Most IDS result from a failure in either the maturation of B-cells or the ability of B-cells to switch from one type of Ig production to another.

With some types of IDS, the cellular immune system* retains its functions. However, B-cells are dependent on T-cells for producing antibodies; thus, some Ig deficiencies result from impaired T-cell function.

Primary IDS Primary IDS are caused by genetic* defects that are inherited as either X-linked or autosomal recessive traits. Recessive traits are usually only apparent in the absence of a normal copy of a gene. Because males have only one X chromosome*, inherited from their mothers, genes for recessive disorders that are located on the X chromosome* (X-linked) usually cause disease only in males. Females have two X chromosomes and are unlikely to inherit two X-linked defective genes*, although they can pass a defective gene on to their offspring. Autosomal recessive IDS are caused by defective genes on chromosomes other than the X chromosome. Autosomal recessive IDS affect both males and females, but tend to be less common than X-linked IDS.

There are many different types of primary IDS, involving many different genes. Some cause deficiencies in all types of Ig molecules and some affect only one or a few types:

- X-linked agammaglobulinemia (XLA) causes severe deficiencies in all Igs due to a mutation* in a gene that is required for the normal maturation of precursor B-cells into B-lymphocytes.
- Common variable immune deficiency (CVID) is a relatively common IDS in which the degree and type of Ig deficiency and other lymphocyte abnormalities vary greatly. Most CVIDs result from the failure of B-cells to mature into antibody-producing plasma cells. In some CVIDs T-helper cells fail to promote a full antibody response or there are an excessive number of killer T-cells. Mutations in several different genes have been associated with CVID, although in most cases the genetic cause is unknown.
- Hyper-IgM (HIM) syndrome* with IgG deficiency can be caused by a variety of genetic defects that prevent interactions between T- and B-cells that are required for switching antibody production from IgM to IgG, IgA, or IgE. These result in normal or increased levels of IgM and deficiencies in IgG and IgA. The most common defect is an X-linked recessive trait that affects only males (XHIM). Defects in two autosomal genes that are involved in IgM switching cause HIM without affecting T-cell function.
- Selective IgG subclass deficiencies affect only one or two of the four IgG subclasses. They can result from defects in B-cell maturation that prevent the switching of IgG production from one subclass to another. Because IgG subclasses have somewhat different functions, a deficiency in one subclass increases susceptibility to only certain types of infections. IgG2 deficiency often occurs in combination with IgG4 and IgM deficiencies.
- Selective IgA deficiency is the inability of B-cells to switch from producing IgM to producing IgA, resulting in the complete absence

What Is Bruton's Agammaglobulinemia?

XLA was one of the first known immunodeficiency disorders. It was described in 1952 by Ogden Bruton (1908–2003).

In 1993 the gene that causes XLA was discovered on the X chromosome. It was named BTK for Bruton's tyrosine kinase.

* **gastrointestinal** (gas-tro-in-TES-tih-nuhl) means having to do with the organs of the digestive system, the system that processes food. It includes the mouth, esophagus, stomach, intestines, colon, and rectum and other organs involved in digestion, including the liver and pancreas.

* **amino acids** (a-MEE-no acids) are the chief building blocks of proteins. In humans, certain amino acids are required to sustain life.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **chromosome** (KRO-mo-zom) is a unit or strand of DNA, the chemical substance that contains the genetic code to build and maintain a living being. Humans have 23 pairs of chromosomes, for a total of 46.

* **X chromosome** (X KRO-mo-som), A chromosome is a structure inside the body's cells containing DNA, the genetic material that helps determine characteristics, such as whether a person has brown hair or blue eyes. The X chromosome carries many different genes. Females have two X chromosomes, while males have only one.

- * **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.
- * **mutation** (myoo-TAY-shun) is a change in an organism's gene or genes.
- * **syndrome** is a group or pattern of symptoms or signs that occur together.
- * **transient** (TRAN-shent) means brief or producing effects for a short period of time.
- * **chronic** (KRAH-nik) lasting a long time or recurring frequently.
- * **diarrhea** (di-ah-RE-a) refers to frequent, watery stools (bowel movements).
- * **nutrients** are the components of food (protein, carbohydrate, fat, vitamins, and minerals) needed for growth and maintenance of the body.
- * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.
- * **spleen** is an organ in the upper left part of the abdomen that stores and filters blood. As part of the immune system, the spleen also plays a role in fighting infection.
- * **allergies** (AL-uhr-jeez) are immune system-related sensitivities to certain substances, for example, cat dander or the pollen of certain plants, that cause various reactions, such as sneezing, runny nose, wheezing, or swollen, itchy patches on the skin, called hives.

of IgA. Most people with selective IgA deficiency have only mild symptoms or none at all; however, some people are extremely susceptible to infection, perhaps because they also lack IgG2 and/or IgG4. Although unknown, the cause of IgA deficiency may be a combination of genetic and environmental factors.

- Selective IgM deficiency is similar to CVID.
- Selective IgE deficiency does not usually cause symptoms.
- Heavy-chain deletions occur when part of a gene encoding an Ig heavy chain is lost. These usually result in the absence of an Ig subclass. In extreme cases they can result in a form of agammaglobulinemia (absence of most or all antibodies).

Transient hypogammaglobulinemia of infancy Infants are born with their mothers' antibodies circulating in their bloodstream. They begin producing their own antibodies by six months of age. Infants with transient* hypogammaglobulinemia have low antibody levels until they reach a year to three years of age. This condition is more common in premature infants and is believed to be due to the delayed development of T-helper cells. It is not inherited.

How Common are Immunoglobulin Deficiency Syndromes?

Primary IDS are much more common than was previously thought. They are the most common type of immunodeficiency disorder, accounting for about 50 percent of all primary immunodeficiencies.

Among selective IgG deficiencies, IgG2 deficiency is the most common in children and IgG3 deficiency is the most common in adults. IgG4 deficiency usually occurs in conjunction with IgG2 deficiency; however, IgG4 is not normally detectable until the age of 10. IgG1 deficiency is very rare.

Selective IgA deficiency is one of the most common IDS, especially among Caucasians, affecting as many as 1 in 500 people. However, many people are unaware of their IgA deficiency.

What Are the Symptoms of Immunoglobulin Deficiency Syndromes?

IDS usually cause recurrent, severe, or chronic* infections—especially respiratory and gastrointestinal infections—from childhood on. The infections can spread to various organs.

Other symptoms of IDS may include the following:

- Chronic diarrhea*
- Malabsorption of nutrients*
- Enlarged lymph nodes* and spleen*
- Allergies*
- Autoimmune diseases* such as arthritis*
- Failure to thrive*

Symptoms of CVID vary from mild to severe. The majority of CVID cases are not diagnosed until early adulthood. In about 20 percent of cases, the first symptom is a very low level of blood platelets* or severe anemia* due to antibodies destroying the body's own blood cells.

Infections due to HIM and selective IgG subclass deficiencies usually begin in the first or second year of life. Failure to produce specific antibodies in response to certain childhood vaccines* is a common symptom of an IgG subclass deficiency.

It is estimated that between 25 and 50 percent of people with selective IgA deficiency develop symptoms over a 20 year period. About one-half of people with known selective IgA deficiency are susceptible to infections and 25 to 33 percent have autoimmune diseases.

How Are Immunoglobulin Deficiency Syndromes Diagnosed and Treated?

Diagnosis IDS are usually diagnosed by measuring the levels of the various Igs in the blood. If family members have IDS and the gene mutation is known, prenatal* diagnosis is possible. Other family members can be also tested to determine whether they carry the defective gene.

Boys with XLA usually have very small or absent tonsils* and lymph nodes, because these tissues are made up of B-lymphocytes, and B-cells are generally absent from the blood. XLA can be confirmed by the absence of BTK protein in white blood cells or platelets or by detecting a BTK mutation in the DNA*. Although there are many different BTK mutations, family members usually share the same one. Any male newborn with a brother or maternal uncle or cousin with XLA should be immediately tested for the percentage of B-cells in his blood, so he can be treated before he becomes ill.

Patients with CVID usually have very low or undetectable levels of antibodies against polio, measles*, diphtheria*, and tetanus* despite immunizations. Sometimes the degree of immunoglobulin deficiency is determined by measuring antibody levels following vaccinations*. The number and function of T-lymphocytes in the blood may also be measured. Tissue cultures* can determine whether B-cells make antibodies and whether T-cells are functioning properly.

XHIM is diagnosed by the absence of a protein called CD40 ligand on the surfaces of activated T-cells and identification of a mutation in the CD40 ligand gene. Autosomal recessive forms of HIM have similar symptoms to XHIM but may occur in females and/or the CD40 ligand is normal. HIM diagnosis can be confirmed by mutation analysis of the genes involved.

Treatment Most primary IDS can be treated effectively. Antibiotics* are used to prevent and treat infections. Severe IDS are treated with immunoglobulin replacement therapy. Other treatments are as follows:

- * **autoimmune diseases** (aw-toh-ih-MYOON) are diseases in which the body's immune system attacks some of the body's own normal tissues and cells.
- * **arthritis** (ar-THRY-tis) refers to any of several disorders characterized by inflammation of the joints.
- * **failure to thrive** is a condition in which an infant fails to gain weight and grow at the expected rate.
- * **platelets** (PLATE-lets) are tiny disk-shaped particles within the blood that play an important role in clotting.
- * **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.
- * **vaccines** (vak-SEENS) are preparations of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.
- * **prenatal** (pre-NAY-tal) means existing or occurring before birth, with reference to the fetus.
- * **tonsils** are paired clusters of lymphatic tissue in the throat that help protect the body from bacteria and viruses that enter through a person's nose or mouth.
- * **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.
- * **measles** (ME-zuls) is a viral respiratory infection that is best known for the rash of large, flat, red blotches that appear on the arms, face, neck, and body.

- * **diphtheria** (dif-THEER-eh-uh) is an infection of the lining of the upper respiratory tract (the nose and throat). It is a disease that can cause breathing difficulty and other complications, including death.
- * **tetanus** (TET-nus) is a serious bacterial infection that affects the body's central nervous system.
- * **vaccinations** (vak-sih-NAY-shunz), also called immunizations, are the giving of doses of vaccines, which are preparations of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself.
- * **cultures** (KUL-churz) are tests in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.
- * **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.
- * **transplants** (TRANS-plantz) are organs or tissues from another body used to replace a poorly functioning organ or tissue.
- * **gamma globulin** (GAH-muh GLAH-byoo-lin) is a type of protein in the blood that contains the antibodies produced by the cells of the body's immune system that help defend the body against infection-causing germs, such as bacteria and viruses.
- * **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.
- * **mumps** is a contagious viral infection that causes inflammation and swelling in the glands of the mouth that produce saliva.

- XHIM is sometimes treated with granulocyte-colony-stimulating factor (G-CSF) and cured by bone-marrow or cord-blood stem cell transplants*.
- Many children under the age of five with selective IgG subclass deficiencies outgrow the disorder.
- Most infants with transient hypogammaglobulinemia have some antibodies and are not prone to infections, although premature infants may require treatment with gamma globulin* and antibiotics.

Managing Immunoglobulin Deficiency Syndromes Maximizing resistance to infection includes the following:

- Balanced nutrition
- Adequate exercise and sleep
- Avoidance of stress

Good hygiene for patients and their families is essential for reducing the risk of infection:

- Routine effective hand washing and use of disposable hand wipes
- Washing of toys
- Immediate first-aid for cuts and scrapes
- Tooth brushing, flossing, and regular dental visits
- Avoidance of people with infections
- Avoidance of drinking water that may be contaminated with *Cryptosporidium*, which can cause severe gastrointestinal problems and chronic liver* disease.

Patients with IDS should not be given any live-virus vaccines such as live polio or measles, mumps*, rubella (MMR).

Impacted Teeth

Impacted teeth are teeth that have not broken through the gum at all or that have not fully emerged from the gum.

What Are Impacted Teeth?

An impacted tooth, also called an unemerged tooth, an unerupted tooth, or a dental impaction, is a tooth that does not emerge through the gum in the correct position. There are two types of impacted teeth. A fully impacted tooth is one that exists in the jaw under the gum line but never breaks through the gum. A partially impacted tooth is one that breaks through the gum line (a process called eruption) but does not fully emerge. Although any tooth may become impacted, the most common teeth to have this condition are the third molars, more commonly known as the wisdom teeth. These are the grinding teeth that are farthest back in the jaw. They normally emerge sometime in the late teens or early twenties.

Researchers are not sure why so many people develop impacted wisdom teeth, but there are several theories. One is that early humans had a larger jaw with enough space for the wisdom teeth. Over the centuries, as the humans began to cook food and their diet became softer, less chewing was needed. As the chewing muscles became smaller, so did the jawbones to which these muscles are attached. Another theory is that the diet of early humans wore down the teeth enough that space was created in the jaw by the time the wisdom teeth were ready to erupt.

Teeth can be impacted in several ways. In the most common type of impacted tooth, a mesial impaction, the third molar (wisdom tooth) comes in at an angle so that it is blocked from erupting by the second molar, which is in front of it in the jaw. Impacted teeth can also be positioned in the jaw in a number of other ways ranging from vertical to completely horizontal, so that their eruption through the gum is prevented either by bone or by other teeth. Some impacted teeth are able to partially emerge before they are blocked, whereas others are unable to break through the gum line at all.

What Can Happen When a Tooth Is Impacted?

Sometimes impacted teeth cause no pain or visible problem, whereas other times they can lead to tooth decay, infection, and gum disease. Normally, partially impacted wisdom teeth cause more health problems than fully impacted teeth. When a tooth partially emerges from the gum, it creates a

▲ Impacted wisdom tooth in the lower jaw. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

Does Having Wisdom Teeth Make You Smart?

Wisdom teeth got their name because they emerge from the gum between the ages of 17 and 25, an age at which people are supposed to develop their full reasoning powers and acquire “wisdom.” However, people with emerged wisdom teeth are no smarter than people whose wisdom teeth are impacted or who, for genetic reasons, never get any wisdom teeth at all.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

tiny opening between the gum and the tooth that cannot be cleaned out through brushing or flossing. Bacteria can then enter this space, reproduce, and cause an infection that dentists call pericoronitis, which causes the gum to become tender and swell. The condition can be very painful and also can cause bad breath and a bad taste in the mouth. Pericoronitis is usually treated with antibiotics to kill the bacteria causing the infection, but the disease may return repeatedly if the partially impacted tooth remains in place.

Tooth decay (cavities) can also develop on the second molar and/or the partially impacted wisdom tooth when bacteria get trapped in the space where the teeth are touching. This space is small, hard to clean, and hard for the dentist to reach if a filling is needed to treat the cavity. Finally, people with partially impacted teeth are more likely to develop periodontal (gum) disease, which often occurs gradually and only becomes evident later in life. Periodontal disease damages the gums so that teeth become loose and may fall out or need to be removed.

How Are Impacted Teeth Diagnosed and Treated?

A partially impacted tooth is obvious to the dentist on examination. The dentist must then determine whether the tooth is in the process of emerging normally or if it is stuck in position and impacted. A dental x-ray that shows what is happening below the gum line may help the dentist decide whether the tooth is impacted. An x-ray is the only way to confirm the presence of a fully impacted tooth, since in some people, wisdom teeth never develop in the jaw. Most dentists take x-rays on a regular basis to help detect tiny cavities and other dental abnormalities. These x-rays are safe and expose people to a very low level of radiation, although special precautions must be taken with women who are or might be pregnant.

The treatment for an impacted tooth is extraction, which is performed by either a dentist or an oral surgeon. An oral surgeon is a person who has graduated from dental school and then had a minimum of four years of hospital-based training in dental, jaw, and related surgery. Extractions can be done using local or general anesthesia or intravenous* sedation depending on the complexity of the extraction and the patient's preferences. The patient is usually given antibiotics* to combat infection and medication to manage pain following the extraction.

Although dentists agree that extraction is the appropriate treatment for an impacted tooth that is causing health problems, there are two philosophies on whether impacted wisdom teeth should be routinely removed. One school of thought is that impacted wisdom teeth are likely to cause health problems and that they should be removed before these health problems arise. The dentists supporting this position point out that wisdom teeth are much easier to remove and healing is much faster in adolescents than in older individuals, because younger people have more flexible bones. The other philosophy is that although some wisdom teeth

should be removed, all wisdom teeth do not need to be routinely extracted when no problems have occurred. People who support this position note that not all impacted wisdom teeth cause problems. People with impacted wisdom teeth should discuss their individual situation with their dentist and review the pros and cons of extraction of teeth that are not yet causing health problems before making treatment decisions.

Impetigo

Impetigo (im-puh-TIE-go) is a very common skin infection among children. It produces blisters and sores, which usually appear on the face and hands, although they may show up any place on the body. The infection is contagious and often spreads from one child to another in childcare facilities or classrooms.

More than a Little Itch: Ariana's Story

Five-year-old Ariana had an itch on her hand and scratched it on and off for a couple of days. During that time, she noticed that the itchy spot was red. Still, she scratched it. By the end of the week, she developed some new red and itchy spots next to her nose. Some of them had noticeable blisters. When her mother noticed the sores by her nose, she thought they looked a bit like acne. When Ariana described the red patch on her hand, her mother decided it was time to take her daughter to the doctor's office. After examining the red patches, the doctor told them that Ariana had impetigo or "school sores." He explained that it was a very common

▲ Impetigo, a bacterial skin infection, occurs as scattered thin-walled skin blisters containing clear yellow or slightly turbid fluid without surrounding redness. *CMSP/Getty Images.*

- * **dermatitis** is a skin condition characterized by a red, itchy rash. It may occur when the skin comes in contact with something to which it is sensitive.
- * **contagious** (kon-TAY-jus) means transmittable from one person to another, usually referring to an infection.
- * **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.
- * **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.
- * **strep throat** is a contagious sore throat caused by a strain of bacteria known as *Streptococcus*.
- * **rheumatic fever** (roo-MAH-tik) is a condition associated with fever, joint pain, and inflammation affecting many parts of the body, including the heart. It occurs following infection with certain types of strep bacteria.
- * **scarlet fever** is an infection that causes a sore throat and a rash.
- * **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

skin infection among children. He gave Ariana's mother some ointment to put on the sores, told her to keep her daughter out of kindergarten for the next two days so her daughter would not infect other children, and recommended that she give Ariana her own towels to use for a couple of days so she would not infect the other members of her family. In addition, he instructed Ariana to leave the sores alone so her skin could heal. Within a week, the redness was gone, and by the next week, Ariana had already nearly forgotten that she had ever had impetigo.

What Is Impetigo?

Impetigo is one of the most common skin infections seen in children. In fact, among children, impetigo is the third most common skin disease. Only dermatitis* warts occur more often. Impetigo produces blisters and sores, usually by the nose and face, and/or on the hands and forearms. It is very contagious* and can readily spread to other parts of the body, too. This infection can also spread from one person to another. Impetigo usually clears up with a simple antibiotics* treatment. If it is not treated, however, the infection can become more serious and lead to other, much more dangerous conditions.

What Causes Impetigo?

Bacteria* cause impetigo. Two common bacteria that lead to impetigo are *Streptococcus pyogenes* and *Staphylococcus aureus*. Both bacteria are too small to be seen by the naked eye. *Streptococcus pyogenes* are round and form chains, so they look a little like strings of pearls. Besides impetigo, this bacteria can cause other illnesses, such as strep throat* (also known as acute pharyngitis), rheumatic fever*, and scarlet fever*. *Staphylococcus aureus*, which is round and sometimes goes by the name golden staph, can also cause other illness besides impetigo. Some of these illnesses, such as pneumonia* and toxic shock syndrome, can be life-threatening.

In impetigo, both *Streptococcus pyogenes* and *Staphylococcus aureus* can infect people when they touch something that has the bacteria on it. For instance, a boy who has impetigo on his hands may dry them on a towel. If a girl then uses the same towel, the bacteria can infect her, and she can develop impetigo herself. These bacteria often infect the skin through a cut or other sore that a person has, but they can also infect unbroken, healthy skin.

Who Gets Impetigo?

Impetigo is especially common among infants and among children up to six years of age. The infection is known as school sores, because it is especially widespread among young, school-aged children who pass it along to their classmates through direct contact. In other words, one child may purposely or inadvertently touch the wound of another child and become infected. Impetigo often spreads from child to child very quickly in child-care centers and classrooms. The more crowded the children are, the more likely impetigo will spread.

Impetigo also occurs among people of any age who play close-contact sports such as wrestling or football. If one player has impetigo and brushes his or her infected site against another player, the infection can spread from person to person. In addition, it is particularly common among children who are undergoing dialysis (dy-AL-i-siss). Dialysis is a treatment procedure for people whose kidneys are not working properly. In this procedure, a dialysis machine acts as an artificial kidney for the patient.

What Are the Symptoms of Impetigo?

Impetigo comes in two main types: impetigo contagiosa and bullous impetigo. A third type of skin infection, known as deep impetigo or ecthyma, also occurs. Each type has its own set of symptoms.

Impetigo contagiosa Most people who have impetigo have the form called impetigo contagiosa (cun-tay-gee-O-suh), which is also sometimes known as nonbullous impetigo. A person with this condition first has a red sore at the site of the infection. Common places for the infection are next to the nose or mouth. The sore oozes liquid, sometimes pus, which hardens into a yellow- or brown-colored crust. As the sore heals, the crust disappears, and the underlying red mark heals up without leaving behind a scar. Most children have several such sores near one another. These sores may itch, and children may scratch them. If the child then touches another area of the body without washing first, the bacteria can spread and produce sores elsewhere on the body.

Sometimes, a child will also have swollen lymph nodes* near the sores.

Bullous impetigo An infection of the *Staphylococcus aureus* bacterium is the cause of bullous (BULL-us) impetigo. This type mainly affects babies and children up to two years of age, although older children and adults are sometimes affected. Children with bullous impetigo get red sores with large, liquid-filled blisters that may look painful, but are not. They are, however, itchy. These blisters often appear on arms and legs and on the trunk of the body. Eventually, these blisters burst and, as happens in impetigo contagiosa, a yellowish to brownish crust forms and later disappears. The underlying red mark in bullous impetigo may heal more slowly than sores from other forms of impetigo. Bullous impetigo appears to be less contagious than impetigo contagiosa.

Sometimes, teachers, childcare workers, or other people may think that the sores look like cigarette burns or scald injuries and mistakenly think that the child is the victim of child abuse, but a doctor can set the record straight.

Deep impetigo In both impetigo contagiosa and bullous impetigo, the sores remain mainly on the skin's surface. In ecthyma (ek-THI-muh), the sores run more deeply into the skin and extend into the second layer,

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

which is called the dermis (DER-miss). Ecthyma sores are painful and may be filled with liquid or pus. They often occur on the legs and on the feet. In addition, the sores may turn into deep ulcers, which means that some of the skin cells have died. Like other forms of impetigo, ecthyma sores ooze and crust over. Ecthyma sores, however, do not heal as well as sores caused by bullous impetigo or impetigo contagiosa, and scars are common. Some children with ecthyma may also have swollen lymph glands near the site of the infection.

How Is Impetigo Diagnosed?

A doctor typically needs only look at the sore to diagnose it as impetigo. Occasionally, the doctor may order a test to confirm the diagnosis, but usually this is not necessary.

How Is Impetigo Treated?

Impetigo will often heal by itself within several weeks and leave no scars behind. Doctors, however, often treat it to help with the itching or with the soreness and to prevent the bacteria from spreading from one person to the next. Common treatments are antibiotic ointments such as mupirocin (myoo-PEER-o-sin, Bactroban) and retapamulin (Altabax). Typically, doctors recommend carefully washing the site and gently removing the crust and then applying the ointment. Sometimes, the doctor may prescribe an antibiotic, such as a penicillin, cephalosporin, or macrolide, which is taken by mouth.

In some people, impetigo may recur. These patients usually become so familiar with the sores that they are able to notice them and treat them very early. They should, however, report the return of the condition to the doctor. The physician may be able to find out where the impetigo-causing bacteria are living—for instance, in the person's nose or elsewhere on the body—and may be able to apply antibiotics to that location to wipe out the bacteria once and for all.

If left untreated, impetigo can become a dangerous infection, one that may lead to more serious problems in the lungs, kidneys, joints, and/or bones.

Can Impetigo Be Prevented?

Medical professionals recommend the following to help children and others avoid getting impetigo or from spreading it to other people:

- In general, all individuals should wash their hands often. In addition, they should wash any wounds—even small cuts and scrapes—with soap and water. Doing so helps reduce the possibility of becoming infected with *Streptococcus pyogenes* or *Staphylococcus aureus*.
- People with impetigo should always use a clean washcloth and towel every time they wash their hands, face, or other parts of the body, and then put the towel and washcloth in the laundry to be cleaned.

- People with impetigo should never share their wash cloths or towels with others, because doing so can spread the bacteria to another person. In addition, children should not share clothing or bedding with others, and adults should not share their razors.
- People with impetigo should always carefully wash their hands, especially after touching the infected site, to lessen the chance of spreading the bacteria to other sites on their bodies or to other people.

Incontinence

Incontinence is a person's inability to control when he or she passes urine or feces*.*

What Is Incontinence?

Older men and women, as well as some children, find they cannot wait when they have to go to the bathroom. Usually, incontinence (in-KON-ti-nens) involves urinating at the wrong time, or it can mean having a bowel movement before reaching a bathroom. Although incontinence occurs mostly in older men and women and younger children, it can occur in people of all ages.

Sometimes incontinence occurs as a small amount of urine is released when a person strains, such as with coughing or laughing too hard. In other instances, it occurs only when the bladder is too full.

What Causes Incontinence?

There are many causes for incontinence. Urinary tract infections, cancer, diabetes, stroke, Parkinson's disease*, and Alzheimer's (ALTS-hy-merz) disease* are some of the illnesses that can cause incontinence. Several problems in the brain or spinal cord can lead to urine and

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

* **feces** (FEE-seez) is the excreted waste from the gastrointestinal tract.

* **Parkinson's disease** is a disorder of the nervous system that causes shaking, rigid muscles, slow movements, and poor balance.

* **Alzheimer's (ALTS-hy-merz) disease** is a condition that leads to gradually worsening loss of mental abilities, including memory, judgment, and abstract thinking, as well as changes in personality.

bowel incontinence. Surprisingly, severe constipation can cause bowel incontinence. Withholding stool (feces) can cause a hardened plug of stool to block the rectum. This plug irritates the lining of the rectum and causes watery stool to leak out from around the hardened plug.

Urinary incontinence affects older women more than it affects men. One reason is that changes in a woman's hormone levels later in life can weaken muscles that control urination. Women who have had children may also experience more incidence of incontinence because the muscles that are stretched during pregnancy and childbirth may become weakened.

Some over-the-counter cold medicines as well as some prescription drugs for conditions such as high-blood pressure can cause incontinence.

How Is Incontinence Treated?

Treatments for urinary incontinence involve avoiding liquids and caffeinated drinks such as coffee near bedtime and going to the bathroom at regular intervals. Also, a woman can do certain exercises to strengthen muscles and help her control her urine. Some adults wear pads to absorb small amounts of urine that leak. Medications and surgery are helpful for some people.

The treatment for bowel incontinence depends on the cause. If the cause is chronic constipation, treatment involves adding fiber to the diet and correcting the constipation. Other causes may require surgery.

Infection

Infection is a process in which bacteria, viruses*, fungi*, or other microorganisms* enter the body, adhere to or enter cells, and multiply. To do this, they must get around or overcome the body's natural defenses at each step. Infections have the potential to cause illness, but in many cases the infected person does not get sick.*

How Does Infection Occur?

Microorganisms that can cause illness are everywhere in the environment: in air, water, soil, and food, as well as in the bodies of animals and other people. Infection occurs when some of the invading microorganisms get past a series of natural defenses. Those defenses include the following:

- **Skin:** The skin physically blocks germs but may let them in if it is cut or scraped.
- **Coughing deeply:** Coughing expels germs from the lungs and breathing passages but may be less effective in weak, sick, or injured people.
- **Bacteria:** Called “resident flora,” normal bacterial flora are present in some parts of the body. They compete with harmful germs and crowd them out. They can, however, be weakened or killed by medications, allowing harmful germs to thrive and cause illness.

* **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.

* **viruses** (VY-rus-sez) are tiny infectious agents that can cause infectious diseases. Viruses can only reproduce within the cells they infect.

* **fungi** (FUNG-eye) are microorganisms that can grow in or on the body, causing infections of internal organs or of the skin, hair, and nails.

* **microorganisms** are tiny organisms that can only be seen using a microscope.

- * **malaria** (mah-LAIR-e-uh) is a disease spread to humans by the bite of an infected mosquito.
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).
- * **tuberculosis** (too-ber-kyoo-LO-sis) is a bacterial infection that primarily attacks the lungs but can spread to other parts of the body.
- * **plague** (PLAYG) is a serious bacterial infection that is spread to humans by infected rodents and their fleas.

- **Inflammatory response:** Inflammation is the body's response to a harmful presence. It is primarily a response of the body's immune system. Certain kinds of white blood cells surround and destroy or otherwise attack microorganisms, often causing fever, redness, and swelling.
- **Antibodies:** These protein molecules are produced by a specialized cell of the immune system. Antibodies target specific microorganisms. This response is also called "humoral immunity." Usually these antibodies are produced in response to a person's having been infected by or exposed to the microorganism.

The immune system's responses may fail if the microorganisms are too numerous or if they are too virulent. "Virulent," from the Latin for "poisonous," describes microorganisms that are particularly good at countering the body's defenses. For instance, some microorganisms can prevent formation of those antibodies that might have targeted them. Another important factor is the level of competence of the immune system. If it is damaged—weakened, for instance, by age or illness—infection is more likely. Babies tend to get more infections because their immune systems have not yet learned to recognize and attack some microorganisms.

Where Does Infection Occur?

Localized infections A localized infection remains in one part of the body. An example is a cut on the hand that leads to a bacterial infection but does not cause problems elsewhere in the body. Localized infections can be very serious if they are internal, for example, appendicitis (localized to the appendix) and endocarditis (localized to the interior wall of the heart).

Systemic infections Most serious infections, however, occur when the microorganisms travel throughout the body, usually by way of the bloodstream, and the sites of infection in the body are multiple. These are called systemic infections, and they include flu, malaria*, AIDS*, tuberculosis*, plague*, and most of the infectious diseases whose names are familiar.

How Do Infections Lead to Illness?

The major causes of infection are viruses, bacteria, fungi, and parasites, including protozoa (one-celled organisms), worms, and insects such as mites (which cause scabies) and lice.

Bacteria can release toxins (poisons). Viruses can take over cells and prevent them from doing their normal work. Bacteria and fungi—and larger infective agents such as worms or other parasites—can multiply so rapidly that they physically interfere with the functioning of the lungs, heart, or other organs. The immune response itself—which can bring on fever, pain, swelling, and fatigue (as by-products of the effort to overcome the offending agent)—often is the major cause of the sick feelings an infected person gets.

Do Infections Always Cause Illness?

Infections often do not cause illness. Of people infected with the bacterium that causes tuberculosis, for instance, only about one in 10 will ever get sick. Some viruses and parasites, too, can remain in the body a lifetime without causing illness. In such cases, called latent infection, people usually get sick only if their immune system weakens.

How Do Infections Spread?

The microorganisms that cause infections are present in water, soil, food, and air; they may be transmitted through contact with these substances; through contact with an infected person's blood, skin, mucus, and/or respiratory secretions expelled during coughing or sneezing; through sexual contact; or through insect bites. Many microorganisms are spread by two or more of these routes; no one microorganism spreads in all these ways. In addition, many disease-causing microorganisms can be transmitted, in pregnant women, from mother to fetus, called a congenital infection in the newborn infant.

What Are the Symptoms of Infection?

The symptoms vary greatly depending on the part of the body and type of microorganism involved. The first sign of bacterial infection is often inflammation: fever, pain, swelling, redness, and partial loss of function. By contrast, viral infections less commonly cause inflammation but may cause a variety of other symptoms, ranging from a runny nose or sore throat to a rash or swollen lymph nodes*.

What Is the Treatment for Infection?

The specific treatment depends on the microorganism that is involved: Doctors prescribe antibiotics for bacterial infections, antiviral drugs for some viral infections (for most, however, no treatment exists), antifungal* medications for fungus infections, and anthelmintic drugs for worms. The doctor's decision to use (or not use) medications may also depend on the exact location of the infection, as well as the age and the general medical condition of the patient. In some cases of localized infection, as when an abscess or collection of pus* forms, the patient may need surgery to drain the infected area.

How Are Infections Prevented?

Disinfecting wounds When a wound occurs, prompt and thorough cleansing of the fresh wound by placing it under running water is one of the most effective ways to prevent infection. Additional methods of preventing infection include using antibacterial ointment or spray and covering the wound. Serious wounds should receive immediate medical attention.

Immunization Systemic infectious diseases can be controlled and even eradicated through immunization. Immunizations are available for such

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **antifungal drugs** (an-ty-FUNG-al drugs) are medications that kill fungi.

* **pus** is a thick, creamy fluid, usually yellow or ivory in color, that forms at the site of an infection. Pus contains infection-fighting white cells and other substances.

diseases as chickenpox, diphtheria, hepatitis A and hepatitis B, influenza, measles, mumps, pertussis (whooping cough), pneumococcal pneumonia, polio, rabies, rubella (German measles), tetanus, typhoid fever, and yellow fever.

Hygiene, sanitation, and public health Individuals can prevent many other systemic infections by washing hands before handling food; by cooking meats thoroughly; by using safer sex techniques; and by controlling or avoiding ticks and mosquitoes. In addition, a clean public water supply and a system for the sanitary disposal of human wastes can help to prevent infections. While clean water supplies and sewage systems are typical in developed countries, many developing countries have neither. To prevent or reduce the incidence of sexually transmitted infection: be responsible, practice safe sex, and know your partner.

Infertility

Infertility (in-fer-TIL-i-tee) means that a couple has difficulty conceiving a child after approximately a year of trying. The man, woman, or both may have problems with their reproductive system that cause them to be infertile.

Fertilization and Implantation

Infertility, the inability to accomplish or maintain a pregnancy, is a widely known medical problem. While beginning a pregnancy is a problem for many couples, maintaining a pregnancy once it begins can also pose an obstacle to successful childbirth.

In order to get pregnant, an egg is released from one of the woman's two ovaries* and travels down the fallopian tube* toward the uterus*. If sperm* are present during this time, the egg may be fertilized while in the fallopian tube.

The fertilized egg continues down the fallopian tube into the uterus, where it implants into the lining of the uterus. The placenta* develops, rich with blood and nutrients, and nourishes the embryo*. The embryo is attached to the placenta via the umbilical cord*.

Infertility results from the interruption of any one of these steps.

What Is Infertility?

Infertility is the failure to become pregnant after about a year of trying many times without using contraception*. Infertility problems increase as a person gets older, and they are more widespread as many women wait to have babies until they are in their 30s and 40s. In the early 2000s, fertility problems affected at least 6.1 million couples in the United States.

Doctors can find no medical cause for up to 20 percent of infertility cases. In 15 to 20 percent of infertility cases, both the man and the woman have fertility problems. The rest of the time, infertility is caused by problems with either the male or the female reproductive system. Some doctors believe that smoking, drinking a lot of alcohol, poor eating habits, stress, excess weight, and generally poor health can make the physical problems causing infertility even worse.

* **ovaries** (O-vuh-reez) are the sexual glands from which ova, or eggs, are released in women.

* **fallopian tubes** (fa-LO-pee-an tubes) are the two slender tubes that connect the ovaries and the uterus in females. They carry the ova, or eggs, from the ovaries to the uterus.

* **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.

* **sperm** are the tiny, tadpole-like cells males produce in their testicles. Sperm can unite with a female's egg to result eventually in conception.

* **placenta** (pluh-SEN-ta) is an organ that provides nutrients and oxygen to a developing baby; it is located within the womb during pregnancy.

* **embryo** (EM-bree-o), in humans, is the developing organism from the end of the second week after fertilization to the end of the eighth week.

* **umbilical cord** (um-BIH-lih-kul) is the flexible cord that connects a baby to the placenta, the organ that unites the unborn child to the mother's uterus, the organ in which the baby develops.

* **contraception** (kon-tra-SEP-shun) is the deliberate prevention of conception or impregnation.

- * **varicose vein** (VAR-i-kose VAYN) is an abnormally swollen or dilated vein.
- * **scrotum** (SKRO-tum) is the pouch on a male body that contains the testicles.
- * **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.
- * **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.
- * **hormone** is a chemical substance that is produced by a gland and sent into the bloodstream carrying messages that have certain effects on other parts of the body.
- * **tumors** (TOO-morz) usually refer to abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.
- * **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.

Infertility in men Roughly 35 to 40 percent of infertile couples are unable to conceive because of a problem with the male reproductive system. Infertility can result when a man does not produce enough sperm, or when the sperm have too short a life span, do not move properly, or cannot penetrate the egg to fertilize it. These problems can be caused by many factors, including abnormalities of reproductive organs, a varicose vein* in the scrotum*, inflammation* in the male genitals, and sexually transmitted diseases, such as chlamydial (kla-MID-eal) infections, gonorrhea (gon-o-REE-a), and syphilis (SIF-i-lis). Some men have trouble ejaculating (discharging sperm), which also can cause infertility. In rare cases, the immune system* of the man or woman may produce antibodies* that kill sperm.

Infertility in women Another 35 to 40 percent of couples are infertile due to a problem with the female reproductive tract. Problems can occur in any part of the system:

- **Ovaries:** The ovaries (O-va-reez) are a pair of organs where egg cells develop and mature. About 25 percent of female infertility is caused by the failure of a mature egg to leave the ovary (a process called ovulation).
- **Hormones:** Problems with hormone* production can prevent pregnancy.
- **Fallopian tubes:** A woman has two fallopian (fa-LO-pe-an) tubes (one associated with each ovary), which carry eggs from the ovaries to the uterus (YOO-ter-us). Infertility can occur when one or both of the fallopian tubes are blocked, scarred, or collapsed.
- **Pelvic inflammatory disease (PID):** Infertility also is common in women with PID, which is an infection of the female reproductive organs (especially the fallopian tubes).
- **Uterus:** The uterus is the muscular organ in which a fertilized egg develops into a fetus (FEE-tus; developing baby). If the uterus contains scar tissue or a piece of tissue dividing it in half, the fertilized egg might not be able to implant and grow.
- **Endometriosis:** Women also can have infertility problems due to conditions such as endometriosis (en-do-me-tree-O-sis), which occurs when pieces of the lining of the uterus grow outside the uterus.
- **Fibroids:** Fibroids (FY-broidz) are noncancerous tumors* that also can cause infertility.
- **Cervix:** The cervix (SER-viks) is the opening between the uterus and the vagina. Infertility can occur if the cervix does not produce enough mucus* to allow sperm to pass into the uterus.
- **Vaginal infections:** The vagina (va-JY-na) is the tubular canal that runs from the cervix to the outside of the body. Certain vaginal infections that spread to the uterus and fallopian tubes can cause infertility.

How Is Infertility Diagnosed?

The first step in treating infertility is finding out the cause. Both the man and the woman require a complete physical examination to determine if a physical disorder is causing infertility.

The first test for male infertility is an analysis of the sperm for shape, movement, and number. The first test for a woman is to find out if she is ovulating. Home ovulation* kits are available for this purpose, as are body temperature charts (the body temperature fluctuates during the menstrual cycle*). Tests of a woman's blood and urine also help doctors to determine if a woman is having normal menstrual cycles. An x-ray of the uterus and fallopian tubes can reveal any blockage that might prevent the egg from being fertilized. In some cases, the doctor may look inside the body with a laparoscope*. The laparoscope has a light and a camera on the end, which conveys images to a monitor screen. This device allows the doctor to see the organs inside the body. This flexible tube is inserted into the abdomen* through a small incision.

How Is Infertility Treated?

Difficulty conceiving a baby may not be a permanent condition, and many couples with fertility problems eventually have a child without medical intervention. However, some couples need medical help to become pregnant, and the treatment depends on the cause of infertility. If a hormone deficiency causes infertility, treatment may involve taking hormones prescribed by a doctor. If there is damage or an abnormality in the female organs, it sometimes can be repaired surgically. For other couples, treatment can range from taking fertility drugs to using assisted reproductive technology (ART). Many treatments for infertility exist; a few of them are described below.

Artificial insemination Artificial insemination (in-sem-i-NAY-shun) is the introduction of a man's sperm into the opening of a woman's uterus with a tube called a catheter (CATH-e-ter). Before insemination, antibodies and unhealthy sperm are removed from the semen (SEE-men), the fluid containing sperm. The sperm used in artificial insemination ideally comes from the woman's male partner. However, in cases in which the man is infertile or carries a genetic disorder, sperm from a donor may be used.

Fertility drugs Fertility drugs can be used to treat problems with ovulation. A number of different medications have been developed that help stimulate the maturation and release of ova (eggs).

In vitro fertilization (IVF) "In vitro" literally means "in glass" (as in a test tube) and, therefore, refers to a procedure performed outside the body. In vitro fertilization (IVF) occurs when eggs are removed from the woman and mixed with sperm in the laboratory. Fertilized eggs, or embryos, then are placed in the woman's uterus. This procedure bypasses the fallopian tubes.

Multiple Births

One of the major problems facing couples undergoing fertility treatment is multiple births. Fertility drugs may result in multiple births, because they can stimulate release of multiple eggs. For example, as many as 10 percent of women who become pregnant with the help of the drug Clomid (KLO-mid), or clomiphene citrate (KLO-mi-feen SY-trayt), have twins, and 1 in 400 women have triplets.

Assisted reproductive technologies such as in vitro fertilization usually place two to five eggs inside the woman's reproductive tract, because not all are expected to survive—but sometimes they all do. On January 26, 2009, Nadya Suleman gave birth to eight babies after undergoing fertility treatment. The births received much media attention and started discussions on the issues surrounding in vitro fertilization.

The more embryos that develop at one time in the uterus, the more likely they are to be born prematurely, to be small, and to have serious health problems such as cerebral palsy (se-REE-bral PAWL-zee) and brain damage. Because of such health problems and because of ethical and financial issues associated with multiple births, fertility treatment can be controversial.

* **ovulation** (ov-yoo-LAY-shun) is the release of a mature egg from the ovary.

* **menstrual cycle** (MEN-stroo-al SYkul) culminates in menstruation (men-stroo-AY-shun), the discharging through the vagina of blood, secretions, and tissue debris from the uterus that recurs at approximately monthly intervals in females of breeding age.

* **laparoscope** (LAP-a-ro-skope) is a fiber-optic instrument inserted into an incision in the abdominal wall to perform a visual examination.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis

Before IVF, women usually take fertility drugs in order to produce multiple eggs. Eggs are taken from a woman's ovaries using a needle inserted through the vagina. The male partner provides a sperm sample, which is mixed with the eggs in a dish in the laboratory. After several days, if the eggs have been fertilized and have developed into embryos, two to five embryos (usually) are placed into the uterus (not all are expected to develop into fetuses). About two weeks later, the woman takes a pregnancy test to see if the procedure was successful.

Coping with Infertility: Jim and Sarah's Story

Jim and Sarah Albertson are among the 10 to 20 percent of the reproductive-aged population in the United States who have difficulty having a baby. Even although pregnancy is possible in more than half of couples pursuing fertility treatment, it does not seem possible for them.

Jim and Sarah began trying to have a baby on their honeymoon, when they were both 34. Five years later, they still have no children. Sarah has had surgery to remove fibroids, and she has taken hormones and fertility pills. Jim has done everything possible to increase his sperm count. They have tried artificial insemination. It seems their whole lives revolve around trying to get pregnant, but nothing is working.

As Jim and Sarah watch one friend after another have a baby, their own home begins to feel empty. They try not to blame each other, but it is hard not to. Even though their health plan does not cover in vitro fertilization, they decided to spend their own money to try to get pregnant that way. Three tries and \$30,000 later, they still have no baby. With the help of marital counseling and the support of other couples with the same problem, Jim and Sarah are learning to accept that they may not have biological children.

* **rectum** is the final portion of the large intestine, connecting the colon to the outside opening of the anus.

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

* **perianal disease** affects the regions around the anus.

Inflammatory Bowel Disease

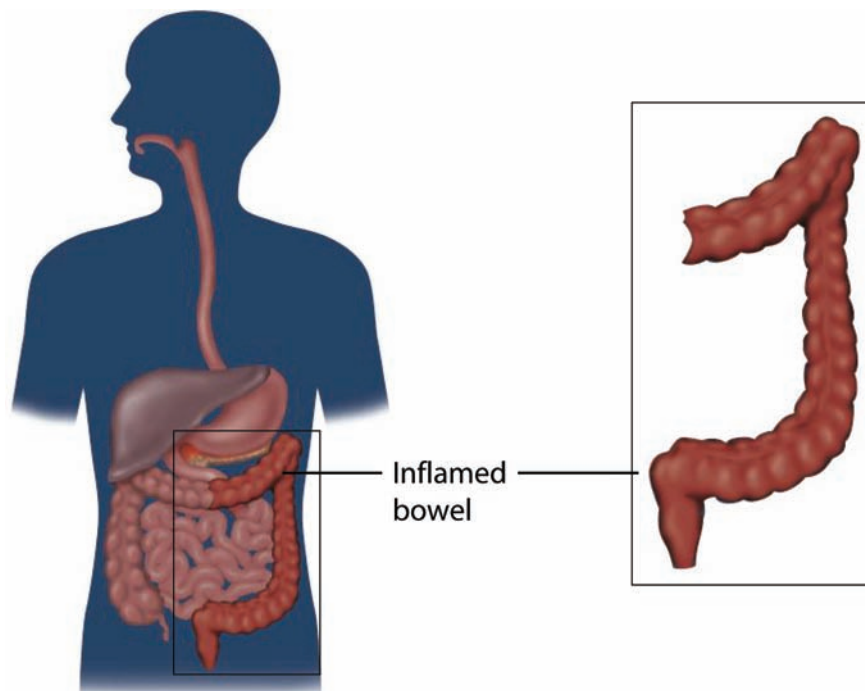

Inflammatory bowel disease (IBD) refers to a group of disorders that cause the intestines to become inflamed. IBD generally refers to chronic (long-lasting) inflammatory bowel diseases of unknown cause. IBD is typically diagnosed as either ulcerative colitis or Crohn's disease, depending on depth of inflammation of the intestinal wall and the affected regions: ulcerative colitis affects the most superficial layer of the colon, called the mucosa, and the inflammation always involves the rectum, whereas Crohn's disease affects all layers of intestinal tissue (transmural involvement) and may occur anywhere along the intestinal tract from lips to anus but most commonly occurs in the lower part of the small intestine (ileum).*

What Is Inflammatory Bowel Disease?

Inflammatory bowel disease (IBD) encompasses several disorders resulting in chronic inflammation* of the gastrointestinal tract. The different types of IBD have many symptoms in common, including abdominal pain, frequent diarrhea (sometimes with blood and mucus), constipation, weight loss, and fatigue. IBD is often associated with other inflammatory conditions, for example, fever, inflammation of the joints (arthritis), skin or eye lesions, and perianal disease*. There are many chronic inflammatory intestinal diseases, including those caused by bacteria (diverticulitis, chronic appendicitis, *H. Pylori* gastritis), parasites (amoebic colitis, *Giardia* duodenitis), physical and chemical agents (radiation enteritis, bile and peptic gastritis, and esophagitis), but the term IBD generally refers to chronic inflammatory bowel diseases of unknown cause.

What is known is that IBD is not passed from person to person. However, up to 25 percent of people with IBD have a relative with the

When inflammation occurs in the large intestine (colon) or in the lower part of the small intestine (ileum), it causes pain and swelling and may lead to diarrhea, weight loss, fatigue, and fever. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **mucosa** (mu-KOH-sa) is the moist tissue that lines some organs and body cavities. It makes mucus, a thick, slippery fluid.

disease, suggesting that genetic factors play a role in its development. Some researchers believe that IBD occurs because a virus or bacterium triggers an inappropriate response from the immune system* in people who have a genetic tendency for the disease. This abnormal response would then cause the digestive tract to become inflamed. But despite decades of study and searching for an infectious agent, as of 2009 none had been identified.

What Are the Different Types of IBD?

The two major types of IBD are ulcerative colitis and Crohn's disease. The disorders have many points in common: the cause of both IBDs remains unknown; they both have unpredictable outcomes; they have common symptoms, which are not necessarily intestinal; laboratory tests are inconclusive; and responses of patients vary to treatment.

Ulcerative colitis Ulcerative colitis involves inflammation of the surface mucosal layer of the colon. The deeper or muscular and serosal layers of tissue are rarely affected. Inflammation always begins in the rectum. If the disease remains limited to this portion of the colon, then it is called ulcerative proctitis. But the disease often extends toward the small intestine for an unpredictable distance and then abruptly stops. Besides the affected segment, no other diseased regions occur that are separated by healthy tissue ("skip areas"), as are present in Crohn's disease. The inflammation typically involves only the mucosa*, with formation of ulcers. These sores often result in bloody diarrhea, and substantial blood

loss can occur. Ulcerative colitis affects only the rectum in approximately 25 percent of cases. It often spreads in continuous fashion to the more proximal large intestine. The small intestine is never involved, except when the ileum is temporarily inflamed. As the disease becomes chronic, the colon wall loses its undulations and starts looking like a “lead pipe”, as seen on imaging tests. In severe cases, it can extend to the submucosa*, but this is very rare.

Most people who develop ulcerative colitis are between the ages of 15 and 40, the most typical symptom being bloody diarrhea, accompanied by abdominal pain, cramping, and fever. The severity of the disease varies from person to person. Some people seldom have an attack of symptoms. Others have almost continuous attacks that interfere with their daily activities. One of the most serious complications of ulcerative colitis is “toxic megacolon,” which can lead to intestinal perforation, sepsis*, and death.

Experts agree that having ulcerative colitis increases the risk of intestinal cancer. Five percent of people with ulcerative colitis develop colon cancer. The longer a person has ulcerative colitis and the larger the affected region, the greater the risk of developing cancer: If only the lower colon and rectum are involved, the risk of cancer is the same as for the general population. But if the entire colon is affected, the risk of cancer becomes 32 times the normal rate. In some cases, cells lining the colon become pre-cancerous, a condition referred to as “dysplasia,” which greatly increases the risk of cancer.

Crohn’s disease Crohn’s disease (sometimes referred to as ileitis or enteritis) is an inflammation that extends deep into the tissues of the intestinal wall, unlike ulcerative colitis, which is only in the mucosa. Crohn’s disease involves all layers of the bowel (transmural inflammation) and frequently involves the small intestine. Here it typically results in areas of marked thickening of the intestinal wall with multiple areas of narrowing resulting in obstruction of the passage of the intestinal contents. These areas may alternate with stretches of normal intestine. These normal areas are called skip areas. Crohn’s disease affects the ileum and cecum* in 40 percent of patients, only the small intestine in 30 percent, and only the colon in 25 percent. Much less commonly, Crohn’s disease can also affect the more central parts of the gastrointestinal tract, including the mouth, tongue, esophagus, stomach, and duodenum*. Perianal complications (fistulas*, fissures*, abscesses*) are common and coincide with the disease’s characteristic transmural inflammation pattern.

There are many conflicting theories about what causes Crohn’s disease. Men and women seem to be afflicted in equal numbers, and about 20 percent of people with the disease have a relative who also has it. Many people with Crohn’s disease have weakened immune systems, but it is not known whether this is a cause or a result of the disease.

The symptoms of Crohn’s disease vary from person to person. Typical symptoms include ongoing abdominal pain, loss of appetite, diarrhea,

* **submucosa** (sub-mu-KOH-sa) is the layer of tissue under the mucosa.

* **sepsis** is a potentially serious spreading of infection, usually bacterial, through the bloodstream and body.

* **cecum** (SEE-kum) the pouch-like start of the large intestine that connects it to the small intestine.

* **duodenum** (dew-eh-DEE-num) is the first part of the small intestine that connects to the stomach.

* **fistulas** (FIS-tu-las) are abnormal connections between two organs or leading from an internal organ to the surface of the body.

* **fissures** are tears in tissue.

* **abscesses** (AB-seh-sez) are localized or walled off accumulations of pus caused by infection that can occur anywhere within the body.

* **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.

* **biopsies** (Bi-op-seez) are tests in which small samples of skin or other body tissue are removed and examined for signs of disease.

weight loss, and fatigue. Perianal disease is experienced by 50 percent of patients. Children with Crohn's disease may develop slowly and not reach their full growth potential because their bodies do not get enough nourishment for normal growth. Adults may also have problems with getting adequate nutrition.

The most common complication of Crohn's disease is blockage of the intestine, because the intestinal walls tend to swell and thicken with scar tissue that eventually impairs the movement of intestinal contents. In some people, inflammation, perforation, and scarring extend into surrounding tissues, creating fistulas and a high risk of additional infection.

How Is IBD Diagnosed?

A medical history, physical examination, and diagnostic tests are required to diagnose IBD. Blood samples may be taken to search for evidence of anemia* and infection. Examination of stool samples for the presence of blood is also helpful in reaching a diagnosis.

Often the colon is examined through a procedure called a colonoscopy. An endoscope (a lighted flexible tube with a camera attached to a television monitor) is inserted through the anus. This procedure allows the doctor to see the inside lining of colon and rectum. Sometimes during

ENDOSCOPY

The word “endoscopy” means “peering within.” Endoscopes allow a physician to see inside the human body.

An endoscope is a long flexible tube with a light and camera inside its tip. It captures an image and sends a magnified form of it back to a video screen. This system makes it possible for the physician to examine the inside of the body in the area of interest.

Endoscopes also contain openings through which the doctor can maneuver tiny surgical tools, such as scissors, forceps, suction devices, and water sprays. Thus, this tool enables the doctor to perform surgery or to take tissue samples without cutting through the wall of the abdomen or chest.

After its approval by the Food and Drug Administration in 2001, wireless capsule endoscopy, also known as the “video pill,” began to be used because it is a less invasive procedure than the conventional endoscope. As the name implies, it is a little camera in the form of a pill that can be swallowed. As it travels through the digestive tract, it produces images that are of the same high quality as those produced by endoscopes. But the areas of interest can not be cleaned of intestinal contents or be repositioned with the inflation of air, nor can biopsies* be taken or bleeding lesions be stopped. For these and other reasons, this technology is less frequently employed. When an abnormality is found with the pill, a conventional endoscopic procedure is almost always required.

the colonoscopy a tissue sample (called a biopsy) is taken from the intestinal lining for further examination under a microscope.

Another diagnostic procedure commonly used is a barium study. A person drinks a mixture of barium that is flavored with another liquid, and then the person is x-rayed. Because barium shows up on x-rays, the doctor can detect abnormalities as the mixture flows through the person's intestines. CT scans* may be useful in evaluating the progress of the disease once it has been diagnosed.

However, invasive procedures such as endoscopies and barium x-rays can be contraindicated during the acute phase of IBD, as they carry the risk of perforating the intestinal wall, which is weakened by inflammation.

How Is IBD Treated?

Because ulcerative colitis and Crohn's disease often have different complications, they also have distinct medical and surgical treatments aimed at relieving specific symptoms.

Medication and Diet Medication and diet are the two primary approaches to controlling IBD. They do not cure the disease but are effective in reducing symptoms in the majority of people. In severe cases of IBD, surgery may be necessary. Anti-inflammatory drugs often are used to help control the inflammation. In some cases, immunosuppressant drugs may be helpful in controlling symptoms that do not respond to anti-inflammatory drugs. Antibiotics are also used to treat Crohn's disease. Several experimental drug therapies were under investigation as of 2009.

Many of the drugs used to treat IBD are powerful and may have undesirable side effects. The physician must balance the undesirable side effects against the positive benefits, sometimes trying several different drug combinations before a successful balance is reached.

In addition to drug therapy, a special diet may be prescribed. Because IBD interferes with nutrition, people with the disease often must increase the amount of calories, vitamins, and minerals they consume. Some individuals find that they must avoid specific foods that aggravate their symptoms. Other people find that a bland, low-fiber diet offers some relief. Because there is no cure for IBD and because the diseases are unpredictable in their course, people with any form of the disease should receive regular medical examinations that include a review of their treatment and diet.

Surgery In severe cases of IBD, a person may need surgery to remove damaged sections of the intestines. About 20 percent of people with ulcerative colitis require surgery at some point in their lives. Severe cases may require removal of the entire colon and rectum. After this procedure, normal bowel movements are no longer possible, so the small intestine is given a surgically created opening through the lower abdomen. (The names of types of surgery that create an opening end with “-ostomy.”) This opening is covered with a bag that collects waste and must be emptied several

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **colostomy** (ko-LOS-to-mee) is a surgical procedure in which a part of the large intestine is removed, and the end of the intestine is attached to an opening made in the abdomen. The stool is passed through this opening into a special bag.

times a day. Different ostomies may be performed. When the colon and rectum are removed, the surgeon performs an ileostomy to attach the bottom of ileum to the stoma (opening). When the only the rectum is removed, the surgeon performs a colostomy* to attach the colon to the stoma. An alternative to using an outside collecting bag is to perform a “continent ileostomy.” In this procedure, the surgeon creates an internal reservoir pouch using a part of the small intestine. A valve is constructed and a stoma is placed through the abdominal wall. A tube can then be inserted through the stoma and valve to drain the pouch.

About 70 percent of people with Crohn’s disease eventually need to have damaged areas of the intestine removed. Removing the damaged parts does not cure the disease, because the inflammation may return in other places in the intestine, usually near the surgical site. Many people with Crohn’s disease need additional surgeries. Multiple surgical resection can lead to short bowel syndrome. Surgery may be necessary to remove or open narrowed areas causing obstruction. Surgery may be required for the removal and healing of fistulae.

Extensive Crohn’s disease may require intravenous feeding to assure normal growth and development in children.

Living with IBD

People with IBD often go for substantial periods when they feel well and have few symptoms. During these times they are able to hold jobs, raise families, and participate in normal daily activities. Throughout the United States, there are support groups for people with IBD that help them learn to cope with their illness and maintain a normal, happy life.

Nevertheless, IBD is very frequently a difficult problem, producing both physical and emotional stresses. Comprehensive care should always offer patients with these problems knowledgeable and sensitive professional services. Addressing these issues is time-consuming yet essential.

Influenza

Influenza (in-floo-EN-zuh), also called the flu, is a contagious viral infection that attacks the respiratory tract, including the nose, throat, and lungs.

Joseph's Story

Joseph was coughing, sneezing, and starting to feel very tired, but he went to school anyway. During lunch, several of his friends asked him if he was sick. As he started to answer, he sneezed. It happened so quickly that he could not cover his nose. None of his friends saw or felt the microscopic droplets that carry influenza virus that came out of Joseph's nose and that they unknowingly inhaled into their own lungs.

The next morning, Joseph woke up and felt as if he could not get out of bed. He had a high fever—about 102 degrees Fahrenheit—but felt shivery. His head, muscles, and whole body ached, and his nose was congested. He had the flu.

For the next few days, Joseph's friends felt fine. They did not know that the flu virus they had inhaled was spreading through their bodies,

▲ Three digitized views of Type A influenza virus. J. L. Carson, Custom Medical Stock Photo, Inc. Reproduced by permission.

* **epidemics** (eh-pih-DEH-miks) are outbreaks of diseases, especially infectious diseases, in which the number of cases suddenly becomes far greater than usual. Usually, epidemics that involve worldwide outbreaks are called pandemics.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

latching onto healthy cells and infecting them. Then one morning, several of Joseph's friends woke up with a fever, sneezing, and coughing. Within a few hours, they felt as if they had no energy. They, too, had the flu.

What Is Influenza?

The respiratory infection influenza, commonly known as the flu, causes symptoms that include fever, muscle aches, sore throat, and a cough. In its early stages, influenza sometimes is confused with the common cold because both affect similar parts of the body, but the flu is more severe, lasts longer, and can cause dangerous, even fatal, complications.

Influenza virus is classified as type A, B, or C. Types A and B cause large flu outbreaks or epidemics* each year, whereas type C flu virus causes only mild symptoms. Type A influenza virus is the most threatening to humans because it is likely to mutate (change) into new strains frequently.

When the human immune system* encounters a foreign protein such as a flu virus, it produces antibodies* that inactivate that particular virus. This process is likely to take a week or two, so that the first time individuals are infected with a particular virus, they get sick. However, if these individuals are later exposed to the same virus, their body recognizes it and is able to quickly produce the specific antibody needed to

EPIDEMIC

There have been epidemics of influenza throughout history, but none compares with the one that circled the planet in 1918 and 1919. (An epidemic that is worldwide is called a “pandemic.”) More than 20 million people died, including almost 500,000 Americans.

The flu began to spread in the spring of 1918, at first in military camps in the United States and France. Soldiers living in very close quarters and the massive movement of troops around the globe contributed to the wide-spread infection. Soldiers from many countries were exposed to one another and to civilians across Europe and the Far East. Later, when the flu spread to Spain, it received a lot of newspaper publicity, which is why this epidemic is sometimes called the Spanish flu.

In 2005 Jeffrey Taubenberger, a researcher at the Armed Forces Institute of Pathology outside Washington, D.C., extracted virus proteins from preserved lung tissue of people who had died in the 1918–1919 flu epidemic. He showed that the epidemic had been caused by a bird flu virus that had mutated so that it was able to infect humans. The human immune system was unprepared to cope with such a radically different type of flu virus, so many more people died in the outbreak than in a normal flu outbreak. More often influenza viruses mutate only slightly, just enough to make people sick but not enough to kill them.

kill the virus immediately. In this second exposure, the individuals do not get sick. This process forms the basis of immunity* to disease.

Influenza viruses have two key proteins on their surface, haemagglutinin (HA) and neuraminidase (NA). These proteins influence the ability of the virus to infect healthy cells. The viral genes that produce these surface proteins mutate rather rapidly, and so the proteins themselves change rapidly. The antibodies made against one type of HA or NA protein do not work well against the mutated (changed) proteins. Thus, a person who has already had flu can get the flu again if he or she is next exposed to a different (mutated) strain.

How Common Is Influenza?

Millions of people contract the flu each year. Influenza is extremely contagious, mostly because people (especially school children) often spread it before they even know that they are sick. Also, those with the infection usually remain contagious for about a week after first showing symptoms. When an infected person sneezes, coughs, or talks too closely to others, the flu virus is transmitted through tiny drops of fluid that are launched into the air and can be inhaled by someone else. The virus can also be left on surfaces that a person with the flu has touched, such as door-knobs, desks, and keyboards, so people who forget to wash their hands after touching these objects can easily become infected from rubbing their eyes or touching their mouth. The virus is very hardy and can live as long as two days on hard surfaces.

Influenza affects people of all ages, but it is a special problem for the very young, the elderly, and people with weakened immune systems, including people with AIDS*, people with certain cancers or who are receiving chemotherapy* to treat cancer, people who have had organ

Flu in the Animal World

Many different subtypes of type A influenza virus cause infection in humans. Other type A subtypes cause influenza in chickens, ducks, pigs, horses, ferrets, whales, seals, and dogs. Normally animal flu does not spread to humans, but there have been a few cases in Asia when avian (bird) flu passed from birds to people who handled them.

* **immunity** (ih-MYOON-uh-tee) is the condition of being protected against an infectious disease. Immunity often develops after a germ has entered the body. One type of immunity occurs when the body makes special protein molecules called antibodies to fight the disease-causing germ. The next time that germ enters the body, the antibodies quickly attack it, usually preventing the germ from causing disease.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **chemotherapy** (KEE-mo-THER-ah-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

What Is the Stomach Flu?

When people complain about the stomach flu, what they actually are describing is gastroenteritis (gas-tro-en-ter-EYE-tis). The stomach cramps, nausea, and vomiting that accompany a bout of gastroenteritis usually only last a day or two and are different from the group of symptoms seen with influenza virus infection.

* **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.

* **opportunistic infections** are infections caused by infectious agents that usually do not produce disease in people with healthy immune systems but can cause widespread and severe illness in patients with weak or faulty immune systems.

* **bronchitis** (brong-KYE-tis) is a disease that involves inflammation of the larger airways in the respiratory tract, which can result from infection or other causes.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **asthma** (AZ-mah) is a condition in which the airways of the lungs repeatedly become narrowed and inflamed, causing breathing difficulty.

transplants, and anyone else who is taking any medication that suppresses the immune system.

When people inhale the flu virus, it enters the airways. The HA proteins help it to attach to healthy cells. The virus then enters the cell and uses the cell's protein-making and nucleic acid-making capacity to make more of the virus. The host cell eventually bursts open, releasing new virus particles that repeat the cycle. Although the body's immune system fights back, it takes time for it to destroy the virus, and during that time, the person develops flu symptoms.

How Do People Know They Have the Flu?

Flu symptoms are usually worse than those seen with a cold. Symptoms include:

- Sneezing, runny nose, and congestion (stuffed-up nose)
- High fever
- Headache
- Chills
- Dry-sounding cough
- Muscle aches
- Abdominal* pain and poor appetite
- Tiredness

Most people have symptoms of the flu for 7 to 14 days. The high fever and body aches usually disappear within a few days, but those symptoms may be quickly replaced by a sore throat, runny nose, and lingering cough. In some cases, fever may even return for a brief period. Feelings of tiredness and exhaustion can last several days or weeks in some people with the flu. Trying to return to a normal routine too quickly can cause symptoms, especially exhaustion, to reoccur.

Many flu symptoms are not caused by the influenza virus, but by the body's struggle to control and destroy the virus. White blood cells produce a protein called interleukin (in-ter-LOO-kin) that leads to aches, fever, and fatigue until the virus is eliminated.

People who get the flu sometimes develop complications. The flu virus weakens the body's defenses against infection. This effect increases the likelihood of developing an opportunistic infections* in the lungs. About two weeks after getting the flu, some people develop bronchitis* or pneumonia*. Bacterial pneumonia can be a serious complication of the flu. It usually occurs when bacteria invade lung tissue that is already inflamed by the flu virus. This complication can be life-threatening in infants and in elderly people. Influenza can also worsen the symptoms of other common heart and lung diseases, such as congestive heart failure, chronic* bronchitis, and asthma*. Hundreds of thousands of Americans are hospitalized every year due to the virus, and about 20,000 die from the flu or its complications.

Because the flu can go from bad to worse very quickly, doctors recommend that people with the flu seek medical care immediately if they experience any of the following:

- A fever that lasts longer than 5 days
- Any breathing difficulty, including wheezing (WEE-zing), a whistling sound that occurs while breathing or coughing
- A continuous cough that makes it difficult to breathe
- A cough that brings up blood or thick green or dark yellow mucus

How Is Influenza Diagnosed and Treated?

Doctors usually diagnose the flu based on the symptoms and information about whether flu is currently common in the patient's area. Laboratory tests to diagnose influenza do exist, but they are not often used because

IS IT A COLD OR THE FLU?

Doctors say that more than 200 different viruses can cause symptoms of the common cold. In fact, many people say that they have the flu when they really have a common cold. How can people tell the difference? Here is some information comparing the common symptoms of a cold with those of influenza.

- **Symptoms** come on slowly with a cold, but suddenly with the flu.
- **Fever** is rare with a cold, but high (lasting 3–4 days) with the flu.
- **Headache** is sometimes present with a cold, but often present with the flu.
- **Aches and pains** are slight with a cold, but typical and often severe with the flu.
- **Fatigue and weakness** is mild with a cold, but typical and may last several weeks with the flu.
- **Extreme exhaustion** is never seen with a cold, but comes early and prominently with the flu.
- **Sneezing** is usual with a cold, but only seen sometimes with the flu.
- **Running nose** is usual with a cold, but only seen sometimes with the flu.
- **Scratchy or sore throat** is common with a cold, but only seen sometimes with the flu.
- **Chest discomfort** is mild to moderate with a cold, but is common and can become severe with the flu.
- **Coughing** is seen both in colds (a hacking cough) and the flu.

H1N1—The New Flu, a Lesson in Epidemiology

In April 2009 an infectious respiratory disease caused by a subtype of the influenza A virus was identified. Initially called a swine flu because it contained swine flu genes, it was quickly renamed H1N1 influenza A.

The H1N1 influenza virus had not been previously identified and the virus and associated flu were subjects of intense research. Information about the virus and its associated flu accumulated rapidly.

What concerned health experts about the H1N1 virus was that it was of unknown lethality and that it had the ability to pass directly from person to person. Because the H1N1 flu was a new strain, humans had no immunity to it. As a result, the resources of the World Health Organization (WHO), the Centers for Disease Control (CDC), state public health departments, and various international organizations charged with protecting public health were mobilized to attempt to prevent and/or mitigate a possible worldwide influenza pandemic. In some areas schools and businesses were shut down and events that would attract crowds such as soccer matches were canceled. Despite preventive actions, new cases of H1N1 were diagnosed worldwide; however, the vast majority of H1N1 flu cases appeared to have the same severity of symptoms, risks of complications, and transmissibility as a normal seasonal flu.

By mid-May 2009, 33 countries had officially reported 6,500 cases of H1N1 influenza with 65 deaths. At the same time, health officials worldwide were watching the Southern Hemisphere where flu season was about to begin to see how the H1N1 virus circulated there. The outcome would determine how aggressively public health officials would approach the H1N1 flu in the fall flu season in the Northern Hemisphere.

- * **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.
- * **Reye's syndrome** (RYES SIN-drome) is a rare condition that involves inflammation of the liver and brain, and sometimes appears after illnesses such as chicken pox or influenza. It has also been associated with taking aspirin during certain viral infections.
- * **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.

of their cost, unreliability, and the time it takes to get a result. To perform a flu test, the doctor uses a small cotton swab to collect some of the fluid from the nasal passages. This fluid sample can then be tested in a laboratory to see if the flu virus is present.

The flu was treated in the early 2000s the same way it was one hundred years before. Patients were advised to rest in bed and drink plenty of liquids to prevent dehydration* and stay warm. Over-the-counter medications can help the fever, aches, and cough, but aspirin should be avoided during the flu or other viral infections because of its relationship to Reye's syndrome*.

Occasionally, doctors prescribe antiviral flu medications, such as amantadine (uh-MAN-ta-deen) or rimantadine (rih-MAN-tuh-deen), for people with the flu. These medications do not offer a cure but can reduce the length and severity of the illness. In order to work, they must be taken within 48 hours of the start of flu symptoms. These drugs are normally given only if the person has a weakened immune system and is likely to become very sick from the flu. Antibiotics, such as penicillin, are not effective against viruses, but they are used to treat complications such as opportunistic bacterial infections.

Can the Flu Be Prevented?

Infection by some strains of influenza can be prevented with a flu vaccination* in the fall. The vaccine contains inactive versions of the three flu viruses—two of type A and one of type B—that researchers suspect will be most likely to cause influenza during the coming winter and early spring. The vaccine contains particles from killed influenza viruses. These killed viruses stimulate the immune system to make antibodies, but they do not cause flu symptoms.

Because the influenza virus is constantly mutating, the flu shot does not guarantee that a person will not get the flu. It does, however, reduce the chance of becoming sick by 80 to 90 percent. Almost everyone should get a flu shot, especially the elderly, people with certain heart and lung diseases, and people who work in places such as hospitals, schools, and daycare centers. Because the virus changes over time, each year the vaccine is designed to target slightly different strains of virus, which means that the shot must be repeated every year.

Because the highly contagious flu virus is easily passed from person to person through the air and through its being left on surfaces, the virus can be almost anywhere. Experts recommend that hands be washed thoroughly with warm, soapy water for at least 15 to 30 seconds after one has used a public restroom and before eating or touching the face.

Avoiding contact with people who have the flu can also lower the risk of catching it. By avoiding close contact in large crowds, especially at schools or in malls, and by not touching used tissues or and not sharing drinks, a person can reduce the chance of becoming sick.

Ingrown Toenail

An ingrown toenail is a toenail that cuts into the skin of the toe.

What Is An Ingrown Toenail?

An ingrown toenail is a common condition in which the corners or sides of the toenail cut into the skin of the toe. This condition usually occurs in the big toe and can affect people of all ages. An ingrown toenail is a serious condition for people with impaired blood circulation or diabetes.

▲
Ingrown toenails that have become infected may be treated with antibiotics. People with diabetes or circulatory system problems should receive regular foot care from a doctor or podiatrist.

Dr. P. Marazzi/Photo Researchers, Inc.

What Happens When People Have Ingrown Toenails?

Ingrown toenails tend to run in families, although they also may be caused by the following:

- wearing shoes that are too tight or that do not fit properly
- trimming toenails improperly or too closely
- repeated trauma to the toenail from everyday activities such as work and sports.

Pain and swelling are the first signs of an ingrown toenail. The area around the ingrown toenail can also become infected. A doctor diagnoses an ingrown toenail through a physical examination.

Treatment Treatment depends upon the type and amount of pain present. Ingrown toenails that are not infected may be treated by putting a cotton pad coated with a medicine called collodion (ko-LO-de-on) under the nail's edge. This medicine relieves the pain and allows the nail to grow properly. Ingrown toenails that are infected may be treated with antibiotics or warm soaks. Sometimes, part of the toenail must be removed. An ingrown toenail is a serious condition for people with impaired blood circulation or diabetes. People with these conditions should have their feet cared for by general doctors or by podiatrists, doctors who specialize in the care of the feet.

Prevention Ingrown toenails can be prevented by wearing shoes that fit properly and by trimming toenails properly. Nails should be cut straight across with a nail clipper, not rounded off at the corners, and the nails should be filed smooth.

Insomnia

Insomnia (in-SOM-nee-a) is a disorder in which people have trouble sleeping or getting enough rest.

The Necessity of Sleep

Humans, like all other living organisms, have cycles of activity and rest, which perhaps evolved partly as a response to the cycles of night and day. Many of the body's hormones* and processes are related closely to such daily cycles. Sleep provides the opportunity to rest, to restore certain essential neurotransmitters*, and even to avoid certain predators. Sleep, in short, is necessary to health and even to life.

Yet millions of people have insomnia. They may have difficulty falling asleep or staying asleep through the night, or they may wake up too early or sleep so restlessly that the body and mind are not refreshed. Insomnia is not defined by how long it takes to fall asleep or by how many hours a person sleeps, because these characteristics vary greatly from person to person. Babies may sleep 16 to 20 hours per day, and school-age children need between 8 and 10 hours every night. Some adults need seven to eight hours of sleep per night, whereas others function perfectly well with just three to four hours. Instead, people are diagnosed with insomnia when sleep problems begin to interfere with daily living, when they can no longer function normally during the day because they are tired or cranky, have no energy, and are unable to concentrate.

Everyone has trouble sleeping sometimes. Young people who are excited about a holiday or stressed about an exam might have trouble falling asleep. Adults who are worried about a sick relative or stressed at work might wake up in the middle of the night and not be able to fall back asleep. These are examples of transient (short-term) insomnia, which are sleep problems that last for one night or even for a few weeks and then disappear. In other cases, episodes of short-term insomnia come and go, which is called intermittent insomnia. But half of all people with insomnia have chronic* insomnia, which is a sleep problem that occurs on most nights for a month or longer.

Insomnia affects people of all ages, but it is most common in older people, especially women. When people travel, start a new job, or move to a new home or school, all of which are changes in routine, they can have trouble sleeping. Physical conditions such as pregnancy, arthritis, the need to urinate frequently, and leg cramps also seem to cause sleep problems. But the most common cause of insomnia is psychological*; anger, anxiety, depression*, and stress keep many people from sleeping well.

* **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

* **neurotransmitters** (nuro-o-trans-MIH-terz) are chemical substances that transmit nerve impulses, or messages, throughout the brain and nervous system and are involved in the control of thought, movement, and other body functions.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **psychological** (SI-ko-LOJ-i-kal) refers to mental processes, including thoughts, feelings, and emotions.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

* **tolerance** (TALL-uh-run-see) a condition in which a person needs more of a drug to feel the original effects of the drug.

* **glaucoma** is a group of disorders that cause pressure to build in the eye, which may result in vision loss.

How Is Insomnia Treated?

If insomnia is transient, it should go away when the stress that triggered it eases, such as when that worrisome exam is over. For underlying psychological or physical issues, seeing a doctor can help improve sleep. Dealing with insomnia, however, is often a matter of lifestyle changes. Choices that may contribute to insomnia include the following:

- Reading, eating, or watching television in bed. Use a bed only for sleeping.
- Taking afternoon naps
- Smoking
- Drinking alcohol
- Drinking coffee, tea, cocoa, colas, or other drinks that contain caffeine late in the day

Choices that may contribute to a better night's sleep include the following:

- Keeping to a sleep schedule, which means going to sleep and getting up at the same time every day
- Exercising during the day (but not after dinner)
- Taking a warm bath before bedtime
- Drinking warm milk at bedtime

Over-the-Counter and Prescription Sleep Aids

Many over-the-counter (OTC) drugs are used for insomnia, most of which contain antihistamine, diphenhydramine, or doxylamine. Various problems attend using these drugs on a regular basis: drug tolerance*; dependency (meaning a person comes to rely habitually on the drug to assure sleeping well); and various side effects, such as drowsiness the next day. These drugs can also cause problems for users who have certain existing conditions, for example, allergies, asthma, emphysema, chronic bronchitis, and glaucoma*. Most of these drugs should not be used during pregnancy. In addition to OTC drugs, certain herbs are believed to assist sleep, such as valerian. While some people may have allergic responses to herbs, other side effects are not associated with them. But even with herbal remedies, use should be as needed rather than habitual.

Prescription sleep medications are highly effective in treating insomnia, but they have disadvantages, chief among which may be physical and psychological dependency. These controlled substances can be abused and if abused can be dangerous, even life-threatening. Prescription sleep medications may contain benzodiazepine (Restoril), eszopiclone (Lunesta), or zolpidem (Ambien). The second and third of these have reduced dependency risk.

For both OTC and prescription sleep aids, users should follow directions carefully, use only as needed rather than habitually, avoid alcohol consumption within several hours of taking the sleep aid, and inform any physician

caring for the user of the drug's use. Sleep aids can be effective in special situations, such as in travel across time zones and following certain medical procedures. But they must be used with caution and care and only as needed.

Intellectual Disability

Formerly referred to as “mental retardation,” intellectual disability is a condition that may be present from birth or childhood that is marked by significantly lower intellectual functioning than the average for individuals of the same age and by delays in developing social skills, communication skills, and the ability to care for oneself and live independently. Its effects range from mild to profound.

What Is Intellectual Disability?

Intellectual disability is characterized by considerable delays in cognitive, social, practical, and abstract learning skills. People with intellectual disabilities may have problems with adaptive skills such as communication, personal care, social skills, community interaction, health and safety, leisure activities, school, and work.

Did You Know?

■ Intellectual disability is present in 1 to 3 percent of the U.S. population

■ Intellectual disability is not the same as mental illness. It is possible for people with intellectual disabilities to suffer from depression, anxiety, or other mental illnesses, just as people with average intelligence do.

■ Intellectual disability affects people from all ethnic, social, and economic backgrounds.

* **intelligence quotient test** also known as an IQ test, refers to a test designed to estimate a person's intellectual potential.

* **motor skills** are muscular movements or actions.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

Intellectual disabilities are often classified based on practical and cognitive tests, as well as intelligence quotient tests*.

Mild disability People in this category account for 75 to 90 percent of all cases of intellectual disabilities. Children may go undiagnosed until they are well into their school years. They have an IQ range of 52 to 69. They are often slower to walk, talk, and feed themselves than most other children, but they can learn practical skills, including reading and math, up to the sixth grade level. Mildly disabled adults usually build social and job skills and can live independently.

Moderate disability People in this category account for 10 to 25 percent of all cases of intellectual disabilities. Children in this group have an IQ range of 36 to 51 and show noticeable delays in developing speech and motor skills*. Although they are unlikely to acquire academic skills such as reading or math, they can learn basic communication skills, some health and safety habits, and other essential skills. As adults, they usually cannot live independently, but they can master some simple tasks and travel alone in familiar places.

Severe disability People in this category account for 10 to 25 percent of all cases of intellectual disabilities. Severely disabled children have an IQ range of 20 to 35 and are often diagnosed at birth or soon after. These children have difficulty with motor development and communication. With training, they may learn some self-help skills, such as how to feed and bathe themselves. They usually learn to walk and gain a basic understanding of speech as they age. As adults, they may be able to follow daily routines and perform simple tasks, but they need to be directed and live in a protected environment.

Profound disability People in this category account for 10 to 25 percent of all cases of intellectual disabilities. Children with profound disabilities have an IQ of less than 20 and are usually diagnosed at birth. These children often have additional medical problems and require nursing care. Children who are profoundly disabled need to be continuously supervised. They show delays in all aspects of development. With training, however, they may learn to use their legs, hands, and jaws. Adults who are profoundly disabled usually learn some speech, and they may learn to walk, but they cannot care for themselves and need complete support in daily living.

What Causes Intellectual Disability?

Intellectual disabilities sometimes have a genetic cause, resulting from one or more chromosomal abnormalities. At other times, though, intellectual disability may be the result of problems during pregnancy or childbirth that affect the development of the fetal brain and central nervous system*. Babies may be born with intellectual disabilities if their mothers do not receive proper nutrition and medical care during pregnancy, if their mothers have

INDIVIDUALS WITH DISABILITIES EDUCATION ACT (IDEA)

In 1975, the U.S. Congress passed Public Law 94-142, the Education for All Handicapped Children Act, which was renamed the Individuals with Disabilities Education Act (IDEA) in 1990.

Updated in 2004, IDEA aims to provide children with disabilities a “free appropriate public education.” It states that children with disabilities should be educated alongside their nondisabled peers to prepare them for extended education, work, and independent living. Teachers, principals, parents, civil rights advocates, and even courts of law have debated whether students with disabilities should be educated in the same classrooms as their nondisabled peers. Some argue that this practice places too great a burden on teachers.

Under IDEA, every disabled child has the right to an annual, written individualized education plan (IEP). Teachers, therapists, and parents work together to develop the best plan for educating the child, which may mean full inclusion in regular classes, partial inclusion supplemented by special education classes, or separate classes full-time.

infections during pregnancy, or if their mothers used alcohol or drugs, or were exposed to environmental toxins* during pregnancy. Many different causes of intellectual disability have been identified, but a specific cause can only be pinpointed in about 25 percent of cases.

Chromosomal abnormalities Chromosomes are threadlike structures in cells that carry genetic information. Most cells in the human body have 23 pairs of chromosomes. Chromosome pair 23 determines whether a person is female (two X chromosomes) or male (one X chromosome and one Y chromosome). Chromosomes 1 through 22 determine all of the other traits and characteristics. Intellectual disabilities may occur when a baby has an extra chromosome, an abnormal or partially missing chromosome, or a mislocated chromosome. Often, embryos that have been assigned the wrong number of chromosomes do not survive, and the pregnancy results in miscarriage*. Nearly 75 percent of early miscarriages occur due to these chromosomal abnormalities. The chromosomal abnormalities most often linked to intellectual disability are Down syndrome, Fragile X syndrome, Prader-Willi syndrome, and Williams syndrome.

DOWN SYNDROME Down syndrome results from an abnormality on chromosome 21. These abnormalities can occur in several ways:

- Trisomy 21 occurs when there are three copies of chromosome 21 throughout the body.
- Mosaic Trisomy occurs when there are three copies of chromosome 21 in some cells.

Definitions Change

As few as 100 years ago, people with intellectual disabilities were identified as “eternal children,” “mentally deficient,” “mental defectives,” “imbeciles,” and the “feeble-minded.” Even doctors used those terms, publishing medical texts with titles such as *Mental Defectives: Their History, Treatment and Training* (1904), *Mentally Deficient Children: Their Treatment and Training* (1900), and “On the Permanent Care of the Feeble Minded,” published in the *Lancet* medical journal (1903).

Fortunately, language has changed along with social attitudes toward people with intellectual disabilities. In the early 2000s it is widely understood that people with intellectual disabilities can live meaningful, fulfilling lives, in a healthy environment with the support they need.

* **toxins** are substances that cause harm to the body.

* **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.

* **ADHD** or Attention Deficit Hyperactivity Disorder, is a condition that makes it hard for a person to pay attention, sit still, or think before acting.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

- Translocation Trisomy 21 occurs when some of chromosome 14 is replaced by extra chromosome 21.
- Partial Trisomy occurs when genetic material only attaches to part of chromosome 21 instead of the whole chromosome.

The physical differences that may result from chromosome 21 errors include a flat facial profile, an upward slant to the eyes, a short neck, a single deep crease on the palm, hearing loss, an enlarged tongue, vision problems, thyroid disorders, and heart disease. Chromosome 21 errors have been linked to a mother's age. The incidence of Down syndrome in the children of mothers older than age 45 is 1 in 30, whereas for children of mothers younger than age 30 the incidence is less than 1 in 1,000.

FRAGILE X SYNDROME Fragile X syndrome results from an abnormality on the X chromosome. It is the most common cause of inherited intellectual disability, including autism. The symptoms of Fragile X syndrome tend to be much more severe in boys than girls. Only about one-third of girls with the syndrome have severe mental impairment. About 20 percent of boys with Fragile X are considered autistic. Fragile X can also cause a large head, protruding ears, flat feet, a prominent jaw, hyperextensible (able to extend to a greater than normal degree) joints, ADHD*, anxiety, and seizures*.

PRADER-WILLI SYNDROME Prader-Willi syndrome is caused by missing material on chromosome 15, which occurs when either the father's genetic material does not contribute a chromosome 15 or the mother's genetic material contributes an extra one. Children with this condition have short stature and eat compulsively, so they become extremely obese. As these children age, they have difficulty learning and problem-solving. They are particularly challenged by step-by-step tasks and sequential processing. Prader-Willi children have mild to moderate intellectual disabilities; however, these limitations are overshadowed by their weak social skills and their inability to adapt well to learning circumstances. Early intervention programs for Prader-Willi students were being developed and improved in the early 2000s so these children could realize their maximum potential.

WILLIAMS SYNDROME Williams syndrome is caused by a slight abnormality on chromosome 7. Children who are born with this syndrome have deep eyes and thin, high ears. As they grow older, they are vulnerable to heart problems and other health complications. Most are hypersensitive to sounds. They tend to have sociable and friendly personalities. They approach strangers without concern. However, they are fearful in certain ordinary situations. They are limited in tasks requiring visual detail or spatial judgment. Their relative strength is in language skills although most are not at age level in this area. They tend to be especially good at accurate, precise auditory perception, which makes them likely to have a particular appreciation of music. Not all children with Williams syndrome are musicians, but those who are tend to quite proficient.

Metabolic disorders Sometimes called “inborn errors of metabolism,” these conditions result from abnormalities in the genes* that govern how the body produces and handles amino acids*, proteins, enzymes, hormones, and nutrients. One metabolic disorder that can cause intellectual disability is phenylketonuria (FEN-il-KEE-toe-NOOR-ee-a) (PKU), which is linked to a lack of the enzyme needed to process the amino acid phenylalanine (FEN-ill-AL-a-noon). Another disorder that causes intellectual disability is hypothyroidism (HY-poe-THY-royd-iz-um), which is linked to an underdeveloped, underactive, or damaged thyroid gland*. The thyroid gland is needed to produce hormones essential for normal growth and brain development. Many other metabolic disorders can be detected at birth by a blood test and treated through special diets, medications, and hormone therapy.

Neurological development disorders Problems that interfere with fetal development of the brain, spinal cord, and central nervous system may result in intellectual disabilities, making proper prenatal medical care and good nutrition essential for pregnant women. Factors that are linked to brain development disorders include the mother’s intake of folic acid (a B vitamin) and her exposure to teratogens (toxins), such as environmental waste, alcohol, tobacco, street drugs, and some prescription medications. Some common brain development disorders are anencephaly*, hydrocephalus*, and spina bifida*. Spina bifida can be operated on during pregnancy or after birth, although surgery does not restore normal function to the spinal cord. When folic acid is taken regularly before conception, the incidence of spina bifida can be reduced by up to 70 percent. Many people with either spina bifida or autism have brain development disorders but are not intellectually disabled.

Fetal alcohol syndrome When a pregnant woman drinks alcohol or takes drugs (legal or illegal), these substances are transmitted directly to the fetus. Intellectual disability that is linked to a mother’s drinking is known as fetal alcohol syndrome (FAS). Children with FAS may have skeletal problems and distinctive facial characteristics, including widely spaced eyes, a shortened or flattened nose, and abnormalities in the shape and placement of the ears. In addition, children with FAS may have growth problems, central nervous system disorders, learning disabilities, vision or hearing problems, and behavioral problems.

Infections Serious infections can harm a baby’s developing brain before birth or early in life. Viral infections linked to intellectual disability include cytomegalovirus (SIE-toe-MEG-a-lo-VY-rus) and the rubella virus, which causes German measles. encephalitis* and meningitis* (MEN-in-JY-tis), two infections that result in inflammation of the brain, can also cause intellectual disability.

Other causes Other possible causes of intellectual disability include premature or difficult birth, severe head injury, malnutrition, mercury poisoning, and lead poisoning.

- * **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person’s body structure and physical characteristics. Inherited from a person’s parents, genes are contained in the chromosomes found in the body’s cells.
- * **amino acids** (a-MEE-no acids) are the chief building blocks of proteins. In humans, certain amino acids are required to sustain life.
- * **thyroid gland** (THY-roid GLAND) is located in the lower part of the front of the neck. The thyroid produces hormones that regulate the body’s metabolism (me-TAB-o-LIZ-um), the processes the body uses to produce energy, to grow, and to maintain body tissues.
- * **anencephaly** (AN-en-SEF-uh-lee) is a condition present at birth in which most of the brain is missing.
- * **hydrocephalus** (HY-droe-SEF-uh-lus) is a condition, sometimes present at birth, in which there is an abnormal buildup of fluid within the skull, leading to enlargement of the skull and pressure on the brain.
- * **spina bifida** (SPY-nuh BIF-ih-duh) is a condition present at birth in which the spinal column is imperfectly closed, leaving part of the spinal cord exposed and often leading to neurological and other problems.
- * **encephalitis** (en-seh-fuh-LYE-tis) is an inflammation of the brain, usually caused by a viral infection.
- * **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.

Diagnosing Intellectual Disability

Chromosomal abnormalities and metabolic disorders are often diagnosed by doctors during prenatal testing or at birth. In other cases, however, a parent, caregiver, or teacher may be the first to notice that a baby or young child is not demonstrating new skills at the same pace as his or her peers. For example, the child may not crawl, walk, or talk by the expected age. Because parents may not notice milder intellectual disabilities, doctors routinely give parents questionnaires to fill out during the child's check-ups. These questionnaires help the doctor to assess the child's developmental skills. If a child is not executing tasks at the same rate as his or her peers, he or she may be referred for more formal testing to determine if any disability is present.

Children who are referred for formal testing meet with a team of professionals that may include physicians, psychologists, social workers, and educators. The team conducts interviews and administers physical and psychological examinations to try to gauge the child's intellectual abilities and adaptive skills. These examinations also rule out other possible causes of the child's delays, such as hearing or vision problems, neuromuscular disorders, emotional or behavioral problems, learning or speech disorders, abuse, or a troubled home life.

Pediatricians use blood tests, brain scans, genetic testing, and other medical tests to detect underlying physical disorders. Psychologists use developmental tests to determine whether babies and children are

SPECIAL OLYMPICS AND BEST BUDDIES

The Kennedy family has been in the spotlight since John Fitzgerald Kennedy became president in 1960. To honor their sister Rosemary Kennedy, who was born in 1918 with severe disability, some members of the Kennedy family have chosen to use their name to improve the quality of life for other people with disabilities.

Eunice Kennedy Shriver founded the Special Olympics in 1968, when she organized the First International Special Olympics Games in Chicago, Illinois. After that, the Special Olympics expanded into an international program of year-round sports training and athletic competition for more than 2.5 million athletes in 180 countries. The program was designed to help participants develop physical fitness and motor skills, self-esteem, and a sense of community.

In 1989, Eunice Shriver's son Anthony started his own program to help people with intellectual disabilities. Best Buddies is a mentoring program that pairs disabled people with nondisabled individuals in the community. As of 2008, more than 1,300 campuses throughout the world had a Best Buddies program.

People can learn more about these organizations by visiting their websites at www.specialolympics.org and www.bestbuddies.org.

developing at a slower pace than their peers, and they use standardized intelligence quotient test to compare the abilities of school-aged children to those of average children in the same age group. Psychologists may also observe the child at play, in school, and interacting with family members before making a diagnosis of intellectual disability. Because developmental delays are not always linked to intellectual disability and because they may improve with physical treatment or changes in the child's environment, psychologists often schedule repeated evaluations to measure delays and assess improvements over time in intelligence and adaptive behaviors.

Can Intellectual Disability Be Prevented?

As of 2009, there was no known way of preventing an intellectual disability. A genetic counselor can help a couple calculate the risk of their having a baby with an inherited disability. Genetic counselors can provide information regarding the options available if the couple is at high risk. One option is in vitro fertilization, which is a medical procedure for conceiving outside of the uterus. In the process of in vitro fertilization, a doctor can test many fertilized eggs from the couple and only chose one that is free from genetic complications. If the woman is over 35 years of age, she may be cautioned about the maternal age-related risk of having a Down syndrome baby. Prenatal tests can detect the presence of Down syndrome and other genetic defects.

Living with Intellectual Disability

Families Parents who learn that an infant or child has an intellectual disability are often shocked, and they may be overwhelmed by such feelings as sadness, guilt, helplessness, and anger until they adjust to the news. Family counselors and support groups are resources that can help parents learn how to meet the special needs of intellectually disabled children and balance those needs with other family responsibilities, including helping siblings to adjust to the situation. To help children with intellectual disabilities, many families work with a team of specialists that includes psychologists, speech-language pathologists, physical and occupational therapists, social workers, and special educators.

Children Children with intellectual disabilities face many physical and emotional challenges. They may know that they are different from their peers in ways that they may not understand and feel frustrated, depressed, and anxious. They may develop behavioral problems to express feelings that they cannot verbalize. Children with intellectual disabilities can benefit from treatment and support in learning academic skills and adaptive behaviors needed for everyday living. They may also get a boost in self-esteem by realizing that they, like other children, are unique and valuable individuals.

Adults Adults with severe or profound intellectual disabilities requiring constant supervision often enter nursing homes or other residential

facilities that offer skilled 24-hour care. However, the majority of adults with mild to moderate intellectual disabilities can achieve varying degrees of independence. Because they may want or need some support and guidance, many continue to live with family members or in group homes or apartment clusters designed especially for people with special needs. Many are able to succeed in jobs and participate in community events. Some even participate in the Special Olympics. These activities help them develop a greater sense of self-worth. Others are able to get married and start their own families.

Internet Addiction Disorder

Internet addiction disorder refers to a compulsion to be online that interferes with obligations of school or work and is indulged in preference to engaging directly with friends and participating in social activities. Because no substance abuse is involved, this addiction is behavioral rather than chemical.

Bill's Story

Bill looked at his watch. He had just finished playing an online game for almost an hour and a half. He was due at his high school play practice in about 50 minutes; that meant he had about 30 minutes before he had to leave. He checked his e-mail; nothing much there. He thought he would take a quick look at his friends' Facebook pages. He was looking through one of them when one of his cyber friends sent him an instant message. "Wassup?" she asked.

"How are you?" he shot back not remembering that she thinks he is in an earlier time zone. "What are you doing online at this hour?" she asked.

He had to think of a good excuse. Why would a Hollywood talent scout be online so early in the afternoon? "I made a big score today, and I am meeting some important people for dinner so I came home early and now I am just chillin' here."

He continued this fantasy conversation until she had to leave. He then looked at his watch. He was a half hour late for practice. This was the third time this week. The director would surely drop him now.

Bill felt frustrated. He was not doing well in school because he never made time for studying. He stayed up late, writing e-mail, sending instant messages, playing online games, making Facebook entries or reading other people's Facebook pages. He did not make time for his school friends any more. His online friends seemed more important; they

- * **tolerance** (TALL-uh-runce) a condition in which a person needs more of a drug to feel the original effects of the drug.
- * **withdrawal** a group of symptoms that occurs when a drug that causes physical or psychological dependence is regularly used for a long time and then suddenly discontinued or decreased in dosage.

bolstered his self esteem. Only, most of them were people he would never meet, and most of them thought he was someone else, like a Hollywood talent scout.

Bill wondered if he had a mental problem.

Using the Internet makes up a large part of many people's lives. Some are online as part of their job; others are online because the cyber world provides escape from the real world.

What Is Internet Addiction?

Internet addiction is a compulsion to be online that controls some people's lives. Kimberly Young of the Center for Internet Addiction Recovery defined Internet addiction as a deterioration of impulse control much like pathological gambling. Adapting eight pathological gambling criteria to Internet use, Young designed a way to diagnose Internet addiction. She found that people meeting her criteria spent 10 times the amount of hours on the Internet as a comparison group did. Those with Internet addiction suffered severe degradation in their studies, relationships, finances, and careers due to the excessive time they spent online.

The concept of Internet addiction disorder was controversial in the early 2000s. Some researchers accepted and used it, whereas others thought it was misleading. In Korea and China, however, the problem of young people ignoring their social and academic responsibilities to be online was so pervasive that Internet addiction was accepted as a disorder in and of itself. The Korean and Chinese statistics, gathered in public Internet cafés, indicated patterns of excessive use, tolerance*, withdrawal*, and negative repercussions, such as poor achievement and social isolation. In the United States as of 2009, there was no nationwide effort to collect statistics regarding this behavior. Internet addiction was not included in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*) of the American Psychiatric Association (APA). Many argued that what is called Internet addiction is a symptom of other disorders played out through Internet use. However, Jerrold J. Block, in the *American Journal of Psychiatry* (2008), recommended that the APA recognize Internet disorder even though 86 percent of the cases he saw involved some other disorder. He argued there is a good chance that two disorders interact. The American Medical Association (AMA) wrote a report recommending that the APA consider including Internet addiction as a mental disorder in *DSM-V*, expected to be published in 2012.

How Common Is Internet Addiction?

The actual number of people affected by excessive use of the Internet was not known as of 2009. However, estimates were between 5 and 10 percent of those who regularly use the Internet. If the percentage remains the same, with the increasing number of people using the Internet, the number of pathological problems was expected to rise.

What Are the Signs of Internet Addiction?

Any behavior that is considered to be an addiction should show symptoms of tolerance and withdrawal. “Tolerance” means that the user needs more of the addictive experience over time in order to experience the original thrill. “Withdrawal” means that stopping the addictive behavior brings on severe negative physical responses. Young recognized that tolerance and withdrawal need to be part of the composition of this disorder if it is an addiction. The question in her recommended survey for identifying tolerance is: “Do you feel the need to use the Internet with increasing amounts of time in order to achieve satisfaction?” The question in her recommended survey for identifying withdrawal is: “Do you feel restless, moody, depressed, or irritable when attempting to cut down or stop Internet use?” These are two out of eight symptoms identified as comprising Internet addiction, yet the recommended standard is five out of the eight. Therefore, these two essential symptoms of an addiction could be absent, according to Young, in a diagnosis of Internet addiction. The other symptoms recommended by Young in a diagnosis of Internet addiction are:

- Preoccupation with Internet activity
- Previous failed personal attempts at curtailing Internet use
- Losing track of time while on the Internet
- Putting at risk important responsibility, serious relationship, or advancement opportunity
- Lying about the time spent with Internet activity
- Using the Internet activity as a means of escaping problems or feelings of depression

The AMA report endorsing a formal diagnostic disorder for Internet/video game addiction relied on Young’s description of the condition. The AMA did not give any detailed symptoms but summarized the symptoms observed by Young.

In his article, Block presented only four symptoms for Internet addiction: “excessive use,” tolerance, withdrawal, and maladaptive behavior. According to Block, tolerance is the constant need to upgrade computer equipment. Withdrawal is the display of negative moods when the Internet is not available. Block notes the seriousness of Internet addiction in China where it has been defined as spending at least six hours per day on the Internet and having some other maladaptive symptom.

The problems noted in China and Korea were accentuated by several high profile cases. One young man died at an Internet café because he stayed at the computer for such a long time without attending to his basic needs. Another young man murdered his parents after going broke buying virtual material for his online game. These cases highlight the existence of a mental disorder associated with Internet use. The cultural similarities between Korea and China and their cultural dissimilarities with western countries may make these cases culturally specific. However,

similar situations might be happening in the United States without being noticed by the public because of the independence of American youth and because of U.S. privacy laws.

Because the term “Internet addiction” was controversial and had not as of 2009 been recognized by the APA, it might be useful to think of the condition as a disorder that is more universally accepted, such as “problematic computer use” or “pathological computer use.” These terms refer to a pattern of excessive computer use that interferes with daily life.

The term “problematic computer use” implies that there are possibly other problems leading to the excessive use of the computer or Internet. These underlying conditions could be depression or an antisocial personality. Both underlying conditions would be better helped with treatment designed to solve that specific condition. Other problems could be a lack of basic social skills. This lack could be addressed through counseling and social training.

Although he used the term “Internet addiction,” Block prefers the term “pathological computer use”, particularly because of the inappropriate implications of the term “addiction.” The main symptom of pathological computer use is the affected person’s inability to distinguish between the virtual world and reality. People affected may also not be able to function well in reality because of situations in the virtual world.

Many mental health professionals distinguish between different types of problematic activities related to Internet use: pornography, explicit sexual conversations online, online gambling, inappropriate involvement in social networking, and compulsive Internet shopping. There may be an underlying psychological issue in all of these. For example, sexual behavior online may be more symptomatic of a sexual disorder than of compulsive Internet use.

How Is Internet Addiction Diagnosed and Treated?

In any given case of problematic or pathological computer use, a qualified mental health professional needs to make an evaluation. If certified by a clinic specializing in Internet addiction, the mental health professional will most likely use checklists designed by the clinic similar to those designed by Young. These self-styled clinics should also be careful to rule out other possible conditions. Treatment would follow the standard procedures for the most clearly manifested disorder. Complications may involve the coexistence and interaction of two or more conditions.

Diagnosis Any diagnosis needs to be made by a qualified mental health professional. The professional has to rule out any recognized mental disorder before considering the possibility of Internet addiction. There are some people with a mental disorder for whom excessive Internet use is secondary to their existing disorder. These people think that acting out their disorder on the Internet is safe and more socially acceptable. For such people,

treating the mental disorder has a greater priority than treating the excessive Internet use.

The self-styled Center for Internet Addiction Recovery appeared to be in agreement with this point: “Internet addicts suffer from emotional problems such as depression and anxiety-related disorders and often use the fantasy world of the Internet to psychologically escape unpleasant feelings or stressful situations.” Thus, it seemed most Internet addicts fit other widely accepted diagnostic labels and should be treated according to these underlying conditions.

Before a professional can make a diagnosis, the reason for the excessive time on the Internet has to be determined. If the reason is not related to a recognized disorder, there are other considerations to be addressed: time management problems, limited social life, or no priorities in personal responsibility. All of these are serious concerns but may not reach the level of a mental disorder.

Treatment In China and Korea where the problem was identified, the recommended therapy is a boot camp for affected young people. The boot camp emphasizes daily responsibility, time management, and social skills development. Graduates are encouraged to pursue more productive and creative pastimes than spending time on the Internet.

Because the description of Internet addiction is modeled on other obsessive behaviors, the therapy follows the model of effective programs for obsessive behavior. A 12-step program was recommended by a number of sources. The 12-step therapeutic program is based on the model developed by the successful organization Alcoholics Anonymous. The method begins with individuals publicly admitting that they have a problem. An important component is constant interaction with a support group. Furthermore, participants have to acknowledge the pain they have caused others through the obsession and work to make amends.

The first step in treatment is to help the person develop appropriate time management skills; some techniques are designed to curb time on the Internet. While full abstinence of Internet is not practical, avoiding “trigger” applications is encouraged. Therapy, then, is focused on helping the person identify and avoid those websites or programs. Finally, group therapy is designed to provide support. Also, family therapy is encouraged for those who have hurt their families through Internet addiction.

Complications The main complication in identifying and treating Internet addiction is the appeal of the new technology and its fascination for young and old. The young always adapt to new technology faster than the older generation. This fact may explain why so many young people are “hooked.” But Young found many older women spending excessive time on the Internet. These women were old enough to remember when typing was considered a feminine skill. It seemed important to them that they were using a familiar skill in a way that gave them new power. A good typist can make more entries and replies on blogs and bulletin boards.

* **gastrointestinal** (gas-tro-in-TES-tih-nuhl) means having to do with the organs of the digestive system, the system that processes food. It includes the mouth, esophagus, stomach, intestines, colon, and rectum and other organs involved in digestion, including the liver and pancreas.

* **small intestine** is the part of the intestines—the system of muscular tubes that food passes through during digestion—that directly receives the food when it passes through the stomach.

* **colon** (KO-lin), also called the large intestine, is a muscular tube through which food passes as it is digested, just before it moves into the rectum and out of the body through the anus.

The Internet is an avenue to virtual worlds. There is much that can be explored in these cyber worlds, and they are ever expanding. These two features may give many “explorers,” young and old, a sense of doing something important or creative.

There is also a possible generational component to the young adults who are addicted to online games that they have played for years. These young adults observed the early versions of these games and have watched the games and their roles in playing them evolve. In short, there are individual reasons why people are hooked on Internet activity.

Can Internet Addiction Be Prevented?

Once schools and families learn about the dangers of excessive online use, education can include guidelines for productive use of the Internet for education and research. There are many online sources and commercial products to help parents control their children’s use of the Internet, in order to protect them from predators.

Intestinal Infections

Intestinal infections are caused by such pathogens (PATH-o-jens, microscopic organisms that cause disease) as bacteria, viruses, and fungi. These infections can affect various portions of the gastrointestinal tract, including the small intestine* and the colon*. Such infections, which often cause diarrhea (dye-uh-REE-uh), are frequently accompanied by gastroenteritis (gas-tro-en-ter-EYE-tis), an inflammation of the stomach and intestines.*

Microorganisms and the Digestive System: What Is Normal?

The inside of the human body is teeming with a wide variety of bacteria, fungi, and other microorganisms, which is perfectly normal, and these microorganisms do no harm in most instances. In fact, some of these

microorganisms are beneficial. The digestive system is one part of the body with an especially high number of normally occurring microorganisms. Estimates suggest that a single person's digestive system is home to some 100 trillion individual microorganisms from 300 to 500 different species. These normally occurring, and either beneficial or typically not harmful microorganisms are collectively known as intestinal microbiota, or sometimes as intestinal flora or gut flora. (The latter two terms are not technically accurate, however, because “flora,” refers to plants and other vegetative matter, and the digestive microorganisms are not plants.) Certain normally occurring, beneficial microbiota have an important part in digestion, and without them, the human body would be unable to break down some foods. Studies also suggest that some types of intestinal microbiota may help defend the body against infection or have other roles in maintaining health.

Although many microorganisms are beneficial or exist in the human body without incident, in some cases microorganisms in the digestive system cause intestinal infections, a number of which can be severe and even fatal.

How Do Intestinal Infections Occur?

Intestinal infections can be spread in many ways. Some people become infected by eating contaminated shellfish, raw or undercooked meat, or unpasteurized* dairy products, or from drinking or swimming in contaminated water. Others get sick by touching something that is contaminated with an infectious organism and then unwittingly transferring that organism to their mouths. This might happen if individuals neglect to wash their hands after touching a surface (such as a kitchen counter or a door handle) or handles anything that might be contaminated with feces (FEE-seez, or bowel movements), such as dirty laundry, or a soiled diaper. Outbreaks of intestinal infections sometimes occur when many people eat or drink the same contaminated food or water.

What Bacteria Are Involved?

One of the most common ways that people get intestinal infections is by eating food or drinking water that has been contaminated with disease-causing microorganisms. Some of the most common of these infections result from bacteria, including those known as *Campylobacter*, *Clostridium*, *Escherichia coli* (or *E. coli*), *Helicobacter pylori*, *Listeria monocytogenes*, *Salmonella*, *Shigella*, and *Staphylococcus*.

Campylobacter infection Diarrhea is usually caused by an infection with *Campylobacter* (kam-pee-lo-BAK-ter) bacteria, and typically with one particular species known as *Campylobacter jejuni* (je-JOO-nee). The Centers for Disease Control and Prevention (CDC) estimates that about 8 out of every 1,000 people in the United States experience *Campylobacter*-caused diarrhea every year. Symptoms, which begin two to five days after infection, include diarrhea that is sometimes bloody,

* **unpasteurized** (pas-CHUR-ized) refers to foods that have not undergone the process of pasteurization (pas-chu-rih-ZAY-shun), in which food is heated to a certain temperature over a period of time to kill organisms and help make the food safer to consume.

* **strains** are various subtypes of organisms, such as viruses or bacteria.

abdominal cramping and pain, and fever. Most people recover on their own within a couple of days to a week.

Campylobacter lives in animals, especially birds. Humans become infected after eating chicken or other poultry that has not been completely cooked or after eating food that has been contaminated by the blood or other juices of uncooked or undercooked poultry. This may happen, for instance, if a person slices a raw chicken on a cutting board and then, without first thoroughly washing the cutting board, uses it again to slice carrots for a raw-vegetable platter. Outbreaks of this type of diarrhea also have occurred after people have drunk contaminated water or unpasteurized milk. In developing countries where clean water is sometimes lacking, *Campylobacter* infections are particularly common, and sometimes result in death. In addition, travelers to foreign lands often unknowingly drink contaminated tap water.

***Clostridium difficile* and *Clostridium perfringens* infection**

Clostridium difficile (klos-TRIH-dee-um DIH-fih-seel) bacteria often live in the intestinal tracts of infants and young children without causing disease. In adults, however, especially the elderly, infection with *C. difficile* can produce fever, watery diarrhea, abdominal pain, and loss of appetite. Risk factors for infection include a hospital stay, gastrointestinal surgery, and having another serious illness. Healthcare workers often spread the bacteria when they touch infected feces or contaminated surfaces then touch patients or give them medicine without first washing their hands. Frequently, infection with *C. difficile* occurs in people who are taking long courses of antibiotics that fight disease-causing bacteria. These antibiotics limit the growth of the harmless, normal bacteria found in the digestive system, which presents a good environment for *C. difficile* to multiply, and when they do, to cause an infection.

The *Clostridium perfringens* bacterium causes perfringens poisoning, which is one of the most common types of food poisoning in the United States. Some *C. perfringens* bacteria may remain in food even after it has been cooked, then multiply when the food is cooled slowly and left at room temperature. People who eat contaminated food may develop intense abdominal cramps, diarrhea, and flatulence (excessive gas), usually within 8 to 22 hours. Most people recover from perfringens poisoning within a day or two, although symptoms can last longer in older people. Quickly refrigerating uneaten cooked food and reheating leftovers to a high enough temperature—at least 165 degrees—can help prevent perfringens poisoning.

***Escherichia coli* infection** *Escherichia coli* (ESH-ur-ick-ee-uh KO-lie) comes in different types, called strains*, and most of these are completely harmless. In fact, it is one of the species of bacteria that normally occurs in the large intestine of the human digestive system, and it plays a part in making vitamin K, which helps blood clot, and in fighting off various infections.

However, a few strains of *E. coli* are harmful. One of these, known as *E. coli* 0157:H7, occurs in the digestive system of numerous animals, including cattle. *E. coli* 0157:H7 produces a toxin that can cause human disease. People come into contact with the bacteria when they eat undercooked beef, such as hamburger, or when they eat other foods contaminated with the bacteria. Such contamination may occur when a farmer uses cow manure as fertilizer on fruit or vegetable crops and a consumer then fails to wash tainted produce before eating it or when a person drinks unpasteurized milk that was contaminated during the milking process. In addition, a person can become infected in other ways, such as by swimming in contaminated water or by being in close contact with an already-infected individual. Occasionally, outbreaks of *E. coli* infections occur when a food-manufacturing plant has a problem with contamination and ships its products over a wide area. Many people may become sick, and some may even die before officials can track down the source of the contamination and issue recalls for the tainted items.

E. coli infections are quite common. The CDC estimates that 73,000 cases of *E. coli* infection occur in the United States each year, and about 60 result in deaths. The symptoms of *E. coli* infection include abdominal cramps and bloody diarrhea, which last about five days. Most people do not need treatment, although those with weak immune systems (such as patients undergoing chemotherapy* or people with HIV* or AIDS*), children, and the elderly require hospitalization if they develop a serious infection.

***Helicobacter pylori* infection** *Helicobacter pylori* is a very common bacterium in the human digestive system, but it is not considered part of the “normal” intestinal microbiota, because it is harmful. Most people have this bacterium living in the stomach and the first part of the small intestine (the duodenum). There, it causes inflammation. Usually, the inflammation is mild and results in no symptoms, so affected individuals are not even aware that it is present. Nonetheless, this bacterium does present a health problem. Research has shown that people with *H. pylori* infection are more likely to have stomach cancer and ulcers, which are open sores on the inner lining of the stomach and/or duodenum. Ulcers are a widespread health condition and affect about 10 percent of the U.S. population. Of those people with ulcers, as many as 80 percent also have *H. pylori* infections.

***Listeria monocytogenes* infection** Listeriosis (lis-teer-e-O-sis) is caused by the *Listeria monocytogenes* bacterium, which is found in the soil, in stream water, in food, and in sewage. People contract listeriosis from eating vegetables grown in contaminated soil or raw or undercooked meat, from drinking contaminated water, or from consuming unpasteurized milk or milk products. Listeriosis is rare, affecting only about 20 of every million people.

Symptoms of illness include fever, headache, nausea, and diarrhea. The bacteria also can spread into the bloodstream or nervous system,

- * **chemotherapy** (KEE-mo-THER-ə-pee) is the treatment of cancer with powerful drugs that kill cancer cells.
- * **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

- * **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.
- * **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.
- * **stillbirth** is the birth of a dead fetus.
- * **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.
- * **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.
- * **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.
- * **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.

leading to meningitis*. Pregnant women are at greater risk for the disease, and about 20 times as many pregnant women as other healthy adults develop listeriosis. The disease can cause miscarriage*, stillbirth*, or serious illness in the newborn. Infants, older people, and people with weak immune systems are also at risk.

Salmonella infection Several different strains of *Salmonella* (sal-muh-NEH-luh) bacteria can cause illness. The *Salmonella typhi* (TIE-fee) bacterium causes the most serious illness, typhoid (TIE-foyd) fever, which is frequent in developing countries. The National Center for Infectious Diseases reports an estimated 12.5 million cases of typhoid fever worldwide each year. In the United States, about 400 cases occur each year, most in people who have traveled to undeveloped countries. Typhoid fever spreads when people eat or drink food or water contaminated with the bacteria. People who are infected may have a high fever, headache, extreme tiredness or weakness, stomach pain, loss of appetite, and sometimes a flat, red rash. A vaccination* for travelers can help prevent typhoid fever, and antibiotics can help patients who become sick.

The *Salmonella* bacteria also cause salmonellosis (sal-muh-neh-LO-sis), which is more common than typhoid fever. The Centers for Disease Control and Prevention (CDC) reports 40,000 cases in the United States each year and estimates that 20 times that number may go undiagnosed. As many as 1,000 people in the United States die from the disease each year. Eating eggs or meat from contaminated animals can cause salmonellosis. Symptoms start 12 to 72 hours after infection and include nausea (NAW-zee-uh), vomiting, diarrhea, fever, and stomach cramps. The disease usually runs its course in four to seven days. Only infants, young children, the elderly, and people with weakened immune systems typically require treatment. (Antibiotic treatment can actually prolong the time that it takes for *Salmonella* bacteria to leave the body.)

Shigella Shigellosis (shih-geh-LO-sis), caused by *Shigella* (shih-GEH-luh) bacteria, inflames the lining of the small intestine. About 18,000 reported cases are documented in the United States each year, but the actual number may be 20 times higher because many people do not seek treatment. Shigellosis is transmitted through contact with feces. Toddlers who are still in potty training are especially at risk, because their hands are prone to becoming contaminated and they may forget to wash their hands or not wash them well. In this age group, the disease can produce complications, including seizures*. In addition, infections can spread through contact with contaminated water, by eating contaminated food, or through some forms of sexual activity.

Symptoms of shigellosis include diarrhea (often with blood or mucus*), fever, vomiting, nausea, and abdominal* cramping. Most people recover without treatment, usually within a week, although doctors may prescribe antibiotics to keep the disease from spreading.

Staphylococcus Toxins produced by certain strains of *Staphylococcus aureus* (staf-ih-lo-KAH-kus AR-ee-us) bacteria can cause food poisoning. When people who are infected with the bacteria handle food such as meat, poultry, egg products, or dishes containing mayonnaise or cream, they may spread the bacteria to the food. The toxins build up when the food sits for a long time at room temperature. When a person becomes infected, symptoms come on quickly, within 2 to 8 hours and last less than 12 hours. They include severe nausea and vomiting, and sometimes abdominal cramping, diarrhea, and headache.

What Viruses Can Cause Intestinal Infections?

A variety of viruses can cause intestinal infections. Some of the most common are enteroviruses, hepatitis A, noraviruses, and rotaviruses.

Enteroviruses Enteroviruses (en-tuh-ro-VY-ruh-sez) are a group of viruses that attack the intestinal tract and cause a wide range of illnesses, including intestinal infections. People who are infected may experience mild diarrhea, vomiting, fever, and abdominal pain. Most get better on their own without treatment from a doctor.

Hepatitis A The hepatitis (heh-puh-TIE-tis) A virus occurs in water contaminated by sewage, in shellfish taken from tainted water, and in fruits and vegetables grown in contaminated soil. The virus can spread when people eat or drink tainted food or water or can pass from person to person during sexual intercourse. Infected people who handle or prepare food can transmit the virus if they do not thoroughly wash their hands after going to the bathroom and then go on to prepare food for others.

Some people with hepatitis A infection show no signs of illness, but others may experience fever, extreme tiredness, loss of appetite, nausea, and vomiting. The patient's liver enlarges and the skin may appear yellowish, a condition known as jaundice*. The disease can lead to permanent liver damage, although this is rare. Symptoms appear two to four weeks after infection and may last several weeks to months. A vaccine is available to protect people at high risk of hepatitis A infection. These include people who travel to developing countries or who engage in illegal drug use or sexual relations with others who already have hepatitis A.

Noravirus infections Infections with noraviruses cause most of the non-bacterial outbreaks of gastroenteritis worldwide. The viruses spread through food or water that is contaminated with feces or through contact with an infected person. Noravirus outbreaks are particularly common on cruise ships, in nursing homes or hospitals, in boarding schools or college dormitories, in prisons, or in other places where people are in long-term and close contact with one another. Symptoms of the infection may include nausea and/or vomiting, diarrhea, abdominal pain, fever and/or headache, tiredness, weakness, and general muscle pain. Most people

* **jaundice** (JON-dis) is a yellowing of the skin, and sometimes the whites of the eyes, caused by a buildup in the body of bilirubin, a chemical produced in and released by the liver. An increase in bilirubin may indicate disease of the liver or certain blood disorders.

* **protozoa** (pro-tuh-ZOH-uh) are single-celled microorganisms (tiny organisms), some of which are capable of causing disease in humans.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

recover within a few days, but infants, elderly people, and people with weakened immune systems may require hospitalization. Noravirus infections are occasionally fatal.

Rotaviruses Rotaviruses (RO-tuh-vy-ruh-sez) can infect people of all ages, but infants and young children are infected most often. Outbreaks occur most frequently from November to April in the United States, with about 1 million children affected each year. Of those, between 55,000 and 70,000 require hospitalization. Deaths from the illness are rare in the United States. Worldwide, however, more than 600,000 children die each year from rotavirus infection, according to the World Health Organization.

Rotaviruses spread when people come into contact with infected human feces. The disease is most common in daycare centers, hospital pediatric wards, and homes with young children. Symptoms appear about two days after infection. They include fever, vomiting, and abdominal pain, which last for two to three days, and diarrhea, which can linger for up to eight days. Most people do not require treatment.

Medical professionals used a rotavirus vaccine in the United States in the late 1990s, but stopped administering it after it caused bowel problems in some infants. As of 2009, research was under way to develop a replacement vaccine.

Other Causes of Intestinal Infection

Parasites cause many intestinal infections. Some common parasitic infections that lead to intestinal symptoms, such as cramping and diarrhea, include *Entamoeba histolytica* (en-tuh-ME-ba his-toh-LIH-tih-kuh), which causes amebiasis (ah-mih-BYE-uh-sis); *Giardia intestinalis* protozoa*, which causes giardiasis (jee-ar-DYE-uh-sis); and *Cyclospora cayetanensis* (sy-klo-SPORE-uh kye-uh-tuh-NIN-sis).

Certain fungi can also cause intestinal infections. One group in particular is the *Candida* fungi, which can multiply and lead to an inflammation of the esophagus, a condition called esophagitis. People who are most prone to fungal esophagitis include those who have taken antibiotics over a long time, are undergoing radiation therapy or chemotherapy, have diabetes*, have AIDS, are alcoholics, are suffering from malnutrition, or are elderly. Symptoms include nausea and/or vomiting, difficulty or an uncomfortable feeling when swallowing, mouth sores, and heartburn. Antifungal drugs usually treat the infection.

How Are Intestinal Infections and Food Poisoning Diagnosed?

Many cases of intestinal infection are so mild that they go unnoticed. Others get better without the patient ever seeing a doctor. The symptoms of gastroenteritis—nausea, vomiting, abdominal pain, diarrhea, and loss of appetite—are common to many intestinal infections and some other

diseases as well. When a patient seeks treatment, a doctor often begins with a physical exam and a series of questions about symptoms and food intake. For mild cases, the doctor may not order any laboratory tests and may be satisfied that the patient will recover even though the actual cause of the infection remains unknown. In more severe cases of illness, however, the doctor may need to know the identity of the infecting organism and will collect samples of a bowel movement to examine under the microscope and send to be cultured*, which will help pinpoint the organism involved.

How Are Intestinal Infections Treated?

Most intestinal infections do not require treatment, and patients get better on their own. People with diarrhea and other signs of intestinal infections should talk to their doctors if the symptoms do not clear up in a few days or become severe.

In most cases, patients can remain at home and maintain a relatively normal schedule. To prevent transmission of the infection between young children, parents should consider keeping an infected child at home and out of daycare until the illness resolves. All patients should drink plenty of fluids to avoid dehydration*. Doctors also advise that they avoid anti-diarrhea medicine because it may keep the infectious agent in the body longer. More severe cases of intestinal infections sometimes require hospitalization so patients can receive intravenous fluids*, antibiotics, or other treatment. In most cases, people should feel better within days to a week, although several more weeks may pass before their gastrointestinal tracts recover completely.

Can Intestinal Infections Cause Other Complications?

In otherwise healthy people, intestinal infections rarely cause complications. Mild dehydration is the most common consequence. Infants and the elderly are most at risk for severe dehydration. For people with weak immune systems, the infectious agent may spread throughout the body, causing widespread disease and even death. In infants and young children, cases of long-lasting illness occasionally lead to malnutrition or a failure to grow properly because the infections interfere with their nourishment.

More specific complications from intestinal infections vary. Several, including *Campylobacter*, *Shingella*, *E. coli*, and *Salmonella*, can cause colitis, which is an inflammation of the colon. Another form of colitis, called pseudomembranous (soo-do-mem-bran-us) colitis, can result from *Clostridium difficile*. The condition typically arises after a patient has been taking antibiotics to treat a different infection. The antibiotic may also lower the number of normal, nonharmful bacteria in the digestive system, and present an opportunity for *C. difficile* to multiply. This overgrowth presents a problem because *C. difficile* produces a toxin, which leads to the pseudomembranous colitis. Symptoms include diarrhea and often a fever.

* **cultured** (KUL-churd) means subjected to a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **intravenous fluids** (in-tra-VEE-nus) are fluids injected directly into a vein.

- * **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.
- * **arthritis** (ar-THRY-tis) refers to any of several disorders characterized by inflammation of the joints.
- * **abscesses** (AB-seh-sez) are localized or walled off accumulations of pus caused by infection that can occur anywhere within the body.
- * **kidney** is one of the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.
- * **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.

Beyond colitis, *Campylobacter*, *Salmonella*, and *Shingella* infections can lead to Reiter (RYE-ter) syndrome, which is characterized by joint pain, eye inflammation, and difficulty and pain with urination. *Campylobacter* may spread into the bloodstream and trigger other problems, including a dangerous whole-body inflammation called sepsis or a condition called Guillain-Barré (GEE-yan bah-RAY) syndrome, which is a nerve inflammation that causes muscle weakness or paralysis*. *Salmonella* infection can result in arthritis*, meningitis, brain abscesses*, and bone infections. In about 3 to 5 percent of cases, *Escherichia coli* infections can lead to hemolytic uremic syndrome, a disease that can progress to kidney* failure, considerable bleeding, and severe anemia*.

Can Intestinal Infections Be Prevented?

The best way to prevent intestinal infection is to practicing good hygiene, which includes the frequent and thorough washing of the hands, especially after changing diapers, after going to the bathroom, and before handling food or eating.

Travelers who plan to visit developing countries must also make sure they have any recommended vaccinations (such as the one for typhoid fever) before they leave. Once there, travelers should drink only bottled water and avoid eating raw fruits and vegetables, food from street vendors, and unpasteurized dairy products. To be safe, travelers should only eat food that is served steaming hot, because high heat kills many disease-causing organisms.

Individuals with weakened immune systems, such as people with AIDS, must take special care to avoid infections, because their bodies are simply unable to wage a strong defense against the intruding bacterium or other pathogen. For this reason, infections can spread very rapidly and lead to serious health problems, including death. A person with a weakened immune systems should follow medical advice carefully to avoid an infection and to treat one should it occur.

Intestinal Obstruction

Intestinal obstruction refers to the partial or complete blockage of the intestinal portion of the gastrointestinal tract.

What Is Intestinal Obstruction?

The intestines make up part of the gastrointestinal* tract, also known as the digestive tract. The gastrointestinal tract is the path by which food travels from the mouth, through the esophagus, into the stomach, then the small and large intestines. The remaining waste is finally expelled through the anus. The gastrointestinal tract is consistently moving in a manner that propels its contents in one direction through the tract. This movement, known as peristalsis, is caused by the rhythmic contraction of sets of smooth muscle that lines the gastrointestinal tract. The rhythmic contractions happen in waves and are involuntary. Peristalsis is specifically initiated by a set of circular smooth muscle contracting behind the food material (called the bolus) to prevent it from moving back toward the mouth, followed by a contraction of longitudinally oriented smooth muscle to push the contents forward.

Intestinal obstruction refers to the partial or complete blockage of the intestinal portion of the gastrointestinal tract. Intestinal obstruction may be mechanical, meaning that there is some type of physical blockage that prevents the contents of the intestines from passing down the tract. Examples of mechanical obstructions include foreign bodies in the intestines and the intestines physically twisting upon themselves thereby causing blockage. Intestinal obstruction is not considered mechanical if it is caused by a lack of the muscular contractions of peristalsis. A condition known as ileus, nonmechanical obstruction, has the same effect of the bolus not moving through the gastrointestinal tract.

What Causes Mechanical Obstruction?

Mechanical obstruction of the intestines may be caused by tumors in the intestine or surrounding structures that have grown enough to cause obstruction of the gastrointestinal tract. Obstructions may be caused by scar tissue that formed as a result of previous abdominal surgeries. Hernias in which the intestinal tissue sticks through a defect in the abdominal wall musculature or through other tight spaces such as the diaphragmatic hiatus may also cause obstruction. Sometimes pouches

* **gastrointestinal** (gas-tro-in-TES-tih-nuhl) means having to do with the organs of the digestive system, the system that processes food. It includes the mouth, esophagus, stomach, intestines, colon, and rectum and other organs involved in digestion, including the liver and pancreas.

* **cystic fibrosis** (SIS-tik fy-BRO-sis) is a disease that causes the body to produce thick mucus that clogs passages in many of the body's organs, including the lungs.

of intestinal tissue called diverticula form on the intestine. If these diverticula become inflamed, they may cause intestinal obstruction. Inflamed diverticula results in a condition known as diverticulitis. For the large intestines, 60 percent of mechanical obstructions are caused by tumors, 20 percent are caused by diverticular disease, and 5 percent are caused by volvulus (a twisting of the intestine upon itself). For the small intestines, the majority of mechanical obstructions are caused by scar tissue or hernia.

Volvulus and Intussusception Volvulus is a condition that involves the intestine twisting on itself so that the movement of intestinal contents is obstructed. Volvulus is most likely to occur in infants less than one year of age, the elderly, and psychiatric patients. If the twisting cuts off the blood supply to that section of the intestines, the tissue can die and gangrene set in. In this case, it is referred to as a strangulating obstruction. Intussusception involves the intestines telescoping into itself and has the same effect as volvulus. Intussusception most often occurs in male infants of three to nine months of age or in adults with intestinal tumors.

Inflammatory bowel disease Crohn's disease is a type of inflammatory bowel disease. One aspect of Crohn's disease is that it causes narrowing of the intestine from repeated cycles of inflammation and fibrosis, the formation of scar tissue as part of the healing process after the damage done by the inflammation. Intestinal obstruction is a potential complication of Crohn's disease. Approximately 30 to 50 percent of Crohn's disease patients experience intestinal obstruction.

Causes of Nonmechanical Obstruction

Meconium ileus Meconium is material that collects in the fetal intestine. It consists primarily of cells sloughed from the intestinal lining. It makes up the bulk of the material in the first passage of feces that occurs after birth of a baby. Meconium ileus is a disorder of newborns in which they are unable to excrete feces after birth. It is often a sign that the infant may have cystic fibrosis*, but it may also occur in infants with very low birth weight.

Postoperative ileus Abdominal surgery usually is accompanied by postoperative intestinal ileus, a condition in which the intestines are temporarily unable to maintain peristalsis. While no mechanical obstruction is present, ileus has the same effect of disturbing the normal passage of intestinal contents down the gastrointestinal tract. This lack of motility (movement) results in an accumulation of gas and fluid in the intestines.

What Are the Symptoms of Intestinal Obstruction?

Mechanical Obstruction Mechanical intestinal obstruction has many associated signs and symptoms. Abdominal pain or cramps may occur in intermittent waves. Cramps are caused by the inability of the intestines to push the bolus along the tract. Nausea and vomiting are also

common. Bowel sounds that can be heard with a stethoscope, and are frequently audible without any aid, are high pitched and gurgling, later falling silent. No gas or feces are passed and the abdomen becomes distended and sore to the touch. dehydration* may be severe and cause imbalances in the electrolytes of the body that may result in kidney failure.

Nonmechanical Obstruction Nonmechanical intestinal obstruction may cause vague, mild abdominal pain and some abdominal bloating. Cramping of the abdomen is usually not a symptom. Nausea and vomiting with resulting dehydration may or may not be present. Gas and feces usually are not passable. The abdomen may be somewhat distended and tender. Unlike mechanical obstruction, in which early hyperactive bowel sounds are present, nonmechanical obstruction causes no bowel sounds early on.

How Is Intestinal Obstruction Diagnosed?

If intestinal obstruction is suspected, imaging studies are done on the abdomen to detect any mechanical obstructions that may be present. Different types of imaging tools may be used, such as abdominal x-ray, CT scans*, or ultrasound*. Depending on the suspected location of the obstruction, contrast-assisted x-ray studies of the upper or lower gastrointestinal (GI) tract may be done. In an upper GI series water-soluble contrast is swallowed and then x-rays are taken to observe the passage of the material through the upper gastrointestinal tract. A barium enema may be used, in which case a white contrast material made of barium sulfate is inserted in the rectum and passed into the colon. The contrast material shows up on film to display the shape of the intestines and any mechanical blockage. Blood work may also show an imbalance in electrolytes, ionized particles present in the body that are necessary for body function. When an obstruction is noted, it is continually watched in case a strangulated intestine occurs at or adjacent to the point of obstruction. If this complication occurs, usually abdominal pain and tenderness increase and a fever may develop along with increased white blood cell production. This developing condition calls for urgent surgical intervention. Because strangulation of the intestines can rapidly progress to death, timing of diagnosis leading to appropriate treatment is critical.

Meconium ileus is diagnosed if the newborn is not passing feces within an appropriate period after birth, and the meconium obstruction is detected by medical imaging techniques. In addition to visualizing the meconium, air-filled loops of intestines are also visible. Because postoperative gut immobility is considered a normal occurrence, obstruction due to postoperative ileus is of concern only if the ileus lasts more than three days after abdominal surgery.

How Is Intestinal Obstruction Treated?

The treatment of obstruction is determined by its cause. Patients with all types of intestinal obstruction are hospitalized, and the contents of the stomach are suctioned out through a nasogastric tube (a plastic tube

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

inserted through the nose and down the esophagus into the stomach). Air is injected down the tube and listened to with a stethoscope over the abdomen to ensure that the tube has been directly inserted into the stomach and did not enter the respiratory system instead.

After the stomach contents have been removed, a barium or air enema may be attempted to relieve mechanical obstructions such as intussusception. Surgery is often necessary to remove mechanical obstructions. If strangulation has occurred, the damaged bowel tissue is removed entirely and the remaining parts are connected together in a process known as resection. Obstructions caused by tumors or scar tissue are removed. Hernias are repaired. Approximately 300,000 intestinal obstruction repair surgeries are performed each year in the United States. After surgery, antibiotic therapy is used to prevent infection from forming at the surgical site.

For nonmechanical obstruction, surgery is not performed. Dehydration and any electrolyte abnormalities are corrected. Medications that are known to decrease the motility of the intestines such as narcotic pain killers are stopped. Other drugs used to increase intestinal motility are applied if necessary. Postoperative ileus sometimes responds to the antibiotic erythromycin, which is known to increase intestinal motility as well as function as an antibiotic. Meconium ileus also responds to medication, but the insertion of a rectal thermometer may be sufficient to stimulate peristalsis and make further treatment unnecessary.

Intestinal Parasites

Intestinal parasites in humans live a part of their life cycle within a person, in certain tracts and systems having to do with digestion.

What Are Intestinal Parasites?

Parasites are organisms such as worms or insects that must live on or inside another organism to survive. An animal or plant harboring a parasite is called its host. Parasites live at the expense of the host and may cause illness. Human intestinal parasites specifically live a part of their life cycle within a person, in certain tracts and systems having to do with

Both public water supplies and natural water sources can become contaminated with human or animal waste (mainly from dogs and beavers) harboring *Giardia lamblia* that causes giardiasis. The disease causes stomach upset and diarrhea when the parasite attaches itself to the lining of the digestive system, where it interferes with the body's ability to absorb fats and carbohydrates. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

digestion. These are: first, the gastrointestinal tract, also known as the alimentary canal, which consists of the mouth, esophagus, stomach, small intestine, colon and anus; second, the digestive system, which consists of the gastrointestinal tract and the associated, and attached, organs of digestion, including the liver and pancreas. Various intestinal parasites may infest the alimentary canal, the liver and biliary system, the pancreas, and in rare cases other organs, such as when ascarids invade the respiratory tract. Intestinal parasites may cause symptoms associated with the gastrointestinal tract such as diarrhea or states of malnutrition despite a healthy diet.

In humans, there are four major types of intestinal parasites: tapeworms (cestodes), roundworms (nematodes), flukes (trematodes), and microscopic organisms called protozoa. These parasites complete a part of their life cycle within the gastrointestinal tract, and some also travel to other parts of the body and invade other organs. While some intestinal parasites are so small they can only be seen under a microscope, others may be many feet long. There are several ways that parasites can infiltrate the human body, such as through oral ingestion or directly through the skin. A parasite life cycle involves different stages of development, such as eggs or larvae, and the adult form. Some parasites are able to enter the body through multiple routes and at multiple life cycle stages. For example, most tapeworms and roundworms lay their eggs within the human gastrointestinal tract. The eggs then pass out of the body through feces and if ingested can hatch and infest other humans with the parasite. Other parasites may enter the human body through egg and larval forms.

What Makes Intestinal Parasites a Health Issue?

Intestinal parasites are especially prevalent in the tropics. The World Health Organization (WHO) estimates that 3.5 billion people worldwide are infested with some type of intestinal parasite, and as many as 450 million of them are sick as a result. Children are most frequently infected with these parasites. Intestinal parasites spread in areas with poor sanitation and are most common in developing countries on the African, Asian, and South American continents. They are not a large problem in the United States, and Americans are most likely to get intestinal parasites when they travel abroad.

How Are Intestinal Parasites Spread?

Intestinal parasites can be acquired in many ways. Some parasites can live in the soil for extended periods. They may penetrate the body directly through the skin or if contaminated soil is ingested accidentally on food items (such as unwashed fruit or vegetables). Other parasites live in animals, such as pigs and cows. People can become infested by eating undercooked meat or drinking unpasteurized milk (milk that has not been processed with heat to kill parasites and bacteria). The eggs of some intestinal parasites pass through the human gastrointestinal tract into the feces. The parasites then spread to other people through unintentional contact with the fecal matter.

Depending on the type of parasite, a person may become infested by touching his or her mouth after contact with feces that contain the organism (such as when changing a diaper or doing laundry) or a contaminated area. Drinking water or swimming in water that has been contaminated are other common routes of infestation. These infestations often occur in outbreaks, where several people have been exposed to the same source and display symptoms at the same time, which is especially likely if many people come into contact with the same supply of contaminated food or water.

What Are Some Common Intestinal Parasites?

Tapeworms (Cestodes) Human tapeworm infestations usually are caused by eating meat or fish contaminated with worm larvae but may also be caused by ingesting soil or water contaminated with human fecal matter containing the eggs. Meat contaminated with tapeworm larvae contains the larvae in cyst form. Like other intestinal parasites, these worms frequently cause infestations in areas with poor sanitation, where livestock animals are exposed to contaminated soil or fish to contaminated water and contain the parasites within their body tissues.

There are three common species of tapeworms: *Taenia saginata* (beef tapeworm), *Taenia solium* (pork tapeworm), and *Diphyllobothrium latum* (freshwater fish tapeworm). After humans ingest contaminated tapeworm encysted meat or fish, the larvae travel to the intestines, where they latch onto the intestinal lining and gradually grow into adults. The largest tapeworms can measure more than 20 feet long in some cases. The worms shed their eggs into the feces, from which they find their way into soil and water, are ingested by animals or fish, and reenter the cycle.

Symptoms of a tapeworm infestation are often mild or nonexistent but can include abdominal pain, diarrhea, and malnutrition. The fish tapeworm is often noted for causing vitamin B12 deficiencies. The pork tapeworm is known for leaving the human gastrointestinal tract in larval form and migrating to other parts of the body to create cysts of worm larvae in human body tissues. While cysts may form in any body tissue, the most commonly affected part of the body is the central nervous system*. The condition of having a tapeworm cyst in the brain is known as neurocysticercosis and may cause seizures*, blindness, or other nervous system abnormalities. Cysts may also form in the heart, eye, or other locations. If the larvae in the cysts die, the body may calcify the region as part of the healing process. Calcified cysts may also cause health problems.

Ascariasis (Nematode) Ascariasis is caused by *Ascaris lumbricoides*, an intestinal roundworm. It is one of the most common intestinal parasites in areas with poor sanitation, affecting people in all parts of the world. In the United States, ascariasis is rare but occurs in rural parts of the Southeast. The life cycle of *Ascaris lumbricoides* begins when an adult worm lays its eggs in the intestines of an infected person. The eggs leave

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **endemic** (en-DEH-mik) describes a disease or condition that is present in a population or geographic area at all times.

the body through the feces and can live in soil for up to two years. When people eat raw food containing this contaminated soil, they may ingest the eggs, which hatch in the stomach as larvae. Part of the life cycle of the larvae is to migrate outside the gastrointestinal tract. The larvae invade the walls of the gastrointestinal tract, migrate through the blood to the lungs and then to the throat, where they are swallowed. Eventually, they pass into the intestines, where adult worms form and begin the cycle again. The adult can grow to be more than 12 inches long and can live one to two years in the small intestine of the gastrointestinal tract.

Ascariasis often causes no symptoms or mild stomach pain and bloating. If individuals are heavily infested with a greater worm load, they may experience more severe pain. Some people may also experience a cough or breathing problems when the larvae move through their lungs. People often discover they have ascariasis when a worm passes in their bowel movements, when they cough up a worm, or when a worm crawls out through the nose. This can be frightening, but the ascaris worm usually does not cause permanent damage to the body. However, because of the relatively large size of adult worms, they may partially block the gastrointestinal tract as well as the ducts leading from the biliary tract (tract that transports bile and enzymes for food digestion) and cause more serious health problems.

Strongyloidiasis/Threadworm (Nematode) Strongyloidiasis is caused by a type of roundworm commonly referred to as the threadworm, *Strongyloides stercoralis*. Although the route of infestation can be fecal-oral, it is most commonly from contact with contaminated soil where the larvae of the parasite can burrow directly through the skin. The larvae travel to the lungs, are coughed up into the mouth, swallowed, and enter the intestines. In the intestines the worm matures to adulthood and begins laying eggs. What is special about this parasite is that the eggs can hatch inside the intestines and the worm can continue to cycle through many generations without leaving the body (called the autoinfective cycle), which causes an infestation that can last for decades. In individuals with weakened immune systems*, particularly those taking drugs such as corticosteroids that depress the immune system, strongyloidiasis can become overwhelming. A great number of larvae may invade the lungs and other organs. This problem is called the hyperinfection syndrome and, although rare, can be fatal.

Strongyloidiasis is endemic* to the tropics and is especially prevalent in West Africa, the Caribbean, and Southeast Asia. Symptoms may include a rash and itch at the site of penetration, diarrhea that may be intermittent with constipation, abdominal discomfort, and vomiting. During the period that larvae are migrating through the lungs there may be cough, difficulty breathing, and low grade fever. Chronic strongyloidiasis may cause a physical sign known as larva currens (racing larva), a wavy-shaped wheal on the skin that extends from the region around the anus as far as the upper thighs and abdomen. These wheals are indicative of larvae invading the skin in the anal region.

Hookworm (Nematode) Hookworms are a type of roundworm and a common intestinal parasite. The Centers for Disease Control and Prevention estimates that one billion people worldwide have hookworm infestations, although improved sanitation reduced the number of cases in the United States. Two species can infest humans: *Ancylostoma duodenale* and *Necator americanus*. The hookworm eggs hatch into larvae in the soil. Hookworms can directly penetrate human skin. Humans may become parasitized by walking barefoot in or touching contaminated soil, as well as ingesting food with contaminated soil on it. The hookworm larvae travel to the lungs via the bloodstream. The larvae then travel to the throat and are swallowed, in a similar fashion to the ascaris worm. When they reach the small intestine, the larvae latch onto the intestinal walls and suck blood. There they mature and eventually lay eggs, which pass out of the body in the feces. Hookworms can live for one to two years in the body.

A rash or itching at the site where the larvae entered the skin may signal hookworm infestation, followed by mild cramping and diarrhea. Heavily infested people may lose their appetite, lose weight, and have abdominal pain. Hookworms may cause serious problems, including malnutrition and anemia (low red blood cell count) from intestinal bleeding. Newborns, young children, pregnant women, and malnourished individuals are most susceptible to these complications.

Dogs and cats may carry their own types of hookworm *Ancylostoma ceylanicum* and *Ancylostoma braziliense*. These hookworms occasionally pass on to humans who come in contact with soil contaminated with cat or dog feces. This type of infestation, called cutaneous* larva migrans or creeping eruption, involves the hookworm larvae burrowing into the skin

* **cutaneous** (kyoo-TAY-nee-us)
related to or affecting the skin.

and causing severe itching, but the worms do not invade any deeper into the tissues. The condition resolves without treatment after several weeks or months.

Enterobiasis/Pinworm (Nematode) Enterobiasis, also known as pinworm infestation, is caused by a staple-size worm known as *Enterobius vermicularis*. It is the most common worm infestation in the United States and is found primarily in children. Outbreaks of pinworm often occur in schools and daycare centers. From there, infested children may spread the worms to their family members.

Pinworms live in the rectum, at the end of the large intestine. They come out at night to lay eggs on the perineum, the area around the anus and genitals. The eggs can spread to sheets and clothing, where they remain with the potential for about two weeks to invade a new host. Infestation occurs when people touch a contaminated area and then their mouths. Itching of the perineum is the most common symptom of pinworm infestation, which can lead to sleeplessness and irritability. Frequently, however, infected individuals show no signs of infestation.

Trichinosis (Nematode) Trichinosis arises from several varieties of roundworms of the genus *Trichinella*. Although once very common, trichinosis was in the early 2000s relatively rare in the United States, with the CDC reporting an average of just 38 cases per year. Trichinosis is more common in developing countries. *Trichinella* larvae live encysted in the tissues of pigs and wild animals. When people eat their meat raw or undercooked, the larval cysts travel to the stomach, where acid dissolves the walls of the cysts and releases the immature, larval worms. They migrate to the small intestine, mature to adults, and lay eggs. Once the eggs hatch, the worms travel through the bloodstream to muscles, where they burrow in, forming new cysts. This ends the cycle in humans.

The first symptoms of trichinosis appear one to two days after infestation and include stomach pain, extreme tiredness, nausea, diarrhea, vomiting, and fever. Headaches, chills, swelling of the eyes, cough, muscle aches and pains, and constipation (infrequent bowel movements) may follow. People with severe infestations also may have heart problems or trouble breathing.

Giardiasis (Protozoan) Giardiasis is the most common waterborne parasitic infection in the United States. Caused by *Giardia intestinalis*, a single-cell protozoan (also known as *Giardia lamblia*), this infection can lead to diarrhea, cramping, and an upset stomach. *Giardia intestinalis* lives in humans and animals. People become infected by drinking or swimming in contaminated water or by accidental oral contact with the feces of an infected person in food or from the hands. Infested individuals may quickly spread the parasite if they do not wash their hands properly. Giardiasis occurs most frequently in settings where contaminated feces can be spread easily, such as in children or the elderly in diapers, which is

especially a problem in daycare centers and institutional settings such as nursing homes. Some people who are infected do not become sick but still can pass the infection on to others. In those who do develop symptoms, stomach pain, bloating, flatulence (gas), and watery diarrhea usually start one to two weeks after infection. About half the people who are infected also lose weight because the parasite interferes with the absorption of fat in the diet, which results in fatty, foul smelling stools. The illness often lasts two to six weeks, or longer in people who are sick with another disease. People most at risk for infection include children, travelers, homosexual men, and those with a compromised immune system. Giardiasis is diagnosed by examining a stool sample. If this method fails and giardiasis is still suspected, then tests for special enzymes in the stool are performed.

Amebiasis (Protozoan) Amebiasis is caused by a single-cell protozoan parasite called *Entamoeba histolytica* and occurs mainly in areas with poor sanitary conditions. The *Entamoeba* parasite has two life cycle forms: the motile (moving) form is responsible for the damage caused inside the gastrointestinal tract, whereas the cyst form is responsible for transmission of amebiasis. Amebiasis spreads when eggs are ingested through contaminated food or water or by touching surfaces contaminated with feces and then touching the mouth. It also can spread through certain types of sexual contact. Symptoms such as mild diarrhea and stomach pain may occur one to four weeks after an infestation, but only one in ten infested individuals develops symptoms.

Amebic dysentery, a more severe form of the illness, is caused when the parasites physically invade and damage the intestinal walls, which causes bloody diarrhea, extreme stomach pain, and fever. Rarely, the infestation spreads to other body organs, particularly the liver. In the liver, amebas may form large abscesses, areas of infection walled off from the rest of the body. Abscesses may also form in the brain. Cases in the United States usually are seen in people who have recently arrived from or traveled to remote areas.

Cryptosporidiosis (Protozoan) Cryptosporidiosis is caused by the protozoan *Cryptosporidium parvum*. Infestation usually occurs from ingestion of soil or water contaminated with fecal matter. Symptoms of cryptosporidiosis include diarrhea with frequent, watery, sometimes explosive bowel movements; loss of appetite; stomach cramps; bloating; nausea; fever; vomiting; and weight loss. The diagnosis can be made by examining a fecal sample under a microscope to view the organism. If the illness is not treated, its symptoms may return. Individuals with weak immune systems, such as those with AIDS*, have the most severe health problems from cryptosporidiosis and usually require treatment. However, the organism can infect people with normal immune systems and is one of the most common causes of protozoal diarrhea in the world. In individuals with healthy immune systems, the symptoms usually resolve on their own without treatment.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **endoscope** (EN-doh-skope) is a tool for looking inside parts of the body. It consists of a lighted tube and optical fibers and/or lenses.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

How Are Intestinal Parasites Diagnosed?

Physicians may use fecal samples, sometimes taken a day or two apart, to diagnose intestinal parasitic diseases. The feces are examined for evidence of parasites, such as eggs, larvae, or adult forms. Blood samples may also be taken to check for antibodies made by the body against specific parasites. Physicians may also use a medical instrument called an endoscope* that allows them to view the internal structures of the gastrointestinal tract and to examine the intestines for infection. To detect pinworms, physicians often request that patients take a tape test. For this test, patients briefly apply a piece of transparent tape to the skin around the anus in the early morning, the time right after the worm has laid its eggs. The tape is removed and examined at the doctor's office for any eggs that might be sticking to it.

How Are Intestinal Parasites Treated?

Some cases of intestinal parasites require little or no treatment, and the parasites eventually disappear on their own. Other cases require drug intervention with antibiotics or anthelmintics (drugs used to fight parasitic infections). Medication used to treat the illnesses varies with the type of infestation. In most cases, patients can remain at home and maintain a normal schedule. Children with infestations must stay out of daycare until they have been treated adequately and can no longer spread the parasites. Patients experiencing diarrhea are usually advised to drink plenty of fluids to avoid dehydration*. Infants and young children are particularly vulnerable to dehydration and nutrition problems when they become infested. Antidiarrheal medicine is usually not recommended because it may keep the parasites in the body longer. More severe cases of infestations may require treatment in the hospital. In individuals with weak immune systems (such as AIDS patients and people undergoing chemotherapy*), infants, and the elderly, parasitic infestations can be fatal.

How Is Intestinal Parasite Infestation Prevented?

Intestinal parasite infestation is best prevented through high standards of personal hygiene, which includes frequent and thorough hand washing, especially after changing diapers, after going to the bathroom, and before handling food. In areas known for parasites that live in the soil and burrow directly through the skin, wearing shoes may prevent parasites from entering the body. Individuals who travel to foreign countries known to have parasite problems are advised to drink and brush their teeth with bottled water and avoid eating raw fruits and vegetables, food from street vendors, and unpasteurized dairy products. In addition, cooking all food until it is steaming hot kills parasites. Avoiding swimming in bodies of fresh water such as ponds, rivers, and lakes in these areas can minimize the risk of contact with contaminated water.

Intracranial Bleeding

Intracranial bleeding refers to the accumulation of blood within the skull due to rupture of a blood vessel.

What Is Intracranial Bleeding?

The brain is covered by layers of membranes (meninges*), which are called (from the innermost layer) pia mater, arachnoid, and dura. In intracranial bleeding, blood can accumulate in spaces between these layers. Intracranial bleeding can be “extra-axial,” meaning the blood collects between the pia and arachnoid (subarachnoid hemorrhage); between the arachnoid and dura (subdural*); or between the dura and skull (epidural* hemorrhage). Intracranial bleeding can be “intra-axial” when blood accumulates within the brain substance (intracerebral hemorrhage or ICH) or in the spaces within the brain (ventricles) where fluid, called cerebrospinal fluid*, circulates. The bleeding of the brain’s ventricular system is called intraventricular hemorrhage. In general, intracranial bleeding refers to bleeding within the brain or the ventricles.

What Is the Source of Intracranial Bleeding?

At the base of the brain lies the Circle of Willis, a network of interconnecting arteries* that routes blood to the cerebrum, a vital part of the brain that has such jobs as directing the body’s movements; processing

▲ Cerebral magnetic resonance image (MRI) showing an intracranial bleed or stroke. *Edward Kinsman/Photo Researchers, Inc.*

- * **meninges** (meh-NIN-jeez) are the membranes that enclose and protect the brain and the spinal cord.
- * **subdural** (sub-DOO-ral) means under the dura, the covering of the brain.
- * **epidural** (ep-I-DOO-ral) means above or outside the dura, the covering of the brain.
- * **cerebrospinal fluid** (seh-ree-bro-SPY-nuhl) is the fluid that surrounds the brain and spinal cord.
- * **artery** An artery is a vessel that carries blood from the heart to tissues in the body.

- * **vein** is a vessel that carries blood to the heart. Veins have greater capacity and thinner walls than arteries and contain valves that prevent blood from flowing backward and away from the heart.
- * **hypertension** (HI-per-ten-chen) is abnormally high arterial blood pressure.
- * **trauma** refers to a wound or injury, whether psychological or physical. Psychological trauma refers to an emotional shock that leads to lasting psychological damage.
- * **cerebellum** (se-re-BEL-um) is the back portion of the brain that is responsible for muscle coordination and balance.
- * **brain stem** is the part of the brain that connects to the spinal cord. The brain stem controls the basic functions of life, such as breathing and blood pressure.

information from the eyes, ears, nose, and taste buds so that a person can see, hear, smell, and taste; allowing a person to learn and to remember; and helping a person to communicate. The Circle of Willis is formed by anterior (front), middle, and posterior (rear) cerebral arteries (one on each side of the brain), the anterior communicating artery (between the two anterior cerebral arteries), and the posterior communicating artery (between the middle and posterior cerebral artery on each side). Each of these arteries subdivides into smaller branches that penetrate the brain substance and give rise to “end arteries.” These end arteries are often the source of bleeding in intracerebral hemorrhage and subarachnoid hemorrhage. Subdural hemorrhage can occur either from a vein* or an artery, and epidural hemorrhage occurs from rupture of one of the arteries (called the middle meningeal artery) that supplies blood to the meninges.

How Common Is Intracranial Bleeding?

Each year, about 12 to 15 intracerebral hemorrhages occur per 100,000 people in the United States. Intracerebral hemorrhages account for 8 to 13 percent of all strokes. Intracerebral hemorrhage is more common in Asians, Hispanics, and African Americans.

In addition, older people are more likely to experience an intracerebral hemorrhage, and the incidence of intracerebral hemorrhage doubles with each decade above the age of 55. This is primarily because the percentage of people with hypertension* increases as the population ages, and hypertension is a risk factor for intracerebral hemorrhage.

What Causes Intracranial Bleeding?

Risk factors for intracranial bleeding include old age, hypertension, high alcohol intake, membership in high risk groups (for instance, African Americans experience intracerebral hemorrhage 1.4 times as often as Caucasians), and use of blood thinners. Trauma*, hypertension, and amyloid angiopathy (amyloid deposits formed on walls of blood vessels in central nervous system) are the most common causes.

Intracranial bleeding may result from trauma, such as penetrating injuries, including skull fractures in which the fractured bone protrudes into the brain or acceleration-deceleration injuries that result from motor vehicle accidents. Such traumatic hemorrhages can be epidural, subdural, subarachnoid, or intracerebral. Traumatic hemorrhage in children often results from so-called shaken baby syndrome, in which a parent or other stronger individual violently shakes a child, causing the thin-walled blood vessels in the head to rupture.

Many people who experience non-traumatic intracerebral hemorrhage have hypertension. Individuals with hypertension are two to six times more likely to have such a hemorrhage, because hypertension weakens the wall of the blood vessel, making it more vulnerable to spontaneous rupture. The common areas for a hypertensive hemorrhage are deeper parts of the brain, which include the basal ganglia, cerebellum*, brain stem*, and ventricles.

Intracranial bleeding can also result from a condition called cerebral amyloid angiopathy. This condition, which is a disease of older patients, causes material to build up along blood vessel walls, which leads to their rupture. These ruptures primarily occur in the parietal and occipital areas (the upper middle and the back) of the cerebral cortex* and cerebellum.

Intracranial bleeding due to malformations* of the blood vessels, especially in young patients, arise from certain bulges, called aneurysms, in blood vessel walls; from a tangle of abnormal veins (cavernous malformations), or from a tangle of abnormal arteries and veins (arteriovenous malformations). When children have intracranial bleeding that is not the result of a trauma, the culprit is often an arteriovenous malformation, which is a birth defect. Scientists are unsure exactly what causes it, but a family history of certain medical conditions may make a child more likely to experience an arteriovenous malformation. Such a malformation may occur at various locations on the body, but the most frequent location is the head. Treatment for these malformations may include a type of radiation therapy called proton-beam radiation, a non-surgical technique called embolization that injects material to block blood vessels, or the surgical removal of the problem area.

If the blood becomes excessively thin (coagulopathy) due to certain disorders such as liver failure, to the use of blood thinners (such as anticoagulants or a common stroke medication called tissue plasminogen activator, or t-PA), or to deficiency of blood-clotting elements such as platelets*, intracranial bleeding occurs. Hemorrhage can also occur in a part of the brain that is dying due to the blockage of the supplying artery (ischemic stroke). Acute rise in blood pressure due to certain drugs such as cocaine* or to strokes* can also cause intracranial bleeding. Other causes for bleeding into brain are tumors* and obstruction of the venous outflow of the brain (cerebral sinus thrombosis*). In premature births*, the lining of the ventricles is very thin and immature and can lead to intraventricular bleeding or to bleeding in an especially fragile part of a newborn's brain called the *germinal matrix*.

What Are the Symptoms and Signs of Intracranial Bleeding?

Symptoms and signs of intracranial bleeding develop over minutes to hours and become worse with time. Many patients have headaches, some of which result when blood irritates the meninges. In subarachnoid hemorrhage, the headache is sudden and intense (*thunderclap headache*). Vomiting is common, and some but not all patients may also experience nausea* before the vomiting. About 10 percent of patients have convulsions*.

Doctors may be able to pinpoint the location of the intracranial bleeding by checking the patient for certain telltale signs, including unequal pupils, limb weakness, various vision problems, and neck stiffness. Patients can be alert, in stupor* and sometimes even in a

- * **cerebral cortex** (suh-REE-brul KOR-teks) is the part of the brain that controls functions such as conscious thought, listening, and speaking.
- * **malformation** (mal-for-MAY-shun) is an abnormal formation of a body part.
- * **platelets** (PLATE-lets) are tiny disk-shaped particles within the blood that play an important role in clotting.
- * **cocaine** (ko-KAYN) is a stimulant, a drug that produces a temporary feeling of alertness, energy, and euphoria.
- * **strokes** are events that occur when a blood vessel bringing oxygen and nutrients to the brain bursts or becomes clogged by a blood clot or other particle. As a result, nerve cells in the affected area of the brain cannot function properly.
- * **tumors** (TOO-morz) are abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.
- * **thrombosis** is the formation or development of a blood clot or thrombus.
- * **premature birth** (pre-ma-CHUR) means born too early. In humans, it means being born after a pregnancy term lasting less than 37 weeks.
- * **nausea** (NAW-zha) refers to a feeling of being sick to one's stomach or needing to vomit.
- * **convulsions** (kon-VUL-shuns), also called seizures, are involuntary muscle contractions caused by electrical discharges within the brain and are usually accompanied by changes in consciousness.
- * **stupor** is a state of sluggishness or impaired consciousness.

- * **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.
- * **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.
- * **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.
- * **angiogram** (AN-jee-o-gram) is a test in which x-rays are taken as dye is injected into the body, showing the flow of blood through the heart and blood vessels.
- * **catheter** (KAH-thuh-ter) is a small plastic tube placed through a body opening into an organ (such as the bladder) or through the skin directly into a blood vessel. It is used to give fluids to or drain fluids from a person.
- * **clotting** is a process in which blood changes into a jellylike mass that stops the flow of blood.
- * **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.
- * **kidney** is one of the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.
- * **echocardiogram** (eh-ko-KAR-dee-uh-gram) is a diagnostic test that uses sound waves to produce images of the heart's chambers and valves and blood flow through the heart.

coma*. Blood pressure becomes high, even among those patients who have not previously had a problem with hypertension. The bleeding in intracerebral hemorrhage usually continues for several hours, and the signs and symptoms of the hemorrhage may heighten. In the ensuing days, swelling of the brain occurs around the bleeding site, and water may accumulate there, too. Over time, this added pressure from the blood and water pushes on the brain, shifting it to the opposite side or downward in the skull, causing damage to other, previously normal parts of the brain that were not affected initially. This shifting is called *brain herniation* and can result in death due to damage of the vital centers in the brainstem.

How Is Intracranial Bleeding Diagnosed?

Intracranial bleeding is a medical emergency. If a person has symptoms of intracranial bleeding, someone should immediately call 911 so medical professionals can take the patient to the emergency room. There, doctors will diagnose the condition by asking either the patient or relatives (if the patient is in a coma) a series of medical questions, by conducting a detailed physical and neurological (nervous system) exam, and most importantly by examining the brain. Doctors may conduct this examination with a computerized tomography* scan, which can detect blood within the brain, the ventricles, or in the subarachnoid, subdural or epidural space, and can detect any associated fractures in case of trauma. It also helps the doctor rule out ischemic stroke, which is actually more common.

Once the patient is stabilized, the doctor may order other forms of brain imaging such as a magnetic resonance imaging* scan, CT angiogram*, or catheter* angiogram to look for the cause of bleeding. Such brains scans are especially useful for diagnosing arteriovenous malformations in children.

Laboratory tests to determine the cause of bleeding include blood counts and clotting* tests to detect coagulopathy or infections, a blood chemistry profile to detect liver* or kidney* failure, and toxicology tests to detect alcohol or drug intoxication. The doctor may also order an electrocardiogram to detect heart rhythm abnormalities and an echocardiogram* to look at the function and structure of the heart and to check for evidence of long-standing hypertension. In some instances when subarachnoid hemorrhage or brain infection is suspected, the doctor may also order a spinal tap* to look for blood or bacteria* in the cerebrospinal fluid.

How Is Intracranial Bleeding Treated?

Treatment usually begins in the emergency room and continues in the intensive care unit. The treating team usually consists of the emergency room physician, a neurologist (a nerve specialist), an intensive care specialist, and in some cases, a neurosurgeon.

Medical therapy is aimed at controlling the blood pressure, protecting the airway in comatose patients by inserting a breathing tube connected

to a ventilator*, treating convulsions, and finally, using medications to decrease brain swelling. In cases of coagulopathy, the patient typically receives vitamin K, fresh frozen plasma, clotting factors, and platelets to restore the normal clotting mechanism.

In selected cases (such as rapid deterioration due to a superficial hemorrhage in a young patient, bleeding into the cerebellum, subdural or epidural hemorrhage), a doctor may recommend surgery to remove the clot. For intraventricular hemorrhage, the patient will undergo a bedside procedure that inserts a catheter into the ventricles to drain blood and cerebrospinal fluid. In addition, medical professionals will surgically clip aneurysms or block them off with metal coils to prevent re-rupture. Both techniques are often used for aneurysms of the Circle of Willis. Patients may need a small hole in their windpipe (a tracheostomy*) to help them breathe and/or a feeding tube directly into the stomach so they can receive nutrition.

Once patients survive intracranial bleeding, they need rehabilitation. For this process, a rehabilitation expert will lead a team of physical and occupational therapists*, speech therapists, and a nutritionist. Patients may go to an inpatient rehabilitation center, a nursing home, or in some cases, to their home, depending to their level of disability and how likely they are to recover well.

What Is the Prognosis for Intracranial Bleeding?

Intracranial bleeding is a fatal disease in several instances, and patients may die even before they can get medical attention. Death usually results from brain herniation or from medical complications such as pneumonia*. In some gravely ill elderly patients, the family members may opt to withdraw life support based on the patient's previously expressed wishes of not wanting to live on life support. Overall, about 50 percent of patients die within 30 days of intracranial bleeding, and those who survive have a long road of rehabilitation ahead of them.

Can Intracranial Bleeding Be Prevented?

One of the best ways for people to prevent intracranial bleeding is to protect themselves from trauma to the head. Children should wear all recommended protective gear when playing sports, which includes wearing a helmet that fits properly and is worn correctly when they ride a bicycle. Everyone should use seat belts when riding in a vehicle.

Irritable bowel syndrome (IBS)

Irritable bowel syndrome (IBS) is a chronic disorder that occurs when the intestines do not function correctly. A person with IBS may experience abdominal pain that often is accompanied by alternating episodes of constipation and diarrhea.*

Georgia Goes Solo

Playing the flute was Georgia's favorite activity. When she got to college, Georgia majored in music and performed regularly with the college orchestra. Until her senior year, Georgia always was healthy and able to make it to concerts, but then she began to have problems with her bowel movements. Either she was running to the bathroom constantly because she had diarrhea, or she suffered from constipation. Her symptoms began to interfere with rehearsals and concerts, so she went to the college health center. The doctor was able to rule out inflammatory bowel disease but did diagnose irritable bowel syndrome. The doctor prescribed medication for Georgia and referred her to a nutritionist and a stress-management program. By graduation, Georgia was able to play a flute solo without having to worry about rushing off to the bathroom.

What Is Irritable Bowel Syndrome?

Irritable bowel syndrome is a disorder in which the nerves that control the muscles of the intestine are unusually sensitive, causing the bowels to function improperly. The result is abdominal discomfort and an altered pattern of bowel movements (either diarrhea or constipation). About 10 to 15 percent of Americans are affected by IBS.

IBS, which is also called spastic colon or spastic bowel, is not contagious; therefore, a person cannot catch it from someone who has it. A person with IBS may experience considerable distress and discomfort from abdominal cramping, gas, constipation, and/or diarrhea, and for some people, these symptoms can seriously disrupt their daily lives. IBS does not, however, lead to other intestinal diseases such as cancer* or ulcerative colitis*.

The cause of IBS is unknown. Diet, drugs, stress, or emotional factors can trigger symptoms, and these triggers vary from person to person. The syndrome is about twice as common in women as in men and usually begins in early adulthood.

How Is IBS Diagnosed and Treated?

Diagnosis To diagnose a person as having IBS, the doctor must determine through medical history, physical examination, and diagnostic tests that the patient does not have another disease such as Crohn's disease, ulcerative colitis, or an infection that might be causing the symptoms. Typically, a person with IBS reports some or all of the following symptoms to the doctor:

- abdominal pain or cramping
- constipation*
- diarrhea* (may alternate with constipation)
- a feeling that the bowel movement is incomplete
- mucus in the stool
- bloated feeling in the abdomen
- considerable gas

Treatment While no cure is available for IBS as of 2009, various methods can be effective in controlling the symptoms. Doctors may prescribe medication to relieve diarrhea and constipation. Changes in diet help many people control their symptoms. People with IBS often benefit from practicing stress-reduction techniques, because stress can lead to symptoms in some people. Other people with IBS help manage their condition by seeking supportive psychological counseling.

J

Jaundice

Jaundice (JAWN-dis) is a yellowish discoloration of the skin and of the whites of the eyes. It is caused by accumulation in the body of a bile pigment called bilirubin (bil-e-ROO-bin). Jaundice is not itself a disease, but it is a sign of several disorders that affect the liver, the blood, the gallbladder, or bile, which is a fluid secreted by the liver to aid in the digestion of fats. The medical term for jaundice is icterus (IK-ter-us).

What Are Bilirubin and Bile?

When a person is in good health, the bile pigment* bilirubin is formed from the normal breakdown of hemoglobin (HE-mo-glo-bin), which is the oxygen-carrying substance in red blood cells. This process occurs naturally as old red blood cells wear out and are replaced in the body. Bilirubin is then carried in the bloodstream to the liver, where it is combined with bile.

Bile, which is also called gall, gets its greenish-yellow color from bilirubin. Bile is a fluid secreted by the liver to aid in the digestion of dietary fat. Bile is stored in the gallbladder. When it is needed for digestion, the

* **pigment** (PIG-ment) is a substance that imparts color to another substance.

◀ Anatomy of the liver. An obstruction in the bile duct may lead to jaundice. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **hemolytic** (he-mo-LIT-ik) refers to destruction of red blood cells with the release of hemoglobin into the bloodstream.

* **hepatocellular** (hep-a-to-SEL-ular) refers to the cells of the liver.

* **physiologic** (fiz-ee-o-LOJ-ik) refers to an organism's healthy and normal functioning.

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

gallbladder pushes it out into the small intestine through a tube called a bile duct. Much of the dark color of stool is the result of bile pigments.

What Causes Jaundice?

There are different kinds of jaundice, but they all occur when the process described above is disrupted and causes too much bilirubin in the blood.

Hemolytic jaundice Hemolytic* jaundice occurs when the rapid breakdown of too many red blood cells results in the overproduction of bilirubin. This may occur in such diseases as malaria, sickle-cell anemia, and septicemia (sep-ti-SEE-me-a), or blood poisoning.

Hepatocellular jaundice Hepatocellular* (liver) jaundice occurs when damage to the liver lessens its ability to remove bilirubin from the blood. Hepatocellular jaundice commonly occurs in cases of hepatitis, cirrhosis of the liver, and liver cancer. Swallowing or inhaling poisonous chemicals and advanced alcoholism can also produce jaundice from liver damage.

Obstructive jaundice Obstructive jaundice, a common form, occurs when the bile duct from the gallbladder to the small intestine narrows or becomes blocked, causing bilirubin to back up and accumulate in the blood. Obstructive jaundice may result from gallstones, injuries, tumors, or inflammation that affects the bile ducts.

Physiologic jaundice of the newborn Physiologic* jaundice sometimes occurs when newborn babies have too much bilirubin in the blood. This form of jaundice usually disappears within a few days as the infant's liver matures in its ability to handle bilirubin.

Is Jaundice a Disease?

Jaundice is not itself a disease, but it is a sign of several disorders that affect the liver, the blood, the gallbladder, or bile. Other signs and symptoms of disease may occur along with jaundice. For example, the urine* may be dark brown owing to the excretion of bilirubin or the stool may be nearly white owing to lack of bilirubin, which produces the normal brown color. Blockage of the bile ducts may also cause intense itching as bile products accumulate in the skin. In hepatitis and other liver diseases, jaundice may be only one among many signs and symptoms.

How Is Jaundice Diagnosed and Treated?

Anyone whose skin becomes abnormally yellow needs to see a doctor to find out why. Making a medical diagnosis may include special blood tests to determine whether the liver is diseased or whether too many red blood cells are being destroyed. A urine sample may be taken to test for bilirubin. A liver biopsy, in which a tiny tissue sample is removed for analysis, may be performed. Ultrasound scanning, which uses sound waves to look inside the body, may be used if the doctor is looking for gallstones

BILE, GALL, AND “THE JAUNDICED EYE”

The words “bile,” “gall,” and “jaundice” have all been associated with negative emotions: bile with anger, gall with insolence and audacity, and jaundice with distaste or hostility, as when one views someone or something with “a jaundiced eye.”

These usages all derive from an ancient concept—first applied to medicine by the Greek practitioner Hippocrates (ca. 470 B.C.E.–ca. 377 B.C.E.) who proposed that different states of the body and mind were caused by “humors,” or body fluids, one of which was black bile.

Bile is quite bitter-tasting. Thus, the term “good humored” came to mean having a pleasant disposition, while “ill humored” came to mean surly or irritable.

or other causes of obstruction. After diagnostic testing, an appropriate treatment plan is chosen according to the disorder identified as the cause of the jaundice.

Jet Lag

Jet lag is a disruption of the body’s internal biological clock that occurs when people cross time zones.

Jet lag is a common affliction that affects airplane travelers who cross time zones. The body’s internal clock is “set” for the time zone in which a person lives. The light and dark schedule regulates many body functions, including when the body feels hungry and sleepy. In the past, when people

* **insomnia** abnormal inability to get adequate sleep.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

traveled by train, ship, horse, or wagon, long-distance trips took months, during which time their bodies continually adjusted their internal clock. With air travel, however, it is possible to cross 8 or 10 time zones in a matter of hours. Thus, the traveler's body becomes confused: a person in the new setting may want to sleep even though it is early morning or may want to start the day in the middle of the night.

A contributing factor to jet lag is the stress that air travel places on the body. Most passengers cope with cramped, uncomfortable seating. Even though the cabin is pressurized, it is still like being at 8,000 to 10,000 feet in elevation. The lower air pressure causes minor effects such as headache, body aches, and insomnia*. The air aboard airplanes is usually dry, which causes minor dehydration*. These stresses and the change in time zones result in jet lag.

Although there is no cure for jet lag, there are strategies that can help minimize it. During long flights, travelers should drink plenty of water and get up and walk around the plane occasionally. It can also help to begin to adjust eating and sleeping schedules to the hours of the destination before the trip.

Kawasaki Disease

Kawasaki disease is an inflammatory illness in children that involves the body's blood vessels. The disease is characterized by high fever, swollen glands, and a rash, and it may lead to complications affecting the heart.

What Is Kawasaki Disease?

For children in the United States, Kawasaki disease is the leading cause of acquired heart disease, that is, heart disease that is not present at birth but develops later in life. In 1967 the Japanese pediatrician Tomisaku Kawasaki (b. 1925) first described the illness. He called it mucocutaneous (myoo-ko-kyoo-TAY-nee-us) lymph node syndrome, but later it became better known as Kawasaki disease. Even after many years of research, the cause of this disease as of 2009 remained unknown, but doctors suspected that an infectious microorganism* may trigger the onset of inflammation in the body. Kawasaki disease sometimes occurs in outbreaks, often in late winter or spring, and can resemble diseases such as measles or scarlet fever*, which suggests a possible link to an infectious organism.

Kawasaki disease can cause inflammation of blood vessels, mucous membranes (moist linings of the mouth, nose, eyes, and throat), lymph nodes*, and the heart. Although it eventually clears up on its own, if left untreated it can damage the blood vessels that supply the heart muscle. Kawasaki disease is associated with a one in five risk of coronary aneurysms*. This blood vessel damage can lead to a heart attack, especially in very young children.

How Common Is Kawasaki Disease?

As many as 3,500 children are hospitalized with Kawasaki disease each year in the United States. Four out of five children who get the disease are younger than five years of age, and the disease is extremely rare in children older than 15. Kawasaki disease develops in boys about twice as often as in girls. It is more common in children of Asian descent, although it occurs in all races.

* **microorganism** is a tiny organism that can be seen only by using a microscope. Types of microorganisms include fungi, bacteria, and viruses.

* **scarlet fever** is an infection that causes a sore throat and a rash.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **coronary aneurysm** (KOR-uh-nair-e AN-yuh-rih-zum) is an abnormal stretching and weakening of a blood vessel that supplies blood to the heart. If it breaks open, it may cause serious damage to the heart, sometimes leading to death.

- * **platelets** (PLATE-lets) are tiny disk-shaped particles within the blood that play an important role in clotting.
- * **echocardiogram** (eh-ko-KAR-dee-uh-gram) is a diagnostic test that uses sound waves to produce images of the heart's chambers and valves and blood flow through the heart.
- * **coronary arteries** (KOR-uh-nair-e AR-tuh-reez) are the blood vessels that directly supply blood to the heart.
- * **blood clots** are thickenings of the blood into a jelly-like substance that helps stop bleeding. Clotting of the blood within a blood vessel can lead to blockage of blood flow.
- * **gamma globulin** (GAH-muh GLAH-byoo-lin) is a type of protein in the blood that contains the antibodies produced by the cells of the body's immune system that help defend the body against infection-causing germs, such as bacteria and viruses.
- * **Reye's syndrome** (RYES SIN-drome) is a rare condition that involves inflammation of the liver and brain, and sometimes appears after illnesses such as chicken pox or influenza. It has also been associated with taking aspirin during certain viral infections.
- * **angiograms** (AN-jee-o-grams) are tests in which x-rays are taken as dye is injected into the body, showing the flow of blood through the heart and blood vessels.
- * **stress test** measures the health of a person's heart while the heart is intentionally stressed by exercise or medication.

Is Kawasaki Disease Contagious?

The disease itself has not been proved to be contagious. Doctors suspect, however, that an infectious microorganism may trigger it and that the organism might be contagious. Nonetheless, it is rare for more than one child in a family to have Kawasaki disease.

What Are the Signs and Symptoms of the Disease?

Kawasaki disease has distinctive features. A high fever, often more than 104 degrees Fahrenheit, usually appears first and lasts for at least five days. Afterward, signs of Kawasaki disease show up in stages and may include a red rash over the entire body; cracked lips; inflamed lining of the mouth; and a red, swollen tongue. Infected children may also have reddened and swollen hands, feet, fingers, and toes, with peeling skin; conjunctivitis in both eyes; sore, stiff joints; and swollen lymph nodes in the neck. Some children experience abdominal pain and diarrhea as well. The earliest phase of the disease, including fever and rash, usually lasts 10 to 14 days. The later phase, with peeling skin and slowly easing joint pain, can persist up to two months. Heart problems, if they occur, are more likely to show up during this time.

Making the Diagnosis

No single laboratory test can identify Kawasaki disease, so doctors make the diagnosis based on the child's symptoms and a physical examination: five days of high fever, accompanied by most of the associated signs mentioned above. Blood tests help support the diagnosis and include tests to determine the numbers of white blood cells (cells that respond to infection) and platelets* and tests that detect inflammation in the body. An echocardiogram* and a chest x-ray are performed to look for evidence of damage to the heart and coronary arteries*.

How Do Doctors Treat Kawasaki Disease?

Kawasaki disease is treated in the hospital. Children typically are given high doses of aspirin to decrease inflammation, prevent blood clots* in the heart's blood vessels, and lessen fever and joint pain. A one-time dose of intravenous gamma globulin* is also given to lower the risk of heart problems, particularly coronary aneurysms. (Even though aspirin is an important part of the treatment for Kawasaki disease, children normally are not given aspirin for minor fever or pain, because Reye's syndrome*, a dangerous condition, has been linked to aspirin use in children.)

Much of the treatment for Kawasaki disease focuses on keeping the patient comfortable while the illness runs its course. After the disease clears up, children still need follow-up testing to make sure it has not caused heart disease. They may have additional echocardiograms or angiograms* to examine the heart for damage and sometimes a stress test* to check the heart's function.

What Are the Possible Complications of Kawasaki Disease?

Up to 25 percent of children with untreated Kawasaki disease may experience complications that involve the heart and coronary arteries. With treatment, that risk goes down to less than 5 percent. Babies younger than one year and children older than nine years have the greatest risk of heart problems. By far the most serious complication of Kawasaki disease is coronary aneurysm. If an aneurysm clots or, more rarely, bursts in a blood vessel supplying the heart muscle, it can cause a heart attack or even death. Kawasaki disease can affect the heart in other ways as well, leading to myocarditis* or an irregular heartbeat.

Can Kawasaki Disease Be Prevented?

Because little was known about its cause as of 2009, there were no proven ways to prevent Kawasaki disease.

Kidney Cancer

Kidney cancer occurs when cells in the kidney divide without control or order, forming a growth called a tumor and sometimes spreading to other parts of the body.

What Are The Kidneys?

The kidneys are two bean-shaped organs located near the spine. Their main function is to filter salts, excess water, and impurities from the blood, producing the liquid waste called urine. Urine drains from the kidneys through a tube called the ureter to the bladder where it is stored until it leaves the body through another tube called the urethra. Besides the job of filtration, the kidneys also help to produce red blood cells and to maintain healthy blood pressure.

* **myocarditis** (my-oh-kar-DYE-tis) is an inflammation of the muscular walls of the heart.

▲ Wilms' tumor, a cancerous tumor of the kidney, shown in a young child. *Illustration by Argosy. Reproduced by permission of Gale, a part of Cengage Learning.*

* **chemotherapy** (KEE-mo-THER-ə-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

If cancer develops in the kidneys, it may affect not only the kidneys but nearby organs as well, including the liver, pancreas, and large intestine. In addition, kidney cancer cells may spread through the bloodstream or lymphatic system to other parts of the body. The most common form of kidney cancer in children is Wilms' tumor, and the most common form of kidney cancer in adults is renal cell cancer.

Wilms' Tumor

Wilms' tumor, the most common cause of kidney cancer in children, begins to develop even before a child is born. As the fetus grows in the womb, the kidney cells develop into netlike structures of blood vessels and tissues that are designed to filter the blood. When these cells do not mature as they should, the baby is born with some underdeveloped cells. Usually these cells mature by the time a child is three or four. Sometimes, however, they start to grow out of control, forming a jumbled mixture of small cells called a Wilms' tumor. The tumor is named after the German doctor Max Wilms (1867–1918), who first wrote about it in 1899.

Doctors find the tumor by feeling a mass while examining a baby's belly. The baby usually has few, if any, symptoms. If the tumor has not spread out of the kidney, the outlook for the child's recovery is excellent. Most children with Wilms' tumor undergo surgery or chemotherapy*. If the cancer has spread beyond the kidney, doctors may also prescribe radiation therapy, which uses focused, high-energy rays to destroy cancer cells.

Adult Kidney Cancer

Kidney cancer in adults, which is much more common than in children, occurs only rarely in people younger than 45 years of age. Overall, medical professionals diagnose more than 50,000 cases of the disease in Americans each year. In four out of five cases, the tumor forms in the tissue responsible for filtering the blood, but it also can affect the renal pelvis, the structure that collects the urine after filtration. Unlike Wilms' tumor, kidney cancer in adults often spreads to nearby organs and to other parts of the body.

Kidney cancer is more common in people who smoke cigarettes. Exposure to certain chemicals and to medications containing the pain-reliever phenacetin appears to increase risk for the disease. Heredity can play a role, too. Many cases of kidney cancer, however, develop without apparent cause. The most common early symptoms of kidney cancer include the following:

- Blood in the urine
- Pain in the lower back
- Unexplained weight loss
- Recurring fevers
- High blood pressure

How Do Doctors Diagnose and Treat Kidney Cancer?

Diagnosis Doctors start with a medical history, physical examination, and laboratory tests of blood and urine samples. Based on their findings, they may order tests that produce pictures of the kidneys and nearby organs. They may also order additional tests, including the following:

- Intravenous pyelogram (IVP) (in-tra-VEN-us PY-e-lo-gram), which is a series of x-rays of the kidneys, ureter, and bladder that are taken after dye is injected.
- Arteriogram (ar-TER-ee-o-gram), which is a similar test that creates images of the network of blood vessels in and around the kidney.
- Imaging tests, such as CT scans*, MRIs*, and ultrasound*.

If a doctor suspects kidney cancer, a surgeon will perform a biopsy by inserting a thin needle into the tumor and removing a sample of tissue to be examined under the microscope. If these cells turn out to be cancerous, doctors need to find out whether the cancer has spread beyond the kidney. Kidney cancer cells often spread through the bloodstream or the lymph nodes*, which filter the infection-fighting fluid called lymph. Doctors may order more imaging tests to examine nearby organs and to check for swollen lymph nodes in the chest and abdomen. They may also order chest x-rays and bone scans because the cancer tends to spread to the lungs or the bones.

Treatment How the disease is treated depends on whether it has spread beyond the kidney. If it has not spread elsewhere, the most common treatments are surgery and radiation therapy. Surgery involves removing part or all of the kidney, a procedure called nephrectomy (nef-REK-tom-ee). The remaining kidney generally is able to perform the work of both kidneys.

Kidney cancer that has spread to other parts of the body can be very difficult to treat. Two treatment options are biological therapy and chemotherapy. Biological therapy, also called immunotherapy, attempts to boost the body's own natural defenses against the cancer. Medical professionals prescribe immune boosters, such as Interleukin-2 and interferon. Chemotherapy delivers anti-cancer drugs into the person's bloodstream through a needle or in pill form.

These treatments have helped only a small percentage of people with advanced kidney cancer. Occasionally, however, some patients experience spontaneous remission, which means that the disease partially or completely disappears for short periods of time or permanently. Although spontaneous remission is rare among patients with kidney cancer, it is still much more common in this type of cancer than in other types of cancers. Because the body in some cases has the ability to fight off kidney cancer on its own, scientists may consider good candidates for immunotherapy. Immunotherapy encourages the body's internal defense mechanism, the immune system, in its fight against a disease. In the early 2000s researchers were conducting studies and clinical trials (research studies with volunteer

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **MRI** short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

patients) to test new treatment approaches. One of these is a vaccine made from a patient's own tumors. This vaccine stimulates the immune system to fight that patient's disease specifically.

In addition to these treatment options, people with advanced kidney cancer and their caregivers may find support groups to be a valuable resource.

Kidney Disease

Kidney disease refers to any condition affecting how well the kidneys work. Kidney diseases range from mild infections that can be treated with antibiotics to chronic (long-lasting) diseases that cause the kidneys to deteriorate and ultimately to stop working.

Structure and Function of the Kidneys

The kidneys are a pair of bean-shaped organs located in the back of the abdominal cavity right above the waist. One lies on each side of the spinal column, and each kidney holds about a million nephrons (NEF-rons). The nephrons perform one of the kidneys' primary jobs: filtering waste out of the blood. Each nephron contains a tiny blood vessel, or capillary, called a glomerulus (glom-ER-you-luss). The glomerulus sits inside a chamber that is known as Bowman's capsule, and the capsule lies within a tangle of small tubes, or tubules. Blood enters the glomerulus, and water and small molecules

The kidneys are located on both sides of the spinal column just above the waist. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

(including ions) filter out of the blood and into Bowman's capsule. From there, this fluid of water and small molecules moves into the tubule system, specifically the part known as the proximal convoluted tubule. While the fluid travels through this tubule, the blood re-absorbs, or resorbs, the nutrients and much of the water from the liquid. At this point, the liquid is known as urine. The urine then travels from the proximal tubule into the loop of Henle (HEN-lee), which is a section of tubule that has a hairpin turn. The loop of Henle removes additional water and ions from the urine, making the urine even more concentrated. From there, the urine enters the next part of the tubule system, the distal convoluted tubule. The urine eventually exits the tubule system and flows into a larger collecting tube, called the ureter (yu-REE-ter), and then on to the bladder. The bladder stores the urine until it empties out of the body when the person urinates.

In all, the kidneys perform a number of functions, chiefly filtering the blood, removing wastes to create urine, and adjusting the chemical and fluid balance in the body by controlling the concentration of urine. The kidneys also are involved in regulating the effects of vitamin D on the body and in stimulating bone marrow to create new red blood cells. In addition, the kidneys participate in the control of blood pressure through the renin-angiotensin (REN-in ann-gee-o-TEN-sin) system. The kidneys help to regulate blood pressure by secreting renin, which is an enzyme. Renin is involved in the production of angiotensin, a hormone that controls blood pressure by changing the size of certain blood vessels. When these blood vessels become smaller, blood pressure rises.

When the kidneys are damaged by disease, some or all of these functions can be impaired. If both kidneys do not function properly, a person can become very ill; when they fail to function at all, a person will die

What Is Dialysis?

When the kidneys stop filtering blood properly because of injury or disease, hemodialysis (hemo means blood) is the most common treatment. A dialysis machine acts as an artificial kidney and connects to a patient via needles and tubes. Blood pumps from the person into the machine where filters do the job of the kidney and remove wastes and excess water. Once the blood has been filtered, it returns to the patient's body through a vein. Some people need dialysis temporarily while their kidneys heal, but many more depend on it permanently to stay alive. The only alternative to dialysis for these people is a kidney transplant.

without treatment. Fortunately, the human body has two kidneys, and if one is damaged or even missing, the other is capable of performing all of the functions quite well. Most people who have only one healthy kidney can live a normal life. Sometimes certain people develop slightly higher blood pressure, however; so a doctor may want to monitor them a bit more carefully than those people who have two kidneys.

Is Kidney Disease a Common Health Problem?

Kidney disease is a major health problem in the United States. According to a 2007 study by researchers at Johns Hopkins University, about 13 percent of the U.S. population has chronic kidney disease, although most remain unaware of it. This figure represents a 3 percent increase over the estimate in 1994. In 2005, more than 485,000 individuals had dialysis treatments or a kidney transplant, resulting in medical costs of approximately \$32 billion, according to the U.S. Renal Data System of the National Institutes of Health. In addition, more than 400,000 U.S. residents have end-stage renal disease (ESRD), the most severe form of kidney disease.

What Are the Different Types of Kidney Disease?

Kidney diseases are divided into three categories: congenital disorders that appear at the time of birth; chronic disorders that may develop gradually over many years; and acute disorders that occur suddenly.

Congenital Disorders Some people are born with a kidney disorder, which is called a congenital disease. They may have one kidney missing, two on one side, or two ureters (the tube that carries urine from the kidney to the bladder) for one kidney. In some cases, the two kidneys may be connected at their base to form a single horseshoe-shaped kidney. The human body usually can adjust to these abnormalities because it can function with one kidney.

Mild Conditions Can Become Serious Chronic kidney diseases are very serious conditions because they cause the kidneys to deteriorate over time. Glomerulonephritis (glom-er-u-lo-ne-FRY-tis) is a condition in which the glomeruli (glom-ER-you-li)—the plural of glomerulus—become inflamed. It often accompanies other diseases such as diabetes* and high blood pressure, or it can develop as the result of a bacterial infection or a disease that affects the immune system. The immune system makes proteins called antibodies to fight infection. In glomerulonephritis, these antibodies become trapped in the glomeruli causing them to become inflamed. Glomerulonephritis is treatable under certain circumstances, but in other cases it may progress and cause severe kidney damage.

Many people who have kidney disease develop anemia, a condition in which an individual has too few of the red blood cells that carry oxygen to cells and organs in the body. This condition occurs when the kidneys do not make enough of the hormone erythropoietin (ee-rith-ro-po-EE-tin). Erythropoietin stimulates the bone marrow to produce the right amount

of red blood cells. Anemia can also result when a patient loses blood from hemodialysis.

In addition, cancer or tumors in the kidneys or a condition called polycystic kidney disease (PKD) can stop the kidneys from functioning properly over time. PKD is a genetic disorder that results in the growth of numerous liquid-filled sacs, called cysts, in the kidneys. These cysts can take the place of functioning kidney tissue and prevent the kidneys from doing their job. Eventually, many of these diseases lead to end-stage renal disease (ESRD), a condition in which the kidneys shut down.

Acute Kidney Failure Acute, or sudden, kidney failure can result from many factors, including injury that greatly reduces blood flow, severe dehydration, exposure to chemicals and drugs that are poisonous to the kidneys, infections, tumors, and kidney stones.

Pyelonephritis (PY-el-o-ne-FRY-tis), or infection of the kidney, is a common type of acute kidney disease. Its symptoms can include pain in the back or abdomen, fever, and frequent or painful urination. Medical professionals can treat it effectively with antibiotics. Another well-known condition is kidney stones, which are hard crystals made of chemicals that separate from the urine and build up in the kidney. Small kidney stones can pass out of the body without medical assistance, but larger stones require a procedure that breaks them into smaller pieces so that they can leave the body in the urine. People may recover from these kidney diseases without permanent damage to the kidneys. If left untreated, however, these diseases can cause permanent damage and kidney failure.

How Is Kidney Disease Diagnosed and Treated?

Medical professionals determine the type and extent of kidney disease through a number of methods: blood tests, urinalysis, kidney imaging (such as x-rays and MRIs*), and renal (kidney) biopsy, which involves taking a sample of tissues to examine under a microscope.

The treatment for kidney disease varies based on the underlying cause. For example, an infection might require antibiotics, whereas a tumor would demand surgical removal. Medical professionals can treat chronic conditions with drugs to reduce symptoms in cases in which the disease cannot be cured. A restricted diet also may help alleviate symptoms. Complete kidney failure requires dialysis two or three times per week or a kidney transplant.

Kidney Stones

Kidney stones are composed of crystals formed by chemicals that separate out of the urine, harden, and build up in the kidney. Most people pass kidney stones out of the body without requiring medical treatment, but in severe cases, they might need surgery.

What Is a Kidney Stone?

The kidneys are bean-shaped organs about the size of a juice-box that are located on either side of the spine toward the back of the abdomen above the waist. They filter water, salts, and waste products out of the blood to make

Kidney stones may develop in the kidneys or in the urinary tract if crystals of calcium phosphate or calcium oxalate that have separated out from urine grow too large to pass out of the body. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

urine, and they maintain the body's water and ion* levels. When the ratio of water and ions in the urine is out of balance, kidney stones can form.

Kidney stones can be as small as a grain of sand or as big as a golf ball. There are four kinds of kidney stones:

- Stones may be made from calcium. Calcium is an important part of a good diet and promotes healthy bones and muscles. If a person's body does not flush out extra calcium, as it should, the calcium can combine with other chemicals in the urine (a common chemical is the mineral oxalate) and then crystallize and adhere to the lining of the kidney. The crystals can also stick to one another and form hard masses, or stones, of various sizes.
- Struvite stones are made from a combination of ammonia, which is a waste product in the urine, and the mineral magnesium. A common cause for these stones is an infection in the urinary system.
- Uric-acid stones form when the urine is too acidic. A common cause for these stones is a diet that contains too much meat.
- Although rare, stones can also be made of cystine, an amino acid which is a building block of protein. Usually, people who have cystine stones also have a family history of them.

The causes of kidney stones often are unknown. However, urinary tract infections, several metabolic disorders, and a family history of kidney stones may make a person more likely to develop them. People who have certain other conditions or genetic disorders may also develop kidney stones. These problems include the following:

- Hyperparathyroidism is a condition caused by overactive parathyroid glands. Located in the neck, these four tiny glands normally regulate calcium levels. When they are overactive, calcium imbalances can occur and this condition can lead to the formation of kidney stones.
- Gout causes an increase in the amount of a certain acid (uric acid) in the urine. This condition can result in the development of kidney stones.
- Cystinuria, a genetic disorder, causes an excess of cystine in the urine, a disease that can trigger stone formation.
- Renal tubular acidosis is a condition in which the kidneys fail to transfer enough acid from the blood to the urine. The blood remains too acidic, and over time, this problem can lead to kidney stones.

What Happens When People Have Kidney Stones?

Symptoms The smallest kidney stones can pass out of the body in the urine without the person even knowing it. The passing of larger stones can cause severe pain, and people have described it as the worst pain they have ever experienced. The pain occurs when the stone moves from the kidney through the ureter*(yu-REE-ter), a tiny tube that conveys urine from the

* **ions** are positively or negatively charged elements or compounds, like hydrogen, sodium, potassium, and phosphate, which are necessary for cellular metabolism.

* **ureters** (YOOR-eh-ters) are tube-like structures that carry urine from the kidneys to the bladder.

Did You Know?

- Kidney stones are mentioned in the Hippocratic (hip-o-KRAT-ik) oath taken by doctors when they begin their medical careers.
- Scientists have found what they think is a kidney stone in a 7,000-year-old Egyptian mummy.
- Approximately 10 percent of all people are likely to have a kidney stone at some time.
- Kidney stones occur in men more often than in women.
- Kidney stones usually affect people who are between 20 and 40 years of age.
- Doctors sometimes ask people with kidney stones to cut back on foods and drinks that contain calcium and oxalate. These may include some fruits and vegetables, some dairy products, coffee, chocolate, tea, and cola drinks.

* **sonograms** (SON-o-gramz) are images or records made on a computer using sound waves passing through the body.

kidney to the bladder. In addition to sharp pain in the back and side, other symptoms may include nausea, vomiting, fever, chills, and blood in the urine. Large kidney stones can be life-threatening if they block the urinary tract and obstruct the flow of urine from the body. The blockage can cause urine to back up into the kidney and cause it to swell in a condition known as hydronephrosis (HY-dro-na-FRO-sis). This problem must be corrected, or it can result in infection, as well as serious kidney damage.

Diagnosis Doctors can typically diagnose kidney stones based on the patient's medical and family history and a physical examination. In some cases, a doctor may also use x-rays and sonograms*, along with analyses of blood and urine to make the diagnosis.

Treatment Most kidney stones pass through the urinary tract on their own, and individuals typically help the process by drinking lots of water and taking pain medication. If the stones are very large (more than 0.5 inches in diameter), doctors can use various techniques to break up the stones while they are inside the kidney or ureter so that the smaller pieces can pass out without further medical intervention. One technique is extracorporeal shockwave lithotripsy (LITH-o-TRIP-see), which uses high-energy sound waves. These shock waves pass harmlessly through the body and break the stone into tiny particles, which the patient can then eliminate in the urine without pain. Surgery (nephrolithotomy) is rarely necessary.

How Are Kidney Stones Prevented?

Kidney stones usually affect people between the ages of 20 and 40. Approximately 10 percent of people experience kidney stones, and once a person has had one kidney stone, he or she has about a 70 to 80 percent chance of developing another. Once a person has passed a stone, a doctor tries to find out what kind it is, often by asking patient who has passed a stone at home to bring it in for laboratory analysis. This information may help the doctor determine why the person is developing the stones. In many cases, individuals can reduce their chances of developing more stones by changing their diet, drinking more water, and/or taking certain kinds of medication. Scientists have explored how certain urinary proteins are involved in stone formation. Their research as of 2009 showed that some proteins can keep the stone-associated chemicals from crystallizing out of urine and, therefore, prevent stone formation.

* **nervous system** is a network of specialized tissue made of nerve cells, or neurons, that processes messages to and from different parts of the human body.

Kuru

Kuru is a disease of the nervous system that is extremely rare in the 21st century but that once was common among people in certain tribes in Papua, New Guinea, who practiced cannibalism.

Mystery in New Guinea

In the 1950s, a strange disease of the nervous system* was killing people in certain tribes in the highlands of New Guinea, an island north of Australia in the Pacific Ocean. The American scientist Daniel Carleton Gajdusek (b. 1923) traveled to New Guinea to study the disease, which the people there called kuru. Eventually, he traced the problem to cannibalism, the eating of human flesh by another human. In this case, cannibalism took the form of a ritual in which people ate the uncooked brains of relatives who had died. Today, those New Guinea tribes no longer practice this ritual, and kuru has practically disappeared.

Gajdusek thought that kuru was passed from a dead person's brain to a living person by a slow virus that takes years to cause symptoms. Many scientists later dismissed this theory. Instead, they speculated that kuru is caused by a prion, a type of protein that can cause infection. Kuru belongs to a group of human and animal diseases of the brain, known as transmissible spongiform (SPUN-ji-form) encephalopathies (en-sef-a-LOP-a-theez), that may be caused by prions. The word "spongiform" refers to the way infected brains develop holes until they look like sponges under a microscope. The most common such disease in humans is Creutzfeldt-Jakob disease.

What Are the Symptoms?

People with kuru have trouble controlling their movements, and this problem gets worse over time. Their arms and legs may appear stiff, or they may have rapid muscle spasms. Occasionally, their muscles may twitch or jerk uncontrollably, or their fingers, hands, toes, and feet may move in a slow, writhing motion. As the disease gets worse, people with kuru may start to lose their mental abilities, such as thought, memory, and concentration. Death usually occurs within 3 to 12 months. Kuru is

Kwashiorkor

Kwashiorkor (kwash-ee-OR-kor) is a type of severe malnutrition that affects young children aged one to four years but which is also found in older children and adults, living in extreme poverty in tropical and subtropical parts of the world. The condition develops among people who have high starch diets without sufficient protein, especially among individuals who are suffering from famine. A nursing baby gets protein in the mother's milk; however, in such dire conditions if the mother stops nursing one child upon the birth of another, the older of the two may develop this protein deficiency. The name of this condition translates as "rejected one," meaning that the older child is replaced at the breast by the newborn. Kwashiorkor produces such physical characteristics as small stature, weight loss, discolored and puffy skin on arms and legs and sometimes on the face, thin and reddish-blond-discolored hair, large and swollen abdomen (commonly called bloated belly), thin arms and legs, and pigment loss.

Tanya's Story

Tanya lived outside Tubmanburg in Liberia with her parents and four older brothers and sisters. Her family was poor, and her parents had a hard time feeding all of the children. Nevertheless, Tanya was a healthy infant because she was breastfed; breast milk contains all of the protein and other nutrients a baby needs. But when Tanya was just over a year old, her mother had another baby and Tanya could no longer breastfeed. Instead, she had to eat the only food available: white rice, cassava, and yams. These foods contain mostly carbohydrates and have almost no protein. Because

of the lack of protein in Tanya's diet, she developed kwashiorkor: Her stomach was bloated, her arms and legs got thin, her skin flaked, and she was very weak. Tanya is typical of many children whose families are too poor to feed their children a complete diet. Overcrowded, unhygienic, and poverty-stricken conditions directly contribute to children being at risk of developing kwashiorkor.

In the 1980s and 1990s, civil wars in Liberia dislocated hundreds of thousands of people and devastated the country's economy. Without labor laws to protect them, children work long hours to help their families. Some companies in Liberia have been accused of ruining the environment in order to increase their profits, activity that further hurts the poorest residents in the area. These larger factors in her society affect Tanya's health, too.

What Is Kwashiorkor?

Kwashiorkor is a disease caused by the lack of protein in a child's diet. It is a type of protein-energy malnutrition (PEM) that is widespread throughout regions where the diet is composed almost exclusively of starchy foods such as rice, yams, maize, cassava, or plantains. People afflicted with kwashiorkor are often deficient in such nutrients as folic acid, iodine, iron, and vitamin C and in such antioxidants as albumin, polyunsaturated fatty acids, and vitamin E. Children living in extreme poverty, such as those suffering through famine or existing in refugee camps, are at increased risk for kwashiorkor.

British physician and pediatrician Cicely Delphine Williams (1893–1992) first described kwashiorkor to the scientific community in 1935 after treating villagers in the area later called Ghana. Williams found first-born children often developed the condition after they were weaned before a second child was born. Thus, the term “kwashiorkor” was derived from a word used in Ghana that means “rejected one.” However, it was not globally recognized as a serious disease until the late 1940s. In the early 2000s Kwashiorkor usually develops after a baby is weaned from protein-rich breast milk (for any reason) and switched to protein-poor foods. In extreme poverty and during famines and wars that displace populations from farmland to refugee camps, protein-rich foods are not available.

What Are the Symptoms of Kwashiorkor?

Children with kwashiorkor have degraded skin conditions such as edema (excess water retention in body tissues that causes swelling and bloating); inflammation of the skin (dermatitis); flaking and peeling skin that contains whitish patches; skin pigment changes; thinning and brittle hair along with lack of curliness and color; and hair that is easily pulled out. Afflicted children have loss of appetite and diarrhea and are usually weak, irritable, and lethargic.

In many cases muscle mass shrinks, and incidence of infections increases due to a weakened immune system. If left untreated, kwashiorkor causes

* **jaundice** (JON-dis) is a yellowing of the skin, and sometimes the whites of the eyes, caused by a buildup in the body of bilirubin, a chemical produced in and released by the liver. An increase in bilirubin may indicate disease of the liver or certain blood disorders.

* **shock** is a serious condition in which blood pressure is very low and not enough blood flows to the body's organs and tissues. Untreated, shock may result in death.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be woken up, and cannot move, see, speak, or hear.

* **oncotic pressure** is the pressure difference of blood plasma and tissue fluid.

* **Starling forces** are hydrostatic and oncotic pressures that control fluid movements in capillary membranes.

enlargement of the liver due to fat buildup, loss of fluids (dehydration) from the bloodstream even when the child has edema, stunted growth, and diminished size of all tissues and organs except for the liver. It also can result in jaundice*, drowsiness, and lowered body temperature, along with lowered mental development. If dietary protein is not supplied to offset malnourishment, the child eventually goes into shock* and coma* and then dies.

Symptoms of kwashiorkor result from a lack of amino acids, which are the building blocks of protein. The amino acids are not present in sufficient quantities for the body to produce the various proteins needed for the body to develop normally.

For example, albumin is an important protein; it plays a vital role in maintaining oncotic pressure* within blood vessels. Oncotic pressure is maintained by the presence of proteins, such as albumin, which helps to keep fluids within the capillaries. However, in kwashiorkor sufferers, the level of albumin is low and more fluid flows out of the capillaries than into them; thus, the fluid tends to accumulate in the tissues. Consequently, these fluids are not available to be used for hydration of the body.

When medical staff and resources are available, kwashiorkor patients are given intravenous fluids to increase fluid balances lost from sweating and urine output and to replace losses from vomiting and diarrhea. Medical professionals would also monitor blood constituents such as albumin that maintain what are called Starling forces*.

How Is Kwashiorkor Treated?

An international team of medical workers traveling in Liberia saw Tanya sitting on the ground too tired to play and realized the extent of her malnutrition. They took her to the hospital in Tubmanburg, where she was kept warm and given fluids to replace those she had lost. Initially, she was given small amounts of milk and vitamin and mineral supplements. Zinc supplements helped stop her skin from flaking. After the edema went away, the doctors gave her a high-calorie diet rich in protein.

Of the children who are hospitalized and treated for kwashiorkor, 85 percent survive. Most children properly treated for kwashiorkor early enough recover completely. However, children who develop kwashiorkor before the age of two years, like Tanya, in areas where medical help is not available usually experience stunted height and growth potentials and diminished mental capabilities.

Tests that can be given to diagnose kwashiorkor include urinalysis (tests on urine); serum creatinine (blood test to evaluate kidney function); creatinine clearance (comparison test of creatinine in urine and blood); blood, urea, nitrogen test (to evaluate thyroid function); serum potassium (blood potassium test); arterial blood gas test (to measure oxygen and carbon dioxide in blood); total protein levels test (to measure protein in blood), and complete blood count (to measure concentration of white

and red blood cells and platelets). The most routine test identifies total plasma protein level, especially with respect to plasma albumin. Such tests available commonly in many hospitals may not be available to individuals in areas suffering from extreme poverty.

Individuals in shock should have their blood volume immediately replenished and their blood pressure constantly monitored. When stabilized, these patients should slowly be given carbohydrates, simple sugars, and fats. Later, proteins, vitamins, and minerals should be given. Milk products should be given. If the patients are lactose intolerant, an enzyme lactase supplement should be substituted.

Can Kwashiorkor Be Prevented?

Because kwashiorkor is a dietary deficiency condition, it can be prevented by individuals consuming a well-balanced diet that consists of appropriate amounts of fat (at least 10% of total calories), carbohydrates, and protein (around 12% of total calories). However, extreme poverty, natural disasters, and wars all too often make it impossible for poor people to enjoy well-balanced diets.

International efforts to provide medical support and food have been unable to meet the severe demands of huge populations. These efforts also include teaching people how to grow other kinds of foods, how to combine available foods to maximize protein intake, and contraception* methods to limit family size. These approaches address the ongoing problem of malnutrition. Within industrial countries, such as the United States, kwashiorkor is rare. When it does occur in developed countries, the cause is often child abuse.

L

Lactose Intolerance

Lactose intolerance (also known as hypolactasia) is the inability to digest lactose, the main sugar contained in milk and other dairy products. This inability occurs as a result of a low level of the enzyme lactase, which aids in the metabolism of lactose.

Erin's Story

Erin's favorite food had been ice cream since her first birthday. On her thirteenth birthday, the rocky road sundae with hot fudge went down without a hitch, but an hour later she felt awful. She had cramps and diarrhea*, and, even more embarrassing, gas. Erin's friend, whose mother had the same reaction to milk products, explained that she probably was becoming lactose intolerant, meaning that she could not digest all of the natural sugar in the ice cream.

What Is Lactose Intolerance?

Lactose intolerance refers to the inability of the small intestine to break down the sugar lactose (LAK-tos) due to a lack of or too little of the enzyme* lactase (LAK-tays). Lactose is a complex sugar found in milk products. Normally, when lactose reaches the small intestine, it is broken down into the simple sugars glucose (GLOO-kose) and galactose (ga-LAK-toz) by a protein, or enzyme, called lactase. Simple sugars can be absorbed easily through the wall of the small intestine into the bloodstream, but larger, more complex sugars such as lactose cannot. If someone is lactose intolerant, that person's intestine does not make enough lactase or the lactase it does make does not work properly.

If lactose is not broken down, it absorbs water, so that the water cannot pass through the intestinal wall into the bloodstream. This extra fluid remaining in the bowel causes diarrhea. Also, bacteria (microorganisms) in the colon convert lactose to lactic (LAK-tik) acid in a process called fermentation (fur-men-TAY-shun). Fermentation causes bowel movements to be acidic and burn, and it also causes gas, bloating, and cramps. Lactose intolerance is not dangerous, but it is uncomfortable.

Lactose intolerance is not the same as cow's milk intolerance, and they are in fact, not related. Lactose intolerance is a condition associated with the digestive system. An intolerance to cow's milk, however, is actually an allergic reaction and it is associated with the immune system.

* **diarrhea** (di-ah-RE-a) refers to frequent, watery stools (bowel movements).

* **enzyme** (EN-zime) is a protein that helps speed up a chemical reaction in cells or organisms.

Nondairy Sources of Lactose

Milk, cheese, butter, and ice cream are obvious sources of lactose, but lactose is often added to the following items:

- Baked goods, including bread, and mixes for baked goods
- Instant breakfast drinks, potatoes, and soups
- Lunch meats
- Margarine
- Nonfat dry milk powder
- Powdered coffee creamer
- Many prescription drugs
- Processed breakfast cereal
- Salad dressing
- Many snack foods
- Whey
- Whipped toppings

* **congenital** (kon-JEH-nih-tul) means present at birth.

Types of Lactose Intolerance

There are three major types of lactose intolerance. *Primary lactose intolerance* is a normal consequence of development and aging. The amount of the lactase contained in the small intestinal lining, or mucosa, varies among racial groups and even among individuals. Characteristically the amount of lactase falls as individuals age. Therefore, the capacity to digest lactose varies among people especially as they get older. In people with primary lactose intolerance the intake of lactose has exceeded the normally diminishing capacity to digest the sugar. *Secondary lactose intolerance* is associated with damage to the small intestinal mucosa and, therefore, loss of the lactase contained within the cells. Diseases such as Crohn's disease or celiac disease, which severely damage the small intestinal mucosa, may result in lactose intolerance. The third type of lactose intolerance is congenital* in nature. Babies having a lactase deficiency present at birth are usually diagnosed as having lactose intolerance during early infancy.

Who Becomes Lactose Intolerant?

Doctors estimate that 30 to 50 million people in the United States are lactose intolerant. Up to 75 percent of people of African, Mexican, and Native American ancestry develop lactose intolerance, as do 90 percent of people of Asian ancestry. People of other ancestry are affected less by the problem.

How Is Lactose Intolerance Diagnosed?

Doctors use three tests to diagnose lactose intolerance. After a person eats or drinks something containing lactose, the doctor can do the following:

- Test for a low level of glucose in the bloodstream, which would show that lactose was not broken down properly and absorbed (lactose intolerance test)
- Test for a lot of hydrogen in exhaled breath, a sign that bacteria are fermenting lactose (hydrogen breath test)
- Test for acidic bowel movements, also a sign that fermentation is occurring (stool acidity test); usually used to test infants and small children

Living with Lactose Intolerance

Symptoms vary from person to person and depend on the amount of lactose eaten. Trial and error helps people learn what not to eat or how much they can eat without becoming ill. Avoiding milk products should eliminate symptoms of lactose intolerance, but people on such a diet must get calcium and vitamin D from other sources. Nonprescription products containing lactase are available that can be taken along with milk products and help the body break down lactose.

Lactose intolerance usually can be managed by following simple strategies:

- Drink milk in small servings: 1 cup or less per serving.
- Eat cheeses that are low in lactose, such as cheddar.
- Only drink milk with meals or other foods.
- Eat active-culture yogurts, which contain less lactose than other dairy products.
- Use low-lactose or lactose-free milk.
- Take lactase enzyme tablets before consuming dairy products or add lactase enzyme drops to regular milk.

Laryngitis

Laryngitis (lair-in-JY-tis) is an inflammation of the vocal cords that causes hoarseness or a temporary loss of voice.

The Vocal Cords and Their Role in Laryngitis

The vocal cords are the two bands of muscle found inside the larynx (LAIR-inks), or voice box, located between the base of the tongue and the top of the trachea*. As they let air into and out of the lungs, the vocal cords are relaxed. When a person talks, however, the vocal cords tighten as air passes through them, causing the cords to vibrate and thereby produce sound.

* **trachea** (TRAY-kee-uh) is the windpipe—the firm, tubular structure that carries air from the throat to the lungs.

Parts of the body involved in the creation of sound and speech include the larynx, epiglottis, trachea, vocal cords, tongue, and palate. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **respiratory tract** includes the nose, mouth, throat, and lungs. It is the pathway through which air and gases are transported down into the lungs and back out of the body.

* **polyps** (PAH-lips) are bumps or growths usually on the lining or surface of a body part (such as the nose or intestine). Their size can range from tiny to large enough to cause pain or obstruction. They may be harmless, but they also may be cancerous.

* **acid reflux** is a condition in which stomach acid flows upward into the esophagus, often causing a burning sensation (so-called heartburn) in the upper abdomen or chest.

People who lose their voice after cheering too much at a sporting event or who begin to sound hoarse or raspy when they have a bad cold probably have laryngitis. Laryngitis refers to inflammation or irritation of the vocal cords. Inflammation causes swelling, which prevents the vocal cords from working properly, and the sounds they produce can seem strange or be hard to hear. Although laryngitis can make it difficult to communicate, it is rarely serious.

Why Do People Get Laryngitis?

Almost everyone gets laryngitis at some point, whether the condition causes a low raspy whisper or a complete loss of voice. Overusing the voice, such as yelling, speaking too loudly or for too long, and even singing, can lead to laryngitis. People who use their voice constantly, such as radio announcers, politicians, and singers, get laryngitis more often than other people do. The larynx is located along the respiratory tract*, which is why respiratory infections such as the flu (influenza) and the common cold can easily spread to the voice box and cause laryngitis. People who have allergies or who develop polyps* on the vocal cords may also experience laryngitis. Smoking, heavy drinking, inhaling harmful fumes, and acid reflux*, all irritate and inflame the vocal cords and can result in long-term or chronic laryngitis.

What Are the Signs and Symptoms of Laryngitis?

The most obvious symptoms of laryngitis are a hoarse or low voice, the inability to speak above a whisper, a raw feeling or sensation of having a lump in the throat, difficulty swallowing, and the need to clear the throat often. When laryngitis is caused by an infection such as the flu, a person may also experience sneezing, coughing, runny nose, headache, and fever.

Severe laryngitis can sometimes lead to breathing problems, especially in young children. Anyone with laryngitis who develops difficulty breathing or high fever or who is not getting better after a few days needs medical care.

How Is Laryngitis Diagnosed and Treated?

A doctor will ask about a person's symptoms and voice use to help determine whether laryngitis is the result of a respiratory infection or some other cause. In some cases, a doctor might take a close look at the vocal cords by holding a small mirror at the back of the throat. To get an even better view, a doctor might use a tiny camera on a long, thin tube that goes through the mouth or nose. This method allows the doctor to watch the vocal cords in action.

How doctors treat laryngitis depends on what is causing it. If the cause is a viral infection, antibiotics will not help, and the laryngitis will go away on its own. Doctors may recommend certain medicines to help relieve symptoms. Other tips that can help a person to feel better sooner are:

- resting the voice for several days, which means speaking rarely even a whisper, to help the vocal cords heal
- using a humidifier at home or sitting in the bathroom while a steamy shower is running, thus putting moisture into the air that can help to soothe an inflamed larynx
- drinking plenty of liquids
- getting lots of rest
- avoiding smoking or drinking alcohol

Laryngitis usually disappears after a few days, but it can last much longer and happen more often in people who are smokers or heavy drinkers or who use their voices for hours at a time in their jobs. It may take weeks of voice rest before the voice returns to normal. Such long-term hoarseness might cause complications that require speech therapy to help prevent further damage. If growths have formed on the vocal cords over time, surgery may be needed.

Preventing Laryngitis

Laryngitis is not contagious, but colds, flu, and other infections that cause it are. Doing what is possible to avoid these infections (such as frequent hand washing) decreases a person's chances of getting laryngitis.

Following these prevention basics can help maintain a healthy voice for life:

- not shouting or talking too loudly for too long
- staying away from cigarette smoke, which irritates the entire respiratory system
- keeping vocal cords from getting dry by drinking enough water every day

Lassa Fever

Lassa fever is a highly infectious and sometimes fatal viral disease that occurs in western Africa.

Hand Washing 101

Hand washing is one of the best ways to prevent the respiratory infections that lead to laryngitis. Rubbing the hands together, front and back, with warm, soapy water for at least 15 to 20 seconds (the length of time it takes to sing the "A-B-C Song") is much better at preventing the spread of germs than just a quick rinse.

▲ A technician draws blood and removes the spleen from a Lassa rat. Lassa fever is a hemorrhagic fever found in West Africa and spread by rodents. *Karen Kasmauski/Science Faction/Getty Images.*

Lassa Fever Statistics

Lassa fever was first identified in 1969.

■ Since 1969 Lassa fever has killed about 5,000 people a year and infected as many as 300,000 in West Africa, the only region where it is found. Those numbers may underestimate the extent of the disease because of poor reporting in some countries.

■ About 15 percent of people who are hospitalized with Lassa fever die. In some areas with high rates of Lassa fever, such as Sierra Leone and Liberia, approximately 15 percent of all hospital admissions involve people with Lassa fever.

* **infectious** means able to spread to others.

What Is Lassa Fever?

Lassa fever is an infectious* disease caused by a virus. It is named after the town in Nigeria where it was discovered. Most people infected with the virus have only mild symptoms. But one out of five people with Lassa fever becomes very ill. Lassa virus affects approximately 100,000 to 300,000 people in western Africa each year.

Lassa virus is spread to humans by the *Mastomys* rodent, which is found in the grasslands and forests of tropical Africa, as well as in human homes. A person can catch the virus by touching objects that have been contaminated with the urine and droppings of these rodents. It is also possible to catch Lassa virus by breathing air near rat droppings or by eating the rats for food. In addition, person-to-person transmission is common in village settings and in hospitals.

Symptoms of Lassa fever may include fever, pain in the chest, sore throat, cough, vomiting, and diarrhea. The virus is so infectious that medical personnel diagnosing the disease must take special precautions. One-third of people with Lassa fever develop deafness that is sometimes permanent. One percent of people infected with the virus die from it.

How Is Lassa Fever Treated and Prevented?

Lassa fever can often be successfully treated with the antiviral drug ribavirin when it is given within the first six days after infection. Because *Mastomys* rodents are found all over western Africa, however, it is unlikely that the virus can be prevented by getting rid of the rats. More promising methods of prevention include educating people about how to keep their homes free of rodents and developing a vaccine for Lassa fever.

Lead Poisoning

Lead poisoning occurs when a person swallows or breathes lead, which can damage many parts of the body, especially in young children.

Timmy's Story

The year Josh turned 12, his parents bought a bigger house so that they would have a bedroom for his little brother, Timmy, who had just started to crawl. Everyone in the family was excited about the move to the house, which was in an older neighborhood with giant trees in the yards.

Josh spent many Saturday afternoons helping his dad fix up the 50-year-old house. Josh's dad knew that chips of paint from homes this age often contain lead, which could be poisonous to Timmy if he put them in his mouth. One of his first projects, then, was to scrape off the old paint and replace it with lead-free paint.

Illustration by Corey Light. Reproduced by permission of Gale, a part of Cengage Learning.

Sources of lead poisoning

Source	Description
Paint	Lead-based paint can be a hazard in older homes. Children eat peeling paint, or come in contact with it during remodeling projects.
Dust and soil	Contamination of soil is usually caused by paint, leaded gasoline, pollution from industrial sites, and smelters.
Foods	Lead can be found in imported canned foods, leaded crystal, and some ceramic dishware.
Activities	Activities such as pottery, stained glassmaking, and furniture refinishing can heighten exposure to lead.
Drinking water	Homes built before 1930 may contain lead water pipes. Newer homes may also contain copper pipes with lead solder.
Traditional remedies & cosmetics	Certain ayurvedic medications, traditionally from India and other Southern Asian countries, may contain lead. Also litargirio (a peach-colored powder used mainly in the Dominican Republic) contains high levels of lead, and the FDA warns against its usage. Kohl is another traditional cosmetic frequently containing high levels of lead.

A few months later, Timmy's doctor tested his blood during a routine checkup and found a high level of lead. His parents had not known that Timmy could get lead poisoning from lead dust as well as paint chips. Luckily, the problem was caught and treated early.

What Is Lead Poisoning?

Lead is a metal that has been mined for thousands of years. In the past, it was an ingredient in many everyday items found in or near homes, such as paint, gasoline, water pipes, and food cans. When a person swallows or breathes lead, however, it can be highly poisonous. It is especially dangerous to children ages six years and younger, partly because the bodies of such young children are changing rapidly and partly because children in this age group tend to put objects in their mouths.

Lead is poisonous because it interferes with some of the body's basic activities. To some extent, the body cannot tell the difference between lead and calcium, a mineral that helps build strong bones. Like calcium, lead stays in the bloodstream for a few weeks. Then it is deposited in the bones, where it can stay for a lifetime. Even small amounts of lead can permanently harm children over time, leading to learning disabilities, behavior problems, decreased intelligence, and other problems. Large amounts of lead can cause seizures, unconsciousness, or even death.

What Causes Lead Poisoning?

There are many familiar items in people's everyday environment that can cause lead poisoning.

Manufacturers used to put lead in paint to make it last longer and cling better to surfaces. In 1978 the sale of lead-based paint for use in homes was banned in the United States. It also became illegal to paint children's toys and household furniture with lead-based paint. However, lead-based paint is still found in more than four out of five homes built before the time of the ban. Old paint that is peeling, chipped, or chalky is a hazard. Because lead has a sweet taste, children may eat chips of lead paint. Even lead-based paint in good condition can pose a risk if it is on surfaces that children chew or that get a lot of wear and tear. Lead-based paint can also be found on old children's toys and household furniture.

The most common way to get lead poisoning is through contact with lead in the form of dust. Lead can get into dust when old paint is scraped or sanded or when painted surfaces bump or rub together. This dust can then settle on objects that people touch or children put into their mouths.

Oil companies used to add lead to gasoline to improve performance. Leaded gasoline allowed lead particles to escape into the air through car exhaust systems. In 1978 the amount of lead allowed in gasoline in the United States was cut, and cars after that used lead-free gasoline. However, the soil around roads may still contain residue of lead from leaded gasoline. Lead also can get into soil when the outside paint on old buildings flakes or peels.

Lead was once widely used in household plumbing. This lead can get into water that flows through the pipes. In 1986 and 1988, the use of lead in public water systems and plumbing was limited in the United States. However, the lead in old faucets, pipes, and solder used to connect pipes remained a problem. The amount of lead in water depends on the water's temperature (warm or hot water can contain more lead), the minerals and acid it contains, how long the water sits in the pipes, and the condition of the pipes.

Lead solder was once used to seal food cans. This lead could mix with the food inside the can. In 1995 the United States banned this use of lead solder, but it continued to be found in some imported cans.

Some other sources of lead are as follows:

- Lead-glazed pottery or leaded crystal can leach lead into foods and drinks.
- Lead smelters and other industries can release lead into the air.
- Jobs that involve working with lead can expose workers to lead dust that settles on their clothes, skin, and hair.
- Hobbies such as making pottery and refinishing furniture use lead and may expose workers to it.
- Folk medicines and homemade cosmetics sometimes contain lead.

Who Is at High Risk?

Anyone of any age can be poisoned by lead. However, the risk is greatest among young children. In the United States, about 310,000 children ages one to five years have a dangerously high level of lead in their blood. The following are some situations linked to increased risk in young children:

- Living in or regularly visiting a home built before 1950.
- Living in or regularly visiting a home built before 1978 that has chipped or peeling paint or that has been remodeled recently.
- Living with an adult whose job or hobby involves contact with lead.
- Having a brother, sister, or playmate who has had lead poisoning.

What Are the Symptoms?

Lead poisoning is not easy to detect. Sometimes no symptoms occur, and at other times the symptoms look like those of other illnesses. Some of the possible early signs of lead poisoning in children are constant tiredness or overactivity, irritability, loss of appetite, weight loss, decreased attention span, trouble sleeping, and constipation.

High levels of lead can cause seizures*, unconsciousness, or even death in children. However, most cases of lead poisoning involve much lower levels of lead. Over time, though, even low levels of lead may cause permanent damage. At low levels, lead can cause problems such as learning disabilities, behavior problems, decreased intelligence, speech problems, decreased attention span, brain or nerve damage, poor coordination, kidney damage, decreased growth, and hearing loss.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

LEAD'S ROLE IN HISTORY

Lead lasts a long time and has a low melting temperature. In ancient Rome, wealthy families had indoor plumbing with lead pipes. (The chemical symbol for lead is Pb, from the Latin word plumbum for a lead weight. The Latin word is also the root for the word “plumber.”) The Romans also lined their outside pipes and water tanks with lead, and they made lead plates and eating utensils. Roman wine makers even sweetened sour wine by adding syrup containing powdered lead.

Modern historians have suggested that lead poisoning may explain the strange behavior of several Roman emperors, including Caligula (12–41 c.e.), who squandered a fortune on public entertainment, banished and murdered relatives, made his favorite horse a public official, and declared himself a god. The decline and fall of the Roman Empire may have been due, at least in part, to lead poisoning.

Contact with lead is especially dangerous for children. However, it can be harmful for teenagers and adults as well. If a pregnant woman comes into contact with lead, it can raise her risk of illness during pregnancy. It can also cause problems, including brain damage or death, in her unborn baby. At high levels, lead in adults can cause problems such as infertility, high blood pressure, digestion problems, nerve disorders, memory problems, decreased attention span, and muscle and joint pain.

How Is Lead Poisoning Diagnosed?

Often lead poisoning has few symptoms. The only way to know whether a person has lead poisoning is to get a blood test that measures the amount of lead in the blood. Children who are not at high risk are usually tested at one and two years of age. Children who are at high risk are usually tested every six months between the ages of six months and two years, then once a year until age six. A blood test can also be done at any time on anyone who has symptoms or may have been exposed to lead.

How Is Lead Poisoning Treated?

The first step in treatment is to avoid more contact with lead. Avoiding exposure means finding and removing any sources of lead in the home. The next step is to make any needed changes in diet. Children should eat at least three meals per day because they absorb less lead when they have food in their systems. Children also should eat plenty of foods high in iron and calcium, such as milk, cheese, fish, peanut butter, and raisins. When they do not get enough iron and calcium, their bodies mistake lead for these mineral, and more lead is absorbed and deposited in their tissues.

If blood levels of lead are high enough, the doctor may prescribe a drug that chelates (KEE-lates), or binds to, lead in the body. Once lead is bound up in this way, the body can remove it through urine or bowel movements. The drug used determines how it is administered: in a vein, by shot, or by mouth.

Getting the Lead Out

The following tips can help prevent lead poisoning:

- Wash the hands often, especially after spending time outside and before eating.
- Wash the floors, windowsills, and other surfaces in the home weekly.
- Use a sponge or mop with a solution of water and all-purpose cleaner to clean up dust.
- Rinse the sponge or mop thoroughly after cleaning dirty or dusty areas.
- Keep younger children from chewing on painted surfaces, such as windowsills or cribs.
- Do not let younger children put toys and other objects with painted surfaces in their mouths.
- Have younger children play in grassy areas instead of directly on soil, which may have lead in it.
- Frequently wash a younger child's bottles, pacifiers, toys, and stuffed animals.
- Use cold tap water for drinking or cooking because lead is more likely to leach into hot water taken from the tap.
- Eat a well-balanced diet that is low in fat and high in iron and calcium.

Learning Disabilities

Learning disabilities are disorders that affect people's ability to interpret information that they see or hear or to link information processed in different parts of the brain. A person with a learning disability may have specific difficulties with language, visual information, or coordination, which in turn can make it very hard to read, spell, write, or do math.

What Are Learning Disabilities?

Learning disabilities differ from learning problems (which are less severe) and from intellectual disabilities (formerly called mental retardation, which refers to more global learning difficulties). Not every learning problem is a true disorder or disability. Some children are just naturally slower than others in developing certain skills, but most children usually catch up and achieve within the normal range for their age and abilities. Children who are intellectually disabled, by contrast, are not able to learn and function socially like other children their age. Their general intellectual capacity is lower than average. Children with intellectual disability have learning problems but do not truly have learning disabilities.

Children with learning disabilities typically have average or even above-average intelligence, so there is a marked difference between their intellectual ability and what they actually learn. In a sense, a person with a learning disability is like a radio that is not tuned exactly to a station. There is nothing wrong with the radio itself or with the signal coming from the station, but the sound is still fuzzy. Similarly, people with learning disabilities can see and hear as well as others, and they have normal general learning capacity, but there is a problem with the way their brains process information.

Learning disabilities are generally classified into two main categories: verbal (having to do with the uses of spoken and written words) and non-verbal (having to do with interpreting visual or spatial information).

Verbal learning disabilities Developmental speech disorders are usually diagnosed in very young children who have persistent trouble making certain speech sounds; for example, they may say “wabbit” instead of “rabbit” or “thwim” instead of “swim.” Often these speech disabilities improve with age or with the help of a speech therapist.

Developmental language disorders involve the way that children express themselves or how they understand others' speech. Children with this type of disorder may speak in short phrases instead of full sentences, call objects by the wrong names, have disorganized speech, misunderstand words, or have difficulties following directions.

Reading is a complex task in which a person has to focus attention on the printed marks, control eye movements across the page, recognize sounds associated with letters, understand words and grammar, build images and ideas, compare new ideas to what is already known, and then

store the ideas in memory. This process requires a rich, intact network of nerve cells that connect the brain's centers of vision, language, and memory. A problem in any of these areas or the connections among them can lead to difficulties with reading. Dyslexia (dis-LEKS-ee-uh), the most common and best-known of the reading disorders, affects approximately 2 to 15 percent of school-age children. Because children with dyslexia have trouble processing the smallest units of language that make up words, they may have trouble with rhyming games or with sounding out individual letters or syllables to form words.

There are other types of reading disorders that affect comprehension (kom-pre-HEN-shun), which is the ability to fully understand and interpret what one reads. A person with this type of disability can read each word but may find it hard to understand the text, form images, or relate new ideas in the text to those in memory. These reading disabilities usually are discovered at a later age than is dyslexia.

A writing disability can result from problems with any area of the brain that controls grammar, hand movement, vocabulary, and memory. Children who have trouble mastering the motor skill of writing are said to have dysgraphia (dis-GRAF-ee-uh).

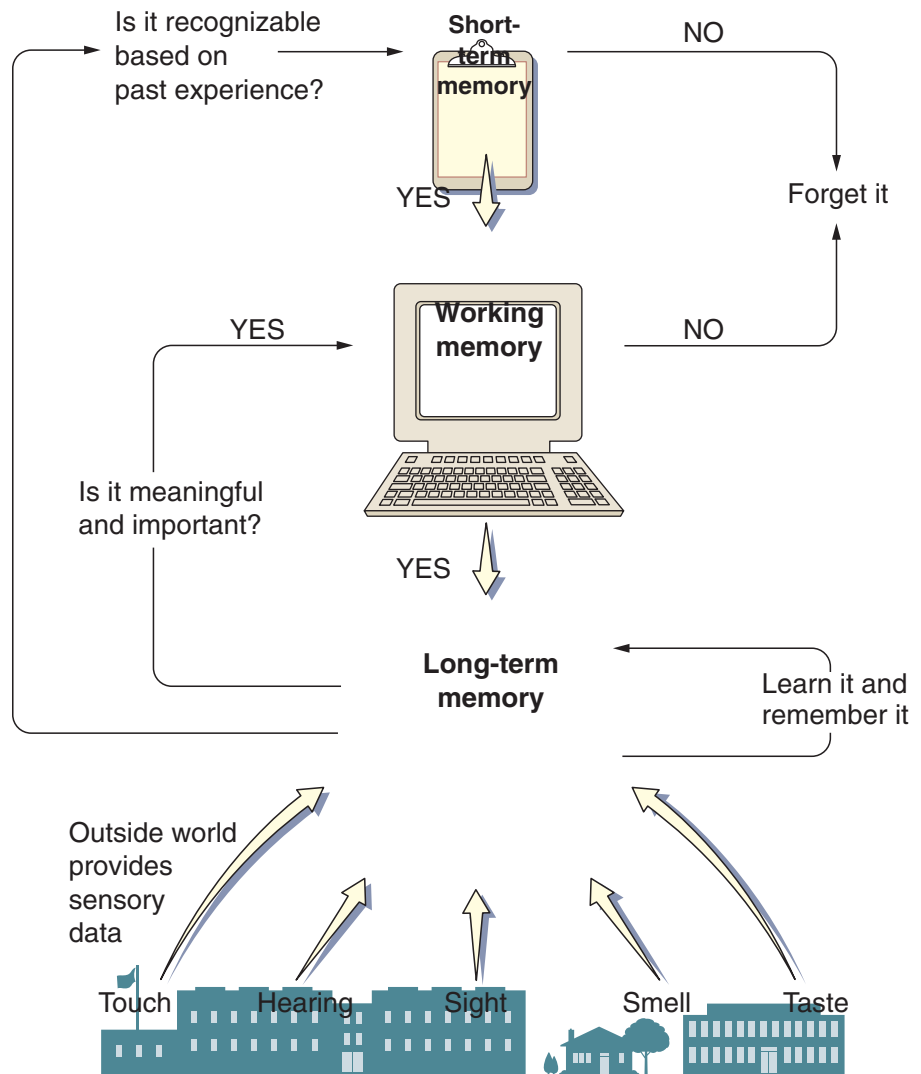

Nonverbal learning disorder Nonverbal learning disorder (also called nonverbal learning disabilities, or NVLD) is not as well understood as verbal learning disabilities. People with NVLD often have problems with visual perception, with recalling visual details, and with spatial relationships. Their eyesight is fine, but they may have trouble processing what they see; for example, a student might find it hard to follow a set of instructions demonstrated by a teacher.

Students with NVLD often find it hard to focus on nonverbal academic material as well, which can make it difficult for them to learn math (a disorder called dyscalculia (dis-KAL-kyoo-lee-uh)) and science. They may have trouble recognizing numbers and symbols, memorizing facts such as the multiplication tables, aligning numbers, and understanding abstract concepts such as place value and fractions. In both math and science class, students may have difficulty solving problems, forming complex concepts, and making educated guesses and then testing them out. Reading comprehension may be affected as well. Even though students with NVLD may read words and sentences with ease, they might not understand the underlying organization of a text. Dealing with brand-new material is likely to overwhelm children with NVLD.

Some children with NVLD have trouble in other areas as well. They may have poor motor skills and problems with coordination; for example, learning to ride a bike can be very difficult for a child with NVLD. They may also have trouble socializing with other children because they do not pick up on nonverbal social cues, such as tone of voice and body language, or they tend to make the wrong comment at a given time. Children with NVLD tend to be easily frustrated and upset. Any new situation can make them anxious because they may have more difficulty adjusting to it.

Learning involves a complex series of events. The brain receives new information from the outside world all the time, but in order to learn new information, the brain must recognize the information's importance, interpret it, analyze its meaning, and store it in memory for later use in processing new information. If the brain does not recognize new information as meaningful and important, it will discard it. Learning disorders affect different aspects of this complex process of recognizing, interpreting, understanding, and remembering new information.

Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.

* **attention deficit hyperactivity disorder** or ADHD, is a condition that makes it hard for a person to pay attention, sit still, or think before acting.

Other types of learning disabilities

There are many other subtypes of learning disabilities, but verbal and nonverbal learning disabilities are the two main categories. Because many aspects of speaking, listening, reading, writing, and arithmetic overlap and build on the same brain capabilities, it is not unusual for someone to have more than one disorder. For example, most disorders that hinder the ability to understand language will also interfere with learning to read, spell, and write.

Attention deficit hyperactivity disorder*, or ADHD, can also interfere with learning. Children with ADHD often have difficulty focusing on any one task for a period of time. Children with attention problems may have learning problems but attention deficits are not classified as specific learning disabilities. However, more than half of children with ADHD also have learning disabilities.

How Do People Know They Have a Learning Disability?

Parents and teachers are usually the first to notice signs of a possible learning disability. A very young child might not speak or listen as well as other children their age or might have trouble with a game's directions or other activities that other children complete with ease. The classroom teacher may notice persistent difficulties in reading, writing, or math.

The first step in diagnosing a learning disability is to rule out any other possible causes, such as vision or hearing problems or some other medical condition. Once a doctor makes sure that other problems are not causing the disability, the child might be evaluated by a psychologist* who specializes in learning disabilities. Diagnosing a learning disorder often takes time. The psychologist usually takes a careful history of symptoms, interviews the child, and gives certain tests that compare the child's level of ability to what is considered appropriate for a person of that age and intelligence.

Why Do People Have Learning Disabilities?

Why certain children develop learning disabilities and others do not remains a mystery in the early 2000s. However, researchers have speculated that learning disabilities may be traced to differences in early brain development that occur before or after birth. During brain development, a few all-purpose cells must grow into a complex organ made of billions of specialized interconnected nerve cells called neurons [NOR-ons]. Researchers are investigating possible causes for differences or disruptions in brain development that include the following:

- Alcohol, tobacco, or drug use by the mother during pregnancy
- Problems during pregnancy or delivery that may cause a decrease in the amount of oxygen that reaches the baby's developing brain
- Head injuries
- Exposure to poisonous substances in the environment, such as lead

Also, because some learning disabilities tend to run in families, researchers have explored how learning differences may be inherited.

Living with a Learning Disability

Because children with learning disabilities typically have normal or above-normal intelligence, they often can find ways to learn in spite of the disorder. They may need to attend special school programs for the learning disabled or to work with a learning specialist several hours each week while attending regular classes.

Special education teachers can help plan out what is called an Individualized Education Program, or IEP, for a learning-disabled child. This plan outlines the specific skills the child needs to develop as well as appropriate learning activities that build on the child's strengths and work

* **psychologist** (sy-KOL-uh-jist) is a mental health professional who can do psychological testing and provide mental health counseling.

around his or her difficulties. For example, a student with dyslexia might be encouraged to listen to a book on tape for English class, and a student with a writing disorder might take notes or complete an assignment using a laptop computer.

Children with learning disabilities often need emotional support because they may see themselves as stupid. They may withdraw from their classmates at school or even get into trouble because they are frustrated when learning is difficult for them. Children and their families can often benefit by working with a trained counselor or support group.

Legionnaires' Disease

Legionnaires' (lee-juh-NAIRS) disease, also known as legionellosis (lee-juh-nel-O-sis), is a bacterial infection that can lead to a serious form of pneumonia (nu-MO-nyah), or inflammation of the lungs.

What Is Legionnaires' Disease?

In 1976 more than 200 people attending an American Legion convention at the Bellevue-Stratford Hotel in Philadelphia, Pennsylvania, suddenly came down with a mysterious illness that caused high fever, chills, and a cough. Thirty-four people died from severe pneumonia. The illness, later named Legionnaires' disease in memory of the convention attendees, was caused by a previously undiscovered bacterium that scientists called *Legionella pneumophila*, (lee-juh-NEL-uh new-MOH-fee-luh). The bacteria were found to be living in the hotel's air-conditioning system. Since the initial outbreak, several other species of *Legionella* bacteria have been discovered, some of which can cause a very similar but less serious disease. Although people often hear about outbreaks of Legionnaires' disease in public places that affect many people at once, such outbreaks actually occur more frequently on a much smaller scale. The disease can even break out in homes.

How Common Is Legionnaires' Disease?

Between 8,000 and 18,000 cases of Legionnaires' disease occur in the United States every year. It is believed that many more may go undiagnosed because the symptoms are so mild that people do not seek treatment. An outbreak is most likely to occur in summer or early fall, but it can happen at any time. The disease can affect people of all ages, but people who are middle aged or older, who smoke cigarettes, or who have chronic* lung conditions, such as emphysema*, may be at especially high risk. People with weakened immune systems, such as those who have AIDS* or cancer, or those who have undergone organ transplantation, also are at greater risk of contracting the disease.

Electron micrograph of the bacteria *Legionella pneumophila*. Worldwide, there are as many as 40 species in the family of *Legionella* bacteria. A.B. Dowsett/Photo Researchers, Inc.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **emphysema** (em-fuh-ZEE-mah) is a lung disease in which the tiny air sacs in the lungs become permanently damaged and are unable to maintain the normal exchange of oxygen and other respiratory gases with the blood, often causing breathing difficulty.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

How Does Legionnaires' Disease Spread?

Legionnaires' disease is not spread from person to person. *Legionella* bacteria live and grow in warm, stagnant (still) water, such as that found in air-conditioning systems, hot-water tanks, or whirlpool spas. People might become infected by breathing in the mist from contaminated water sources (for example, the vents of air conditioners at a hotel or the showers at a gym).

Signs and Symptoms

Symptoms of *Legionella* infection can range from mild to severe. In fact, some people infected with the bacteria may show no symptoms at all. Those who do might experience high fever, chills, and a cough that usually produces sputum (SPYOO-tum), a mixture of thick, slippery mucus (MYOO-kus) and other material coughed up from the inflamed lungs and windpipe. Some people also have extreme tiredness, muscle aches, headache, shortness of breath, stomach pain, diarrhea, and loss of appetite. Symptoms typically begin within 2 to 10 days of exposure to the bacterium. Kidney problems also may occur. *Legionella* bacteria have also been found to cause a less serious disease called Pontiac fever, which is characterized by mild flu-like symptoms, without signs of pneumonia.

How Do Doctors Diagnose and Treat the Disease?

Legionnaires' disease can be difficult to distinguish from other types of pneumonia. There are very specific tests for it, but before ordering these tests, doctors need to learn as much as possible about their patients. First, doctors ask patients about their general health and recent activities. This history helps determine whether the patient might have been exposed to *Legionella* bacteria. Doctors then perform a physical examination of patients and take chest x-rays to look for signs of pneumonia in the lungs. If a doctor suspects Legionnaires' disease at this time, more specific laboratory tests might be ordered, including blood tests, to determine whether the patient's body is producing antibodies* to *Legionella* bacteria. Cultures of fluids from the patient's lungs may be done. To perform a culture, a person's sputum is placed on special material called a culture medium. If *Legionella* bacteria are present in the sputum, the medium will help them grow so that the bacterium can be identified. A urine test also can help confirm the presence of infection. The disease is treated with antibiotics and usually requires a stay in the hospital. In the hospital, patients receive supportive care, such as oxygen if they are having trouble breathing and extra fluids to replace what has been lost during periods of high fever.

What Are the Complications of Legionnaires' Disease?

Some people with *Legionella* infection experience only mild symptoms of illness, whereas others may be hospitalized for several weeks. Afterward, they may continue to be very tired for several more months. Most people who

THE CDC IN ACTION

When Legionnaires' disease broke out at the American Legion convention in Philadelphia in the summer of 1976, theories about its cause ranged from swine flu to chemical poisoning to communist conspiracies against American veterans. As fears mounted, the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia, in cooperation with other federal, state, and local authorities, launched one of the largest joint disease investigations in history. Investigators looked at the possible sources of the outbreak and the ways the infection could have spread. Survivors were examined; bodies were autopsied; and specimens of air, water, soil, and various hotel materials were tested. Comparing tissue samples from people who had become infected with samples held in storage at the CDC, investigators were even able to link the Philadelphia cases to unidentified cases of illness dating back as far as the 1940s. Finally, in 1977, doctors isolated the culprit bacterium from the hotel's cooling tower, and federal authorities put in place new hygiene safeguards to limit future problems. The CDC continued thereafter to work in disease prevention and control, addressing such wide-ranging topics as air pollution, water contamination, and unsafe working conditions and implementing educational programs and various other strategies to protect the health of Americans.

become ill with Legionnaires' disease recover, but in people with chronic lung problems, *Legionella* can make the condition worse, leading to severe illness. Up to 30 percent of cases of Legionnaires' disease are fatal.

Can the Disease Be Prevented?

There is little that people can do to avoid becoming infected with *Legionella*. In public places, better maintenance of plumbing and air-conditioning systems, including regular inspection and cleaning, can help limit the growth of the bacteria. If there is an outbreak, government health teams step in to decontaminate the suspected source of the bacteria.

▲ Cutaneous leishmaniasis affects the skin, causing sores that may look like volcanoes: they have a central pit and a raised rim. The disease can destroy tissue and lead to permanent scarring. AP Images.

* **parasite** (PAIR-uh-sites) is an organism such as a protozoan (one-celled animals), worm, or insect that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. A parasite lives at the expense of the host and may cause illness.

* **cutaneous** (kyoo-TAY-nee-us) related to or affecting the skin.

* **mucous membranes** are the thin layers of tissue found inside the nose, ears, cervix (SER-viks) and uterus, stomach, colon and rectum, on the vocal cords, and in other parts of the body.

* **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.

Leishmaniasis

Leishmaniasis (leesh-muh-NYE-uh-sis) is a parasitic infection spread by sand flies. It causes symptoms ranging from sores on the skin to damage to internal organs.

What Is Leishmaniasis?

The disease occurs when a person becomes infected with any of several types of *Leishmania* parasite*. They spread to people through the bite of female sand flies and can cause different forms of illness, all of which are called leishmaniasis. Cutaneous* leishmaniasis affects the skin; mucocutaneous (myoo-ko-kyoo-TAY-nee-us) leishmaniasis attacks the mucous membranes* in the mouth, nose, and throat; and visceral (VIH-suh-rul) leishmaniasis (also known as systemic leishmaniasis or kala azar) damages internal organs, such as the liver* and spleen*.

Cutaneous and mucocutaneous infections can lead to severe scarring and permanent disfigurement. In patients with a mucocutaneous infection, the disease can destroy soft tissue in the mouth and nose, drastically deforming the face. The visceral form of the disease is considered the most dangerous. It can grow worse over time and is usually fatal if not treated. Leishmaniasis damages the immune system so that it cannot fight off infections; these infections are generally the cause of death, not leishmaniasis itself. In some countries, visceral disease has been found with increasing frequency among people who also have human immunodeficiency virus* infection.

How Common Is the Disease?

The infection is most common in tropical and subtropical regions, such as countries in South America, Africa, and Asia, and the number of areas where it occurs continues to grow. The Centers for Disease Control and Prevention (CDC) estimates that one and a half million people around the world contract cutaneous leishmaniasis each year and half a million people experience the more serious visceral form of the disease. Ninety percent of the visceral cases are found in just five countries: India, Nepal, Bangladesh, Sudan, and Brazil. Leishmaniasis is exceptionally rare in the United States, although a few cutaneous cases have been diagnosed in rural southern Texas.

Is It Contagious?

People cannot get leishmaniasis directly from other people. Instead, the disease spreads through the bite of blood-sucking sand flies. A fly bites an infected animal or person and takes in the parasite with its meal of blood. The *Leishmania* parasites reproduce in the fly, which can spread them when it bites another person. Sand flies are quite small—about one-third the size of a mosquito—and fly silently, so people often do not even know

the flies are nearby. Less often, the disease can be transmitted through contaminated blood in a transfusion*, by sharing or reusing needles for injecting drugs, or from a mother to her baby during pregnancy or birth.

What Are the Signs and Symptoms of Leishmaniasis?

Cutaneous leishmaniasis is marked by sores that often look like volcanoes: They have a central pit and a raised rim. They can be painful or painless and may be covered by scabs. The sores tend to appear on the face, arms, and legs, and some people have as many as 200 of them. Patients with cutaneous leishmaniasis also may have swollen lymph nodes* near the sores. In mucocutaneous cases, the lesions appear in the mouth, nose, and throat and gradually destroy the soft tissues in those areas.

The visceral form of the disease can cause lack of appetite, serious weight loss, fever (which can last from two weeks to two months), and increasing weakness. It also can lead to an enlarged spleen and liver and sometimes swollen lymph nodes. Blood tests may show that the patient has low levels of white blood cells, red blood cells, or platelets*. As the disease progresses, the skin can become dark and dry—a symptom that gave the disease the name kala azar (meaning “black fever”). In children, visceral leishmaniasis often begins suddenly, with fever, diarrhea, and cough.

How Do Doctors Make the Diagnosis?

A key to making the diagnosis is learning whether the patient has traveled to a country where leishmaniasis occurs. During the physical examination, the doctor also checks the patient’s body for the types of sores seen with the infection. The doctor may take blood samples and tissue samples from any sores that are found. These samples will be cultured*, examined for signs of the parasite, or tested for antibodies* to the parasite. For suspected cases of visceral infection, biopsies* of the abnormal tissue may be done.

What Is the Treatment?

Doctors treat the infection with prescription medications; many of these medicines contain antimony*. Cutaneous cases usually can be treated at home, but visceral disease may require hospitalization and supportive care, such as intravenous* fluids. Patients who have severe disfigurement from cutaneous, and especially mucocutaneous, leishmaniasis often need reconstructive surgery to regain a normal appearance. However, such extensive (and expensive) treatment is not available to vast numbers of people in developing countries who contract this disease.

How Long Does the Disease Last?

Although some cases of cutaneous leishmaniasis clear up without medical intervention, most cases of mucocutaneous and visceral infection will not get better without treatment. Left untreated, visceral disease typically

* **spleen** is an organ in the upper left part of the abdomen that stores and filters blood. As part of the immune system, the spleen also plays a role in fighting infection.

* **human immunodeficiency virus** (HYOO-mun ih-myoo-no-dih-FIH-shen-see), or HIV, is the virus that causes AIDS (acquired immunodeficiency syndrome), an infection that severely weakens the immune system.

* **transfusion** (trans-FYOO-zhun) is a procedure in which blood or certain parts of blood, such as specific cells, is given to a person who needs it due to illness or blood loss.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **platelets** (PLATE-lets) are tiny disk-shaped particles within the blood that play an important role in clotting.

* **cultured** (KUL-churd) means subjected to a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body’s immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **biopsies** (BI-op-seez) are tests in which small samples of skin or other body tissue are removed and examined for signs of disease.

* **antimony** (AN-tih-mo-nee) is an element that has properties of both metals and nonmetals and can kill or inhibit the growth of certain bacteria.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **peripheral nerves** (puh-RIH-fer-ul) are a network of nerve fibers throughout the body that send and receive messages to and from the central nervous system (the brain and spinal cord).

* **mucous membranes** are the thin layers of tissue found inside the nose, ears, cervix (SER-viks) and uterus, stomach, colon and rectum, on the vocal cords, and in other parts of the body.

leads to death within two years. Cutaneous cases may take several months to heal, even with treatment, and may return after the treatment has been completed.

What Are the Complications of Leishmaniasis?

The cutaneous and mucocutaneous forms of leishmaniasis often cause widespread scarring. In mucocutaneous cases, destruction of tissue in the mouth and nose can lead to facial deformity. Visceral disease can damage the immune system to the point that it is unable to fight off other infections. Some patients may need to have the spleen removed if it is trapping and destroying too many of the person's blood cells, and advanced cases of disease often result in death.

Can the Disease Be Prevented?

Avoiding sand fly bites is the best way to limit the spread of leishmaniasis. In areas where the flies live, people are advised to stay inside from dusk until dawn, when the insects are most active. Wearing long-sleeved shirts, long pants, and socks and tucking pants into socks can reduce the amount of bare skin that is vulnerable to fly bites. Using insect repellent, staying in screened-in or air-conditioned areas, sleeping under mosquito netting, and spraying living areas with an insecticide to kill flies also can help lessen the risk of being bitten. But these preventative measures are often not possible for people living in extreme poverty.

Leprosy (Hansen's Disease)

Leprosy (LEH-pro-see) is a chronic, infectious disease that damages the skin, peripheral nerves*, and mucous membranes* of the mouth, throat, and eyes. Leprosy also is known as Hansen's disease.*

Hassan Abdu Salaam, a resident since 1944 in the Abu Zaabal leprosarium, basks on a bench in the sun March 5, 2006. *Khaled Desouki/AFP/Getty Images.*

What Is Leprosy?

His equipment was inadequate and his colleagues thought his theories were laughable. Still, Gerhard Henrik Armauer Hansen (1841–1912) spent day after day bent over his microscope, determined to prove that leprosy was caused by bacteria. In 1873 the Norwegian physician identified the rod-shaped bacterium *Mycobacterium leprae* (my-ko-bak-TEER-e-um LEH-pray) as the cause of the illness. Hansen's discovery was immensely valuable in the treatment of leprosy, and it was a scientific milestone—the first proof that bacteria could cause human disease. In modern times, the use of the word “leper” is considered insulting because it defines a person by the disease he or she has. Many advocates for people with leprosy prefer to call it Hansen's disease.

The name paucibacillary (paw-sih-BAH-sih-lair-e) Hansen's disease comes from the Latin word *pauci*, meaning few, and it is used to describe a mild form of leprosy. Paucibacillary Hansen's disease begins in the peripheral nerves and spreads to the skin, causing patches of skin to become numb and hypopigmented, which means that the skin has lost its coloring and appears white. Multibacillary (mul-tie-BAH-sih-lair-e) Hansen's disease is a more severe form of the disease. Multibacillary Hansen's disease also causes skin lesions (LEE-zhuns), or patches of damaged tissue; nodules, or lumps; and thickening of the skin. Without treatment, this type of leprosy can worsen, resulting eventually in severe skin and tissue damage and disfigurement.

How Common Is Leprosy?

Throughout human history leprosy has caused untold suffering. Even after Hansen's groundbreaking discovery, the disease remained unchecked in many parts of the world. In 1991 the World Health Organization

* **immunity** (ih-MYOON-uh-tee) is the condition of being protected against an infectious disease. Immunity often develops after a germ has entered the body. One type of immunity occurs when the body makes special protein molecules called antibodies to fight the disease-causing germ. The next time that germ enters the body, the antibodies quickly attack it, usually preventing the germ from causing disease.

* **neurocutaneous** (nur-o-kyoo-TAY-nee-us) means affecting the skin and nerves.

(WHO) began a global campaign to reduce the number of cases of leprosy. A decade later the organization announced that it had reached its goal. In 2007 there were 224,717 cases of leprosy worldwide. From 2002 to 2007 the number of new cases of leprosy dropped at an average rate of nearly 20 percent per year. The disease is most common in tropical and subtropical regions, and in 2007 it remained a particular problem in Angola, Brazil, Central African Republic, Democratic Republic of Congo, India, Madagascar, Mozambique, Nepal, and the United Republic of Tanzania. Leprosy is most common in densely populated areas with poor sanitation and health care, and children are at greater risk than adults of getting the disease. In the United States about 200 cases are reported each year, many of them in people who have recently immigrated.

Is the Disease Contagious?

Leprosy is contagious but does not spread easily. Researchers believe that *Mycobacterium leprae* is transmitted from person to person via respiratory droplets, bits of moisture that leave the mouth or nose when a person laughs, talks, sneezes, or coughs. Most people seem to have a natural immunity* that enables them to resist the disease. Of those in whom leprosy is diagnosed, most have had prolonged and close contact with someone who has an active infection. Once a person with leprosy has been taking medication for three or four days, the disease is no longer active or contagious.

What Are the Signs and Symptoms?

Leprosy begins as an infection in the nerve endings and spreads gradually; the skin near the infected nerves may become numb and hypopigmented, meaning lacking in color or pigment. In severe cases, these skin lesions become wider and thicker. The muscles in the hands and feet can become weak or paralyzed (unable to move) because of damage to the peripheral nerves. That loss of sensation can lead to accidental injury because a person loses the withdrawal reflex that helps protect against injury from hot or sharp objects. Left unchecked, the most severe form of the disease can progress, producing large, disfiguring nodules and enlarged facial features that give a person the lion-like appearance associated with severe leprosy.

How Is Leprosy Diagnosed?

Leprosy is not difficult to diagnose once it is suspected. A procedure in which a tiny piece of skin is scraped or cut away and then examined under a microscope usually reveals the presence of *Mycobacterium leprae* in the multibacillary form of leprosy. (The bacteria may not be found using this method in milder, paucibacillary disease.) The procedure can be done quickly and relatively painlessly in a doctor's office or clinic. It is an important part of the diagnosis because in the early stages of the disease leprosy lesions look very much like skin damage caused by other neurocutaneous*

3,000 YEARS OF LEPROSY

Leprosy has left a record of pain, suffering, and death that dates back thousands of years. Archeologists have uncovered skeletal remains with erosion in the bones of the nose that is characteristic of leprosy. Researchers translating from ancient Indian and Chinese texts have found descriptions of the disease. As explorers and military men roamed the globe, the germ that causes leprosy traveled with them. Researchers believe that in the first century B.C.E., Roman soldiers fighting in Egypt carried the disease back to Italy. In the Middle Ages, the disease spread from Italy throughout Europe. During the Crusades, a series of wars spanning the eleventh to the thirteenth centuries, European soldiers and travelers carried the disease as far as Jerusalem in the Middle East. The disease continued to follow the paths of conquering armies. The Spanish conquistadors and the slave trade brought the disease to North and South America, and European colonists probably spread the disease to islands in the Pacific Ocean.

diseases. The presence of the characteristic lesions, accompanied by a history of living in areas where the disease is common, incline doctors to suspect the diagnosis.

Can Leprosy Be Treated?

Early diagnosis and treatment are essential for stopping the spread of leprosy to other people and preventing long-term damage to the patient. Doctors most often prescribe multidrug therapy (MDT), combining two or three drugs that kill the bacteria: dapsone (DAP-sone), rifampicin (rye-FAM-pih-sin), and clofazimine (klo-FAY-zuh-mein). The MDT approach has been preferred since the early 1980s, when researchers noticed that the bacterium was becoming resistant to some treatments. Patients may take the drugs for as little as six months or as long as two years. Patients who have become disfigured or who experience disabilities may need surgery to correct these problems.

What Are the Complications and Course of Leprosy?

With MDT, paucibacillary Hansen's disease can be cured within 6 to 12 months and multibacillary Hansen's disease within two years. Untreated, leprosy can cause blindness, permanent nerve damage, and deformity. People may lose the use of their hands or feet because over time decreased sensation may result in repeated injuries to the limbs.

How Can Leprosy Be Prevented?

Despite centuries in which people with leprosy were vilified, shunned, and even isolated in far-off communities called leper colonies, there is no need to separate people with leprosy from the rest of society to avoid the spread

of infection. MDT treatment is more effective and far more humane, and it has been determined that leprosy is much less contagious than once was believed. Hand washing, disinfection, and monitoring of close contacts are recommended to help prevent the spread of the disease.

Leukemia

Leukemia (loo-KEY-me-a) is a type of cancer in which the body produces a large number of immature, abnormally shaped blood cells. It usually affects the white blood cells, or leukocytes (LOO-ko-sites), which help the body fight infections and other diseases.

Sam's Story

Sam had been looking forward to the basketball season for weeks. Now that it had actually started, though, he was having trouble keeping up during practice and in games. He just did not have the energy that he usually had, and he felt pain in his joints like never before. He found that he always needed to ask the coach to give him breaks during games. His

teammates accused him of being out of shape, but Sam knew that it was more than that. His mother noticed that, even though he was playing less, he had more bruises than he did last season. Eventually, Sam had to sit out for a few weeks with a bad case of what appeared to be the flu: He felt constantly weak and tired, and he kept getting fevers. His mother decided that it was time to see the doctor and figure out what was going on.

After hearing about Sam's symptoms, the doctor ran some blood tests. These showed that Sam had leukemia, and further testing indicated that it was a type called acute lymphocytic (lim-fo-SIT-ik) leukemia, or ALL. This is the most common type of leukemia in children.

Overall, leukemia accounts for about 30 percent of cancer cases in children. However, like most other types of cancer, it is much more common in adults. More than 40,000 adults and about 3,800 teenagers and children in the United States are diagnosed with leukemia each year.

What Is Leukemia?

Leukemia is a type of cancer that affects the bone marrow, the soft, spongy center of the bone that produces most of the three types of cells in the blood. They are as follows:

- the white blood cells, or leukocytes, which help the body fight infections and other diseases
- the red blood cells, or erythrocytes (e-RITH-ro-sites), which carry oxygen from the lungs to the body's tissues and take carbon dioxide from the tissues back to the lungs
- the platelets, which help form blood clots that control bleeding.

Normally, the marrow produces these cells in an orderly, controlled way as the body needs them. With leukemia, however, the process gets out of control. In most cases, the marrow produces too many immature white blood cells (called blasts) that are abnormally shaped and cannot carry out their usual duties. This symptom explains why the disease is called "leukemia," which literally means "white blood." As these blasts multiply and crowd the bone marrow, they interfere with the production of other types of blood cells. When the blasts move into the body, they can collect in different places, causing swelling or pain.

Different types of leukemia occur:

- Acute (a-KUTE) leukemia gets worse quickly, with fast multiplication of abnormal, immature blasts.
- Chronic (KRON-ik) leukemia worsens gradually. Abnormal blasts are present, but they are more mature and can carry out some of their functions.
- Lymphocytic leukemia affects certain white blood cells called lymphocytes (LIM-fo-sites), which control the body's immune response by finding and destroying foreign substances.
- Myelogenous (my-e-LOJ-e-nus) leukemia affects other types of white blood cells in the bone marrow.

Understanding Leukemia Lingo

Many of the terms associated with leukemia, including the name of the disease itself, are derived from the Greek language. Breaking down the words into their Greek roots makes them easier to understand.

- **Leuk-** or **leuko-** means white or colorless and is used to form the words leukemia and leukocyte.
- **-emia** means blood and is found in the words leukemia and anemia.
- **-cyte** means cell and is used to form the words leukocyte, erythrocyte, and lymphocyte.
- **Erythr-** or **erythro-** means red. Erythrocytes are red blood cells.
- **Chron-** or **chrono-** means time. Chronic leukemia develops over a long period of time.

- * **risk factors** are any factors that increase the chance of developing a disease.
- * **radiation** is energy that is transmitted in the form of rays, waves, or particles. Only high-energy radiation, such as that found in x-rays and the sun's ultraviolet rays, has been proven to cause human cancer.
- * **radiation therapy** is a treatment that uses high-energy radiation from x-rays and other sources to kill cancer cells and shrink cancerous growths.
- * **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

In all, the disease has four main forms: acute lymphocytic leukemia (ALL), acute myelogenous leukemia (AML), chronic lymphocytic leukemia (CLL), and chronic myelogenous leukemia (CML). Another less common form is called hairy cell leukemia, a chronic condition in which the cells develop projections that look like tiny hairs.

What Causes Leukemia?

In most cases of leukemia, doctors cannot pinpoint a specific cause. However, researchers have identified a few possible risk factors*. Studies have shown that people who are exposed to high or repeated doses of radiation*, such as Japanese survivors of the atomic bomb dropped at Hiroshima during World War II, and people with other types of cancer who have been treated with radiation therapy*, are more likely to develop leukemia. Workers who are exposed to certain chemicals, such as benzene that is used in certain manufacturing processes, also develop leukemia more frequently. In addition, researchers have explored whether certain viruses may play a role in the disease.

Researchers also are examining how a person's genes* may be involved in causing leukemia. In studying the cells of people who have the disease, researchers have found that they often share certain genetic abnormalities.

Some people have suggested a possible connection between childhood leukemia and the low-energy waves given off by high-voltage electric power lines, but numerous studies have not shown a relationship.

GERTRUDE ELION: WOMAN OF SCIENCE

Gertrude Belle Elion (1918–1999) was a research chemist who patented more than 45 drugs including the first leukemia-fighting drug 6-mercaptopurine, Azathioprine (Imuran), a drug that helps the body accept transplanted organs, Trimethoprim (Septra), for bacterial infections, and Acyclovir (Zovirax), a drug used to fight herpes.

Elion's grandfather died of stomach cancer when she was 15-years old, and she decided then to become a cancer researcher. After graduating *summa cum laude* (with highest honors) in chemistry from Hunter College, she was rejected for jobs by 15 institutions where it was believed that research positions should be filled by men. Elion worked as a lab assistant, food analyst, and teacher, and received her master's degree in chemistry from New York University. Finally in 1944, she was hired by the pharmaceuticals company Burroughs Wellcome (now GlaxoSmithKline) to work with George H. Hitchings. It was during her 39-year career there that Elion made most of her scientific advances.

In 1988 Gertrude Elion was awarded the Nobel Prize in Medicine with Hitchings and Sir James Black. After she retired, Elion continued to do research and teach.

What Are the Symptoms of Leukemia?

When someone has leukemia, the abnormal, immature white blood cells that form cannot help the body fight off infections. As a result, the person may have frequent infections and develop flu-like symptoms, such as fever and chills. As these cells keep multiplying and move out into the body, they tend to collect in the lymph nodes* or in organs such as the liver* or spleen*. This symptom may cause pain and swelling. If the cells collect in the central nervous system (the brain and spinal cord), they may cause headaches, vomiting, confusion, loss of muscle control, or seizures.

The oversupply of white blood cells also interferes with the normal production of red blood cells and platelets, causing bleeding problems and a condition called anemia (a-NEE-me-a). Individuals may look pale or feel weak and tired. They may also bleed or bruise easily or find that their gums are swollen or bleeding. Other possible symptoms of leukemia include loss of appetite and/or weight; tiny red spots under the skin; sweating, especially at night; and bone or joint pain.

How Is Leukemia Diagnosed?

Doctors who see patients with these symptoms usually start by doing a full physical exam and feeling for swelling in the liver, the spleen, and the lymph nodes under the arms, in the groin, and in the neck. They may also take a sample of blood and examine it under a microscope to see what the cells look like and to determine the ratio of mature cells to immature cells. Although blood tests may reveal that a patient has leukemia, they may not show what type it is. To check further for leukemia cells or to identify what type of leukemia a patient has, a doctor may have to perform a bone marrow aspiration*. In this test, the doctor inserts a needle into a large bone, usually the hip, and removes a small sample of bone marrow to examine under a microscope for leukemia cells.

If leukemia is present, the doctor may order additional tests to look for abnormal cells in other parts of the body. A spinal tap involves taking a sample of the fluid that fills the spaces in and around the brain and spinal cord, so that it can be checked for leukemia cells. Chest x-rays and special scans can reveal signs of the disease elsewhere in the body.

How Is Leukemia Treated?

Once acute leukemia is diagnosed, doctors start treating it right away because it tends to worsen quickly. The goal is to bring about a complete remission, which means that the patient's bone marrow and blood no longer show any evidence of leukemia. Doctors can then give further treatment to help prevent a relapse, which means a return of the signs and symptoms of the disease after a period of improvement. In the early 2000s, many people with acute forms of leukemia are cured. Just a few decades before, medical professionals considered acute lymphocytic leukemia to be incurable.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.

* **spleen** is an organ in the upper left part of the abdomen that stores and filters blood. As part of the immune system, the spleen also plays a role in fighting infection.

* **aspiration** (as-puh-RAY-shun) is the sucking of fluid or other material out of the body, such as the removal of a sample of joint fluid through a needle inserted into the joint.

* **Identical twins** are twins produced when a single egg from the mother is fertilized and divides to form two separate embryos of the same sex with nearly identical DNA.

Medical professionals can sometimes detect chronic leukemia through a routine blood test before symptoms appear. People with chronic leukemia may not need treatment right away if they are not having symptoms yet, and doctors continue monitoring the disease until treatment is needed. Doctors usually cannot cure chronic leukemia, but they can control it.

Chemotherapy The most common treatments for leukemia are chemotherapy (kee-mo-THER-a-pee), radiation therapy, and/or bone marrow transplantation. In chemotherapy, patients take one or more anticancer drugs, often by mouth or intravenously (through a tube in one of the veins). In certain cases, doctors need to inject the drugs directly into the fluid that surrounds the brain and spinal cord. Chemotherapy can cause side effects, such as hair loss, nausea, fatigue, or easy bruising, depending on the drugs used. Most side effects go away gradually between treatments or after treatment stops.

Radiation therapy In radiation therapy, doctors use a special machine to deliver high-energy rays that damage cancer cells and stop them from growing. They can direct the rays to one specific area of the body where leukemia cells have collected, such as the spleen, or to the whole body. Like chemotherapy, radiation therapy can cause temporary side effects, such as fatigue, hair loss, nausea, or red, dry, itchy skin.

Bone marrow transplantation In bone marrow transplantation, doctors give high doses of chemotherapy and radiation to destroy all of the patient's bone marrow. Doing so kills the cells that are the source of the cancer. They then give the patient healthy bone marrow from a donor whose tissue is similar. Ideally, the donor is an identical twin* or sibling. They also might give bone marrow that was removed from the patient earlier and specially treated to eliminate leukemia cells. A patient who has a bone marrow transplant usually stays in the hospital for several weeks. The risk of infection is high until the transplanted bone marrow begins to produce enough white blood cells.

Biological therapy Another treatment is biological therapy, which uses substances produced by the body to increase its ability to fight off leukemia. In the early 2000s, scientists had identified several of these substances that are involved in the immune response, which is the body's way of protecting itself from infections and other diseases. Scientists can produce some of these substances in the lab and use them to help the body defend itself against leukemia and other forms of cancer. As of 2009 one drug had been particularly successful in treating some forms of adult and pediatric chronic myelogenous leukemia. The drug imatinib mesylate works by targeting an abnormal protein that is involved in the overproduction of abnormal white blood cells. The drug is designed to rid the blood of the abnormal white blood cells and allow healthy blood cells to return in good numbers.

Living with Leukemia

Living with leukemia can be difficult. Not only can the disease make someone feel sick, but many of the treatments can, too. Fortunately, though, these treatments often make the disease go into remission. Patients who are in remission still need to see their doctors often for follow-up exams and tests. That way, if the leukemia comes back, medical professionals can detect it as early as possible.

Having leukemia can be difficult emotionally, too. Patients are scared when they find out they have a form of cancer and worry about what the future may hold. Some people withdraw, get angry, or become depressed. With the support of family, friends, support groups, and health professionals, however, a spirit of realistic optimism can win out.

Lice

Lice are tiny insects that can be found on the scalp, body, pubic area, or clothing and whose bites may lead to severe itching.

▲ Head louse clinging to a human hair seen under an electron microscope. CNRI/Photo Researchers, Inc.

▲ Human hair infested with *Pediculus humanus capitis* (louse) nits. The condition is known as pediculosis. *St. Bartholomew's Hospital/Photo Researchers, Inc.*

* **parasites** (PAIR-uh-sites) are organisms such as a protozoan (one-celled animals), worm, or insect that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. A parasite lives at the expense of the host and may cause illness.

A Lousy Deal

Lice are tiny insects found on the hairy parts of the body or in clothing. A single one of these insects is known as a louse, and the eggs of a louse are known as nits. The bites of these insects can cause an allergic reaction that results in severe itching. Judging from the way people talk, lice are not too popular. When people have an awful day, they say it was lousy. When they make a mess of things, they say they have loused up. When they are overly critical, they are said to be nit-picking.

What Are Lice?

The medical term for having lice is pediculosis (pe-dik-yoo-LO-sis). Lice are parasites* (PAIR-a-sites) that feed on human blood. There are three types of lice that live on humans:

- Head lice (*Pediculus humanus capitis*), usually found on the scalp
- Body lice (*Pediculus humanus corporis*), usually found in clothing and bedding from which they travel to the skin to feed, sometimes called clothing lice
- Pubic (PYOO-bik) lice (*Phthirus pubis*), found in the pubic area, surrounding the genitals, also known as crab lice because of their appearance under a magnifying glass

Who Gets Lice and How?

Lice are a common problem. Anyone can get lice. They are easily spread from person to person. Head lice are spread by close contact with a person who already has them. They also can be passed by sharing combs, brushes, hats, barrettes, pillows, headphones, and the like. Head lice are especially common in young children and their families. They may spread quickly among children in school or camp. They are not a sign of dirtiness or poor hygiene.

Body lice usually are passed through contact with clothing and bedding in which the lice are living. They are more likely to be found in people who live in crowded conditions where clothes are not changed or washed very often. Pubic lice usually are spread by close physical contact involving the genital area, such as sexual contact, so typically they are found in people who are sexually active. In rare cases, they may be picked up from bedding or clothing.

What Are the Symptoms?

Head lice do not cause serious medical problems. They usually are found on the scalp. Often they are seen at the back of the neck and around the ears. In a few cases, head lice are found on the eyelashes or eyebrows. The bite of the head louse can cause an allergic reaction that is annoying. The first sign of trouble usually is severe itching on the part of the body where the lice are biting. It may take as long as two to three weeks for the itching to start. Although it may be difficult, a person with lice should

try not to scratch, because doing so can spread the lice to other parts of the body. It also can lead to infection if germs enter the sores caused by scratching. Another possible sign of lice is a tickling feeling of something moving in the hair.

Although lice are tiny, they can be seen with the naked eye if a person looks closely. The nits, or eggs, are tiny yellow or white ovals firmly attached to the hair near the scalp. They may be confused with dandruff or drops of hair spray, but nits are much harder to detach from the hair than either of these. Nits take about a week to hatch into baby lice, known as nymphs. These babies turn into adults in another seven days or so. Adult lice have six legs and are about the size of a sesame seed. They can live for up to 30 days on a person.

Body lice are hard to see on the body, because they burrow into the skin. They are usually easiest to see in the seams of clothing, from which they travel to the skin to feed. Body lice are known to transmit three disease: epidemic typhus, trench fever, and epidemic relapsing fever. Body lice are less common than head lice. They tend to spread in conditions such as refugee camps or after natural disasters when many people are crowded together in colder climates and lack bathing and laundry facilities.

Pubic lice are found on the skin and attached to the hair in the pubic area around the genitals. Pubic lice are not known to transmit any diseases.

How Are Lice Treated?

Lice usually can be identified by sight. If the lice themselves are not seen, finding nits close to the scalp proves that a person has lice. The treatment for lice involves using a special shampoo, cream rinse, or lotion that contains a medicine that kills lice. Such medicines are known as pediculicides (pe-DIK-yoo-li-sides). Some are sold over the counter, but others are sold only with a doctor's prescription. Home remedies that do not include a louse-killing medicine may not always work.

When using a louse-killing medicine, individuals should read the label and follow the instructions carefully. These medicines may be harmful if not used correctly and should be used with adult supervision, as follows:

- Remove all clothing before the treatment.
- Apply the product according to instructions.
- Do not use a regular cream rinse or combination shampoo-conditioner first.
- Do not wash the hair again for a few days.
- Put on clean clothing after the treatment.

Special combs are used to help remove any leftover nits from the hair, which can be a tedious and time-consuming process. The louse-killing medicine may need to be used again in 7 to 10 days to make sure that no nits have survived. If the treatment does not work, people should talk to a doctor. They should not use extra amounts of medicine or more treatments than suggested.

What Else Can Be Done?

These steps must be followed along with the use of lice-killing shampoos, rinses, or creams to help prevent the spread of lice to others:

- Machine wash in hot water all clothing and bedding that the person with lice touched during the two days before treatment.
- After washing, put the clothes and bedding in a dryer on the hot cycle for at least 20 minutes.
- Dry clean any clothes that cannot be washed.
- Store any clothing, bedding, or stuffed animals that cannot be washed or dry cleaned in a sealed plastic bag for at least two weeks.
- Soak combs and brushes for about an hour in rubbing alcohol or Lysol, or wash them in soap and hot water.
- Vacuum the floors and furniture.
- Inform the school about students who have lice. Keep affected children home until 24 hours after treatment or as long as the school requires.
- Check other people who have had close contact with a person with lice for signs that they may have caught lice.
- Regarding pubic lice, affected individuals should inform all sex partners from the month before treatment and these individuals should be treated as well.

How Can Head Lice Be Prevented?

These steps can help prevent the spread of head lice:

- Never share combs and brushes.
- Always bring a personal sleeping bag and pillow to a sleep-over.
- Do not try on a friend's hat or headphones.
- If your head itches, have someone check it for lice immediately; do not wait.

Liver and Biliary Tract Cancers

Liver and biliary tract cancers are cancers of the liver and/or the biliary tract.

What Are Liver and Biliary Tract Cancers?

Liver and biliary tract cancer are malignancies* of the liver*, and/or the biliary tract*, the system of tubes that carry digestive juices (bile) between the liver, gall bladder*, and small intestine.

What Causes Liver and Biliary Tract Cancer?

Liver cancer can be primary, meaning that it originates in the liver from liver cells, or secondary, meaning that it occurs due to the spread or metastasis of cancer cells from some other organ. Because the body's entire blood supply is filtered through the liver, the organ is particularly

- * **malignant** (ma-LIG-nant) a condition that is severe and progressively worsening.
- * **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.
- * **biliary tract** (BIH-lee-ah-ree) refers to the organs and ducts, including the liver and gallbladder, that produce, store, and transport bile, a substance which aids in digestion.
- * **gall bladder** is a small pear-shaped organ on the right side of the abdomen that stores bile, a liquid that helps the body digest fat.
- * **metabolize** refers to the processes within the body that are involved in converting food into energy and waste products.
- * **pancreas** (PAN-kree-us) is a gland located behind the stomach that produces enzymes and hormones necessary for digestion and metabolism.

ABOUT THE LIVER AND BILIARY TRACT

The liver is the body's largest internal organ. It is located in the abdomen under the right lung, protected by the ribs on that side of the body. All of the body's blood circulates through the liver, which serves a variety of important functions, including acting as a filter to remove waste products from the body, breaking down (metabolize*) nutrients and other substances (including drugs) into usable parts, storing nutrients, producing chemicals necessary for normal blood clotting, and secreting digestive juices into the small intestine.

The biliary tract is the system of tubes that carries bile from the liver to the small intestine. Tubes or ducts from the gall bladder and from the pancreas* also empty into the main liver duct. The gall bladder and the pancreas also contribute important products that are involved in the process of digestion.

- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.
- * **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.
- * **chronic** (KRAH-nik) lasting a long time or recurring frequently.
- * **hepatitis** (neh-puh-TIE-tis) is an inflammation of the liver. Hepatitis can be caused by viruses, bacteria, and a number of other noninfectious medical conditions.
- * **cirrhosis** (sir-O-sis) is a condition that affects the liver, involving long-term inflammation and scarring, which can lead to problems with liver function.
- * **jaundice** (JON-dis) is a yellowing of the skin, and sometimes the whites of the eyes, caused by a buildup in the body of bilirubin, a chemical produced in and released by the liver. An increase in bilirubin may indicate disease of the liver or certain blood disorders.

susceptible to receiving cancer cells that originate in other body organs. Lung, breast, and colon cancers are particularly likely to spread to the liver. In the United States, only about 2 percent of all cancers are due to primary liver cancer.

There are a number of different types of primary liver cancers. Seventy-five percent of all primary liver cancers arise in the most prominent type of liver cell, called the hepatocyte. These cancers are called hepatocellular carcinoma. Ten to 20 percent of all primary liver cancers are the type called cholangiocarcinomas, meaning that the cancer has originated in the cells that line the bile-carrying tubes or ducts. More rare forms of primary liver cancer originate in the blood vessels of the liver and are called angiosarcomas or hemangiosarcomas. These types of liver cancer are usually found only after they have already spread significantly. They are difficult to treat and frequently fatal within a few months after diagnosis.

Who Gets Liver and Biliary Tract Cancer?

In the United States, about 21,370 people are diagnosed with primary liver cancer and bile duct cancer every year, and about 18,410 people die of the disease annually. Over the course of their lifetimes, about one in 114 men and one in 250 women develop the disease.

Men are twice as likely as women to develop a primary liver cancer. In the United States, people over 50 years of age are also at higher risk of liver cancer; in Africa and Asia, people between 20 and 50 years of age are at high risk of developing liver cancer. Other risk factors for the development of liver cancer are diabetes*, obesity*, chronic* hepatitis*, family history of liver cancer, exposure to aflatoxin (a toxic substance produced by fungi that grow on crops such as corn, soybeans, and peanuts), diseases of the liver or bile ducts (such as cirrhosis* of the liver or the bile duct disease called primary sclerosing cholangitis), arsenic in the water supply (as can occur in some developing countries), use of anabolic steroids or male hormones, use of birth control pills, excess alcohol consumption, smoking, and exposure to toxic substances (particularly those used in plastics manufacturing).

What Are the Symptoms of Liver and Biliary Tract Cancer?

Symptoms of liver and biliary tract cancer include unintentional weight loss; decreased appetite; a sensation of fullness after eating only a small quantity; abdominal swelling, especially in the area of the liver (on the right side of the abdomen); pain in the abdomen, sometimes stabbing through to the back and or shoulder; yellow cast to the whites of the eyes and/or the skin (jaundice*); itchy skin; dark urine; significant loss of energy, weakness, fatigue; nausea and vomiting; fever, chills, and/or night sweats; increased severity of symptoms associated with pre-existing hepatitis or liver cirrhosis.

How Is Liver and Biliary Tract Cancer Diagnosed?

Liver and biliary tract cancer may be suspected based on the presence of characteristic symptoms, as well as due to knowledge of the individual's personal or family history. A physical examination may reveal tenderness or swelling in the area of the liver. Blood tests may be ordered to see whether the liver is functioning properly and to test for levels of a substance called alpha-fetoprotein, which is elevated in liver cancer. Tests such as an ultrasound*, computerized tomography* (CT) scan, or MRI* may be performed in order to visualize the liver and look for tumors. An angiogram involves the use of dye, which is injected into an artery; the dye goes through the liver's blood circulation, allowing x-rays to reveal the presence of liver tumors and demonstrating which blood vessels are feeding those liver tumors. A biopsy may be performed in order to remove a small sample of liver tissue, either with a very thin needle (fine needle aspiration), a hollow needle (core biopsy), through a tiny incision during laparoscopic surgery, or through a classical incision during an open operation. Examination of this tissue under a microscope allows identification of the specific type of cancer cell.

How Is Liver and Biliary Tract Cancer Treated?

Liver and biliary tract cancer is treated in various ways. Surgery may be used to remove tumors. Chemotherapy involves the use of drugs that are toxic to the cancer cells (but also, unfortunately, often to normal cells as well). Radiation therapy uses x-rays to shrink tumors. Embolization is a technique in which the blood vessels that feed liver tumors are injected with a substance that blocks the blood flow to the tumors, thus depriving the cancer cells of the oxygen and nutrients they require to grow. Cryosurgery uses extremely cold temperatures to kill abnormal tissue within the liver, whereas ablation uses radio-wave-generated heat or injections of alcohol to kill tumor cells. In cases in which the liver cancer is completely confined to the liver, liver transplant may be considered.

Can Liver and Biliary Tract Cancer Be Prevented?

The risk of developing liver and biliary tract cancer can be lowered by making sure that people are vaccinated against hepatitis B; avoiding behaviors that increase the chance of being exposed to hepatitis C (such as sharing dirty needles, having unprotected sex, or receiving contaminated blood transfusions); improving food storage (to decrease aflatoxin exposure); discouraging smoking and excess alcohol use; and purifying drinking water.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **MRI** short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

Lung Cancer

Lung cancer is an abnormal growth of cells in the lungs, usually caused by smoking cigarettes, that frequently spreads to other parts of the body and is often fatal.

Even the Marlboro Man Was not Immune

In the 1960s, actor David McLean was hired to portray the Marlboro Man, a macho, cigarette-smoking cowboy, in television and print advertising for the tobacco company Philip Morris. McLean smoked many packs of cigarettes to get the right, ruggedly handsome look for each ad, and later he continued to receive boxes of cigarettes as gifts from the company. McLean had begun smoking at age 12, and he never was able to quit. In 1985 he began to suffer from a lung condition called emphysema* due to smoking,

and in 1993 he was diagnosed with cancer of the right lung. By 1995 the cancer had spread to his brain and spine. McLean died that year at age 73.

Fast Facts about Lung Cancer

Lung cancer is the world's top cancer killer, claiming 1.3 million lives and accounting for 15 percent of all newly diagnosed cancers in the United States each year. A difficult cancer to treat, lung cancer is responsible for 30 percent of all cancer deaths per year. Nearly three of every four people who are newly diagnosed with lung cancer die within two years. The single biggest cause of lung cancer is cigarette smoking.

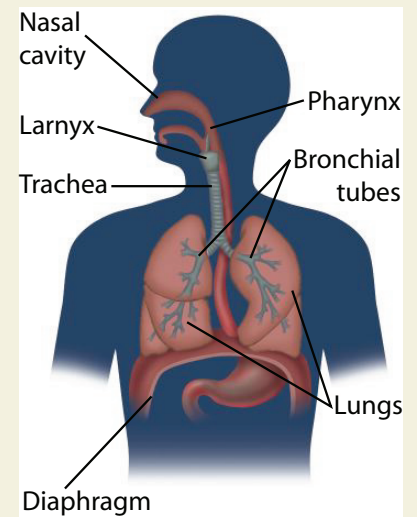

How Do the Lungs Work?

The lungs allow people to breathe by bringing air in and out. Lungs take in oxygen and get rid of carbon dioxide, a gas that is a waste product of the body. The lungs are two sponge-like organs in the chest. The right lung has three sections, called lobes, and the left lung has two. A lining, called the pleura (PLOOR-a), surrounds the lungs and helps protect them. Air travels into the lungs through the trachea (TRAY-kee-a) (also called the windpipe), which divides into two tubes called bronchi (BRONK-eye), which in turn divide into small branches called bronchioles (BRON-kee-oles). At the distant tips of these branches are millions of tiny air sacs called alveoli (al-VEE-o-lye), which look like little buds. These structures together make up the lungs.

How Does Lung Cancer Start?

Lung cancer usually starts in the lining of the bronchi. However, it can begin in any other part of the lungs. The disease takes a long time to develop. Lung tissue, like other kinds of body tissue, contains DNA*. This material that people inherit from their parents contains the instructions, or genes*, for everything the cells do. Gene changes, called mutations, can cause normal cells in the lungs to behave abnormally and to form cancers. Some genes tell cells when to grow, and others tell them when to stop growing. Mutations in these genes may tell cells to grow too much, or they may fail to tell them to stop growing. In either case, the result is cells that are out of control. The cells have repair mechanisms to correct the faulty signals, but when a cell is growing very fast, errors may slip past.

Most of the mutations that occur in lung cancer are not believed to be changes that are inherited from a person's parents. Instead, the mutations seem to occur during the person's lifetime. However, it is possible for a person to inherit a reduced ability to break down certain kinds of cancer-causing chemicals. Because cases of lung cancer sometimes cluster in families, scientists think some lung cancers may develop due to a combination of genes and cigarette smoking. In other words, people who have inherited certain genes and who also smoke might be more likely to develop lung cancer than other people who smoke but do not have

Young People and Smoking

A study published in the *Journal of the National Cancer Institute* in 1999 showed that lung cancer patients who had started smoking before age 15 had twice as many DNA changes in their lung tissue as those who started after age 20. The message from this study is that smoking at a very young age may be especially likely to cause permanent lung damage.

those genes. The specific genetic factors that increase risk for lung cancer remained unclear as of 2009. A large study of 5,000 persons, funded by the National Institutes of Health, searched for genes that increase the risk of lung cancer in people who smoke or have been exposed to various environmental agents.

Who Gets Lung Cancer?

In the United States, there are more cases of lung cancer each year than cases of breast cancer, prostate cancer, and colon cancer combined. In 2003, 105,508 men and 84,798 women in the United States were diagnosed with lung cancer. It was estimated that in 2008, 215,020 people (114,690 men and 100,330 women) would find out they have the disease.

Lung cancer occurs more often in men (78.5 cases per 100,000 men in 2003) than in women (51.3 cases per 100,000 women in 2003). Black men are 50 percent more likely to get lung cancer than white men. This trend does not hold for women; rates of lung cancer are about the same in white and black women. Hispanics, who are less likely to smoke cigarettes, get lung cancer less often than either whites or blacks. Lung cancer is a concern in Asian and Native American populations, too. The disease is rare in people under age 45, because lung cancer takes years to develop. The number of cases increases with age, particularly after age 65.

More people die from lung cancer each year than from any other kind of cancer. The American Cancer Society estimates that in 2008, 40,480 people would die from breast cancer, 28,660 people from prostate cancer, and 50,330 from colon cancer, but 161,840 people from lung cancer. While men are more likely to die from lung cancer than women, in the late 20th century, women were catching up. In 1979 only 26 percent of lung cancer deaths occurred in women, but by 2003 this figure had increased to 43 percent.

The rates of death from lung cancer vary by state. For example, in 2002 Utah had the lowest rate of lung cancer deaths: 20.1 lung cancer deaths for every 100,000 women and 38.1 deaths for every 100,000 men in 2002; whereas Kentucky had the highest rate, with 73.0 lung cancer deaths for every 100,000 women and 133.8 deaths for every 100,000 men. Louisiana, Mississippi, Arkansas, Tennessee, Indiana, and West Virginia had high rates of death from lung cancer. These differences in death rates correspond to cigarette smoking trends: states with higher rates of cigarette smoking have higher rates of death from lung cancer. In addition, the American Cancer Society stated that the states with the highest death rates from lung cancer were states without strong public health programs that discouraged tobacco use. In the 1990s the death rate from lung cancer in people 30 to 39 years of age fell by 19 percent in California and 28 percent in Oregon after those states developed strong anti-tobacco programs. During those same years, the rate of death from lung cancer increased in states with weak anti-tobacco programs, including West Virginia, Kentucky, and Missouri.

What Causes Lung Cancer?

More than 80 percent of lung cancer is caused by smoking. Tobacco smoke damages cells in the lungs of smokers in ways that can lead to cancer. Smokers are 10 times more likely than non-smokers to get lung cancer, and the longer a person has been smoking, the greater the risk. Breathing second-hand smoke, the smoke given off by burning cigarettes or exhaled by smokers, causes about 3,400 lung cancer deaths each year.

At least 15,000 deaths from lung cancer each year are caused by radon gas. Radon occurs naturally in soil and rocks that contain uranium. Radon gas seeps into homes through cracks and other openings. It is estimated that 8 million homes in the United States have unsafe levels of radon. Radon in homes cannot be seen or smelled, but it can be measured with a simple test kit.

People who have worked with asbestos, a substance once widely used as an insulating material that was later banned in the workplace and in home products, also have a higher risk of getting lung cancer. Other risk factors for the disease include cancer-causing chemicals in the workplace.

What Happens When People Have Lung Cancer?

Symptoms Symptoms of lung cancer often do not appear until the disease is advanced. Many times, the cancer is discovered when a person gets a chest x-ray for an unrelated reason. When symptoms do occur, they are so general that many conditions could cause them. Possible symptoms include a cough that does not go away, chest pain, hoarseness, bloody sputum*, and shortness of breath. The only way to find out for sure whether cancer is causing these symptoms is to be examined medically.

Diagnosis The doctor will perform a physical exam and if lung cancer is suspected will probably order a chest x-ray. The doctor may also take a sample of sputum to be examined for abnormal or cancerous cells. In addition, if a tumor* is found on the x-ray, the doctor can perform a biopsy* of the lung tissue. This procedure uses special instruments to remove a small sample of abnormal tissue from the lung for examination under a microscope.

How Is Lung Cancer Treated?

Staging First, tests are done to find out how advanced the cancer is and if it has spread. Based on these tests, the cancer usually is assigned a Roman numeral from I to IV. This process is called staging. The smaller the number, the less the cancer has spread. The larger the number, the more it has spread and the more serious disease. This system is used for most types of lung cancer, including the types called squamous cell cancer, large cell cancer, and adenocarcinoma. One-fourth of lung cancers are a type called small cell lung cancer. Instead of getting a Roman numeral,

* **sputum** (SPYOO-tum) is a substance that contains mucus and other matter coughed out from the lungs, bronchi, and trachea.

* **tumor** (TOO-mor) is an abnormal growth of body tissue that has no known cause or physiologic purpose. A tumor may or may not be cancerous.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

So Long, Joe Camel

For a long time, cigarette advertising on billboards was a familiar feature of the American landscape. One of the most famous signs was a 72-foot-high billboard in New York's Times Square that showed Joe Camel puffing out smoke rings, which was displayed for 25 years.

During the 1980s one in three billboards advertised tobacco. However, in 1999, as part of a \$206 billion agreement between tobacco producers and 46 states to settle lawsuits related to smoking, cigarette makers and outdoor advertising companies removed tobacco billboards all over the United States.

* **chemotherapy** (KEE-mo-THER-ə-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

this type is rated as either limited (not widespread) or extensive (in both lungs, for example, and spread to distant organs).

The best treatment for lung cancer is determined by the type of cancer, the stage, and the person's overall health. Treatment usually consists of a combination of surgery, chemotherapy*, and radiation therapy.

Surgery For cancer that has not spread, surgery offers the chance of a cure by removing the diseased part of the lung. However, some tumors cannot be removed by surgery due to their size or location, and some patients cannot have surgery for other health reasons.

Chemotherapy Chemotherapy is the use of anticancer drugs to kill cancer cells. The drugs are given into a vein or as pills. Because these drugs enter the bloodstream and can reach all areas of the body, they may be useful for treating cancer that has spread beyond the lungs. Chemotherapy can have side effects, however, including nausea (a feeling of wanting to throw up) and hair loss. Not everyone reacts to chemotherapy in the same way. Usually, the side effects disappear and hair begins to grow back when the treatment is over.

Radiation therapy Radiation therapy is the use of high-energy x-rays to kill or shrink a tumor. In lung cancer patients who are not healthy enough for surgery, radiation may be the main treatment. For other patients, radiation may be used after surgery to kill small areas of cancer cells too tiny to be seen during surgery. Radiation can make a person feel tired, and the skin in the treated area may look first sunburned, then tan. The skin eventually returns to normal.

Can Lung Cancer Be Prevented?

No smoking The best way to prevent lung cancer is by not smoking. People who do not smoke should not start, and people who do smoke should quit. Because the nicotine in cigarettes is so addicting, it is not easy to quit, but it is well worth the effort. Simply switching to "low tar" or filtered cigarettes does not prevent cancer, nor does it diminish the addictive properties of nicotine. People should also avoid breathing in other people's smoke. In addition, people can test their home for radon, find out whether cancer-causing chemicals are used in their workplace, and take steps to protect themselves.

Advances anticipated in the 21st century Researchers are looking at new approaches to chemotherapy, surgery, and radiation and trying to find the best combinations of therapies. For example, chemotherapy followed by surgery and radiation helps some patients to live longer. Giving two types of chemotherapy at the same time or giving chemotherapy and radiation at the same time instead of sequentially is another promising approach. In the early 2000s, studies were testing a type of radiation therapy in which smaller doses are given more often in hopes

of killing more cancer cells. Treatments that help the patient's immune system* fight lung cancer more effectively was also a focus of research. In addition, gene therapy* may one day be able to repair the genetic mutations that lead to lung cancer.

Research also explored ways to prevent lung cancer in people at high risk by using vitamins, foods, and medications, but the results as of 2009 were not very helpful. Researchers also looked into ways of detecting lung cancer earlier. As of 2009, prevention seemed to offer the greatest chance for fighting lung cancer. The best prevention is not to start smoking, but if people do smoke, then the best choice is for them to quit.

Living with Lung Cancer

Some people recover from lung cancer, but even in the least severe cases, only 50 percent of people with lung cancer are living five years after their diagnosis. When all cases of lung cancer are taken together, including both most severe and least severe cases, the survival rate at five years drops to 15 percent. This statistic explains why it is so important not to start smoking and for smokers to quit smoking.

Because of the low rate of cure, lung cancer patients typically have concerns about whether the cancer will come back after treatment and how long they will live. People need their lungs to breathe, so in advanced cases, as the cancer takes up more and more of the space usually occupied by air, breathing becomes difficult. In addition, growth of the cancer around certain nerves may cause severe pain. Medications can relieve this pain, and patients should not hesitate to ask for them.

Lupus

Lupus (LOO-pus) is a chronic (long-lasting) disease that causes inflammation of connective tissue, the material that holds in place the various structures of the body.

Julia's Story

"Oh, not again!" shouted 18-year-old Julia, her toothbrush falling into the sink with a clatter. It was the fifth morning this week that it had slipped from her hands. She had been waking up with achy, puffy hands, and she was finding it hard to grip objects with her stiff fingers. A few weeks later, when filling out a form for a back-to-school physical, she wrote about her stiff hands and also mentioned that she had been feeling really tired all summer. Her doctor suggested she get some blood tests and called Julia's mother a few days later with a referral to a rheumatologist*. He suspected that Julia had lupus.

What Is Lupus?

Lupus is one of several diseases that are grouped under the collective term of collagen vascular diseases. Collagen vascular diseases are those that affect the connective tissues, materials that hold the various structures of the body in place. Specifically, lupus causes inflammation of connective tissues in the body. The medical name for lupus is lupus erythematosus (er-i-thee-ma-TO-sus).

Lupus is divided into two main types:

- Discoid lupus erythematosus (DLE), which mostly causes red-dened patches on the skin
- Systemic lupus erythematosus (SLE), which affects the skin but also involves other tissues and organs.

A third condition, called lupus vulgaris, is unrelated to lupus erythematosus. It is a rare form of tuberculosis that typically produces nodules, or small lumps, on the skin.

Who Gets Lupus?

Lupus is a disorder that occurs worldwide and in people of all ages. In the United States, the Lupus Foundation of America estimates that 1.5 to 2 million, and possibly more, Americans have some form of the disease.

In the United States, lupus is more prevalent among people of African, American Indian, Asian, and Latino ancestry than in people of European descent.

Although members of both sexes can get lupus, more than 9 out of 10 people who have the disease are women. Like Julia, most women show their first signs of the disorder between the ages of 15 and 25.

What Causes Lupus?

Lupus is not a contagious disease. One person cannot catch it from another, and nobody needs to avoid being near someone who has lupus.

In 5 to 10 percent of cases, certain prescription drugs, such as those used for irregular heartbeat or high blood pressure, can cause symptoms of SLE. (The symptoms usually go away when the drugs are discontinued.) Medical professionals most often see this condition, which they call drug-induced lupus, in elderly patients.

For the remaining 90 percent of SLE cases and in all instances of DLE, the cause or causes of the disorder remained unclear as of 2009. Although many people who have studied lupus agreed that it is an autoimmune disorder, which is a reaction of the immune system against one's own body, they still had many questions because the causes of immune disorders were not well understood. Researchers and medical professionals did, however, believe that some factors can play a role in the development of lupus.

One of those factors is heredity. Researchers determined that a person with a close relative who has SLE is slightly more likely to develop the disease than someone who does not. For instance, about 5 percent of children born to a parent with lupus develop the disease themselves. Scientists explored the genetic connection and found genes on two chromosomes that show connections to lupus among some families.

Certain environmental influences may play a part in the onset of lupus. Researchers believe that bacteria, viruses, extreme stress, sunlight, certain antibiotics, or food additives may trigger autoimmune responses in some individuals. Nonetheless, not everyone gets lupus because they caught a particular virus or bacterium, are stressed, took a certain antibiotic, or ate a certain food.

In addition, the fact that women are much more likely to get lupus than men suggests that hormones may also be associated with the disorder.

What Are the Symptoms of Lupus?

The signs and symptoms of lupus vary greatly in different individuals, both in the parts of the body involved and in the degree of severity. The symptoms may also come and go and may disappear for weeks or months at a time. Although lupus occurs much more frequently in women than in men, the symptoms in males are no less severe than in females.

Discoid lupus erythematosus The mildest and most common form of lupus, DLE usually involves only the skin. It produces a rash of thickened, scaly reddish patches on the face and sometimes other parts of the

Did You Know?

- The name “lupus erythematosus” comes from the word “lupus,” which is Latin for “wolf,” and the word “erythema,” which refers to reddened skin. In the past, people thought that patients with the facial rash looked as though they had been bitten or scratched by a wolf.
- The large majority of lupus patients are women.
- Lupus is not contagious.
- No one symptom or one test is enough to tell whether someone has lupus.
- Many lupus patients develop arthritis.
- Many people with lupus have to stay out of the sun.
- Most lupus patients can lead nearly normal lives.

What Is an Autoimmune Disorder?

Nearly everyone is familiar with allergies such as hay fever and asthma, either in their own experience or that of friends or family. An autoimmune disorder is rather like a kind of allergy, except that the immune system attacks parts of one's own body instead of outside substances such as dust and pollen.

The normal function of the immune system is to protect the body from invading microorganisms or toxic substances. To perform this function, it produces antibodies and special white blood cells (lymphocytes) that recognize and destroy the intruders. In autoimmune disorders, these responses (for reasons that were not fully understood as of 2009) occur against the body's own cells, tissues, and organs. This reaction can produce a number of problems, including rheumatoid arthritis, a type of diabetes, and lupus.

* **arthritis** (ar-THRY-tis) refers to any of several disorders characterized by inflammation of the joints.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.

body. Often the rash spreads in a characteristic butterfly-shaped pattern over the cheeks and bridge of the nose. After a few weeks or months, when healing has taken place, dark-colored or pale scars may remain. If the condition extends to the scalp, the person may lose some of his or her hair.

Sunlight tends to trigger and worsen the rash of lupus. In DLE, the patches sometimes nearly disappear during the winter months. Most people who have DLE are otherwise in good health. The condition only rarely progresses to SLE.

Systemic lupus erythematosus People with SLE may have the same type of rash as those with DLE, and they may lose hair as well. In SLE, however, the skin lesions may spread and cause damage to the mucous membranes, such as those in the nose or under the eyelids, and other tissues. Some SLE patients, however, do not get these skin problems.

Arthritis* may be the first symptom in some people with SLE. In fact, SLE is medically classified in the same family of diseases as rheumatoid arthritis; they are both collagen vascular diseases. Rheumatoid arthritis is a disorder that causes painful inflammation in the joints. Other early symptoms of SLE may include weakness, extreme fatigue, fever, sensitivity to sunlight, and loss of weight. In addition, about 40 percent of people who have lupus get Raynaud's disease, which can cause sudden numbness or coldness in the fingers or toes. Although it is less common, some patients with SLE also have another collagen vascular disease, called scleroderma. Doctors sometimes call this combination mixed connective tissue disease, or MCTD. Unlike lupus, scleroderma is characterized by a thickening and in some cases a hardening of the skin.

SLE may also affect internal organs, which frequently causes serious disorders. People with SLE commonly have problems with kidney function, and if the kidneys fail, they may experience uremia (yoo-REE-me-a), or the buildup of toxic substances in the blood. Uremia can be fatal. SLE may also have an impact on the nervous system and cause psychological problems, seizures*, or other symptoms. It can also involve the lungs, heart, liver, and blood cells.

In some cases, people with lupus also have certain antibodies, called anti-phospholipid (AN-ti-fos-fo-LIP-id) antibodies, in their systems. These antibodies interfere with the normal function of the blood vessels and can bring on a stroke or heart attack. In pregnant women, they can cause a miscarriage*.

How Is Lupus Diagnosed? Medical professionals often have a difficult time diagnosing lupus, especially if the patient has only a few symptoms, because no one sign or symptom unquestionably means someone has lupus, and no single laboratory test is able to diagnose it either. For these reason, doctors must rely on a combination of a thorough medical history, observations, and tests to make a definite diagnosis of lupus.

To diagnose systemic lupus erythematosus, which is one type of lupus, doctors may order blood tests to check for certain antibodies that attack

the nucleus of cells, and for specific white blood cells, called LE (lupus erythematosus) cells, that destroy other blood cells and are an indication of lupus. They may also perform a skin biopsy* (removal of a small sample) to examine it for antibodies active in lupus.

These tests can help the doctor to make an early diagnosis, which is important so that treatment can begin as soon as possible.

How Is Lupus Treated?

Depending upon the particular needs and symptoms of a lupus patient, a doctor may select from numerous treatment options, including prescribing one or more drugs to counteract pain, inflammation, and related problems.

Nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin, ibuprofen*, and naproxen, are common choices for lessening pain and inflammation in the joints and muscles. Another group of medications, called corticosteroids*, helps reduce inflammation and activity of the immune system. A third group, called anti-malarials because they also are used to treat malaria, can help with skin and joint symptoms. A doctor may also recommend ointments and creams that contain corticosteroids and sunscreens to treat skin eruptions.

In the early 2000s, doctors sometimes also prescribed transplant drugs, such as mycophenolate mofetil (MMF) and azathioprine (AZA), and chemotherapy* drugs, called cyclophosphamide, to treat lupus. These drugs help fight the kidney inflammation associated with lupus.

Some of the drugs prescribed to treat lupus can cause unwanted side effects. For this reason, and because symptoms may change, patients need ongoing medical advice and regular checkups to stay on top of the disease, its symptoms, and possible unwanted drug reactions.

Does a Cure Exist for Lupus?

As of 2009, no cure was available for lupus, but effective treatment could maintain normal body function and control symptoms in the great majority of patients. Nonetheless, SLE can be a life-threatening disease, particularly when the kidneys are involved. The most common causes of death are kidney failure, bacterial infection, and heart failure.

Living with Lupus No specific preventive measure, such as vaccination*, was available to help a person avoid getting lupus as of 2009. People who were diagnosed with lupus, however, were advised to take steps to reduce the likelihood of “flares,” or sudden worsening of symptoms. Patients who were sensitive to sunlight could help prevent rashes by avoiding excessive exposure to the sun, using sunscreens, or wearing broad-brimmed hats. Although no lupus vaccination existed, doctors recommended immunizations against other infections.

Lifestyle changes help patients with lupus avoid or control symptoms as well. Regular exercise can prevent some muscle weakness and fatigue. Quitting smoking or resisting excessive alcohol consumption can bring

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **ibuprofen** (eye-bew-PRO-fin) is a nonsteroidal anti-inflammatory drug (NSAID) used to reduce fever and relieve pain or inflammation.

* **corticosteroids** (kor-tih-ko-STIR-oyds) are chemical substances made by the adrenal glands in the body, including maintaining blood pressure during stress and controlling inflammation. They can also be given to people as medication to treat certain illnesses.

* **chemotherapy** (KEE-mo-THER-α-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

* **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.

How to Remove a Tick

Using thin-tipped tweezers, grasp the tick as close to the person's skin as possible.

Pull straight upward firmly and steadily until the tick lets go (do not squeeze or twist the tick body).

Clean the skin with soap and warm water, alcohol, or other antiseptic.

Save the tick for identification.

Petroleum jelly, lit matches, nail polish or other products do not help in tick removal and should not be used.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

about general health improvements. Joining support groups and talking with family, friends, and physicians can ease the effects of stress.

Lyme Disease

Lyme (LIME) disease is a tick-borne illness, the most common tick-borne illness in the United States. It is a bacterial disease that is spread to humans by the bite of an infected tick. It usually begins with a distinctive rash and/or flu-like symptoms and, in some cases, can progress to a more serious disease with complications that affect multiple body systems.

What Is Lyme Disease?

Lyme disease was first described in 1977 when a group of children living in and around Lyme, Connecticut, became ill with arthritis. In its early stage, Lyme disease produces flu-like symptoms; if untreated, the disease can progress to affect the joints, heart, and central nervous system*, especially in adults.

Lyme disease is caused by a corkscrew-shaped bacterium called *Borrelia burgdorferi* (buh-REEL-e-uh burg-DOR-fe-ree). It is most commonly carried by very small, immature ticks of the genus *Ixodes* (iks-O-deez) group called deer ticks or black-legged ticks. Deer ticks spread Lyme disease in the

Northeast, Midwest, and some other parts of the United States; another kind of *Ixodes* tick, the western black-legged tick, is the source of Lyme disease in the western United States. Lyme disease also occurs in other countries, such as China, Japan, and some countries in Europe.

Lyme disease is not spread from person to person. It is spread by ticks that become infected with *Borrelia burgdorferi* after feeding on an animal, usually a mouse. Ticks then pass the bacteria to humans while attached to the person's skin and feeding on the person's blood. To infect a human, the tick must be attached for at least 24 hours. A bite by a tick does not mean that the individual will get Lyme disease; most tick bites do not cause disease.

How Many People Get Lyme Disease?

In 2007, 27,444 cases of Lyme disease were reported in the United States, according to the Centers for Disease Control and Prevention (CDC). Although cases of Lyme disease have been reported in nearly every state, most cases are reported in New York State, Connecticut, Massachusetts, Maine, Rhode Island, New Hampshire, Pennsylvania, New Jersey, Delaware, and Maryland, and in Minnesota, Wisconsin, and California. These areas have natural habitats of *Ixodes* ticks.

People who live, play, or work in tick-infested wooded areas or areas of overgrown brush are most at risk of getting the disease. Lyme disease is most common during the late spring and summer months in the United States (May through September), when ticks are most active and people are frequently outdoors.

What Happens When a Person Has Lyme Disease?

Signs and symptoms Within a few days to weeks after being bitten by an infected tick, about 80 percent of people develop at the site of the bite a characteristic red circular rash the size of a quarter or larger known as erythema migrans (air-uh-THEE-muh MY-granz). The center of the rash may clear as it grows, giving the appearance of a bull's-eye pattern. The rash may be warm to the touch, but it is usually not painful or itchy. Other symptoms in the early stage of Lyme disease may include tiredness, fever, chills, joint pain, muscle aches, headache, stiff neck, and swollen lymph nodes* (glands). Not everyone who is infected with the bacterium gets ill. Some people have no noticeable symptoms, and some only have the non-specific, flu-like symptoms, such as fever and headache.

If untreated, Lyme disease can progress to the next stage, called the early disseminated stage, as the infection spreads and starts to affect a range of body functions. This more advanced stage appears a few weeks to as long as three months after a bite by an infected tick. Symptoms may include two or more areas of rash, severe headache, severe tiredness, stiffness in the joints and neck, one-sided facial paralysis* (Bell's palsy*), tingling or numbness in the legs and arms, irregular heartbeat, fever, and meningitis*.

▲ The telltale “bull’s eye” circular rash at the site of a tick bite on the human arm. ©CDC/Peter Arnold, Inc.

- * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.
- * **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.
- * **Bell's palsy** (PAWL-zee) is a condition in which there is weakness or loss of function of muscles on one side of the face.
- * **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.

Mothers Lead the Charge

In 1975 the mothers of a group of children who lived near each other in Lyme, Connecticut, contacted the Connecticut State Health Department and Yale Medical Center to report that children in their area were being diagnosed with rashes and pediatric arthritis. After a two-year investigation, Allen C. Steere of Yale University called the condition Lyme arthritis. In 1982 Willy Burgdorfer of the Rocky Mountain Laboratory in Hamilton, Montana, discovered the cause of the disease, a spirochete (a type of bacterium), which was subsequently named *Borrelia burgdorferi* in his honor.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

* **endemic** (en-DEH-mik) describes a disease or condition that is present in a population or geographic area at all times.

A late stage of Lyme disease may develop weeks to years later if the disease remains untreated. In this stage, symptoms can include chronic Lyme arthritis (episodes of pain and swelling in the joints, especially in the arms and legs), memory loss (which is rare in children and teens), and numbness in the hands, arms, legs, and feet.

Diagnosis Diagnosing Lyme disease can be difficult because the symptoms often look like those of other diseases. In addition, doctors may have difficulty in distinguishing it from conditions with similar symptoms, particularly in cases in which the characteristic rash is not present. A known recent tick bite or the erythema migrans rash is often key to the diagnosis of Lyme disease. Following a physical examination and the taking of a medical history that has included the doctor's asking about the patient's exposure to tick-infested areas, the doctor may order blood tests that look for the presence of antibodies* to *Borrelia burgdorferi*. If any joints are swollen or signs of meningitis are present, joint fluid or spinal fluid is sometimes evaluated for evidence of *Borrelia* infection.

Some blood tests for *Borrelia* infection can give false negative results, particularly if performed within the first month after infection. False positive test results can also occur. Because of this, doctors may have difficulty interpreting Lyme disease test results and confirming a diagnosis.

Treatment Lyme disease is usually treated with antibiotics*, which are taken for three to four weeks. Antibiotics used to treat Lyme disease are typically taken by mouth, but in severe or advanced cases of Lyme disease they may be given by injection. If treatment begins at the early stage of the disease, a complete cure is likely; it generally takes a few weeks or months for the symptoms to go away. Sometimes symptoms recur, making it necessary for a patient to take another course of antibiotics. If treatment is not started until later in the progression of the disease (at the early disseminated or late stage), antibiotics are still effective, but recovery may take longer; the patient's symptoms may last for months or even years. Children usually recover from Lyme disease faster and with fewer complications than do adults.

A person who is not ill may be treated preventively with a single dose of antibiotics if the following applies to the case: the tick has managed to remain attached to an individual's skin for several days and has become engorged with blood; the tick was acquired in a Lyme-endemic* area; and the individual is not showing symptoms of Lyme disease.

Is Lyme Disease Preventable?

The best way to prevent Lyme disease is to prevent tick bites. Experts recommend the avoidance of areas that are likely to be infested with ticks, particularly in the spring and summer when nymph (immature) ticks feed. For any activity in tick-infested areas, it is wise to take the following precautions:

- Wear light-colored clothing so that ticks can be spotted easily.
- Keep arms and legs covered.

- Wear high rubber boots, because ticks usually are found close to the ground.
- Tuck shirts into pants and pants into socks or boots to help keep ticks from reaching the skin.
- Wear a hat and keep long hair pulled back.
- Shower and wash clothing after being in tick-infested areas.
- Inspect pets for ticks after they have been in the woods.

Applying insect repellents containing 10 percent DEET*, which is safe to use on children and adults, on both clothes and exposed skin, and permethrin (per-ME-thrin) (which kills ticks on contact) on clothes, may also help reduce the risk of tick attachment. If ticks are found attached to skin, they should be carefully removed with tweezers or forceps.

As of 2009, vaccines to prevent Lyme disease were under development but not yet available for use.

Did You Know?

Immature ticks of the genus *Ixodes* (called nymph ticks) are about the size of a poppy-seed. Adult ticks are only the size of a sesame seed.

* **DEET** (abbreviation for N,N-Diethyl-meta-toluamide) is the active ingredient in many insect repellants.

▲ A lymphedema (swelling) is an accumulation of lymph fluid caused by obstructed lymph vessels. The red areas on the skin of the leg are due to an infection. Lymphedemas make the area more susceptible to infection.
Dr P. Marazziti/Photo Researchers, Inc.

* **lymphatic** (lim-FAH-tik) means relating to the system of vessels and other structures that carry lymph, a colorless fluid, throughout the body's tissues; the lymphatic system plays an important role in protecting the body from infections.

* **lymphatic system** (lim-FAH-tik) is a system that contains lymph nodes and a network of channels that carry fluid and cells of the immune system through the body.

* **radiation therapy** is a treatment that uses high-energy radiation from x-rays and other sources to kill cancer cells and shrink cancerous growths.

* **cancer** is a condition characterized by abnormal overgrowth of certain cells, which may be fatal.

Lymphedema

Lymphedema, also called lymphatic obstruction, is swelling, usually of an arm or leg, due to the accumulation of fluids and other substances in soft tissues of the body. Lymphedema is caused by a blockage or malfunction in the body's lymphatic system*. It is a common complication of surgery or radiation therapy* for treating cancer*.*

What is Lymphedema?

Primary lymphedemas are rare inherited disorders in which components of the lymphatic system are abnormal or absent. Most lymphedemas are secondary or acquired, usually as a result of surgery or trauma* resulting in a malfunction in the lymphatic system. Secondary lymphedema can be temporary or acute*, lasting less than six months, or chronic*, lasting six months or longer—perhaps for the remainder of one's life.

Lymphedema can occur anywhere in the body but usually affects an arm or leg. What area is affected is determined by the cause of the lymphedema. Lymph-node removal to treat breast cancer can result in lymphedema in the arm. Treatments for gynecological cancer may result in lower-limb lymphedema.

The lymphatic system The lymphatic system is a network of vessels and nodes located throughout the body that collects excess fluid and other substances from tissues and transports them to the circulatory system*. The walls of the lymphatic vessels take up water, proteins, fats, cell waste products, and foreign* substances, including bacteria* and viruses*. Valves in the vessels keep the clear lymphatic fluid flowing through progressively larger vessels in the direction of the heart. Lymph from the right arm and right side of the head and chest flows to the right lymphatic duct and is released into the large vein* under the right collarbone. The left lymphatic or thoracic duct collects fluid from both legs, the left arm, and left side of the head and chest and empties into the large vein under the left collarbone.

The lymphatic system is an integral part of the body's immune* defenses. Lymph carries lymphocytes* or white blood cells and other immune system* cells for fighting infection and disease. The fluid passes through lymph nodes*—small bean-shaped structures that filter out harmful substances, recognize infectious organisms, and initiate an immune response.

If the volume of the lymphatic fluid exceeds the capacity of the system, protein-rich fluid collects in the tissues of the affected region. The accumulating fluid increases the size and number of channels in the tissues, which swell and begin to harden. The accumulating fluid also reduces the availability of oxygen*, interferes with healing, and creates a suitable environment for bacterial infection.

WHAT IS A PRIMARY LYMPHEDEMA?

Primary lymphedema can affect any or all of the limbs, but most often a foot or calf. It may be associated with other vascular* abnormalities. The three most common types of primary lymphedema are:

- Milroy disease or congenital* lymphedema, a malformation* of the lymph nodes that becomes evident during infancy
- Meige disease or lymphedema praecox, which develops in childhood or at the onset of puberty*, is far more common in females than in males, and is characterized by lymph vessels without valves to prevent the fluid from flowing backwards
- Late-onset lymphedema or lymphedema tarda, a very rare condition that develops after about age 35

Acute versus chronic lymphedema There are four types of acute lymphedema:

- Brief mild lymphedema that develops a few days after the surgical removal of lymph nodes or injury to the lymphatic vessels or veins under the collarbone
- Lymphedema caused by inflammation* of the lymphatic vessels, occurring six to eight weeks after surgery or during radiation therapy
- Lymphedema occurring after an insect bite, minor injury, or burn that leads to infection of the skin and lymph vessels near the skin surface
- The most common type—gradual-onset lymphedema—which develops slowly, becoming noticeable many months or years after surgery or other cancer treatment

Failure to control lymphedema in its early stages can lead to a chronic condition. Chronic lymphedema occurs when the lymphatic system cannot meet the increased requirement for fluid drainage from body tissues. As the lymphatic vessels expand, the fluid flows back into the tissues, worsening the condition.

Causes of lymphedema Secondary lymphedema usually results from physical damage to the lymphatic system, most often the lymph nodes in the groin, pelvis, and/or armpits. Scar tissue resulting from surgery and/or radiation treatments for cancer, especially breast or testicular cancers, can disrupt the flow of lymphatic fluid and is the most common cause of lymphedema. The removal of a large number of lymph nodes or radiation to an area where lymph nodes have been removed increases the risk of lymphedema. Poor drainage of the lymphatic system following

* **trauma** refers to a wound or injury, whether psychological or physical. Psychological trauma refers to an emotional shock that leads to lasting psychological damage.

* **acute** describes an infection or other illness that comes on suddenly and usually does not last very long.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **circulatory system** (SIR-kyoo-luh-tor-e) is the system composed of the heart and blood vessels that moves blood throughout the body.

* **foreign** means coming from outside a person's body.

* **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.

* **viruses** (VY-rus-sez) are tiny infectious agents that can cause infectious diseases. A virus can only reproduce within the cells it infects.

* **vein** is a vessel that carries blood to the heart. Veins have greater capacity and thinner walls than arteries and contain valves that prevent blood from flowing backward and away from the heart.

* **immune** (ih-MYOON) means resistant to or not susceptible to a disease.

* **lymphocytes** (LIM-fo-sites) are white blood cells, which play a part in the body's immune system, particularly the production of antibodies and other substances to fight infection.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

What Is Filariasis?

Lymphedemas caused by parasites or other infections are common in tropical and sub-tropical regions and in developing countries. Some 200 million people—primarily in Southeast Asia, India, and Africa—suffer from a form of lymphedema called filariasis, sometimes referred to as elephantiasis. It is caused by filarial larvae—contracted from infected mosquitoes—that invade the lymphatic system and mature into worms in the peripheral lymphatic vessels.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **oxygen** (OK-si-jen) is an odorless, colorless gas essential for the human body. It is taken in through the lungs and delivered to the body by the bloodstream.

* **vascular** refers to veins and arteries (the blood vessels).

* **congenital** (kon-JEH-nih-tul) means present at birth.

* **malformation** (mal-for-MAY-shun) is an abnormal formation of a body part.

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

* **prostate** (PRAH-state) is a male reproductive gland located near where the bladder joins the urethra. The prostate produces the fluid part of semen.

* **bladder** (BLAD-er) is the sac that stores urine produced by the kidneys prior to discharge from the body.

removal of lymph nodes or radiation therapy also can lead to infection and even minor infections can cause serious lymphedema.

In addition to surgeries for breast and testicular cancers, lymphedema is a possible complication of any surgery in which lymph nodes are removed, including surgeries for the following:

- Melanoma
- Gynecological cancers
- Head and neck cancers
- Prostate* cancer
- Bladder* or colon* cancer

Other causes of lymphedema include the following:

- Liposuction
- Surgery on blood vessels
- Leakage of protein into a surgical site through surgical drains
- Inflammation of a limb following surgery
- Cancer cells or tumors* that block lymphatic vessels or nodes
- Abdominal* or pelvic tumors that put pressure on lymphatic vessels and/or the large lymphatic ducts in the chest and block drainage of lymph
- Trauma or injury that affects the lymphatic system
- Burns
- Infection in the lymph vessels or nodes that restricts fluid flow
- Immobility of a limb for a period of time

How Common Is Lymphedema?

Lymphedema is both under-diagnosed and under-reported. However, it has been estimated that about 3 million Americans are affected by secondary lymphedema. It also has been estimated that 20 to 40 percent of cancer survivors—especially the elderly—develop lymphedema at some point.

Lymphedema of the arm occurs in about 10 to 15 percent of women who have full axillary lymph node surgery for breast cancer. It occurs in only about 1 percent of women who are treated with a sentinel lymph node biopsy*. Proper skin care and exercise can reduce the risk of lymphedema following a mastectomy*.

A study published in 2007 found that 10 percent of gynecological cancer survivors had been diagnosed with lymphedema and another 15 percent reported lower-limb swelling. Lymphedema had been diagnosed in 36 percent of vulvar cancer survivors.

What Are the Symptoms of Lymphedema?

The classic symptoms of lymphedema are discoloration and swelling of the affected region. The severity of the symptoms depends on the type of lymphedema:

- Acute lymphedema immediately following surgery or injury makes the affected limb warm and reddish. It is usually not painful.
- Acute lymphedema occurring weeks after surgery or during radiation therapy makes the affected limb tender, warm or hot, and red.
- Acute lymphedema from an infection or in a chronically swollen limb makes the affected area very tender, hot, and red.

Symptoms of gradual-onset acute lymphedema, the most common form, can include:

- Skin discomfort or tightness
- Hardening or thickening of the skin
- Weakness, heaviness, aching, or pain in an arm or leg
- Rings, bracelets, or shoes that suddenly become too tight
- Loss of flexibility in the hand, wrist, or ankle
- Reduced range of motion in an arm or leg
- Aching in the neck, shoulders, spine, or hips, caused by muscle overuse or stretching of soft tissues
- Changes in posture caused by the increased weight of the affected limb
- Recurring infections in the affected limb
- Loss of sensations of touch, temperature, or pain in the affected area

Chronic lymphedema is characterized by severe and painful swelling, heat, and redness. Chronic lymphedema can be distinguished from temporary lymphedema by the texture of the skin. With temporary lymphedema pressing on the skin of the affected area with the fingertips leaves an indentation. With chronic lymphedema the skin is hard and stiff and does not indent.

How Is Lymphedema Diagnosed and Treated?

Diagnosis Lymphedema is often first diagnosed by a swelling or feeling of heaviness in the arm or leg. In its early stages, diagnostics may include the following:

- A history of edema*, surgery, or radiation therapy
- Weight appropriateness, since obesity* can increase the risk of lymphedema
- Diameter measurements of the arms and/or legs to detect swelling
- Blood protein levels, which may be elevated with lymphedema
- Ability to perform daily activities
- Concurrent conditions such as diabetes*, hypertension*, kidney* disease, heart disease*, or phlebitis*

* **colon** (KO-lin), also called the large intestine, is a muscular tube through which food passes as it is digested, just before it moves into the rectum and out of the body through the anus

* **tumors** (TOO-morz) are abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.

* **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **mastectomy** (mas-TEK-to-mee) is the surgical removal of the breast.

* **edema** (e-DEE-ma) means swelling in the body's tissues caused by excess fluids.

* **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **hypertension** (HI-per-ten-chen) is abnormally high arterial blood pressure.

* **kidney** is one of the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.

* **heart disease** is a broad term that covers many conditions that prevent the heart from working properly to pump blood throughout the body.

* **phlebitis** (fle-BY-tis) refers to inflammation of a vein.

* **MRI** which is short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **blood clot** is a thickening of the blood into a jelly-like substance that helps stop bleeding. Clotting of the blood within a blood vessel can lead to blockage of blood flow.

Diagnostic imaging techniques may include the following:

- Lymphoscintigraphy, in which a radioactive material is injected to follow the flow of the lymphatic fluid
- MRI*
- CT scans*
- ultrasound* to visualize blood vessels and blood flow and to rule out the presence of a blood clot*

Staging Lymphedema is sometimes categorized as grades 1 through 4, with 4 being the most serious. It may also be classified in stages:

- Stage 1 or spontaneously reversible lymphedema is the pitting stage: the tissue holds an indentation. Upon awakening, the limb is of normal or near-normal size.
- Stage 2 or spontaneously irreversible lymphedema is characterized by spongy tissue that is non-pitting: It pops back without leaving an indentation. The affected limb may have begun to harden and increase in size.
- Stage 3—sometimes called lymphostatic elephantiasis—is present when the limb or limbs have become very large and the swelling is irreversible. The tissue is hard and unresponsive.

Treatment Appropriate treatment requires identifying the cause of the lymphedema. It is most often treated by physical means and/or medications. In its earliest stages, the swelling can be relieved by supporting the limb in a raised position, exercising it gently, and wearing elastic support garments. Acute lymphedema following surgery or injury can usually be relieved within a week by keeping the affected limb raised and contracting the muscles, such as repeatedly making a fist with the hand of an affected arm.

Other physical methods of treating lymphedema include the following:

- Compression wrapping, in which bandages, special compression garments such as sleeves or stockings, or specialized devices apply controlled pressure to the limb
- Therapeutic exercises
- Manual lymphatic drainage—a special light massage or mechanical manipulation that helps move fluid from the end of the limb toward the trunk
- Cleansing and care of the skin to prevent infection
- An appropriate protein-rich diet
- Sequential compression pumps or pneumatic compression devices attached to a cuff around the arm or leg that inflate and deflate to apply pressure for improving fluid flow and preventing fluid accumulation.

Complex physical therapy or complex decongestive therapy (CDT) use a combination of these methods. Some specialists believe that CDT

should not be used on patients with recurrent or metastatic cancers due to the risk of spreading the cancer through the lymphatic system. The presence of blood clots must be ruled out before using manual lymphatic drainage, which could move clots toward the heart or lung. Some physicians believe that compression pumps can actually worsen the lymphedema.

Drug treatments for lymphedema include the following:

- Antibiotics* to prevent or treat infections
- Anti-inflammatory drugs for lymphedema occurring some weeks after surgery or during radiation therapy
- Medications for pain
- Anticoagulants to treat blood clots

Repeated episodes of lymphedema, which stretch body tissues, increase the likelihood of recurrence. There exists no effective treatment for advanced chronic lymphedema. Physical treatments provide no relief. Although surgery can reduce severe swelling, it cannot cure lymphedema. Reconstructive or debulking surgery is sometimes used to remove excess tissue in stage 3 lymphedema. However, because lymphedema surgery usually results in complications, it is rarely used on cancer patients.

Complications Lymphedema can cause tissue damage by interfering with the uptake of nutrients* and by preventing limb mobility. Other complications of lymphedema include the following:

- Breakdown of the skin, especially in the hips, knees, or elbows
- Urine retention caused by lymphedema in the groin or pelvis
- Constipation* from opioid medications

Chronic lymphedema often leads to lymphangitis*—an inflammation of the lymphatic vessels that affects the connective tissue* under the skin. Repeated infections cause scarring that makes the tissue even more susceptible to swelling and infection. These lead to tissue hardening or fibrosis, which is characteristic of advanced chronic lymphedema. When the skin becomes so thick that it is difficult to move the limb, the limb may become permanently enlarged and deformed. The skin becomes so weak that ulcers* and infections become chronic. These complications are irreversible. In addition to these physical challenges, lymphedema can be so disfiguring, painful, and disabling that mental and sexual problems arise.

Can Lymphedema Be Prevented?

Risk factors for lymphedema include the following:

- Advanced age
- Inadequate diet
- Being overweight

What Is Lymphangiosarcoma?

Lymphangiosarcoma is a tumor of the lymph vessels. It is a rare, fatal complication of chronic lymphedema. The average time span between a mastectomy and the development of lymphangiosarcoma is about 10 years.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

* **nutrients** are the components of food (protein, carbohydrate, fat, vitamins, and minerals) needed for growth and maintenance of the body.

* **constipation** is the sluggish movement of the bowels, usually resulting in infrequent, hard stools.

* **lymphangitis** (lim-fan-JIE-tis) is inflammation of the lymphatic system, the system that carries lymph through the body. Lymph is a clear fluid that contains white blood cells.

* **connective tissue** helps hold the body together, is found in skin, joints and bones.

* **ulcers** are open sores on the skin or the lining of a hollow body organ, such as the stomach or intestine. They may or may not be painful

Methods for preventing or controlling lymphedema include the following:

- Early identification and careful monitoring of at-risk patients
- Keeping affected skin clean and moisturized with lotion
- Proper nutrition and weight control
- Keeping the arm or leg raised above heart level whenever possible
- Exercises for improving lymph drainage: hand and arm exercises following a mastectomy; leg or foot exercises following surgery that affects drainage of the pelvic lymph nodes
- Avoiding strenuous activity of the limb while recovering from radiation or surgery
- Avoiding rapid circling with the arm or leg, which collects blood in the lower portion of the limb
- Avoiding heat on the affected limb
- Avoiding pressure on the arm or leg
- Avoiding injections or blood pressure readings on an affected limb
- Avoiding tight clothing
- Precautions for preventing infection, such as wearing gloves and shoes
- Permanently protecting a treated limb from injury or infection, since lymphedema can develop 30 years or more after surgery

Lymphoma

Lymphoma (lim-FOH-mah) are cancers that are grouped together because they arise in the lymphocytes, a type of white blood cell located within lymph nodes of the immune system*. Generally, the lymphatic system is the network of vessels that carry the fluid lymph, which contains blood cells throughout the immune system. Within this system lymphoma first occurs. Hodgkin's lymphoma is one well-known example of lymphoma. Non-Hodgkin's lymphoma is sometimes used to refer to all lymphomas other than Hodgkin's lymphoma. However, the scientific classification of lymphoma includes a wide variety of forms: More than 30 types of lymphomas had been identified as of 2009.*

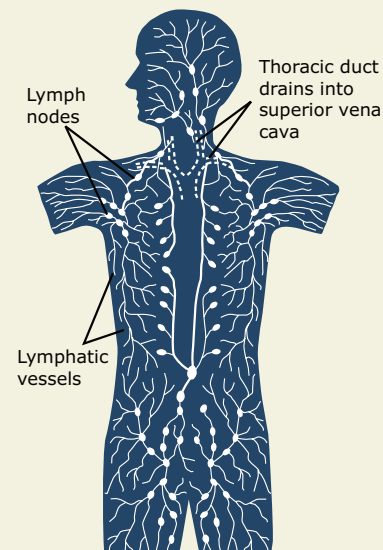

What Is Lymphoma?

Lymphoma is a general term for a group of cancers that begin in the lymphatic system, which is the part of the body system consisting of the tissues and organs used to make, store, and carry white blood cells for fighting infections and other diseases. This system includes the bone marrow*, spleen*, and hundreds of bean-sized lymph nodes* throughout the body. Lymphoma results when white blood cells, or lymphocytes (LIM-fo-sites), undergo changes and start to multiply out of control. Eventually, the cells crowd out healthy cells and create tumors*. Lymphoma can occur in a single lymph node, a group of lymph nodes, or in other parts of the lymphatic system. Eventually, it may spread to almost any part of the body.

The different types of lymphoma vary in severity, survivability, and frequency. Some types do not occur often. For instance, hairy cell leukemia (within chronic lymphoid leukemia) is diagnosed in only about 2,000 new cases each year in North America and Western Europe. Hodgkin's lymphoma is very survivable, being one of the most curable types of lymphoma, with a cure rate of more than 90 percent. By contrast, Mantel-cell lymphoma, an aggressive type of non-Hodgkin's lymphoma, is one of the deadliest lymphatic cancers.

Lymphoma has traditionally been divided into two main types: Hodgkin's disease, named after British physician Thomas Hodgkin (1798–1866), and non-Hodgkin's lymphoma. The division occurs, in part, because the cancer cells in Hodgkin's lymphoma look different under a microscope than do the cells in non-Hodgkin's lymphoma. However, both cancers make a person sick in the same way. Some types of lymphoma are among the most common childhood cancers. However, most cases of lymphoma occur in adults.

According to a plan of the World Health Organization, lymphoma is classified by the cell type associated with a particular tumor (neoplasm). The three major divisions are: B-cell tumors, T-cell and natural killer cell tumors, and Hodgkin's lymphoma. Previous classification systems, which

▲ The lymphatic system includes a network of tiny tubes that branch, like blood vessels, into tissues throughout the body. Lymph nodes are located along this network. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **bone marrow** is the soft tissue inside bones where blood cells are made.

* **spleen** is an organ in the upper left part of the abdomen that stores and filters blood. As part of the immune system, the spleen also plays a role in fighting infection.

- * **tumors** (TOO-morz) are abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.
- * **biopsies** (BI-op-seez) are tests in which small samples of skin or other body tissue are removed and examined for signs of disease.

continued in use in the early 2000s, only contain two divisions: either Hodgkin's lymphoma or non-Hodgkin's lymphoma. Under such representation, B cell tumors and T cell/natural killer cell tumors would be considered non-Hodgkin's lymphoma.

Under B-cell tumors, B cells—also called B lymphocytes (in which the “B” stands for *bursa of Fabricius*, a bird gland where the tissue was first found)—are a component of the blood that makes antibodies*, which is essential in the body's defense against toxins, viruses, and bacteria.

T cells—also called T lymphocytes (in which “T” stands for *thymus*)—are a type of white blood cell found within the blood. They protect the body by attacking foreign substances. Damage to T cells can be caused by diseases. When damaged, T cells degrade (reduce) the body's ability to defend itself against infections. Natural killer cells, a specific type of T cell, have the ability to destroy microbes and tumor cells by releasing small granules.

Hodgkin's lymphoma—sometimes also called Hodgkin's disease—is the least severe form of lymphoma. One distinction of Hodgkin's lymphoma is the appearance of Reed-Sternberg cells in biopsies*. Derived from B cells, they are large, distinctive looking cells—sometimes described as looking like an owl's eye. Hodgkin's lymphoma spreads in an orderly fashion, from one lymph node group to another. As the disease advances, the symptoms increase in number.

There are numerous divisions within each major category. Within the B-cell tumor group, major types include small cell lymphoma (which is found mostly in the lymph nodes), chronic lymphocytic leukemia (bone marrow and blood), and B-cell prolymphocytic leukemia (a severe form of chronic lymphocytic leukemia). Two other B-cell lymphomas are follicular lymphoma (whose cells contain a vague clustering pattern) and Burkitt's lymphoma (which is associated with Epstein-Barr virus and causes mononucleosis).

Some of the major lymphomas within the T-cell and natural killer cell tumor group are: T-cell prolymphocytic leukemia (involving blood, bone marrow, liver, spleen, skin), T-cell large granular lymphocytic leukemia (peripheral blood, bone marrow, spleen, liver), and mycosis fungoides (also known as Alibert-Bazin syndrome, involving the skin).

The Hodgkin's lymphoma group contains such lymphomas as nodular lymphocyte-predominant Hodgkin's lymphoma and classical Hodgkin's lymphoma. Classical Hodgkin's lymphoma involves the steady distribution of cancer among the lymph nodes. It was one of the first types of cancer to be cured. In the early 2000s, it is cured in the vast majority of cases. Nodular lymphocyte-predominant Hodgkin's lymphoma was separated from classical Hodgkin's lymphoma because it progresses differently and contains cells shaped like popcorn.

What Causes Lymphoma?

No one knows exactly what causes lymphoma. It is not contagious, like a cold or chickenpox. Although as of 2009 scientists did not know what causes it, they did know when it occurs and that it causes genetic damage

to the body. White blood cells in the lymphatic system sometimes become cancerous and spread into the body, trying to replace healthy cells. Burkitt's lymphoma, for instance, contains cancerous B cells, which spread into the blood, bone marrow, and central nervous system*.

Oncogenes, which are involved in lymphoma, are the result of a normal gene* (called a protooncogene*) mutating through cell division. Such gene mutations are thought to increase the chances of healthy cells becoming tumorous, which can lead to cancers such as lymphoma. Oncogenes were first discovered in retroviruses* and, later, identified as a part in the development of cancer.

People with other kinds of cancer sometimes have what are known as risk factors. A risk factor is anything that increases a person's chances of getting a disease. Having AIDS* or an autoimmune disease* increases the risk for lymphoma. However, most people with lymphoma have no known risk factors.

DNA* may cause normal lymphocytes to become lymphomas. DNA is material that people inherit from their parents, which carries the instructions for everything the cells do. Just as people get bumps and scrapes during their lifetimes, the genes*, which are composed of DNA, also suffer different kinds of damage or malfunction. When that happens, a cell may receive wrong signals that cause it to grow out of control and form a tumor.

In addition, certain viruses appear to cause changes in genes that can lead to lymphoma. Epstein-Barr virus* can cause lymphoma in people with weakened immune systems. In people with healthy immune systems, the same virus has been linked to a form of the disease called Burkitt's lymphoma, which occurs in children and adults in Central Africa but is rare in the United States. A virus called HTLV-1* causes a kind of lymphoma seen almost exclusively in certain geographical areas, particularly Japan, the Caribbean, and the southeastern United States. In most cases, however, as of 2009 doctors had no idea why lymphoma develops.

What Are the Symptoms of Lymphoma?

Some people with lymphoma have early symptoms that cause them to go to the doctor. Others may have no symptoms at all, or they may mistake their symptoms for the flu (influenza) or another ordinary illness. This is because the body responds to lymphoma as though it were an infection. For example, Jacqueline Kennedy Onassis (1929–1994), the widow of President John F. Kennedy (1927–1963), was diagnosed with lymphoma after she went to the doctor thinking she had the flu. John Cullen (b. 1964), a former professional hockey player, experienced his first symptom as a pain in his chest after a game.

Lymphoma is generally characterized by enlarged lymph nodes in one or more parts of the body, such as painless swellings of the lymph nodes in the neck, armpit, chest, or groin. Other common symptoms include night sweats, weight loss, fever, malaise, tiredness, and reddening of the skin. Vomiting and nausea can sometimes occur. In addition, the

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

* **proto-oncogene** (pro-toe-AN-keh-gene) is a gene that is used to divide normal cells for specialized uses.

* **retrovirus** is a virus whose genetic information is found in ribonucleic acid (RNA), a nucleic acid that is found in all living cells.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **autoimmune disease** (aw-toh-ih-MYOON) is a disease in which the body's immune system attacks some of the body's own normal tissues and cells.

* **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

- * **Epstein-Barr virus** (EP-stine-BAHR VI-rus) is a common virus that causes infectious mononucleosis.
- * **HTLV-1** short for human T-cell lymphotropic virus type 1, is a virus that is associated with certain kinds of adult leukemia and lymphoma.
- * **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.
- * **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.
- * **MRI** which is short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

same physical reaction that causes itchiness in allergic reactions can cause widespread itching in lymphoma. Various other symptoms can eventually occur, depending on where the cancer has spread. For example, lymphoma that has spread into the lungs will cause a cough, whereas abdominal pain usually indicates the cancer has spread into the gastrointestinal tract.

How Is Lymphoma Diagnosed?

If lymphoma is suspected, the doctor can order various medical tests, including imaging studies to allow the doctor to see inside the body. Because many of the symptoms of lymphoma can be caused by non-cancerous problems such as infections, the only way to be sure that a person has lymphoma is to do a biopsy (BY-op-see). This procedure involves removing a sample of tissue from a lymph node, or sometimes even an entire node, for examination under a microscope. If cancerous cells appear from the microscopic examination, physicians make further investigations in order to learn what type of lymphoma is present.

Specifically, medical professionals determine the stage at which the lymphoma is present in the body by performing such tests as CT scans* and x-rays; ultrasound* tests, MRIs*, and positron emission tomography scans; bone marrow biopsies; lumbar puncture tests; and a comprehensive set of blood tests, including complete blood count.

Genetic and immunologic studies help to distinguish among the numerous types of lymphoma. A wide range of tests are important to properly assess the spread of lymphoma cells in the body and to accurately determine the cell type involved so that the most effective type of treatment can be identified and performed. The clinical analysis usually divides lymphomas into three grades: low, intermediate, and high. The low-grade form is the most survivable form.

How Is Lymphoma Treated?

Once the doctor knows for sure that a patient has lymphoma, the next step is to do something called staging. This activity involves determining what cell type is involved, whether the cancer has spread, and if so, how far. Staging is essential for deciding what kind of treatment a person with lymphoma should receive and what the outlook for survival is for the patient. The systems used to stage the different types of lymphoma are different, but the goal is always to decide the best treatment for the patient.

Early stage non-Hodgkin's lymphoma (involving B-cell tumors and T-cell/natural killer cell tumors) that has not spread is usually treated with radiation therapy, which uses high-energy waves to damage and destroy cancer cells. If the disease is widespread, it will probably require chemotherapy (kee-mo-THER-a-pee), which uses anticancer drugs that can reach throughout the body to fight cancer cells. Chemotherapy drugs are given either through a vein in the arm or as pills taken internally.

Sometimes chemotherapy is combined with radiation. Hodgkin's disease is also treated with radiation, chemotherapy, or both.

Both chemotherapy and radiation can have side effects, because treatments that kill cancer cells can affect healthy cells, too. The most common side effects of chemotherapy are nausea (feeling sick to the stomach), vomiting, hair loss, and tiredness. Nausea and vomiting can be prevented with medication, and, fortunately, most of these side effects go away after the treatment is completed.

Immunotherapy (also sometimes called biological therapy) uses artificially made substances that are modeled after substances naturally made by the immune system. Such therapies use various substances to kill or slow down the growth of lymphoma cells. They are also used to prepare a patient's immune system to better fight cancer cells brought on by lymphoma. One group of substances called monoclonal antibodies are designed to attack a specific target. One type of monoclonal antibody is rituximab (Rituxan), which seeks out special molecules on the surface of cancer cells.

Sometimes a bone marrow or stem cell* transplant is performed after the use of chemotherapy or radiation. Cancer cells are killed off in the chemotherapy or radiation process, and later, healthy bone marrow or stem cells are introduced back into the body with the use of such transplants.

Is It Possible to Prevent Lymphoma?

Unlike many other kinds of cancer, there are no known factors related to lifestyle, such as exposure to sunlight or specific eating habits, that a person could change in the hope of lowering the risk of getting lymphoma. However, preventing HIV* (AIDS virus) infection would prevent many cases of non-Hodgkin's lymphoma.

Will Treatment for Lymphoma Change in the Future?

As of 2009, researchers were studying how normal lymphocytes develop into cancer cells. This information may be used one day in gene therapy* to replace abnormal genes with normal ones and allow cells to grow normally again. This same knowledge was also being used to try to detect lymphoma earlier and to test how completely lymphoma was destroyed by treatment.

Lymphoma cells sometimes become resistant to chemotherapy: The cancer cells are able to change (mutate) so that the drugs are no longer effective. Various drugs were being studied that could interfere with this resistance, thus making chemotherapy more effective. Biological treatment, what is called immunotherapy, was being investigated to help patients' immune systems recognize and destroy the lymphoma cells.

Living with Lymphoma

Because treatment of both non-Hodgkin's lymphoma and Hodgkin's disease usually involves chemotherapy and radiation, one of the most difficult parts of living with lymphoma is coping with treatment. Many side

A Poison that Saves Lives

Near the end of World War II (1939–45), an Allied ship loaded with sulfur mustard, a poisonous gas used by the Germans during World War I (1914–18), blew up in an Italian port. Doctors treating the injured soldiers noticed that the gas had an effect on soldiers' immune systems. Because certain cancers form in the immune system, the doctors wondered whether a related gas called nitrogen mustard could be used to treat the cancers. They discovered that it could. In the 21st century, nitrogen mustard is one of about 30 anticancer drugs used to save or prolong the lives of people with lymphoma and other cancers.

* **stem cell** an unspecialized cell that gives rise to differentiated cells.

* **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).

* **gene therapy** is a treatment that works by altering genes.

effects of chemotherapy and radiation are short-term and go away when treatment stops. However, other side effects are long-term. For example, treatment may affect a person's ability to have children, or it may trigger the development of a different lymphoma many years later.

Follow-up care may continue for years or even decades. Aside from doctor's visits, though, once all signs of cancer are gone, people can go back to doing whatever they did before they got lymphoma. Most children with childhood lymphoma survive it, and they can expect to lead normal lives as adults.

Malaria

Malaria (mah-LAIR-e-uh) is a disease caused by a parasite that is spread to humans by the bite of an infected mosquito.

What Is Malaria?

Malaria, which literally means bad air, was once thought to be spread in the air around stagnant marshes. It was later discovered that mosquitoes, particularly female *Anopheles* (a-NOH-fel-eez) mosquitoes, spread the parasites that cause malaria. Four different species of a parasite in the genus *Plasmodium* (plaz-MO-dee-um) cause malaria. They are *falciparum* (fal-SIP-ar-um), *malariae* (ma-LAIR-e-eye), *ovale* (o-VAL-e), and *vivax* (VI-vax). Of the four, *P. falciparum* is the most common and the most deadly. *Plasmodium* requires time in both the mosquito vector* and human host* to complete its life cycle.

How Common Is Malaria?

Forty percent of the world's population is at risk for contracting malaria from infected mosquitoes, primarily in tropical and subtropical regions. Worldwide, there are 300 to 500 million cases of malaria and more than one million deaths from malaria each year. More than 90 percent of all malaria deaths occur in sub-Saharan Africa, a vast area south of the Sahara Desert, and 75 percent of deaths occur in children. *Plasmodium falciparum* causes malaria in this region, and poverty, poor nutrition, and poor access to health care all contribute to the high death rate. Malaria is increasingly common in Central and South America, Asia, the Middle East, and the Pacific Islands. About 1,200 cases of malaria are diagnosed in the United States each year, mostly in recent immigrants or travelers from countries where malaria is found.

Female *Anopheles gambiae* mosquito seen under an electron microscope. There are about 2,700 species of mosquitoes, including more than 90 species of *Anopheles* mosquitoes, many of which carry malaria. *Anopheles* mosquitoes typically bite between dusk and dawn. Only female mosquitoes suck blood and, thus, spread malaria. Dr. Tony Brain/Custom Medical Stock Photo, Inc. Reproduced by permission.

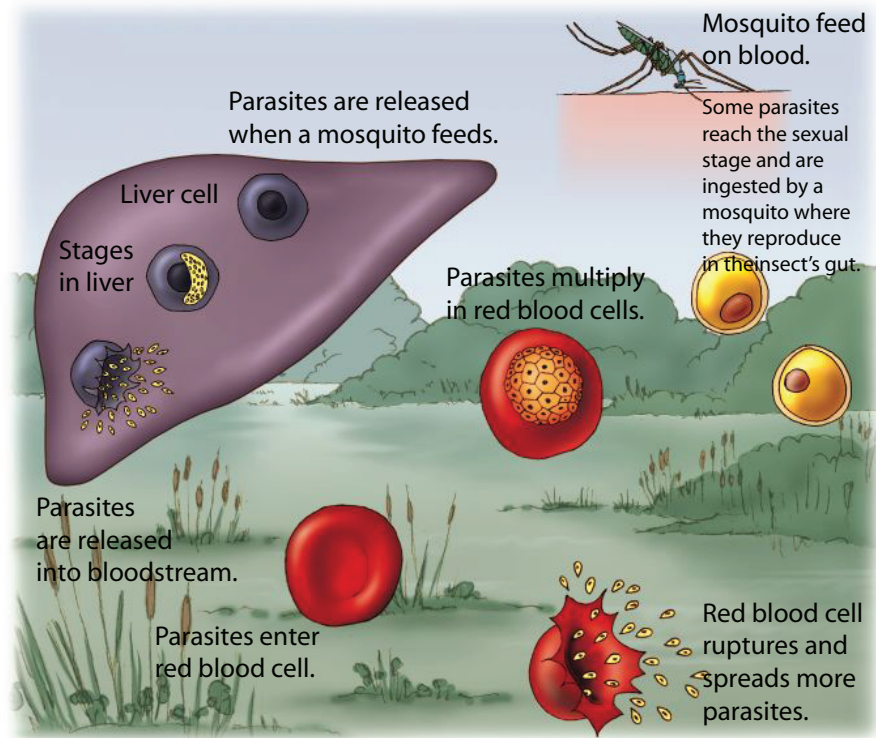

* **vector** (VEK-tor) is an animal or insect that carries a disease-causing organism and transfers it from one host to another.

* **host** is an organism that provides another organism (such as a parasite or virus) with a place to live and grow.

Malaria

Cycle of malaria infection. *Plasmodium* parasites can reproduce inside the *Anopheles* mosquito and be transmitted to people through mosquito bites. In people, the parasites can multiply in the liver and in the red blood cells.

Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.

* **incubation (ing-kyoo-BAY-shun) period** is the time between infection by a germ and when symptoms first appear. Depending on the germ, this period can be from hours to months.

* **toxins** are substances that cause harm to the body.

Mosquito control has virtually eliminated malaria in areas with temperate climates. However, the disease has made a comeback as mosquitoes have become resistant to insecticides and *Plasmodium* becomes resistant to medications used to treat malaria.

Is Malaria Contagious?

Malaria is not passed directly from one person to another. Mosquitoes spread the disease. When a mosquito bites an infected person, it ingests malaria parasites contained in that person's blood. The parasites need an incubation period* of about one week in the mosquito before the mosquito can spread the disease when it bites another person. Once in a person's body, the parasites travel to the liver where they can remain dormant, or inactive, for months or even years. In the liver, the parasites grow and multiply and are then ready to move into the body's red blood cells, where they continue to grow until the red blood cells burst, freeing more parasites to attack more blood cells. The parasite can be ingested by a mosquito and spread to another person only during the time that *Plasmodium* is in the blood.

What Are the Signs and Symptoms of Malaria?

Malaria causes fever and symptoms similar to those of the flu. In the early stages of the disease when the parasite is in the liver, the infected person does not feel sick. When the parasites invade the red blood cells and cause them to burst, toxins* are released into the blood, and the person experiences fever, chills, sweating, headache, muscle aches, and tiredness. Symptoms typically begin 9 to 16 days after infection with the parasite,

but the time may vary depending on the infecting species. Episodes of these symptoms reoccur every 48 to 72 hours. Other symptoms may include nausea*, vomiting, and diarrhea*.

How Is Malaria Diagnosed and Treated?

Under the microscope, a blood sample from a person who has malaria will show one of the four species of *Plasmodium* parasites within the red blood cells. Malaria is treated with antimalarial drugs, many of them derived from quinine, which is found naturally in the bark of the cinchona tree from Peru. Which drug is chosen to treat a patient depends on the parasite causing the infection, the severity of symptoms, the age of the patient, and whether the parasite is resistant to certain drugs. Some patients may need intensive hospital care.

Treatment can last several weeks or months. In some infections, the parasite can remain dormant in the liver for months or years, and the disease may return even after treatment. Destruction of red blood cells in cases of malaria can result in anemia* and jaundice*. Severe and untreated infection may cause liver and kidney* problems, seizures*, mental confusion, coma*, and death; malaria is fatal in 1 in 500 cases. Children and pregnant women are particularly vulnerable to complications. Infected pregnant women are at risk for miscarriage*, premature delivery*, and stillbirth*, and anemia in children can have long-term effects on growth and development.

Can Malaria Be Prevented?

In areas where malaria is endemic*, people can avoid being bitten by mosquitoes by wearing long-sleeved shirts and long pants, using insect repellent, and staying in a screened or air-conditioned room from dusk to dawn when mosquitoes are most active. Bed nets treated with certain insecticides repel mosquitoes for 6 to 12 months.

Anyone traveling to a malaria-endemic area should visit a doctor four to six weeks prior to travel to receive the appropriate vaccinations for certain tropical infections and proper prescriptions to prevent malaria. This precaution applies to people who grew up in a malaria endemic area and have lived elsewhere for a period of time.

In the early 2000s, scientists were working to develop a vaccine that would prevent malaria. However, the different species of *Plasmodium* and the complicated life cycle of these parasites have made developing a vaccine difficult.

Maldigestion and Malabsorption Syndromes

Maldigestion and malabsorption syndromes are conditions that result in abnormalities in the digestion of food or in the intestinal absorption of nutrients into the bloodstream. These conditions often occur together.

What Are Maldigestion and Malabsorption Syndromes?

In order for the body to use food, it must be chemically broken down into smaller compounds and then absorbed from the intestine into the bloodstream. If maldigestion occurs, the food a person eats is not broken down enough for the intestine to absorb it. If malabsorption occurs, the food is correctly digested, but abnormalities in the intestine prevent its absorption. As a result the body does not get all the nutrients it needs; undigested or unabsorbed nutrients are lost in feces*. Maldigestion and malabsorption can occur with proteins, fats, carbohydrates (sugars and starches), and any of the vitamins or minerals the body needs. Often more than one type of nutrient is affected.

What Causes Maldigestion and Malabsorption Syndromes?

Many different diseases can cause malabsorption of various nutrients. The most common disease causing malabsorption is celiac disease, also called celiac sprue or gluten-sensitive enteropathy. About 3 million people in the United States and another 3 million in Europe are affected. People with celiac disease cannot tolerate gluten, a protein found in wheat, rye, and barley. When people with celiac disease eat food containing gluten, their immune system* responds by causing the cells lining the wall of the small intestine to become inflamed. Over time, the inflammation* damages these cells so that they no longer can absorb a normal amount of nutrients.

The second most common cause of maldigestion and malabsorption is cystic fibrosis. This complex inherited disease involves the lungs, pancreas*,

liver, and intestines. One aspect of the disease is that the pancreas does not produce enough digestive enzymes* (a problem of maldigestion), and abnormal chemistry of the intestines prevents normal absorption of nutrients.

Lactose maldigestion is a condition in which the cells lining the small intestine do not produce the enzyme lactase needed to digest the sugar lactose found in cow's milk. According to the National Institute of Diabetes and Digestive and Kidney Diseases, between 30 and 50 million American adults are lactose intolerant; these people may produce some lactase and can consume small amounts of dairy products, but they do not produce enough of the enzyme to digest the quantity of dairy products found in the standard American diet.

Other conditions and diseases that cause malabsorption include short bowel syndrome, Crohn's disease, and some weight control surgeries (bariatric surgeries) that shorten the intestine. AIDS* can also cause malabsorption of nutrients as can diseases of the pancreas, including pancreatitis and pancreatic cancer. Infection with certain intestinal parasites* can interfere with the absorption of food. Certain drugs may also interfere with absorption of specific nutrients for as long as the drug is taken. Absorption normally improves after the drug is stopped.

What Are the Symptoms of Maldigestion and Malabsorption Syndromes?

Regardless of the cause, malabsorption and maldigestion syndromes produces somewhat similar symptoms. The most common symptoms are a bloated abdomen* (belly); chronic* diarrhea, passing a great deal of gas, bulky, bad-smelling stools, excessive fat in the stool (a condition called steatorrhea; stool often floats in the toilet because fat is lighter than water); weight loss; anemia*; general weakness; fatigue; and fluid retention. Infants and young children gain little weight and do not reach developmental milestones at the times expected, a condition called failure to thrive.

How Are Maldigestion and Malabsorption Syndromes Diagnosed and Treated?

Diagnosis begins with review of medical history, symptoms, and a physical examination. Blood tests are done to detect abnormalities in the level of iron, vitamin B-12, folate, cholesterol, triglycerides*, and various electrolytes. Imaging studies such as an endoscopy* may be performed to observe the appearance of the small intestine and to biopsy* the innermost surface called the mucosa. Specific diagnostic tests are performed for fat, protein, and carbohydrate malabsorption as well as for malabsorption of certain vitamins and minerals. Because many malabsorption syndromes are caused by other diseases, the issue is often not one of diagnosis, but rather of measuring the degree of nutrient deficiency and attempting to correct it.

* **enzymes** (EN-zimes) are proteins that help speed up a chemical reaction in a cell or organism.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **parasites** (PAIR-uh-sites) organisms such as a protozoan (one-celled animals), worm, or insect that must live on or inside a human or other organism to survive. An animal or plant harboring a parasite is called its host. A parasite lives at the expense of the host and may cause illness.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.

* **triglycerides** (try-GLISS-eh-rides) are a type of fatty substances found in the blood.

* **endoscopy** (en-DOS-ko-pee) is a type of diagnostic test in which a lighted tube-like instrument is inserted into a part of the body.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **cystic fibrosis** (SIS-tik fy-BRO-sis) is a disease that causes the body to produce thick mucus that clogs passages in many of the body's organs, including the lungs.

* **malignant** (ma-LIG-nant) refers to a condition that is severe and progressively worsening.

* **cutaneous** (kyoo-TAY-nee-us) related to or affecting the skin.

Treatment depends on the cause of the syndrome. Eliminating gluten from the diet helps people with celiac disease. Limiting or eliminating dairy products helps people who are lactose intolerant. Some low-lactose and lactose-reduced products are available in the supermarket. Lactase, the enzyme that breaks down lactose so that it can be absorbed, can be eaten as a digestive aid. People with cystic fibrosis* are given supplemental pancreatic enzymes to aid digestion. Based on the specific nutrients deficiencies, people with malabsorption syndrome are given supplements of various vitamins and minerals, and amount of calories in their diet may be increased. Malabsorption syndromes usually require life-long dietary adjustments and monitoring. Complications frequently arise based on deficiencies in specific vitamins and minerals.

Malignant Melanoma

Malignant melanoma is a skin cancer that originates in the pigment-producing cells in the upper layer of the skin known as melanocytes (me-LAN-oh-sites). Malignant melanoma is one of the less common types of skin cancer, but it causes the highest number of deaths, accounting for 75 percent of all deaths resulting from skin cancer. Most melanomas begin in the skin, but some begin in the eye or even the intestines. Melanoma that starts in the skin is called cutaneous* melanoma. Melanoma that starts in the eye is called uveal (YOU-vee-ul) or ocular melanoma.*

Malignant melanoma. Highly malignant tumor of the melanin cells (skin pigment) which can be pigmented, as in this case, or without pigment. Malignant melanoma form on the skin, eyes, and mucous membranes then spread to the lymph nodes and elsewhere. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

John's Story

John, a high-school senior, lives for baseball season, when he spends hours each day practicing with teammates as well as playing games against teams from other schools. His chief concerns with health matters are drinking enough water in hot weather and not overworking his pitching arm. He was surprised when the coach told him and his teammates before the start of spring training that they would have to be more careful about protecting their skin from the sun. The coach had read a bulletin from the American College of Sports Medicine about the dangers to young athletes from too much sun exposure, particularly the risk of melanoma.

John had never thought of sunlight as harmful to his skin. He has always enjoyed hiking in the mountains of the Southwest as well as sports and other outdoor activities. He is also three-fourths Native American and does not sunburn as easily as some of his lighter-skinned teammates. But the coach told John that people from any racial or ethnic group can get melanoma if they have a history of it in their family, live in hilly regions like northern New Mexico or Arizona, or have had occasional severe sunburns in childhood. The coach also said that as recently as the early 1990s, doctors rarely saw teenagers with melanoma, but that more and more cases were being found among young people John's age. John decided that he would ask his doctor to recommend an effective sunscreen for his skin type and that he would be careful to always wear a baseball cap and shirt during practice, because boys are more likely than girls to develop melanomas on the head, neck, and chest.

What Is Malignant Melanoma?

Malignant melanoma is a type of skin cancer that begins in certain cells in the epidermis (ep-ee-DER-miss), which is the outermost layer of the skin. These specialized cells are called melanocytes because they produce and

* **ultraviolet** light is a wavelength of radiation beyond visible light; on the spectrum of light, it falls between the violet end of visible light and x-rays.

* **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

* **mutations** (mu-TAY-shuns) are changes in a chromosome or a gene.

contain a brownish-black skin pigment called melanin (MELL-uh-nin). In humans, melanin provides the color in the skin, hair, and the colored part of the eye called the iris. There are between 1,000 and 2,000 melanocytes in each square millimeter of skin. The difference in skin color between fair-skinned and darker-skinned people does not depend on the number of melanocytes in the skin but on their level of activity. When skin is exposed to the sun, the melanocytes become more active, produce more melanin, and cause the skin to darken, that is, they cause a suntan.

The development of melanomas from normal skin was not completely understood as of 2009. Some researchers thought there may be several different pathways to melanoma, depending on whether they occur on skin that is exposed to the sun only occasionally (such as the chest or back area in women) or on skin that is frequently exposed to the sun (head, face, neck, and hands). In general, melanoma is caused by the interaction of ultraviolet* (UV) radiation from the sun and the melanin in melanocytes. UV radiation can damage the DNA* in skin cells both directly and indirectly. Researchers have found that 92 percent of melanomas are caused by indirect damage to DNA and 8 percent by direct damage.

When the DNA in a skin cell is damaged by UV radiation, the cell can undergo a series of mutations* that lead to abnormal multiplication of new cells. In some cases the changed DNA makes the cell more vulnerable to the damaging effects of UV radiation. About 40 percent of melanomas begin in moles, with the remaining 60 percent starting in normal-looking skin.

Melanomas grow in two stages or phases. The first is a phase of outward or radial growth. The second phase, which is much more dangerous, is a phase of vertical growth into deeper layers of tissue. It is during this second phase of growth that melanomas become harder to treat and able to spread to other parts of the body.

How Common Is Malignant Melanoma?

Malignant melanoma was considered a rare form of cancer until the 1970s, but its rate among Caucasians in the United States tripled between 1985 and the early 2000s. As of 2009 it was the sixth most common cancer in the United States. The current lifetime risk for developing invasive melanoma is one case for every 60 Americans, a 2000 percent increase since 1930. This risk rises to one case for every 32 Americans if early-stage melanoma (Stage 0 below) is included.

The highest annual rates of melanoma in the world, however, are not found in the United States but in Australia, New Zealand, and Israel. There are approximately 57 cases of melanoma annually per 100,000 people in Australia and 40 cases annually per 100,000 people each year in Israel.

One unusual finding in the United States is the rapid increase of deaths from melanoma in older males. Although the death rate among younger men (44 years or younger) dropped between the late 1990s and 2009, most likely as a result of public health education campaigns about

MELANOMA AND CLIMATE CHANGE

Melanoma was a rare form of cancer until the 20th century. The earliest known surgical removal of a melanoma was performed in 1787 by a British surgeon, but the disease was little studied until the 1840s and 1850s, when two other British doctors described the stages of melanoma and found that it runs in some families. The connection between melanoma and sun exposure was not made until 1956, when the Australian physician Henry Lancaster (1913–2001) found that high intensity of sunlight is a risk factor for melanoma. In the 1970s scientists began to notice that the ozone layer—a layer of oxygen molecules consisting of three atoms of oxygen in the upper atmosphere—was becoming thinner. The ozone layer helps to block a high-energy type of ultraviolet radiation known as UVB from reaching the earth's surface, so doctors began to wonder whether a thinner ozone layer could contribute to an increase in the rate of melanoma and other skin cancers.

As of 2009, however, doctors did not think that the rise in cases of melanoma since the 1980s was due primarily to changes in the ozone layer. One reason is that depletion of the ozone layer is most severe over

Antarctica, which is not a heavily populated continent. Another is that advances in genetics indicate that heredity plays a larger role in melanoma than was thought to be the case in the 1980s. Still another reason for skepticism about the role of the ozone layer in melanoma is that some studies indicated that a lower-energy form of ultraviolet radiation called UVA triggers the development of melanoma rather than the UVB blocked by the ozone layer. If this finding is accurate, then changes in the ozone layer are not related to melanoma. It is also likely that the increase in the number of reported cases of melanoma since the 1990s is due partly to better diagnostic instruments and earlier diagnosis.

Research into the rise in cases of melanoma was ongoing in the United States in the early 2000s. According to a report published by the Department of Health and Human Services, the Climate Change Science Program for 2009 will include studies on the effect of UVA and UVB radiation on the skin, research into the effectiveness of various sunscreen products, and the role of genes in triggering melanoma and other skin cancers.

the dangers of sun exposure, it rose 66 percent in men between the ages of 45 and 64, and 157 percent in men over 65.

Who Gets Malignant Melanoma?

Genetic* factors are involved in malignant melanoma, in part because skin color and sensitivity to the sun are inherited characteristics. In addition, melanoma is known to run in some families. Researchers have identified mutations in certain genes on chromosomes* 1, 9, and 12 in families with histories of malignant melanoma.

Although melanoma is more common in women than men up to age 40, in adults over 40 it is more common in men. The average age of Americans at the time of diagnosis of melanoma is 53 years; however, it is the most common cancer in women between the ages of 25 and 29 and is second only to breast cancer in women between the ages of 30 and 34. In terms of racial groups in the United States, melanoma affects Caucasians twenty times more often than African Americans, and six times more often than Hispanics.

The parts of the body where melanoma is most likely to start differ somewhat between men and women and between African Americans or Asians and members of other races. Men are more likely to develop melanoma on the head, neck, or chest; women, on the lower legs. African

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **chromosomes** (KRO-mo-somz) are threadlike chemical structures inside cells on which the genes are located. There are 46 (23 pairs) of chromosomes in normal human cells. Genes on the X and Y chromosomes (known as the sex chromosomes) help determine whether a person is male or female. Females have two X chromosomes; males have one X and one Y chromosome.

Americans and Asians are more likely to get melanoma under the nails or on the palms of the hands and soles of the feet.

There are other factors that increase the risk of melanoma. These include the following:

- Having fair skin that freckles or burns easily
- Living in areas that get high levels of ultraviolet radiation, such as mountainous regions or countries closer to the equator
- Having a job that requires working outdoors during daylight hours
- Having a family history of melanoma, particularly in a parent or sibling
- Having a previous personal history of melanoma or another type of skin cancer
- Having atypical moles known as dysplastic nevi (diss-PLAS-tik NEE-vye). Dysplastic nevi are usually larger than ordinary moles and have irregular and indistinct borders. They are most likely to appear on the chest in men and on the legs in women.
- Having more than 50 ordinary moles
- Having a disorder that affects the immune system or a history of radiation therapy for cancer
- Scars or burns on the skin; fragile skin is more easily damaged by sun
- Exposure to certain chemicals in the environment, including arsenic and some types of weed killers
- Having a history of blistering sunburns before age 20
- Older age; people over 50 are at increased risk of developing melanoma and dying from it

How Is Malignant Melanoma Diagnosed?

About 80 percent of melanomas and other skin cancers are found by patients who notice suspicious changes in their skin and go to their doctor. The signs of melanoma are sometimes called the ABCDEs. A mole or patch of skin developing into melanoma may have the following features:

- **Asymmetry.** One side of the mole looks different from the other side in size, shape, or color.
- **Border irregularity.** The mole has a ragged or poorly defined border.
- **Color.** The color is not uniform; the mole has dashes of blue, red, or white mixed in with patches of brown or black.
- **Diameter.** The mole is larger than the end of a pencil eraser (about one-fourth inch in diameter).
- **Evolution.** The mole keeps changing in size, shape, or color.

Early-stage melanomas may itch or shed small flakes of skin, whereas more advanced melanomas may bleed or ooze fluid as well as itch. Advanced melanomas may also become hard or lumpy in texture. Melanomas do not, however, usually cause pain.

How Serious is Malignant Melanoma?

Malignant melanoma is the deadliest form of skin cancer. As was noted above, although melanoma accounts for only 4 percent of skin cancers in the United States, it is responsible for 75 percent of deaths from skin cancer. About 8,500 Americans die each year from melanoma, 5,500 men and 3,000 women. The World Health Organization reports that 160,000 cases of malignant melanoma are diagnosed worldwide each year, with 48,000 deaths.

Malignant melanoma is curable if caught early. When a melanoma is not removed in its early stages, however, cancer cells will start to grow downward from the skin surface and invade healthy tissue. The disease can then spread to other parts of the body, where it is difficult to control. Measuring a cancer's size, thickness, and likelihood of spreading is called staging. Melanomas are graded in five stages from 0 to 4. The chief factor in determining a patient's chances of recovery is the thickness of the melanoma. This is measured in millimeters and is called Breslow's depth, after the doctor who first connected it to the patient's chances of survival in 1970.

The five stages of melanoma and a person's chances of five-year survival at each stage are as follows:

- Stage 0: The cancerous cells are found only in the outer layer of skin and have not invaded deeper tissues. Survival rate is 99.9 percent.

OCULAR MELANOMA

Ocular melanoma, or melanoma of the eye, is a cancer that develops in the parts of the eye that contain melanocytes—the iris and other nearby structures that belong to the middle pigmented layer of the eye. It affects about 6 persons per million per year in the United States and is most likely to develop in people with blue eyes and fair skin. Ocular melanoma is more common in Denmark and other Scandinavian countries than in the United States. It is slightly more common in men than in women. The average age of a person diagnosed with this type of melanoma is 55.

Ocular melanomas can grow slowly for years without producing any symptoms, although they eventually cause blurred vision, gradual loss of sight, and sometimes pain in the eye. This type of melanoma often spreads from the eye to the liver, lungs, or even the central nervous system before it is diagnosed. Most patients die from the spread of the cancer to these vital organs rather than from the effects of the cancer on the eye itself. About half of all patients diagnosed with ocular melanoma die within 10 years after diagnosis and treatment. The standard forms of treatment for this type of cancer are radiation therapy and surgical removal of the affected eye.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **biopsy** (Bl-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **local anesthesia** (an-es-THEE-zha) means using medicine to block or numb pain in one part of the body while patients remain awake. General anesthesia blocks pain over the entire body while patients sleep.

- Stage 1: The melanoma is no more than one-twenty-fifth of an inch thick (1 millimeter) and has not spread to nearby lymph nodes*. Five-year survival rate is 85 to 95 percent.
- Stage 2: The tumor is between one and two millimeters thick but has not spread to nearby lymph nodes. Survival rate is between 40 and 85 percent.
- Stage 3: The melanoma has spread to nearby lymph nodes or to skin just outside the original tumor. Survival rate after five years is between 25 and 60 percent.
- Stage 4: The melanoma cells have spread to other organs, to lymph nodes, or to skin areas far away from the original tumor. The five-year survival rate is 7 to 10 percent, with an average life expectancy of 6 to 9 months.

Young children are an exception to the survival rates for adults. For reasons not fully understood as of 2009, survival in children is more closely related to age than to the thickness of the cancer, with younger children being less likely to survive than older children or teenagers.

How Is Malignant Melanoma Diagnosed and Treated?

Diagnosis A family doctor can often spot suspicious-looking changes in a patient's skin, but will usually refer the patient to a dermatologist (DER-muh-TAWL-oh-jist) for a definite diagnosis. Dermatologists are doctors with specialized training in diagnosing and treating skin disorders.

To diagnose cutaneous melanoma, a dermatologist first uses a dermatoscope, which is a special palm-sized instrument with a magnifying lens and built-in light. The use of dermatoscopes increased the accuracy of diagnosing malignant melanoma by 20 percent, because the doctor can make digital images of suspicious moles or skin areas and save them for comparison with images from later checkups.

If the dermatoscope images suggest that the patient may have melanoma, the next step is to take a sample of the abnormal mole or area of skin to be sent to a laboratory for analysis under a microscope. This procedure is called a biopsy*. In the case of melanoma, the doctor removes the entire mole, rather than just a portion of it, to obtain an accurate measurement of Breslow's depth. Biopsies are done under local anesthesia*.

To evaluate whether the melanoma may have spread beyond the skin, the doctor may perform a sentinel lymph node biopsy. A sentinel lymph node is the lymph node closest to the melanoma, the one to which the cancer is most likely to spread.

There was no blood test as of 2009 that could detect malignant melanoma.

Treatment The only definite cure for malignant melanoma is surgical removal of the cancerous mole or patch of skin before the melanoma reaches a Breslow depth of one millimeter. The surgeon removes a margin

of normal skin surrounding the melanoma as well as the tumor itself to make sure that no cancerous cells are left behind.

Patients with later-stage melanomas are treated with surgery to remove cancerous lymph nodes. Surgery by itself, however, is not effective in treating melanoma that has spread to other organs. In these cases a combination of chemotherapy*, radiation therapy*, or biological therapy is necessary. Biological therapy is a newer form of cancer therapy in which the patient is given vaccines or other agents to boost the response of the immune system to the cancer. It is also called immunotherapy.

Can Malignant Melanoma Be Prevented?

Limiting sun exposure People cannot change certain risk factors for melanoma, such as their genes or basic skin type, but they can lower their risk of melanoma by taking care of their skin. One way is to be careful about sun exposure. Some specific strategies are as follows:

- Avoiding the use of tanning booths and sun lamps. People who use tanning beds regularly increase their risk of developing melanoma by eight times.
- Considering the use of tanning extenders (also called sunless tanners) or bronzers if looking tanned is important. These products are considered cosmetics by the Food and Drug Administration (FDA) and do not protect the skin against ultraviolet radiation, but they are harmless when used properly.
- Staying out of the sun between 10 a.m. and 4 p.m. A handy rule is to stay out of the sun when one's shadow is shorter than one's height.
- Using a sunscreen with a sun protection factor (SPF) of 15 or higher every day. People with very fair skin should use a product with an SPF of 30 or higher.
- Applying sunscreen over the entire body 30 minutes before going outside and reapplying the product every two hours.
- Using a lip balm that contains sunscreen.
- Wearing clothing that covers as much of the body as possible, including a broad-brimmed hat and sunglasses to protect the eyes.
- Keeping infants under six months out of the sun altogether and using sunscreen on infants older than six months

Regular self-examination Another important way to lower one's risk of malignant melanoma is regular self-examination of one's skin. The American Academy of Dermatology outlines the steps to take:

- Individuals should first become familiar with all of their birthmarks, moles, freckles, and other skin blemishes in order to spot new growths or suspicious changes in existing moles or patches of skin.
- In a private room with plenty of light and a full-length mirror, individuals should use a handheld mirror in order to see their back, buttocks, and other parts of the body that require a second mirror.

* **chemotherapy** (KEE-mo-THER- α -pee) is the treatment of cancer with powerful drugs that kill cancer cells.

* **radiation therapy** is a treatment that uses high-energy radiation from x-rays and other sources to kill cancer cells and shrink cancerous growths.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

- It is important to check all parts of the body, not just those exposed to sunlight. People should begin with the upper body, front and back, then the arms. Women should look underneath their breasts.
- Next, while sitting in front of the mirror, individuals should examine their legs, genitals, soles of the feet, and the skin between the toes.
- They should examine the back of the neck and scalp using the hand-held mirror. They should part the hair at intervals to check the entire scalp. If necessary, they can ask another family member to help.

Other approaches Because slightly more than half of melanomas do not start in moles, doctors do not think that removing normal moles in teenagers or young adults is a useful way to prevent melanoma.

As of 2009, melanoma vaccines were undergoing clinical trials as biological therapies for patients with Stage 2 or Stage 3 melanoma, but the results were expected to take several years to evaluate. As of 2009, none of these vaccines was being tested as a possible way to prevent melanoma.

Malingering

Malingering (ma-LING-er-ing) means intentionally pretending to be sick or injured to avoid work or responsibility. The illnesses faked may be physical, such as the flu, or mental, such as depression. Similarly, a person may pretend to have severe back pain due to an injury. Sometimes a person may actually have a mild illness or injury and exaggerate the symptoms.*

Why Do Some People Malingering?

Although there are rare instances in which malingering may have a positive or useful purpose, such as faking illness as a prisoner of war, it is generally considered to be unacceptable behavior. Why then do people sometimes act this way?

People may fake a disorder for many reasons. They may wish to shirk military service or jury duty or avoid going on trial for some criminal act. Some people feign illness to get extra time off from school or their job. Others may fake or exaggerate an injury or disease to get undeserved money from an insurance company. Some people may malingering to get extra attention, sympathy, or help from family or coworkers.

Distinguishing Malingering from a Real Illness

As long as there have been malingerers, there have likely been others who understood what they were trying to do. The Greek physician Galen, who lived in the second century C.E., wrote, “People for many reasons may pretend to be ill; it is desirable, then, that the physician should be able to arrive at the truth in such cases.” Using their experience with actual diseases, he said, physicians need to distinguish tricks of the malingerer from the “true signs” of disease.

Physicians in modern times face many of the same basic problems with malingering that Galen did. To tell malingering from a real illness, doctors need to perform a thorough physical examination that may include tests to find out whether the symptoms a person claims to have are real and are in fact a sign of disease or injury. Doctors also need to be aware of circumstances in their patients’ lives, such as unwanted work or duties, that might cause them to fake a disorder.

Certain mental disorders could be confused with malingering. For example, in hypochondria*, conversion disorder*, and Munchausen syndrome*, the patients’ symptoms may not arise from actual physical conditions, yet these mental disorders are not the same as malingering. When people miss work or school due to physical symptoms that occur because of stressful changes or emotional upsets in their lives, they are not considered to be malingering. Individuals who are malingering know they are not sick and intentionally pretend to be ill for specific secondary gain.

Marfan Syndrome

Marfan syndrome involves the body's connective tissue and is characterized by abnormalities in the skeleton, heart, and eyes. It is caused by an abnormal gene that usually is inherited. People with Marfan syndrome are generally taller than average, have little body fat, and have long, thin fingers.*

What Is Marfan Syndrome?

Marfan syndrome was first described in 1896 by the French physician Antoine Marfan (1858–1942). Some famous people of the past, such as violinist Niccolò Paganini, who had very long fingers, and Egyptian King Tutankhamen, are believed by some to have had Marfan syndrome. In the early 2000s, the disorder received attention in the media as a result of health problems and deaths among celebrities such as Joey Ramone from the punk rock band The Ramones and Jonathan Larson, author and composer of the hit musical *Rent*. Still, the disorder is rare.

Marfan syndrome affects only about 1 to 2 people of every 10,000. In the United States, it has been estimated that between 60,000 and 200,000 people have the disorder. It affects men and women in equal numbers, as well as people of all racial and ethnic groups. Marfan syndrome can affect the heart and aorta*, the eyes, and the skeleton.

What Causes Marfan Syndrome?

For many years, it was known that Marfan syndrome is inherited. It was observed that if someone had the disorder, each of his or her children would have about a 50 percent chance of developing it as well. However, it was not known what gene or genes were responsible for the disorder.

In the early 1990s, researchers found that the condition is caused by a single abnormal gene. This gene is involved in the production of a type of protein, called fibrillin, which gives connective tissue its strength. Connective tissue holds in place all the structures of the body. When the gene is defective, it causes critical changes in fibrillin that may weaken and loosen the connective tissue. This effect, in turn, causes the wide range of features, such as tall stature and loose joints, that are found in Marfan syndrome. It was not known as 2009 just how alterations in the genes produce these features.

Although anyone born to a parent with Marfan syndrome has a 50-50 chance of inheriting the disorder, an estimated 25 percent of people with Marfan syndrome do not have a parent who has it, which is because a

person can have the defective gene owing to a spontaneous mutation, or change, in the normal gene.

What Are the Signs and Symptoms of Marfan Syndrome?

The characteristic signs and symptoms of Marfan syndrome usually do not begin to become apparent until a person is 10 years of age. When they do emerge, they may involve any or all of three parts of the body: the skeleton, the circulatory system (heart and blood vessels), and the eyes.

* **glaucoma** is a group of disorders that cause pressure to build in the eye, which may result in vision loss.

Skeleton A person who has Marfan syndrome usually (but not always) grows to be very tall and thin. The fingers also tend to be long and thin, or “spidery.” The head is sometimes elongated too, and the chest may have a caved-in look. The joints tend to be supple and loose and are prone to becoming dislocated. There may be scoliosis (sko-lee-O-sis), a side-to-side curvature of the spine.

Circulatory system The most serious features of Marfan syndrome involve the heart and aorta, the main artery that carries blood directly from the heart to the body. A characteristic defect in one of the valves of the heart (mitral valve) can cause irregular heart rhythm. Weakness in the aorta can allow it to widen, eventually leading to the development of an aneurysm (AN-yoo-riz-um), a bulge in the wall of a blood vessel. If untreated, the weak spot in the aorta can rupture, causing severe internal hemorrhage and death, without warning.

Eyes A common symptom of Marfan syndrome is myopia (my-O-pee-uh), or nearsightedness. In addition, detachment of the retina or early-onset glaucoma* have been described as complications of Marfan syndrome.

How Is Marfan Syndrome Diagnosed?

Marfan syndrome can be difficult to diagnose. As of 2009, no single laboratory test could identify it. Some people with the condition do not have all of its characteristic signs. Conversely, most people who are tall, lanky, and nearsighted do not have Marfan syndrome. (Again, the disorder is rare.)

Accurate diagnosis is made from a combination of one’s family history and a complete physical examination that focuses on the skeleton, heart and aorta, and the eyes. An echocardiogram (ek-o-KAR-de-o-gram), a picture of the heart produced by using sound waves, can detect abnormalities in the heart and aorta. Eye doctors can look for possible lens dislocations.

The identification of the gene that causes Marfan syndrome and of fibrillin as the component of connective tissue affected by the gene was expected as of 2009 to aid in future diagnosis.

How Is Marfan Syndrome Treated and Prevented?

Treatment and prevention of complications depend upon the individual symptoms of the person affected by the syndrome. Main aspects include annual echocardiograms to watch for enlargement of the aorta and to monitor heart function, and continuing eye examinations to detect lens dislocation. Medications called beta-blockers may be prescribed to lower blood pressure in an attempt to prevent aneurysms from developing in the aorta. If a significant size aneurysm is found on evaluation, or if the aneurysm leaks or ruptures, surgical repair becomes necessary and life-saving. The surgery performed is usually aortic grafting, with or without aortic valve repair. Although this procedure is complicated,

the prognosis is generally good if the surgery is performed on an elective basis before a rupture of the aorta. Braces can be used to correct spinal curvature.

In terms of lifestyle, strenuous sports may have to be avoided to reduce the risk of damage to the aorta. Genetic counseling is advisable for anyone thinking about having children because of the risk that children will inherit the condition. Although there is no cure for Marfan syndrome, working closely with one's doctor in an ongoing monitoring and treatment program can greatly improve the outlook for long life.

Mastoiditis See *Otitis (Ear Infections)*.

Measles (Rubeola)

Measles (ME-zuls) is a viral respiratory system infection that is best known for the rash of large, flat, red blotches that appear on the arms, face, neck, and body.*

What Is Measles?

Measles, also known as rubeola (roo-be-O-luh), is a highly contagious* viral infection caused by the measles virus. Most people are familiar with its most recognized feature: a near full-body rash of red blotches. In fact, measles is primarily an infection of the respiratory system. The disease has been diagnosed throughout the world, and before a vaccine* was available it commonly appeared in the United States in springtime epidemics* every few years. In the United States, one to two deaths occur for every 1,000 cases of measles. In developing countries, the fatality rate can be as

* **respiratory system** or respiratory tract, includes the nose, mouth, throat, and lungs. It is the pathway through which air and gases are transported down into the lungs and back out of the body.

* **contagious** (kon-TAY-jus) means transmittable from one person to another, usually referring to an infection.

* **vaccine** (vak-SEEN) is a preparation of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.

* **epidemics** (eh-pih-DEH-miks) are outbreaks of diseases, especially infectious diseases, in which the number of cases suddenly becomes far greater than usual. Usually, epidemics that involve worldwide outbreaks are called pandemics.

high as one in every four people who contract the disease. Most deaths from measles in the United States are caused by pneumonia*, either from the measles virus itself or from a bacterial infection that arises as a complication of measles.

How Common Is Measles?

Before the introduction of the measles vaccine* in 1963, approximately 500,000 reported cases of measles and 500 deaths occurred in the United States each year. After measles vaccination programs began, though, infection rates dropped by more than 98 percent, and epidemics* all but disappeared. According to the Centers for Disease Control and Prevention, between 1993 and 2001 there were fewer than 500 cases of measles diagnosed in the United States each year (in 2000 there was an all-time low of 86 cases). However, a previous resurgence of measles between 1989 and 1991 led to more than 55,000 diagnosed cases and 123 deaths. This epidemic arose because many children were not being vaccinated.

By contrast, measles in the developing world remained a serious problem in the 1990s and early 2000s. The disease accounted for about 873,000 deaths worldwide in 1991. Because of intensive vaccination efforts, which were begun in 2001 by the Measles Initiative, global deaths by 2005 had fallen 60 percent to 345,000. Limited access to the vaccine was the primary reason that developing countries continued to see large numbers of measles cases. Immigrants to the United States who had not received the vaccine in their native countries accounted for the majority of cases of the disease in the United States. However, the Measles Initiative set its worldwide goal on a 90-percent drop in mortality by 2010.

How Does Measles Spread?

Measles is highly contagious and can spread quickly among people who have not been immunized against it. The measles virus spreads by direct contact with an infected person or by breathing in tiny drops of fluid sent into the air when the person sneezes, coughs, or laughs. A cough or sneeze releases thousands of microscopic particles that contain the virus. These can stay in the air, able to infect people, for up to two hours. In some cases, people have caught measles after entering a room that an infected person had already left. A person with measles is contagious from one to two days before the symptoms begin until four or five days after the rash appears.

What Are the Signs and Symptoms?

After a person has been exposed to the virus, there is an incubation period that averages 10 to 12 days. The first symptoms include fever, runny nose, cough, and reddened eyes that are sensitive to light. Koplik spots, a unique sign of measles, break out one to two days before the rash begins and usually are gone by the time it appears; they are bluish-white dots found

THE SPREAD OF MEASLES

Historically, infectious diseases have affected huge populations. They have toppled kingdoms, swept through countries with devastating results, and altered world economies and religions. Measles traveled around the globe with European adventurers and explorers. The disease killed many inhabitants of the Pacific Islands and the Americas (North America, South America, and Central America). When the Spanish conquistadors Hernán Cortés (1485–1547) and Francisco Pizarro (ca. 1475–1541) arrived in the Americas, they unknowingly carried with them measles and smallpox, which resulted in the death of an estimated one-third of the native populations.

on the inside of the cheeks and other places on the mucous membranes (moist linings) in the mouth.

The measles rash typically begins on the forehead and extends across the face, neck, and body. It generally takes several days for the rash to travel from head to toes. The red blotches often spread out and join, completely covering the skin, especially on the face and shoulders. Once the rash appears, two to four days after the onset of illness, the fever rises and may peak at 104 to 105 degrees Fahrenheit. During this time, the patient looks and feels very ill. Symptoms improve soon after the rash has traveled down to the legs and feet, usually accompanied by a rapid drop in temperature. The rash fades along the same path that it appeared, beginning at the forehead and working its way down. As the rash disappears, the skin may temporarily look brown, dry, and flaky. Other symptoms of measles include loss of appetite, vomiting, and diarrhea (dye-uh-REE-uh), especially in young children. Hemorrhagic (heh-muh-RAH-jik) measles is a rare and serious form of the disease characterized by hemorrhaging (uncontrolled or abnormal bleeding), high fever, seizures* and delirium*.

How Do Doctors Make the Diagnosis?

Measles can be diagnosed by asking a patient about symptoms and performing a physical examination. If there is a question about the diagnosis or if it is necessary to confirm a suspected case of measles, blood tests can determine whether antibodies* to the virus have developed in the body.

What Is the Treatment for Measles?

Because measles is caused by a virus, treatment generally is aimed at keeping the patient comfortable until the infection runs its course. The high fever and sweating that accompany measles raise the risk of dehydration*, so patients should have plenty of rest and fluids. Taking vitamin A may aid recovery in some cases, especially among children with

Measles Redux

Cases of measles infection rose dramatically from 1989 to 1991 in the United States and other countries. Nearly half of the U.S. patients were unvaccinated preschool children living in urban areas. The epidemic began because of a lapse in measles vaccinations and public education. Many people were unaware that measles was still a threat. The general assumption was that years of public vaccinations had controlled the infection; moreover, some individuals were afraid of adverse reactions to the vaccine itself. Emergency vaccinations eventually contained the epidemic, but the outbreak revealed the persistence of a virus that many believed was no longer a cause for concern.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **delirium** (dih-LEER-e-um) is a condition in which a person is confused, is unable to think clearly, and has a reduced level of consciousness.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

- * **intravenous fluids** (in-tra-VEE-nus) are fluids injected directly into a vein.
- * **croup** (KROOP) is an infection involving the trachea (windpipe) and larynx (voice box) that typically occurs in childhood. It causes inflammation and narrowing of the upper airway, sometimes making it difficult to breathe. The characteristic symptom is a barking cough.
- * **subacute sclerosing panencephalitis** (sub-uh-KYOOT skluh-RO-sing pan-en-seh-fuh-LYE-tis), or SSPE, is a chronic brain disease of children and adolescents that occurs months or years after having had measles; it causes convulsions, movement problems, and mental retardation and is usually fatal.
- * **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.
- * **premature labor** is labor (the birth process) that begins too early, before the fetus has developed fully in the womb.
- * **immune globulin** (ih-MYOON GLAH-byoo-lin), also called gamma globulin, is the protein material that contains antibodies.

poor nutrition. Serious cases may require a hospital stay and intravenous fluids*. Antibiotics are given when bacterial infections (such as ear infections or pneumonia) develop as complications of the disease.

What to Expect

Measles generally lasts between 10 and 14 days from the onset of symptoms through the fading of the rash. Ear infections, croup*, and pneumonia sometimes accompany measles. Less commonly, inflammation of the brain (known as encephalitis, en-seh-fuh-LYE-tis) or inflammation of the heart muscle (known as myocarditis, my-oh-kar-DYE-tis) can occur. Subacute sclerosing panencephalitis* (SSPE), a type of encephalitis, is an extremely rare late complication of lasting measles virus infection that can cause gradual loss of brain function. SSPE may occur months, years, or even decades after measles infection, but it is almost never seen in the United States, as a result of widespread use of the measles vaccine. If a pregnant woman contracts measles, the infection can harm her developing baby, leading to miscarriage*, premature labor*, or low birth weight.

How Can Measles Be Prevented?

The best protection against measles is immunization. The vaccine usually is given as part of a combined measles-mumps-rubella (MMR) vaccine that children typically receive twice in their lives. The first round is given when an infant is 12 to 15 months old and the second when the child is ready to start school, at four to five years of age. Children also may receive the second vaccine when they are 11 or 12 years old, if they do not receive it earlier. Because about 5 percent of people do not develop protective antibodies after the first MMR vaccine, the second dose offers better protection against infection. If someone comes into contact with a person who has measles and then is vaccinated within three days of that exposure, the vaccine may prevent or lessen the severity of a case of measles. Immune globulin* can have the same result if it is given within six days of exposure to the virus.

Memory and Amnesia

Memory is the ability to remember and to recall previous sensations, ideas, experiences, or such information as has been consciously learned. Amnesia (am-NE-zhah) is the loss of memory about one or more past experiences that goes beyond normal forgetfulness in a person who has a normal level of consciousness (that is, the person is not asleep or in a coma). Amnesia can be caused by a variety of physical and mental illnesses.*

Brain Structures, Memory, and Amnesia

To understand human memory and how diseases, toxic substances, or physical injuries can interfere with it, it is necessary to have a basic understanding of the structures in the human brain that are involved in memory formation, storage, and retrieval. One important part of the brain is the temporal (TEM-puh-rul) lobes, located toward the lower front of

Research has linked memory to the amygdala and to the hippocampus, two structures deep inside the brain. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

- * **epilepsy** (EP-i-lep-see) is a condition of the nervous system characterized by recurrent seizures that temporarily affect a person's awareness, movements, or sensations. Seizures occur when powerful, rapid bursts of electrical energy interrupt the normal electrical patterns of the brain.
- * **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.
- * **Alzheimer's (ALTS-hy-merz) disease** is a condition that leads to gradually worsening loss of mental abilities, including memory, judgment, and abstract thinking, as well as changes in personality.
- * **encephalitis** (en-seh-fuh-LYE-tis) is an inflammation of the brain, usually caused by a viral infection.
- * **epilepsy** (EP-i-lep-see) is a condition of the nervous system characterized by recurrent seizures that temporarily affect a person's awareness, movements, or sensations. Seizures occur when powerful, rapid bursts of electrical energy interrupt the normal electrical patterns of the brain.
- * **thalamus** (THAL-uh-mus) refers to a pair of large egg-shaped areas located in the middle of the brain just under the cerebral cortex. The plural form is thalami.
- * **cortex** (KOR-tek-s) is the top outer layer of the brain. It controls the brain's higher functions, such as thinking, learning, and personality.

the brain over the ears. In the 1930s, while performing brain surgery on patients with epilepsy*, Canadian neurosurgeon Wilder Graves Penfield (1891–1976) used an electrical probe to stimulate different parts of the brain. Because the brain itself does not feel pain, the patients could remain awake during surgery. Penfield found that some patients reexperienced vivid events or scenes from their lives when he stimulated the temporal lobes. The temporal lobes, however, can be easily damaged by a concussion or more severe head trauma, or by a loss of blood supply to the brain caused by a stroke*.

Inside each temporal lobe is the hippocampus (HIP-po-KAM-pus) (plural, hippocampi), a seahorse-shaped structure that stores short-term memories. It is one of the first portions of the brain destroyed by Alzheimer's (ALTS-hy-merz) disease*; it can also be damaged by encephalitis*, oxygen deprivation, or temporal lobe epilepsy*. When surgeons removed the hippocampi from a patient known by the initials H.M., hoping to treat his epilepsy, they discovered that H.M.'s epilepsy improved, but his short-term memory disappeared. H.M. could remember events that happened many years before, but not events of the previous day or the previous hour. H.M.'s doctors had to reintroduce themselves to him every single day. On his death on December 2, 2008, H.M. was identified as Henry Gustav Molaison.

Another important brain structure is the thalamus*. The thalamus is a structure that lies between the cortex* of the brain and the brain stem*. It relays information from the senses to the cortex and also regulates a person's level of awareness. Damage to the thalamus impairs recent memory and the ability to form new memories.

The formation and recall of memory have an emotional as well as a cognitive* dimension. Experiences that make people feel happiness, sadness, intense fear, or some other strong emotion are more likely to be remembered. The structures in the brain that are most closely involved with processing emotion-laden memories are the hippocampus and the amygdala*, a small almond-shaped structure in the middle portion of the temporal lobe. The amygdala plays an important role in regulating the emotion of fear and of long-term memory consolidation. The amygdala's activity level increases when a person is highly aroused emotionally; memories formed at that time are more likely to be retained than those associated with less exciting situations. The amygdala is activated by traumatic events and by recalling memories of trauma. Certain studies using various brain imaging techniques indicated that high levels of activity in the amygdala are found in patients with psychogenic amnesia.

How Does Human Memory Work?

Human memory is generally divided into two broad categories: short-term and long-term.

Short-term memory Short-term memory is the form of memory that a person uses for such activities as remembering a new phone number after calling directory assistance. The person may repeat the number silently

before dialing it and then promptly forget it. If the person is distracted before dialing and did not write down the number, the person may have to call directory assistance again. That is because short-term memory is fairly easily disrupted. When students must learn new material, they must go over it several times, perhaps even write it out, rather than just see it one time. They are converting the information from unstable short-term memory into more stable long-term memory by paying close attention to it and rehearsing it.

People who experience a severe head injury demonstrate how easily the process of short-term memory can be interrupted. For example, a car accident victim may not recall what happened just before impact or even during the accident itself. Some athletes who are knocked unconscious during an especially rough play may not remember what happened minutes before they were hit. This type of amnesia occurs because there was not enough time for experiences to be converted from short-term to long-term memory.

Long-term memory Long-term memory, which is much more permanent and stable than short-term memory, can be further subdivided into two types: implicit and explicit. Implicit memory, or procedural memory, is the ability to repeat automatic tasks or procedures, such as riding a bike, driving a car, typing, or swinging a tennis racket. Explicit memory, by contrast, refers to recalling specific facts or events. This type of memory is what comes into play when a person takes a history test, for example, or remembers someone's name. Amnesia is more likely to affect explicit memory than procedural memory.

The Many Faces of Amnesia

He is a well-known Australian artist who was diagnosed in 1994 with Wernicke-Korsakoff (VER-ni-kee-KOR-sa-kof) syndrome, a disorder of memory most often caused by alcoholism. Once wealthy from the sales of his art, Charles Blackman (b. 1928) survives on money channeled into a trust fund. His memory comes and goes; when his amnesia returns, he resorts to confabulation* in order to carry on conversations with visitors. It is difficult for them to know how much of what he tells them really happened and how much is confabulated.

She was 16 years old when she collided with another player on the basketball court and hit her head sharply. The next day she felt nauseated, dizzy, and her vision was blurred. Then she had problems remembering what she was supposed to be learning in school; her memory was failing. Tracy had amnesia following a concussion*. She had three years of therapy in order to regain her memory well enough to complete high school.

He is a man in his 40s from Bellingham, Washington, who found himself in Denver, Colorado, in September 2006 with no idea of how he got there or who he is. He appeared on a Denver news show after three weeks in a local hospital asking the public for help in identifying him. His family had filed a missing person report; they were contacted by the Denver police. The man had been on his way to Canada to visit a dying

* **brain stem** is the part of the brain that connects to the spinal cord. The brain stem controls the basic functions of life, such as breathing and blood pressure.

* **cognitive** associated with thinking, learning, perception, awareness, and judgment.

* **amygdala** (a-MIG-da-la) is a small almond-shaped structure in the brain that plays a part in processing emotions.

* **confabulation** filling in gaps in memory by making up or fabricating facts. The gaps occur because the memory function is impaired.

* **concussion** (kon-KUH-shun) is an injury to the brain, produced by a blow to the head or violent shaking.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

friend when his emotional stress triggered a rare form of amnesia known as a fugue (FYOOG) state. According to the man's mother, he does not remember his entire past life, let alone the trip to Denver.

He had served as the thirty-third governor of California and the fortieth president of the United States. Starting about four years after Ronald Reagan left office, however, his family and friends started to notice that his memory was failing. In the fall 1992, Reagan asked one of his personal physicians what he should do next after making a speech. In February 1994 the former president made his last trip to Washington; he failed to recognize one of his long-term Secret Service agents and told his wife when they returned to their hotel room that he was not sure where he was. In November 1994 Reagan told the American public that he had been diagnosed with Alzheimer's disease, the disease that finally killed him in 2004.

He is a middle-aged Englishman living in a mobile home who was found by his friends in a confused and disoriented state in late 2007. He had no memory of what had happened. His doctors performed a range of diagnostic tests that included brain imaging, a muscle biopsy*, and a test of the patient's spinal fluid. The tests did not yield any useful results. Several weeks later, the patient's amnesia suddenly cleared up. His most recent memory was turning on his gas heater for the first time when the weather turned cold. A repairman went to the patient's home and found that the heater had been releasing carbon monoxide into the air. This colorless and odorless but toxic gas was the cause of the patient's amnesia as well as of his physical symptoms.

She is a survivor of the Cocomanut Grove nightclub fire of 1942, the second-worst single-building fire in U.S. history. She has no conscious memory of the disaster. Yet every year on November 28, the anniversary of the tragedy, she suddenly begins to ask those around her how many women they rescued from the fire. Her anniversary reaction is a symptom of dissociative amnesia.

What Is Amnesia?

As these case studies indicate, amnesia is a loss of memory in a person with a normal level of consciousness that can arise from a bewildering variety of conditions or accidents. It is not a disease or disorder in its own right but rather a symptom of an underlying physical or psychological condition. Amnesia may last from a few hours to a lifetime; it may be reversible or permanent; it may improve, stay the same, or get worse over time.

What Are the Different Types of Amnesia?

There are three distinct phases in human memory: registering the event in the brain, storing the information, and retrieving the information that has been stored. Disorders or injuries affecting any of these phases may cause amnesia. Amnesia can be classified in several different ways:

- **According to the time sequence of the events forgotten and the cause of the amnesia.** Anterograde amnesia is the inability to learn

new information. A person with this type of amnesia can accurately recall events in the past that happened before the trauma but has marked difficulty remembering any new information for more than a few minutes. In contrast, retrograde amnesia is the partial or complete loss of memory of events that occurred before the trauma. A person with retrograde amnesia can, however, process, store, and recall new information. It is possible for a person to have both anterograde and retrograde amnesia at the same time.

- **According to the length of time the amnesia lasts.** Amnesia that lasts only for a brief period of time is called transient or temporary amnesia. Amnesia that lasts for a long period of time is called non-transient or chronic amnesia.
- **According to whether the amnesia is total or partial.** Amnesia that includes all the person's memories of his or her past is known as global amnesia. Amnesia that affects only memories processed through a given sense, such as hearing or taste, is called sense-specific amnesia.
- **According to whether the amnesia stays at the same level of severity for long periods of time or gets worse.** Amnesia that gets worse with time, like the amnesia associated with Alzheimer's disease, is called progressive amnesia. Amnesia that does not worsen over time is called fixed amnesia.

What Causes Amnesia?

Amnesia can be caused by a range of physical injuries, drug reactions, toxic substances, seizure disorders, infectious diseases, or emotional traumas. Amnesias resulting from a physical disorder are classified as organic, or body-related, while those resulting from an emotional shock are called psychogenic* amnesias. As a rule, memory loss in organic amnesias is gradual and incomplete rather than sudden or total, which is more likely in psychogenic amnesia.

Organic causes of amnesia Specific organic causes of amnesia include the following:

- Head injuries. The most common causes of head injuries in children are sports and bicycle accidents; among adults, the most common causes are falls and auto accidents.
- Brain tumors.
- Seizures.
- Thiamine deficiency. Thiamine, or vitamin B₁, is necessary for the brain to use glucose (sugar) efficiently. Heavy drinking interferes with the body's ability to supply the brain with thiamine and causes direct damage to the thalamus.
- Infectious diseases. Infectious diseases that cause inflammation of the meninges* or the brain tissue itself can cause amnesia. Diseases

* **psychogenic** (SIGH-ko-JEN-ik) originating in the mind as a result of emotional conflict.

* **meninges** (meh-NIN-jeez) are the membranes that enclose and protect the brain and the spinal cord.

* **Epstein-Barr virus** (EP-stine-BAHR VI-rus) is a common virus that causes infectious mononucleosis.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **syphilis** (SIH-fih-lis) is a sexually transmitted disease that, if untreated, can lead to serious life-long problems throughout the body, including blindness and paralysis.

* **diuretics** (dye-yoor-EH-tiks) are medications that increase the body's output of urine.

* **transient ischemic attack** (TRAN-shent iss-KEE-mik) a temporary loss of blood supply to a particular area of the brain

known to cause amnesia include human herpesvirus-6 infection, dengue fever, Epstein-Barr virus*, AIDS*, late-stage syphilis*, Rocky Mountain spotted fever, and streptococcal toxic shock syndrome. Herpesvirus-6 infection destroys cells in the hippocampus and amygdala as well as causing inflammation.

- Drug abuse or intoxication. Alcoholics sometimes have blackouts, or episodes of amnesia caused by a rapid increase in blood-alcohol concentration. Alcohol specifically impairs the brain's ability to take short-term memories and experiences and transfer them to long-term memory. Illegal drugs that can cause amnesia include cocaine, LSD, PCP, and mescaline. Glue sniffing, or inhaling the solvents used in glue, nail polish, turpentine, spray paint, or similar products in order to get "high," can cause amnesia by direct destruction of brain tissue as well as cutting off the oxygen supply to the brain temporarily.
- Prescription medications. Several prescription drugs, including aminophylline, barbiturates, bromide, digoxin, diuretics*, isoniazid, methyl dopa, and tricyclic antidepressants, have been reported to cause transient amnesia.
- Carbon monoxide poisoning. Carbon monoxide damages the brain by interfering with its oxygen supply.
- Stroke. Stroke interferes with the blood supply to brain tissue. The parts of the brain involved in memory formation and retrieval can begin to suffer damage within minutes after the loss of blood supply.

Transient global amnesia, or TGA, is a form of memory loss that appears suddenly and causes confusion, disorientation, and forgetfulness for 30 minutes to 24 hours. This type of memory loss typically clears up on its own. The causes of TGA are not completely understood as of 2009; however, many doctors think that the disorder is an organic amnesia. Various explanations include an unusual form of migraine headache; a seizure in the temporal lobe of the brain; or a transient ischemic attack* or TIA, sometimes called a mini-stroke, that affects the thalamus or hippocampus.

Functional (psychogenic) amnesia Functional or psychogenic amnesia refers to amnesia triggered by psychological stress rather than a known physical cause. It may be localized (covering only specific events or a period of time in the person's life) or global. It may also be systematized; that is, the person may have amnesia only for certain types of information or for specific people and have normal memory for everything else. The basic mechanism of psychogenic amnesia is dissociation, a process in which the formation of memories is interrupted or altered by extreme fear in response to trauma. Memories of the frightening event or time period remain in the mind but are not accessible to explicit memory. There is evidence from brain imaging studies that the hippocampus is damaged by exposure to high levels of psychological stress and that the amygdala becomes more easily activated after a traumatic experience.

Traumatic memories may, however, reemerge in the form of nightmares or flashbacks* when a sound, sight, or even smell reminds the person of the traumatic event. A group of doctors in Boston caring for Cambodian refugees with post traumatic stress disorder (PTSD) reported in 2004 that 45 out of 100 patients reported flashbacks triggered by odors. Flashbacks and nightmares are generally thought to result from activation of the amygdala.

Specific disorders characterized by psychogenic amnesia include:

- Post-traumatic stress disorder. People diagnosed with PTSD may have amnesia related to the traumatic event, may suffer from flashbacks, and may find it difficult to learn new information.
- Dissociative amnesia. In dissociative amnesia, the patient cannot remember certain specific parts of the past (ranging from hours to years) but has an otherwise normal memory. The gaps in memory (almost always related to trauma) are usually clearly marked off from the portions of the past that the person does remember.
- Dissociative fugue. Dissociative fugue is marked by an amnesia in which individuals cannot recall some or all of their past and either lose their identity or form a new identity. They may travel far away from their home and take up a new occupation. Fugues are usually triggered by severe and long-standing emotional stress and a desire to escape from it.
- Dissociative identity disorder (DID),*. Dissociative identity disorder, or DID, used to be called multiple personality disorder. It is characterized by two or more identities called alters that alternate in directing the patient's outward behavior. The disorder includes inability to recall important personal information relating to some of the alters.

How Common Is Amnesia?

Amnesia is not an unusual symptom by itself, but the frequency of different types of amnesia in the United States varies considerably:

- Alzheimer's disease: 5 million adults.
- Brain tumors: about 44,000 new cases per year.
- Carbon monoxide poisoning: about 5,000 reported cases each year. The actual number may be higher.
- Concussion: 6 cases per 1,000 people per year. Some doctors think this estimate is too low, however.
- Dissociative amnesia: 2 to 7 percent of the general population. It is most likely to develop in survivors of wars or concentration camps; in patients with a history of child abuse or sexual abuse; in victims of torture; and in survivors of natural disasters.
- Dissociative fugue: about 2 adults in every 1,000 per year.
- Dissociative identity disorder: between 30,000 and 300,000 people.

* **flashbacks** are intensely vivid, recurring mental images of a past traumatic event. People may feel or act as if they were reliving the experience.

* **dissociative identity disorder (DID)**, formerly known as multiple personality disorder (MPD), is a severe psychiatric condition in which a person has two or more distinct sub-personalities that periodically take control of his or her behavior. The sub-personalities are thought to be caused by repeated episodes of an extreme form of dissociation.

* **psychotherapy** (sy-ko-THER-a-pea) is the treatment of mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth.

* **spinal tap** also called a lumbar puncture, is a medical procedure in which a needle is used to withdraw a sample of the fluid surrounding the spinal cord and brain. The fluid is then tested, usually to detect signs of infection, such as meningitis, or other diseases.

* **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.

* **encephalitis** (en-seh-fuh-LYE-tis) is an inflammation of the brain, usually caused by a viral infection.

* **electroencephalogram** an instrument that records the electrical activity of the brain.

- Infections of the brain: about 10,000 cases each year.
- Post-traumatic stress disorder: about 7.7 million adults.
- Seizure disorder: about 1 in every 100 persons.
- Stroke: 700,000 cases per year.
- Transient global amnesia: 5.2 cases in every 100,000 people in the general population; 23 cases per 100,000 people over the age of 50.
- Wernicke-Korsakoff syndrome: 1 to 3 percent of adults over 30.

How Do People Know They Have Amnesia?

People may or may not know that they have amnesia. As President Reagan's case indicates, those in the early stages of Alzheimer's disease are often aware that their memory is starting to fail. Many try to cope by writing notes to themselves or asking family members to remind them of appointments or such household chores as paying bills. Patients in the later stages of the disease, however, gradually lose their awareness of their memory loss.

People with dissociative identity disorder often become aware that something is wrong when they find items in their closet that they do not remember purchasing or when a person they do not recognize calls them by an unfamiliar name.

People in a fugue state may not realize that they are suffering from amnesia until they are asked for personal information, then they become aware that they do not know who they are. In some cases, the dissociative fugue clears up by itself with dramatic speed, and individuals are bewildered by finding themselves in an unfamiliar setting.

People with dissociative amnesia may or may not be aware that they have gaps in their memory. Some who are aware that they have periods of "lost time" in their past may recover their memories through psychotherapy*; however, others do not succeed.

People who have blackouts as a result of heavy drinking or glue sniffing usually recognize afterward that they had amnesia for the period of intoxication.

People with some forms of organic amnesia, such as late-stage syphilis or Wernicke-Korsakoff syndrome, are unaware that they have amnesia.

How Do Doctors Diagnose and Treat Amnesia?

Physical examination and laboratory tests The first step in diagnosing amnesia is to obtain a medical history and evaluate the patient for possible physical causes of the amnesia. A physical examination is particularly important if the patient appears to be disoriented, feverish, intoxicated, or severely injured. The doctor will typically order a complete blood count and brain imaging studies to rule out stroke, brain tumors, and a possible concussion. Urine tests may be done if the patient's condition seems to be drug-related. A spinal tap* may be ordered if the doctor suspects meningitis*, encephalitis*, or late-stage syphilis. An electroencephalogram (EEG)* may be done to rule out seizure disorder.

The physical examination of the patient includes neurological tests. These include tests of the patient's level of consciousness, sight, sense of touch, and hearing; and tests of the patient's reflexes, sense of balance, muscle strength, and ability to walk normally.

Interview and mental status examination Patients whose chief symptom is memory loss are interviewed by a psychiatrist so that possible emotional or progressive causes of the patient's amnesia can be evaluated. The psychiatrist gives these individuals a mental status examination, or MSE. The doctor asks questions to determine their level of alertness; ability to think, pay attention, and carry out simple instructions; their ability to speak and their tone of voice; and their emotional condition. Short-term memory is tested by asking the patients to repeat the names of three objects listed by the doctor after a one-minute delay. Long-term memory is tested by asking patients a question about their past, such as "Where were you born?" or "What kind of car did you use when learning to drive?" The MSE is useful in distinguishing between psychogenic amnesia and memory loss caused by Alzheimer's disease or a mood disorder* such as depression.

It is also important for the doctor to distinguish between a patient with genuine psychogenic amnesia and one who is malingering*, or faking their amnesia. There are cases of people faking amnesia caused by AIDS* or PTSD in order to qualify for disability benefits. There are several diagnostic interviews that psychiatrists can use to distinguish real psychogenic amnesia from faking.

Treatment Treatment of amnesia depends on the cause. Amnesia that has an organic cause is treated by identifying and treating or removing the underlying cause. Infectious diseases, Alzheimer's disease, stroke, seizure disorder, Wernicke-Korsakoff syndrome, and substance abuse can be treated, but the amnesia may or may not improve. If it does not, there were no specific treatments for the memory loss as of 2009.

Amnesia caused by prescription medications usually clears up when the drug is discontinued. Transient global amnesia and dissociative fugue often clear up on their own, sometimes within a few hours.

Amnesia related to PTSD, dissociative amnesia, or dissociative identity disorder usually requires psychotherapy, often combined with hypnosis*. Hypnosis can be helpful in healing the trauma that caused the dissociation as well as retrieving some of the patient's dissociated memories. In some cases the doctor may also prescribe tranquilizers or antidepressant medications* to help the patient cope with the emotions stirred up by traumatic memories.

Can Amnesia Be Prevented?

Some of the organic causes of amnesia are at least potentially preventable by attention to safety measures. People can lower their risk of head injuries by wearing protective equipment during sports competition; by

* **mood disorder** is a mental disorder that involves a disturbance in the person's internal emotional state. Depressive disorders, bipolar disorders, and mood disorders are associated with the use of drugs or medical illnesses.

* **malingering** (ma-LING-er-ing) means intentionally pretending to be sick or injured to avoid work or responsibility.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **hypnosis** refers to a trance-like state, usually induced by another person. The person under hypnosis may recall forgotten or suppressed memories and be unusually responsive to suggestions.

* **antidepressant medications** are used for the treatment and prevention of depression.

driving or riding a bicycle safely; and by checking their households for hazards that put the elderly at risk of falls. Installing and maintaining carbon monoxide detectors and having gas-powered appliances checked regularly can reduce the risk of carbon monoxide poisoning.

Other organic causes of amnesia are potentially preventable by lifestyle changes. Eating a healthful diet, keeping one's weight at the right level, exercising regularly, and quitting smoking can lower the risk of stroke. Practicing safe sex can reduce the risk of syphilis, AIDS, and other sexually transmitted diseases. Avoiding heavy drinking, illegal drugs, and glue sniffing lowers the risk of drug-related amnesia and Wernicke-Korsakoff syndrome.

Some organic amnesias could not be prevented as of 2009 because doctors did not yet fully understand the causes of the disorders associated with the memory loss. These disorders included Alzheimer's disease, some types of brain tumors, and seizure disorder.

Psychogenic amnesia was not preventable as of 2009 because doctors did not know why some people react to abuse or other traumatic experiences by dissociating and others do not. It was also not known why some people develop dissociative disorders without a history of trauma.

Meningitis

Meningitis (meh-nin-JY-tis) is an inflammation of the membranes that surround the brain and the spinal cord (the meninges, meh-NIN-jeez). Meningitis is most often caused by infection with a virus or a bacterium.

What Is Meningitis?

Meningitis is an inflammation of the meninges, the membranes that enclose and protect the brain and the spinal cord. It is usually caused by infection, most often from viruses or bacteria. Meningitis caused by bacteria is known

◀ The meninges surround the brain and spinal cord. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

- * **echoviruses** a group of viruses found in the intestinal tract. The word echo in the name is acronym for enteric cytopathic human orphan viruses. When these viruses were named, they were not associated with any disease, hence the use of the word orphan. However, later these viruses were associated with various diseases, including meningitis and encephalitis.
- * **vaccine** (vak-SEEN) is a preparation of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.
- * **pathogens** (PAH-tho-jens) are microorganisms that can cause disease in another living organism.
- * **Lyme disease** (LIME) is a bacterial infection that is spread to humans by the bite of an infected tick. It begins with a distinctive rash and/or flu-like symptoms and, in some cases, can progress to a more serious disease with complications affecting other body organs.
- * **tuberculosis** (too-ber-kyoo-LO-sis) is a bacterial infection that primarily attacks the lungs but can spread to other parts of the body.
- * **syphilis** (SIH-fih-lis) is a sexually transmitted disease that, if untreated, can lead to serious life-long problems throughout the body, including blindness and paralysis.
- * **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV)

as septic meningitis. Meningitis caused by other organisms, including viruses, fungi, and parasites, is called aseptic (a-SEP-tik) meningitis. Viral meningitis is the most common and mildest form of the disease, and most people fully recover from it without complications. Bacterial meningitis, if not diagnosed early, can cause serious and sometimes fatal complications.

Enteroviruses, a group of viruses that includes several strains of coxsackieviruses (kok-SAH-kee-vy-ruh-sez) and echoviruses*, cause about 90 percent of cases of aseptic meningitis. Two types of bacteria that are most likely to cause septic meningitis are *Streptococcus pneumoniae* (strep-tuh-KAH-kus nu-MO-nye) and *Neisseria meningitidis* (nye-SEER-e-uh meh-nin-JIH-tih-dis), also called meningococcus (meh-NIN-guh-kah-kus). Before the introduction of a vaccine* in the 1980s to prevent infection with *Haemophilus influenzae* type b (Hib), the bacterium was a common cause of septic meningitis in young children. Meningitis can be caused by other pathogens* as well, such as some species of parasites and fungi and the bacteria that cause Lyme disease*, tuberculosis*, and syphilis*. Meningitis from these organisms is usually a complication of widespread infection throughout the body and is more likely to be seen in people who have immune problems or other diseases, such as those with AIDS* or cancer. Sometimes, chemical irritations, severe drug allergies, or tumors can lead to inflammation in the central nervous system*, resulting in meningitis.

How Common Is Meningitis?

Bacterial meningitis, especially meningococcal meningitis, sometimes occurs in epidemics* in underdeveloped parts of the world, but epidemics are less common in the United States. Because of vaccinations (vak-sih-NAY-shunz) against some of the bacteria that can cause meningitis, the overall number of cases of septic meningitis steadily declined after 1990. Vaccinated infants and young children are much less likely to contract bacterial meningitis. However, after the late 1990s there was an increase in the number of cases of meningococcus infection seen in young adults, particularly in college students who live in dormitories.

How Does Meningitis Spread?

Some forms of bacterial meningitis are contagious, but these are not easily spread (compared to germs that cause colds and the flu). Bacterial meningitis almost never results from simply being in the same room or building with someone who has meningitis. Only a small fraction of people who come in contact with these bacteria and viruses actually develop meningitis.

Bacteria that can cause meningitis are sometimes found in the throats and noses of healthy people. They are spread through direct contact with respiratory secretions (drops of fluid from the mouth, nose, or lungs), which means they can be passed to someone who kisses an infected person or to someone who touches the secretions from someone who is sneezing or coughing and then touches his or her own nose or mouth. Meningococcus can spread in this way through households, daycare centers, and college dormitories.

Enteroviruses commonly are passed from person to person through contact with respiratory secretions, by breathing in drops from someone who is coughing or sneezing and from contact with an infected person's feces (FEE-seez, or bowel movements).

What Are the Signs and Symptoms of Meningitis?

Symptoms of meningitis often include fever, headache, stiff neck and back, photophobia (painful sensitivity of the eyes to light), abnormal sleepiness, and confusion. Vomiting may also be seen. Infants' symptoms are not as specific as those in older children and adults but usually include irritability, lethargy, poor feeding, crying when moved, and vomiting. Infants may not have neck or back stiffness while ill with meningitis. Meningococcus can cause a reddish-purple rash (from bleeding under the skin) that rapidly spreads over the body. Seizures* can occur in anyone with meningitis, regardless of age.

How Is Meningitis Diagnosed and Treated?

A doctor first asks questions about the illness, does a physical examination, and then performs some tests. The brain is sometimes viewed with a computerized tomography* (CT) scan to rule out other reasons for severe headache and illness, such as an abscess*, tumor, or other problems within the brain. A lumbar puncture (also called a spinal tap) is usually done to take a sample of the cerebrospinal (seh-ree-bro-SPY-nuhl) fluid (CSF), the fluid that surrounds the brain and spinal cord. The CSF is then examined under a microscope in order to identify bacteria or other infectious agents and to calculate increased numbers of white blood cells indicating inflammation.

Antibiotics are not used to treat viral meningitis because it is caused by a virus, not bacteria. Once a case of meningitis is known to be viral, rest and pain medication for body aches and headache can help the person feel better until the infection resolves on its own.

Bacterial meningitis requires prompt medical treatment, usually in the hospital. Antibiotics are given to fight the invading organism for at least two weeks. Treatment of complications may require intensive care and other medications.

Meningitis that results from other types of infection or other causes is treated with medications, such as antifungal* or antiparasitic drugs and may require hospitalization, especially during the early stages of medical care.

Most cases of viral meningitis last one to two weeks, and most people recover completely. Symptoms from bacterial meningitis can last weeks, and people may have severe complications from the disease, especially if it is not diagnosed and treated promptly.

What Complications Can Meningitis Cause?

Complications from viral meningitis are not as common as those from bacterial meningitis, but they can include inflammation and swelling of the brain. Sometimes, permanent learning disability and other brain damage can result.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

* **epidemics** (eh-pih-DEH-miks) are outbreaks of diseases, especially infectious diseases, in which the number of cases suddenly becomes far greater than usual. Usually, epidemics that involve worldwide outbreaks are called pandemics.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **abscess** (AB-ses) is a localized or walled off accumulation of pus caused by infection that can occur anywhere in the body.

* **antifungal drugs** (an-ty-FUNG-al drugs) are medications that kill fungi.

- * **sepsis** is a potentially serious spreading of infection, usually bacterial, through the bloodstream and body.
- * **shock** is a serious condition in which blood pressure is very low and not enough blood flows to the body's organs and tissues. Untreated, shock may result in death.
- * **kidneys** are the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.
- * **chronic** (KRAH-nik) lasting a long time or recurring frequently.
- * **prophylactic** (pro-fih-LAK-tik) refers to something that is used to prevent an illness or other condition, such as an infection or pregnancy.

Complications from bacterial meningitis can occur rapidly and be severe, even with quick diagnosis and treatment of the disease. Complications include sepsis*, brain swelling, seizures, shock*, organ failure (such as of the kidneys*), and death. Up to 15 percent of cases of meningitis caused by meningococcus are fatal. Long-term effects are seen in about 10 percent of those who survive bacterial meningitis and can include hearing loss, seizure disorder, learning disabilities, and other problems resulting from brain injury. Meningitis caused by the bacteria that cause tuberculosis is particularly likely to damage the nervous system.

Can Meningitis Be Prevented?

Vaccinations against *Haemophilus influenzae* type b and *Streptococcus pneumoniae* are given routinely to children in the United States before the age of two years. A vaccine against meningococcus is also available, although it is not regularly used in the United States and is not effective in young children. Young people going off to college, especially those who plan to live in a dormitory, should consider getting the vaccine, as recommended by the Centers for Disease Control and Prevention and the American Academy of Pediatrics. It also is recommended for people traveling outside the United States, people living in certain institutional settings, the elderly, and people with some chronic* medical conditions.

During outbreaks of bacterial meningitis, especially those caused by meningococcus, in schools, dormitories, or daycare, people may be given prophylactic* antibiotics to keep the disease from occurring in those who were in close contact with the infected person.

It is difficult to keep viruses such as enteroviruses from spreading from person to person. Risk of viral infection can be decreased by washing hands regularly, especially after using the toilet, and avoiding close contact with anyone who is ill, including not sharing food, eating or serving utensils, razors, or other personal items.

Menopause

Menopause (MEN-o-pawz) is the time in a woman's life when menstruation (men-stroo-AY-shun or men-STRAY-shun) has permanently stopped and the woman is no longer fertile. Although it is a natural occurrence and is not an illness, menopause and the time surrounding it can cause a number of symptoms, which vary from one woman to the next.

What Is Menopause?

Women go through a number of natural stages in their lives, and menopause is one of them. A woman typically begins her menstrual cycle* by her early teens and continues to have periods for many years afterward. Eventually, when she gets older, her periods become less frequent, and she may begin to skip a month or several months at a time even though she is not pregnant. This time of irregular periods is called perimenopause (PARE-e-men-o-pawz). When a woman has not had a period for an entire year, she has reached menopause. Menopause, therefore, is the permanent end to a woman's menstruation. Once her periods have stopped, she can no longer become pregnant. Sometimes, perimenopause and menopause are together known as “the change of life” or “the change.” After the onset of menopause, the next stage of a woman's life is called postmenopause, which simply means “after menopause.”

Women go through perimenopause and reach menopause at different ages, and they also have different symptoms. Some women have very few symptoms, whereas others may struggle with a number of both physical and emotional issues that can be quite difficult. Treatments exist for many of these symptoms.

What Causes Perimenopause and Menopause?

Perimenopause and menopause are caused by changes in the levels of certain hormones*, known as progesterone (pro-JES-ter-one) and estrogen (ES-tro-jen), or collectively as female sex hormones.

* **menstrual cycle** (MEN-stroo-al SYkul) culminates in menstruation (men-stroo-AY-shun), the discharging through the vagina of blood, secretions, and tissue debris from the uterus that recurs at approximately monthly intervals in females of reproductive age.

* **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

- * **autoimmune disease** (aw-toh-ih-MYOON) is a disease in which the body's immune system attacks some of the body's own normal tissues and cells.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.
- * **chemotherapy** (KEE-mo-THER-ah-pee) is the treatment of cancer with powerful drugs that kill cancer cells.
- * **radiation therapy** is a treatment that uses high-energy radiation from x-rays and other sources to kill cancer cells and shrink cancerous growths.
- * **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.
- * **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.

WHEN DOES MENOPAUSE START?

The age at which women reach menopause varies widely. Usually women who live in developed countries reach menopause when they are between 45 and 55 years old, but some women are a little younger and some are a little older when it happens. Due to the dramatic increase in life expectancy in developed countries, most women can expect to be postmenopausal for half of their adult years. Menopause that occurs between the ages 40 and 45 is called early menopause. Menopause occurring prior to the age of 40 is called premature ovarian failure and is considered abnormal. The causes of premature ovarian failure include autoimmune disease*, thyroid disease, diabetes*, chemotherapy*, and radiation therapy*, but usually, the causes are unknown.

Estrogen is important in helping a girl to begin developing into a woman. As a girl approaches puberty*, her ovaries (O-va-reez), which are small, oval-shaped organs in the reproductive system, begin secreting estrogen. The estrogen causes a number of changes in the girl's body, including the growth of hair in her armpits and in her pubic area and also the gradual development of breasts. Estrogen's role continues once a girl begins menstruating, and its level increases and decreases during each menstrual cycle. In addition, estrogen prepares the woman's body for the fertilization of an egg, which is also produced by the ovaries.

The ovaries also make progesterone, which is important during a woman's child-bearing years. It helps prepare the uterus* so that it is a good environment in which a fertilized egg can develop into a fetus and eventually into a baby.

The ovaries continue to make estrogen and progesterone for many years after a girl first starts to menstruate. During this time, a woman begins to use up her supply of eggs. Once a woman reaches a certain age, and this age can vary from woman to woman, her egg supply becomes low, the ovaries start to shrink, the levels of hormones begin to fluctuate, and she enters perimenopause. The ups and downs of the hormone levels cause menstrual periods to become irregular. In some women, periods can become more frequent or even heavier, but in others, periods can come less often and may be lighter. Eventually, the ovaries start making less and less estrogen, until they make so little that a woman no longer has periods at all and cannot become pregnant anymore. Once a year has passed without a period, a woman has reached menopause and begins postmenopause. Within about a year, estrogen levels reach a certain low point and remain there, and progesterone levels drop to nearly zero.

Besides this natural progression during a woman's life, a female who has her ovaries surgically removed starts menopause immediately, even if she is very young.

What Are the Symptoms of Perimenopause and Menopause?

The symptoms of perimenopause and menopause vary among women. Some women may have almost no symptoms, whereas others may have severe symptoms. Symptoms may include none, one, or a combination of the following:

- Hot flashes, in which a woman suddenly feels flush for no reason, and night sweats, in which she begins sweating heavily
- Sudden irritability, changes in mood, or crying
- Loss or thinning of hair on the head and most of the body, but an increase in facial hair
- Extreme tiredness
- Either more headaches or fewer headaches than normal
- Rapid, irregular heartbeat, such as a fast flutter
- Difficulty staying focused and remembering
- Becoming confused
- Incontinence*, especially urinating when sneezing, coughing, or laughing
- Muscle tension
- Breast tenderness
- Drying and thinning of the skin
- Itchiness in different areas of the body
- Depression
- Lightheadedness, even dizziness
- Weight gain, particularly around the waist
- Dryness in the vagina
- Increased anxiety
- Indigestion, increased gas, and sometimes nausea
- Insomnia*
- Change in the desire for or interest in sex

Usually, a woman stops having most symptoms about a year after menopause. In some women, however, symptoms may continue, sometimes for many years. Medical professionals believe this may result from a woman having especially low estrogen levels.

All women should be alert to several health concerns that are associated with postmenopause and related to a lower estrogen level. These may include increased bone loss, which can lead to osteoporosis*, a serious health condition that can result in broken bones; osteopenia, low bone mineral density that is often considered a precursor to osteoporosis; heightened risk of tooth loss and gum disease*; and an increased risk for heart disease*. In addition, postmenopausal women may notice that they have more wrinkles, thinner and drier skin, and increased infections of the urinary tract and the vagina.

* **incontinence** (in-KON-ti-nens) is loss of control of urination or bowel movement.

* **insomnia** abnormal inability to get adequate sleep.

* **osteoporosis** os-te-o-por-O-sis) is the loss of material from the bone. This makes the bones weak and brittle.

* **gum disease** is an infection caused by bacteria that affect the tissues surrounding and supporting the teeth.

* **heart disease** is a broad term that covers many conditions that prevent the heart from working properly to pump blood throughout the body.

How Is Menopause Treated?

For most women, perimenopausal or menopausal symptoms eventually disappear on their own. Medical professionals encourage women to eat a healthy diet and exercise regularly to help them through their “change of life.” Women who want assistance in coping with their symptoms should see their physicians to select treatments that are right for them.

A common treatment in the late 20th century was hormone replacement therapy, which was usually a combination of estrogen and a synthetic (man-made) version of progesterone called progestin. Doctors sometimes prescribed hormone therapy to treat particularly troublesome hot flashes or vaginal dryness. Studies indicated that hormone therapy could prevent postmenopausal bone loss and, therefore, reduce hip fractures that occur due to osteoporosis; could lower the risk of colorectal cancer; and might also reduce the chance that a woman would experience heart disease. In addition, hormone therapy might help a woman sleep better and reduce her mood swings. However, hormone therapy was shown to have certain risks, according to a 2002 Women’s Health Initiative study. The study found a small but significant increased risk of breast cancer, heart attacks or stroke, blood clots, and gall bladder disease in women taking hormone replacement therapy. These findings led to a significant drop in usage of hormone replacement therapy in the early 2000s.

In addition, a study of women who took estrogen-progestin hormone therapy or took estrogen alone found that they had a higher incidence of abnormal mammograms (MAM-o-gramz), which are special types of x-rays used to look for possible evidence of breast cancer. The abnormal mammograms reported “false positives,” which means that they found signs of cancer although the women did not have the disease. The false positives may have resulted from estrogen in hormone therapy making the breast tissue more dense, which made it look like cancer even though none was present.

Hormone therapy may also cause a number of side effects, such as nausea, headaches, breast tenderness, and vaginal bleeding. A woman’s doctor will typically prescribe the lowest possible dose of hormone therapy to get the desired results and prescribe it only for a short time. The doctor will typically also schedule a follow-up appointment when that period of time is almost over to determine whether to continue hormone therapy. Hormone therapy comes in a number of different forms, including pills, skin patches, vaginal creams, and others.

For women who have reached menopause because they have had their ovaries removed in surgery, doctors sometimes prescribe hormone therapy with just estrogen. For other women, however, doctors typically recommend estrogen combined with progestin because estrogen alone can increase the risk of uterine cancer.

Many women try to treat their symptoms on their own. The following are home treatments for some menopausal symptoms:

- For hot flashes, some women find success by avoiding hot or spicy foods and alcoholic or caffeinated beverages; by engaging in regular exercise and by running a fan or by removing some layers of clothing.
- For insomnia, women may find that regular exercise sessions of 30 minutes everyday can help with certain symptoms. In addition, they may avoid daytime naps; drink a non-caffeinated, warm beverage before bed; and keep a regular sleep schedule by going to bed and getting up at the same time every day.
- For mood swings and memory problems, women often do well by getting enough sleep and remaining physically active.

Natural, or “alternative,” treatments for the symptoms of perimenopause and menopause are increasingly common. One of the most popular is soy, a plant that contains phytoestrogen, which is a plant chemical similar to estrogen. Soy comes in many forms, including soy beans (also called edamame), tofu, and soy milk (which is soy flour mixed with water). Soy is also available as a supplement in pill and powder form. Other commonly used alternative therapies for perimenopausal and menopausal symptoms are:

- Black cohosh (*Actaea racemosa* or *Cimicifuga racemosa*), an herb that is sometimes used to treat hot flashes. Studies of this herb have not conclusively shown that it has an effect on hot flashes.
- Ginseng (*Panax ginseng* or *Panax quinquefolius*), which may help with mood swings and sleeping problems.
- Dong quai (*Angelica sinensis*), which is used to treat hot flashes. Women who take the drug warfarin should not take dong quai, as this combination can lead to bleeding problems.

Medical professionals highly recommend that women who are considering alternative therapy consult with their doctors before trying them. Doctors can tell their patients whether the therapy will have any interaction with any other drugs they are taking and can also discuss possible safety issues.

Menstruation and Menstrual Disorders

Menstruation (men-stroo-AY-shun) is the discharge of the blood-enriched lining of the uterus. Menstruation normally occurs in females who are physically mature enough to bear children. Most girls have their first period between the age of 9 and 16. Menstruation ceases during pregnancy and with the onset of menopause. Because it usually occurs at about four-week intervals, it is often called the monthly period.

Anatomy of the female reproductive system, including an unfertilized egg (ovum) in one of the fallopian tubes. Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning

Menstrual (MEN-stroo-al) disorders result in abnormal menstrual periods. Usually, these disorders occur when the hormones* that control menstruation (men-stroo-AY-shun or men-STRAY-shun) are out of balance. In some cases, however, another medical problem is the cause. Menstrual disorders include pain during periods; changes in the length of the menstrual cycle; and heavy, prolonged, or too-frequent periods.

Kim's Story

Kim plays soccer in the fall, plays basketball in the winter, and does gymnastics in the spring and summer. Her friends call her the “lean, mean, fighting machine,” because she is almost all muscle and no fat. Kim is proud of her athletic ability, but she feels self-conscious because she has not developed as quickly as other girls her age. She has noticed some changes in her body, such as breast buds (puffing up of the nipples and the tissue surrounding them), pubic and armpit (axillary) hair, and a little bit of a rounding of her hips, but other girls have more noticeable curves. In addition, even though she just turned 16, she still has not gotten her period. All of her friends got theirs a few years ago. Kim is embarrassed and a little bit scared, because her mother made Kim an appointment with a gynecologist* to find out why Kim has not had her period.

The doctor examined Kim and asked her a number of family history and health questions, including questions about sports and how long she has been playing. The doctor told Kim that she probably had nothing to worry about; some girls just get their period later than others. Just to be sure, the doctor ordered some blood tests that would show if Kim had a medical condition affecting her menstrual cycle. The tests showed she was indeed fine, and three months later Kim got her first period.

* **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

* **gynecologist** (gy-ne-KOL-o-jist) is a doctor who specializes in the reproductive system of women.

▲ The 28-day menstrual cycle, showing changes in the thickness of the endometrial lining. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

What Are the Menstrual Cycle and Menstruation?

The menstrual cycle is a normal part of being a healthy female of reproductive age. About once per month in this cycle, the female's reproductive system yields an egg that is ready to be fertilized, as well as the environment in which the fertilized egg can develop. This environment is the blood-rich lining of the uterus* (YOO-ter-us). If the egg is not fertilized, menstruation, also called menses (MEN-seez), occurs. During menstruation, the uterine lining sheds, resulting in blood and tissue being expelled from the body.

The female reproductive system, located in the abdomen*, consists of two ovaries (O-va-reez), two fallopian (fa-LO-pe-an) tubes, and the uterus, cervix (SER-viks), and vagina (va-JY-na). The almond-sized ovaries contain the female reproductive cells, or eggs. A girl is actually born with all the eggs she will need in her whole lifetime, but they are not mature (ready to be fertilized) until a few weeks before she has her first period. A delicate interaction of hormones controls the menstrual cycle. It starts when a gland in the brain, the hypothalamus, releases a hormone called gonadotropin-releasing hormone, which triggers another gland in the brain, the pituitary, to start releasing two other hormones: follicle-stimulating hormone and a small amount of luteinizing hormone. These stimulate the follicles, which are sacs around the eggs, to start to mature. The follicles then secrete the hormone, estrogen, that tells the uterine lining to thicken and soon also stimulates the pituitary to release even more luteinizing hormone. The flood of luteinizing hormone prompts a follicle to release an egg. The release of the egg is called ovulation (ov-yoo-LAY-shun).

Eggs move through the fallopian tubes to the uterus, which provides the environment in which a fertilized egg can grow and develop into a fetus. If the egg is not fertilized, the lining of the uterus sheds, and blood and tissue fragments exit the uterus through its opening, the cervix, and travel through the vagina to the outside of the body.

The hormonal interaction in a typical menstrual cycle The following are the major events in a typical menstrual cycle.

- Day 0 to 5: At the very beginning of the cycle, the levels of the hormones estrogen (ES-tro-jen) and progesterone (pro-JES-te-rone) in the body are low. Menstruation begins, and blood and tissue are

expelled from the uterus. The ovaries start making more estrogen, and the lining of uterus, called the endometrium (en-do-ME-tree-um), begins to thicken. Meanwhile, an egg in one of the ovaries begins to mature in a small sac of tissue.

- Day 14: The egg leaves the ovary (which is called ovulation [ov-yoo-LAY-shun]) and travels through the fallopian tube to the uterus. Three hormones control ovulation: gonadotropin (gon-a-do-TRO-pin)-releasing hormone (GnRH), follicle (FOL-i-kul)-stimulating hormone (FSH), and luteinizing (LOO-tee-in-eye-zing) hormone (LH). The empty sac in the ovary that once held the egg is now called the corpus luteum (KOR-pus LOO-te-um), and it makes the hormone progesterone. The combination of estrogen made by the ovaries and progesterone cause the endometrium to continue growing thicker. A woman can get pregnant just before, during, or right after ovulation. If the egg is fertilized, the thickened endometrium is ready to nourish the developing embryo*.
- Day 17 to 27: If the egg is not fertilized, hormone levels decrease.
- Day 28: The endometrium begins to break down, and menstruation begins. Cells in the uterine lining produce the hormone prostaglandin (pros-ta-GLAN-din), which causes blood vessels to narrow, slows the supply of oxygen to the uterus, and causes the muscles of the uterus to contract. This process helps to expel the blood and tissue of the uterine lining.

What Is Normal?

In a woman who is not pregnant, the menstrual cycle—calculated from the first day of one period to the first day of the next—occurs approximately every 28 days. However, the length of the cycle can vary from 21 to 35 days in normal, healthy girls and women. Usually, bleeding lasts for several days, which is the basis for the term menstrual “period.” A woman wears a pad in her panties or a tampon inserted into the vagina to absorb the blood, which typically amounts to two to eight tablespoons during an entire monthly period. Normally, menstrual blood does not clot. Women who experience clotting should mention it to their doctor.

The first time a young girl gets her period is called menarche (MEN-ar-kee). Some girls find menarche scary thing; others are eager to experience it. In the United States, the average age when menarche occurs is about 12-and-a-half years of age, but some girls start menstruating at 10 or younger and others at 16 or older. After menarche, a woman usually will get her period for 30 to 40 years, until she goes through menopause*.

A huge variation exists among women in the length and duration of the menstrual cycle and in whether they bleed a lot or a little. Some women have a period every 23 days, others every 35. Some periods last three days, whereas others last seven. And some women use three

* **embryo** (EM-bree-o), in humans, is the developing organism from the end of the second week after fertilization to the end of the eighth week.

* **menopause** (MEN-o-pawz) is the end of menstruation.

* **tumors** (TOO-morz) usually refer to abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.

* **anorexia nervosa** (an-o-REK-se-a ner-VO-sa) is an emotional disorder characterized by dread of gaining weight, leading to self-starvation and dangerous loss of weight and malnutrition.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **eating disorder** is a condition in which a person's eating behaviors and food habits are so unbalanced that they cause physical and emotional problems..

tampons or pads per day, whereas others need several more. Because of this wide range, determining if a woman has a menstrual disorder can be difficult. It requires that a woman knows her own body and what is normal for her.

What Are Menstrual Disorders?

Menstrual disorders occur when something goes wrong with the normal monthly menstrual cycle. Disorders come in many types. Usually, they occur when the hormones controlling menstruation are out of balance for some reason. Underlying medical conditions, however, can cause menstrual disorders. A woman who experiences changes in her menstrual cycle—especially if these changes include heavy bleeding or cause problems with daily living—should see her doctor right away.

Disorders in menstrual cycle length Amenorrhea (a-men-o-REE-a) means “no menstrual periods.” Primary amenorrhea means not having a first period by the time a girl is 16 years old. Secondary amenorrhea occurs when a woman or girl stops getting her monthly period.

A related problem is oligomenorrhea (OL-i-go-men-o-REE-a), which occurs when menstrual periods are more than 35 days apart. Once doctors diagnose problems with menstrual cycle length, they then try to find out what is causing it.

Kim's story provides an example of primary amenorrhea. This condition may be caused by a hormonal imbalance or a developmental problem. Young female athletes often experience primary or secondary amenorrhea or both. Strenuous exercise seems to lower estrogen levels, thus causing periods to stop.

Shelly, a 25-year-old woman who usually gets her periods like clockwork, stopped having her period for three months. Her doctor first ordered a pregnancy test. It was a surprise to Shelly and her husband to learn she was pregnant. Pregnancy is the most common cause of amenorrhea in women in their reproductive years. A little while after the baby was born, Shelly resumed her regular menstrual cycle.

When Anne turned 48, the amount of time between her periods started getting longer and longer. When she did not get her period for four months, she went to see her doctor. The doctor examined Anne and did some tests. Anne learned that her amenorrhea was caused by approaching menopause, the natural time in a woman's life when she no longer has periods and cannot become pregnant anymore.

Medical problems, such as cysts (fluid-filled sacs) in the ovaries, abnormal growths or tumors* in the reproductive organs, anorexia nervosa*, and diabetes*, can also cause amenorrhea or oligomenorrhea.

Altered hormone levels can cause anovulation (an-ov-yoo-LAY-shun), which occurs ovulation does not take place, which in turn often causes amenorrhea. Hormones are affected when a woman exercises too much, loses or gains a lot of weight, is stressed, is breast-feeding a baby, or has an eating disorder*. All these situations can lead to amenorrhea.

Bleeding disorders Sometimes women have menstrual disorders in which they bleed too much, too often, or for too long. For example, Sally has menorrhagia (men-o-RA-jah), which means very heavy periods, and the bleeding goes on for almost 12 days. Sally will not even go to work on the first day of her period; she goes through a tampon and a pad every hour for the first five hours, and every month she ends up with bloodstains on her pants. Barb, by contrast, gets her period every 19 days, which is far too often for her liking; this condition is called polymenorrhea (pol-ee-men-o-REE-a). These conditions are classified as abnormal uterine bleeding, or AUB. AUB also includes bleeding, or spotting, between periods and bleeding after menopause.

In 80 percent of women with menorrhagia, the cause is either a hormone imbalance or the presence of fibroids (FY-broidz), which are abnormal growths in the uterus. Other causes of menorrhagia include the following:

- Endometrial (en-do-ME-tree-al) cancer
- Infections of the vagina or cervix
- Small growths on the cervix or uterine wall (polyps)
- Thyroid* conditions
- Diseases of the liver*, kidney*, or bloodstream.

Dysfunctional uterine bleeding (DUB) is another name for menorrhagia and other bleeding disorders that are caused by hormonal imbalances. Often, DUB occurs because of anovulation or when estrogen and progesterone are out of balance. Without proper hormonal cues, normal monthly shedding of the uterine lining does not occur, and the endometrium continues building up. The abnormally thick endometrium eventually starts to break down, and results in heavy and prolonged bleeding. DUB is common in teenagers, whose hormones have not yet been fine-tuned and who often do not ovulate regularly. Anovulation is also common in women about to go through menopause.

Painful periods Linda's school attendance was affected by her menstrual periods. Four months in a row, Linda went home sick from school each time she started her period. Linda was not faking it; she went home to bed with a backache and severe cramps, only getting up when she thought she might have to vomit.

Linda suffers from dysmenorrhea (dis-men-o-REE-a), or painful periods. Almost every woman has this condition at some time in her life. The symptoms of dysmenorrhea range from mild, uncomfortable cramps to abdominal pain, a sore back, nausea, and vomiting. Linda has primary dysmenorrhea, which means painful periods with no underlying medical disease. This type of dysmenorrhea is very common, especially among teenagers. The symptoms result from the hormone prostaglandin, which is released by the cells that are being shed from the uterus.

Secondary dysmenorrhea is caused by medical conditions such as polyps*, fibroids, and narrowing of the cervix. One common cause is endometriosis

* **thyroid gland** (THY-roid GLAND) is located in the lower part of the front of the neck. The thyroid produces hormones that regulate the body's metabolism (me-TAB-o-LIZ-um), the processes the body uses to produce energy, to grow, and to maintain body tissues

* **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.

* **kidney** is one of the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.

* **polyps** (PAH-lips) are bumps or growths usually on the lining or surface of a body part (such as the nose or intestine). Their size can range from tiny to large enough to cause pain or obstruction. They may be harmless, but they also may be cancerous.

Can a Girl or Woman Exercise Too Much?

How much estrogen a woman's body produces appears to be linked to her level of body fat. Gymnasts, ballerinas, and other athletes who regularly take part in strenuous exercise typically do not have much body fat and do not make much estrogen. If their hormone production is low enough, they might not get their first period until they are 16 or 17. Other young athletes who have normal periods for a while may develop amenorrhea when they resume strenuous exercise.

Because bone mass is linked to the level of estrogen in the body, some scientists suggest that even a few years of amenorrhea, especially during a girl's teens, can have lasting effects on bone formation or contribute to excessive bone loss. Young athletes should see their doctor if they experience a menstrual disorder. Diet and hormone therapy may fix the immediate problem and have a positive effect long into the future.

To ensure good bone health in general, doctors may recommend the following: exercising daily; maintaining a healthy, not-too-thin weight; getting enough calcium and vitamin D every day; managing stress, because stress can actually cause bone loss; staying away from cigarettes; and cutting back or eliminating caffeine from the diet. For girls with menstrual disorders, a doctor may also prescribe progesterone supplements. This hormone stimulates cells, called osteoblasts, to build new bone.

* **antidepressant medications** are used for the treatment and prevention of depression.

(en-do-me-tree-O-sis). Endometriosis is a condition in which uterine tissue grows outside the uterus, and it affects both young and older women. Even though fragments of endometrial tissue, also called implants, are not in the uterus, they still respond to hormones just as the normal endometrial tissue does. Therefore, in response to estrogen and progesterone, the implants grow, break down, and bleed. Because the blood has no opening that would allow it to leave the body, the blood causes irritation, which can be very painful. Sometimes, the implants keep growing and form scar tissue, or they act as an adhesive and stick organs together. Endometriosis can prevent a woman from getting pregnant, because implants may block the fallopian tubes or prevent the eggs from leaving the ovary. Endometriosis is found in 10 to 15 percent of 25- to 33-year-old women who are actively menstruating.

Infection of the endometrium causes another type of pain that accompanies menstrual periods. This pain, seen in pelvic inflammatory disease (PID), needs rapid diagnosis and medical treatment.

Premenstrual syndrome Every month, Stacy can tell her period is a week away by three signs: her skin breaks out, her lower back begins to ache, and her breasts feel sore. Her friend Sonya experiences a different set of symptoms: She feels bloated, is incredibly tired, has bad headaches, and feels depressed and grumpy.

Stacy and Sonya have premenstrual syndrome, or PMS, which is a set of symptoms that includes both physical and emotional symptoms. Most women with PMS have particular symptoms that occur each month at the same time. Fortunately, the symptoms disappear when the period begins.

No one knows for sure what causes PMS, but most scientists agree that it is linked to hormones. PMS symptoms appear during the second half of the menstrual cycle, after ovulation has taken place and when progesterone levels are highest. Health professionals may recommend one or more of the following to treat the symptoms of PMS:

- Regular exercise
- A daily supplement of calcium, vitamin B6, and or vitamin E
- The herbal supplement, evening primrose, for breast tenderness
- A reduction in the amount of symptom-related substances, such as caffeine, salt, and sugar in the diet
- Over-the-counter medications for cramps, headache, and other symptoms
- Prescribed medications, such as antidepressants*, or spironolactone, danazol, and bromocriptine for breast tenderness

At one time, doctors frequently prescribed birth-control pills to treat PMS. Studies showed, however, that they were not widely effective. In addition, the estrogen in birth-control pills can increase the risk of uterine cancer if it is not combined with another hormone, progestin, and studies have shown that progestin alone does not treat PMS symptoms.

Treatment for Menstrual Disorders

To determine if a woman has a menstrual disorder, doctors take a medical history and ask questions about her menstrual cycle. Doctors need to know what has changed from past normal periods. A pelvic exam may also be necessary. During this exam, doctors examine the reproductive organs by feeling and pushing on the uterus through the abdomen and by feeling the vagina, cervix, uterus, fallopian tubes, and ovaries through the vaginal opening. This procedure is slightly uncomfortable but not painful, and it takes only 5 to 10 minutes. The doctor may also order blood tests to measure the levels of hormones in the body. In rare cases, a doctor uses other techniques to find out what is happening in a woman's body. These include ultrasonography (ul-tra-so-NOG-ra-fee), a procedure in which sound waves produce images of organs inside the body, and hysteroscopy (his-ter-OS-ko-pee) or laparoscopy*, where instruments are inserted into the body through a small incision to take a direct look at the internal organs.

For all menstrual disorders, treatment depends on the underlying cause. Therefore, a woman should see a doctor if her menstrual cycle seems abnormal.

Hormonal imbalance When a hormonal imbalance is the cause of a menstrual disorder, hormone therapy often helps menstrual cycles return to normal. Hormone therapy includes taking birth control pills, mixtures of estrogen and progesterone, or just progesterone.

Dysmenorrhea and PMS Products such as ibuprofen* and naproxen (na-PROKS-en) suppress prostaglandin and are helpful in treating dysmenorrhea. Over-the-counter products to relieve menstrual cramps and bloating help some women with PMS. Birth-control pills also reduce painful periods in some women, as does exercise.

Endometriosis and other conditions For some women with endometriosis, the doctor may prescribe medicines to relieve symptoms. Women with severe endometriosis may need surgery to remove implants.

Methods of eliminating severe menstrual disorders include destroying the endometrial tissue in the uterus or removing the uterus (and sometimes also the ovaries) in a procedure known as hysterectomy (his-ter-EK-to-mee). This treatment is better for older women who are past childbearing years. This is not a treatment for younger women who want to have children.

For medical conditions, such as fibroids, polyps, or cancer, a woman may need surgery and other treatments to correct the problem.

Literal Meanings of Menstrual Terms

Many words used to describe menstruation and menstrual disorders come from Latin and Greek. The following are a few:

- Menses comes from the Latin word “mensis,” which means month. “Mensis” also derives from the Greek word “mene” for moon; the Moon travels around the Sun once every nearly 28 days, about the length of a month.
- Menarche, a girl's first period, comes from “mensis” and “archaios,” meaning “from the beginning.”
- Menopause, or the end of monthly periods, comes from “mensis” and “pauses,” meaning “to cease.”
- Menorrhagia means “heavy or prolonged bleeding” and is derived from “mensis” and “rhegynein,” meaning “to burst forth.”
- Menorrhea comes from “mensis” and “rhoia,” meaning “to flow” and refers to the “normal flow” of blood and tissue from the uterus during a menstrual period, also called menses and menstruation.
- The prefix “a-” means “not” and amenorrhea is the “cessation of menses.” The prefix “dys-” means “bad or painful,” and dysmenorrhea means “painful periods.” The prefix “oligo-” means “little or few,” and oligomenorrhea means having “infrequent periods.” The prefix “poly-” means “many,” and polymenorrhea means “periods that come too frequently.”

- * **laparoscopy** (lap-uh-ROS-kuh-pee) a type of surgery in which a small fiberoptic instrument is inserted through a very small incision to examine the inside of the abdomen or remove small amounts of tissue. It is also called minimally invasive surgery.
- * **ibuprofen** (eye-bew-PRO-fin) is a nonsteroidal anti-inflammatory drug (NISAD) used to reduce fever and relieve pain or inflammation
- * **nervous system** is a network of specialized tissue made of nerve cells, or neurons, that processes messages to and from different parts of the human body.
- * **convulsions** (kon-VUL-shuns), also called seizures, are involuntary muscle contractions caused by electrical discharges within the brain and are usually accompanied by changes in consciousness.

Mental Retardation See *Intellectual Disability*.

Mercury Poisoning

Mercury poisoning damages the nervous system and is caused by exposure to mercury. Mercury is a metal in the form of a silvery liquid at room temperature, but it can also turn into a vapor. It forms chemical compounds known as salts that are used in industry and can form compounds in the ocean that can enter the human body through the consumption of saltwater fish.*

The Cat Dancing Disease

In the early 1950s, people living in the town of Minamata in southern Japan began to notice that the local cats were acting strangely. They would stand on their hind legs, run around aimlessly, go into convulsions*, and

die. The townspeople called this mysterious illness the “cat dancing disease.” They also noticed that there were dead fish floating on the sea and dead crows along the edge of the ocean. In April 1956 the illness spread to humans; eleven people in the town were treated by doctors for convulsions and difficulty in walking and talking. The doctors thought at first that the patients were suffering from a contagious disease that affected the central nervous system*. By October 1956, 40 people in Minamata had been diagnosed with the illness and 14 had died.

Researchers from a nearby university were called in to solve the puzzle. They found that the patients all came from fishermen’s families living along the bay and that all ate fish and shellfish on a daily basis. Their cats were fed the leftover fish. The researchers then suspected a kind of food poisoning caused by a heavy metal. In 1959 mercury was identified as the metal in question, and its source was identified as a chemical factory in Minamata that had been releasing mercury into the bay in its waste water. The fish and shellfish absorbed the mercury and concentrated it in their bodies. Larger and larger amounts of mercury built up in the local food chain*. When the mercury in the fish and shellfish increased to a high level, humans and their pets began to suffer from mercury poisoning.

By 2001, 2,265 patients had been identified as suffering from Minamata disease; 1,784 had already died. The chemical factory was forced to give the victims a financial compensation as well as change its manufacturing methods.

What Is Mercury Poisoning?

Mercury poisoning is a potentially fatal condition of the nervous system, lungs, kidneys, and other organs caused by exposure to liquid mercury, mercury vapor, mercury salts, or organic mercury (mercury combined with carbon). Some mercury enters the environment naturally from volcanoes and the breakdown of certain rocks in the earth’s crust; coal-burning power plants, explosives, and other human industrial processes also release mercury into the air. The mercury in the atmosphere enters the food chain when it falls back to earth and is absorbed by tiny organisms in the ocean that provide food for fish and shellfish.

People can be exposed to mercury by touching liquid mercury from a broken thermometer or fluorescent light bulb; breathing the vapors that liquid mercury releases at room temperature; accidentally swallowing small disk batteries or other substances that contain mercury compounds; or eating large amounts of fish with organic mercury in their tissues. Mercury can also affect the fetus* of pregnant women who ingest it; their fetus can die before birth or the baby can be born with serious birth defects.

How Common Is Mercury Poisoning?

Mercury poisoning was more common several centuries ago than it is in the early 2000s because it was used in making felt and some other industries. The phrase “mad as a hatter” came about because the people who made felt hats were exposed to mercury during the manufacturing process

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

* **food chain** the eating relationships between different organisms in a specific environment.

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

* **syphilis** (SIH-fih-lis) is a sexually transmitted disease that, if untreated, can lead to serious life-long problems throughout the body, including blindness and paralysis.

* **latex** (LAY-tex) is a substance made from a rubber tree and is used in such things as medical equipment (especially gloves), toys, and other household products.

* **placenta** (pluh-SEN-ta) is an organ that provides nutrients and oxygen to a developing baby; it is located within the womb during pregnancy.

* **miscarriage** (MIS-kare-ij) is the end of a pregnancy through the death of the embryo or fetus before birth.

* **mental retardation** is a condition in which people have below average intelligence that limits their ability to function normally.

and eventually suffered brain damage. Mercury was also used to make cosmetics and to treat syphilis*, a sexually transmitted disease. It was even used in laxatives. After mercury was found to cause brain damage and even death, people began to find replacements for it in manufacturing, cosmetics, and medical treatments.

Mercury poisoning is relatively uncommon in the United States in the early 21st century. The American Association of Poison Control Centers reported 3,362 cases of exposure to mercury in 2003; 569 were in children younger than six years of age. Of these patients, 44 had moderate effects, 6 had severe effects, but no one died. Fatal cases of mercury poisoning in the 1990s were accidents. In 1997 a professor of chemistry at Dartmouth College died seven months after spilling a mercury compound on her latex* glove. At that time it was not known that this particular form of mercury could seep through latex to reach the skin. In March 2008 a man in Oklahoma died of mercury poisoning after trying to use mercury to extract gold from computer parts.

Is Mercury Poisoning Contagious?

Mercury poisoning can be transmitted from a pregnant woman to her fetus because organic mercury from eating fish can cross the placenta and affect fetal growth. In many cases the woman has a miscarriage* or the baby is born with mental retardation*.

As the case of the Minamata tragedy indicates, mercury poisoning can affect groups of people as well as individuals, and it can be mistaken at first for an outbreak of a contagious disease. Mercury poisoning, however, is not spread from person to person in the way that bacterial or viral diseases are.

How Do People Know They Have Mercury Poisoning?

The symptoms of mercury poisoning vary somewhat depending on the form of mercury to which the person was exposed. Liquid mercury is not easily absorbed through the skin but can damage the lungs and travel to the central nervous system when a person breathes its vapors. The compounds of mercury that are found in batteries can be taken into the body through the skin or through accidental eating. They accumulate in and eventually damage the kidneys. Organic mercury is absorbed through the digestive tract and builds up in the brain, kidney, liver, hair, and skin. Some forms of organic mercury, such as the compound that killed the chemistry professor, can be absorbed directly through the skin.

The most noticeable symptoms of mercury poisoning are:

- Muscle weakness
- Skin rashes or a pinkish discoloration of the cheeks, fingertips, or toes
- Mental problems, including depression, mood swings, memory loss, and anxiety
- “Pins and needles” sensations in the hands, feet, and area around the mouth

- Problems with speech, hearing, and vision
- Loss of coordination, tremors, and difficulty speaking or writing
- Headaches
- Insomnia

People who have swallowed batteries containing mercury may have vomiting and other severe digestive problems caused by the mercury damaging the tissues of the intestines.

Long-term exposure to mercury vapor can cause loss of teeth, inflammation of the gums, a metallic taste in the mouth, chest pain, difficulty breathing, and heavy sweating.

How Do Doctors Diagnose and Treat Mercury Poisoning?

Diagnosis The diagnosis of mercury poisoning can be easily missed by doctors because the condition can take years to develop before symptoms appear; because several different organs may be affected; and because many of the symptoms can be mistaken for those of such other disorders as Alzheimer's or Parkinson's disease* (especially in the elderly), brain tumors, cerebral palsy, acute kidney failure, amyotrophic lateral sclerosis (Lou Gehrig'disease), and myasthenia gravis.

To diagnose mercury poisoning, the doctor needs to take a thorough patient history, including the person's occupation, hobbies, and the amount of seafood the person eats. There are many occupations and hobbies that increase a person's risk of exposure to mercury, including work in chemistry laboratories, the perfume industry, photography, embalming and taxidermy, electroplating, ink and dye production, paper pulp production, and gold and silver production. Pesticides and fungicides used in farming also contain mercury. In addition, some folk medicines that are made in Mexico and used by some Hispanics in the United States also contain high levels of mercury.

The doctor can also take samples of the patient's blood and urine* to see how much mercury is in the body. These tests do not always help in confirming the diagnosis, however. Urine tests are useful in evaluating whether the patient was exposed to liquid mercury or mercury salts.

Treatment Individuals who have breathed in large amounts of mercury vapor or have swallowed certain mercury compounds need emergency treatment in a hospital to keep their airway open. Contaminated clothing is removed and exposed skin is washed down with generous amounts of water. If the patients show signs of kidney failure, they are treated with hemodialysis*.

Doctors use chelation therapy* for patients with severe mercury poisoning. Chelation therapy involves the use of medications that combine with the mercury to prevent the body from absorbing it and make it easier for the body to excrete the mercury.

Most adults with mild exposure to mercury recover completely. Children, however, are more vulnerable to long-term damage from mercury poisoning than adults; babies born to mothers who have eaten

* **Parkinson's disease** is a disorder of the nervous system that causes shaking, rigid muscles, slow movements, and poor balance.

* **urine** is the liquid waste material secreted by the kidneys and removed from the body through the urinary tract.

* **hemodialysis** (HEE-mo-dye-AL-is-is) is a method for removing waste products from the blood in patients with kidney failure.

* **chelation therapy** (chee-LAY-shun) therapy is a technique used to treat patients with lead or mercury poisoning by administering medications that combine with the metal to keep the body from absorbing it

fish containing high levels of mercury are at risk of lifelong muscle disorders, learning disorders, and problems with vision or hearing. There are six factors that influence the person's chances of recovery:

- Age. Fetuses are the most vulnerable to mercury poisoning.
- The chemical form of mercury involved. Organic mercury compounds are the most deadly.
- The length of time the person was exposed.
- The amount of mercury to which the person was exposed.
- The path of entry into the body (e.g., skin contact, eating, breathing vapors).
- The person's overall health.

Can Mercury Poisoning Be Prevented?

Mercury poisoning is preventable with proper precautions. In terms of mercury in the food chain, the Food and Drug Administration recommended in 2004 that pregnant women and young children should avoid eating fish with high levels of mercury, such as king mackerel, swordfish, and shark. They can safely eat 12 ounces per week (two average meals) of fish and shellfish that are low in mercury, such as shrimp, water-packed tuna, salmon, pollock, and catfish.

In terms of occupational exposure, many industries removed mercury in their manufacturing processes and products. Mercury was removed from indoor paints in the United States in 1990, for example. In 2006 the Environmental Protection Agency issued guidelines for phasing out the use of mercury in other industries and for finding better methods for safe disposal of used batteries and other products containing mercury.

In the home or workplace, people can lower their risk of mercury poisoning by using wood preservatives, insecticides, explosives, and other products containing mercury only in well-ventilated areas. People who work in chemistry laboratories should follow safety guidelines for working with mercury very precisely, remembering that mercury can penetrate latex gloves. Fluorescent bulbs or thermometers containing mercury should be handled very carefully if broken because of the danger of inhaling mercury vapor. The mercury from a broken thermometer or light bulb should be sponged up, sealed inside a plastic bag, and taken to a hazardous waste facility rather than removed with a vacuum cleaner, because vacuuming will spread mercury vapor.

Mesothelioma

Mesothelioma (me-zo-thee-le-O-muh), also called malignant mesothelioma, is a rare, deadly cancer* of the mesothelium*—the tissue that lines the lungs, stomach, heart, and other organs. Most mesotheliomas are caused by exposure to asbestos.*

What Is Mesothelioma?

Mesothelium is the two-layered membrane* that covers most of the organs of the body. It produces a lubricating fluid between the layers that cushions the organs and permits movement. Mesotheliomas can originate in four different types of mesothelium:

- About 75 percent originate in the pleura of the chest cavity and are called pleural mesotheliomas.
- About 10 to 20 percent originate in the peritoneum* of the abdomen* and are known as peritoneal mesotheliomas.
- Pericardial mesotheliomas are very rare, originating in the pericardium surrounding the heart.
- Mesothelioma of the tunica vaginalis—the lining of the testicles*—is extremely rare.

There are three types of mesothelioma:

- Epithelioid mesothelioma accounts for 50 to 70 percent of cases and has the best prognosis.
- Sarcomatoid mesothelioma accounts for 7 to 20 percent.
- Mixed/biphasic mesotheliomas account for 20 to 35 percent.

Although most people who develop mesothelioma have lived or worked where they may have inhaled or swallowed asbestos, the cancer

- * **malignant** (ma-LIG-nant) refers to a condition that is severe and progressively worsening.
- * **cancer** is a condition characterized by abnormal overgrowth of certain cells, which may be fatal.
- * **mesothelium** (me-zo-THEE-le-um) is epithelium derived from embryonic mesoderm that lines the body cavities.
- * **membrane** (MEM-brain) is a thin layer of tissue that covers a surface, lines a cavity, or divides a space or organ.
- * **peritoneum** is the membrane that lines the abdominal cavity.
- * **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.
- * **testicles** (TES-tih-kulz) are the paired male reproductive glands that produce sperm.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **susceptibility** (su-sep-ti-BIL-i-tee) means having less resistance to and higher risk for infection or disease.

* **virus** (VY-rus) is a tiny infectious agent that can cause infectious diseases. A virus can only reproduce within the cells it infects.

can take 20 to 50 years to develop. Household members of people who worked with asbestos are also at risk for mesothelioma. However, many people with prolonged asbestos exposure never develop the disease, whereas some people with no known exposure do. There is some evidence that genetic* susceptibility* may play a role in mesothelioma. Some studies have suggested the possibility that exposure to simian virus* 40 (SV40) may increase one's risk for mesothelioma. Some injectable polio vaccines manufactured between 1955 and 1963 were contaminated with SV40, potentially affecting an estimated 10 to 30 million people.

WHAT IS ASBESTOS?

Asbestos is a group of naturally occurring fibrous silicate minerals. Small amounts of asbestos are present in the air, soil, and water. Curly chrysotile asbestos fibers are the predominant type used in commercial applications. Amphibole asbestos has straight needle-like fibers that may pose a greater risk for mesothelioma because they tend to remain in the lungs longer.

Starting in the late 1800s asbestos was mined for use in numerous industrial products, including cement, plastics, roofing, insulation, floor coverings, ceiling tiles, fireproofing, paints, coatings, adhesives, and textiles. It was used in the shipbuilding and automotive industries. However, there was a health risk in these uses. Tiny particles of asbestos that become airborne during manufacturing processes can be inhaled or swallowed, causing a range of serious health problems, including mesothelioma and other cancers.

In the early 1940s industrial use of asbestos increased sharply, and millions of Americans were exposed to asbestos dust. Because of the rise in mesothelioma and other diseases among asbestos workers, the Occupational Safety and Health Administration (OSHA) set limits on workplace exposure, and workers began wearing protective clothing and equipment. Workers were later usually required to shower and change clothing before leaving the workplace, to avoid bringing asbestos dust home on clothing, shoes, skin, and hair.

In the late 1970s the Consumer Product Safety Commission banned the use of asbestos in wallboard patching compounds and gas fireplaces. In 1979 electric hairdryer manufacturers voluntarily abandoned their use of asbestos. In 1989 the Environmental Protection Agency (EPA) banned all new uses of asbestos. The EPA also required schools to remove or encase damaged asbestos. The EPA estimates that as many as 733,000 schools and public buildings in the United States contain asbestos insulation. U.S. manufacturers voluntarily eliminated asbestos-containing talcs from crayons, and the EPA recommended caution when using vermiculite-containing garden products. Domestic use of asbestos dropped from 803,000 metric tons in 1973 to 2,400 metric tons in 2005.

How Common Is Mesothelioma?

Although it remains a relatively rare cancer, the incidence* of mesothelioma in American males increased between 1970 and 1990 and then stabilized at about 2,000 to 3,000 new cases annually. The incidence of mesothelioma in Europe continued to rise through the late 20th century and into the early 2000s. Mesothelioma is five times more common in men than in women, and 70 to 80 percent of patients have a history of workplace asbestos exposure. The risk for mesothelioma increases with age. Three-fourths of cases are in people over 65 years of age, and the cancer is rare in those under 55.

What Are the Symptoms of Mesothelioma?

Early symptoms of mesothelioma are nonspecific and often overlooked. More than half of people with pleural mesothelioma complain of pain in the lower back or side of the chest. Other symptoms of mesothelioma include:

- Shortness of breath or trouble breathing
- Problems swallowing
- Cough
- Sweating
- Fever
- Fatigue
- Weight loss
- Hoarseness
- Coughing up blood
- Swelling of the face and arms
- Muscle weakness
- Sensory loss

Symptoms of peritoneal mesothelioma include:

- Pain, swelling, or lumps in the abdomen
- Nausea* or vomiting
- Bowel obstruction

Mesothelioma can also cause blood-clotting* abnormalities or anemia*.

How Do Doctors Diagnose and Treat Mesothelioma?

Diagnosis Mesothelioma is rare and misdiagnosis is not unusual because the symptoms are similar to other diseases, including lung cancer. A history of asbestos exposure may suggest mesothelioma. A physical exam or imaging tests can detect fluid in the chest, abdominal cavity, or pericardium.

Who Has Been Exposed to Asbestos?

Workers at risk for asbestos exposure include:

- Asbestos miners and millers
- Manufacturers of asbestos textiles and other products
- Construction workers who handle insulation
- Drywall removers
- Demolition workers
- Firefighters
- Shipbuilders
- Automobile workers
- Railroad workers

Living near asbestos mines or deposits is also a risk. Libby, Montana, is believed to have the highest rate of mesothelioma in the United States because of the W. R. Grace vermiculite mine that operated near the town until 1990.

* **incidence** means rate of occurrence.

* **nausea** (NAW-zha) refers to a feeling of being sick to one's stomach or needing to vomit.

* **clotting** is a process in which blood changes into a jellylike mass that stops the flow of blood.

* **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.

Will 9/11 Result in Increased Mesotheliomas?

Rescue, recovery, and cleanup workers at the site of the September 11, 2001, terrorist attacks on the World Trade Center in New York City were considered to be at risk for mesothelioma and other asbestos-related health conditions. Asbestos was used in the construction of the North Tower and when the building collapsed hundreds of tons of asbestos were released. Firefighters, police, and volunteers working in the rubble at the site were believed to be at the highest risk. Residents and school children in the immediate vicinity were also thought to be put at risk.

* **bronchoscopy** (brong-KOS-ko-pee) is a procedure used to examine the bronchi, the major air passages in the lungs, with an instrument called a bronchoscope, which is a tool for looking inside the lungs that is made up of a lighted tube with viewing lenses. A bronchoscope has channels through which samples of material can be taken from the lungs for study in the laboratory.

* **trachea** (TRAY-kee-uh) is the windpipe—the firm, tubular structure that carries air from the throat to the lungs.

* **biopsies** (BI-op-seez) are tests in which small samples of skin or other body tissue are removed and examined for signs of disease.

* **aspiration** (as-puh-RAY-shun) is the sucking of fluid or other material out of the body, such as the removal of a sample of joint fluid through a needle inserted into the joint.

Other procedures for diagnosing mesothelioma include:

- Lung function tests
- A complete blood count
- Red-blood-cell sedimentation rates
- Bronchoscopy*, in which a viewing instrument called a bronchoscope is inserted through the nose or mouth into the trachea* and lungs to detect disease or remove tissue for examination
- Examination of cells from fluid around the lungs or abdomen

Because it is difficult to distinguish mesothelioma from other cancers by the appearance of the cells, laboratory tests look for markers present on mesothelioma cells.

Biopsies* used to diagnose mesothelioma include:

- Fine-needle aspiration* of the lung
- Thoracoscopy, in which a viewing instrument called a thoracoscope is inserted into the chest between two ribs
- Thoracotomy, in which an incision is made between two ribs to examine the inside of the chest
- Peritoneoscopy, in which a viewing instrument called a peritoneoscope is inserted through the abdominal wall
- Laparotomy, in which an incision is made in the abdominal wall

Staging Following a diagnosis of mesothelioma, additional imaging tests are performed to stage the cancer and determine if it has spread and if so, where. Stage I mesothelioma is localized in the lining of the chest wall and possibly the linings of the lungs, diaphragm*, or pericardium around the heart on the same side of the chest.

Advanced mesothelioma is staged as follows:

- Stage II: The same as stage I except that the cancer has spread to the lymph nodes* on the same side of the chest.
- Stage III: The cancer has spread to the chest wall, the area between the lungs, the heart, beyond the diaphragm, the peritoneum, and/or lymph nodes on the other side of the chest.
- Stage IV: The cancer has spread to distant organs or tissues.

Treatment Because mesothelioma is not a single tumor* mass, it is usually not possible to remove it completely by surgery and/or radiation therapy*. If the cancer is localized and the patient is otherwise in good health, curative surgery may be attempted. Extrapleural pneumonectomy removes one lung, the diaphragm, part of the chest lining, and the pericardium. The diaphragm and pericardium are reconstructed with prosthetic material. However, the cancer cells tend to spread and are difficult to detect. Thus, surgery may extend life but is unlikely to cure mesothelioma.

HOW DOES ASBESTOS CAUSE MESOTHELIOMA?

Asbestos is a known human carcinogen. When asbestos breaks up—as during mining or insulation removal—the airborne dust can be inhaled or swallowed. Tiny fibers travel to ends of small air passages, reaching the pleura. There the fibers cause scarring and inflammation* of mesothelial cells and stimulate their growth. The fibers may damage the cells' DNA* leading to uncontrolled growth. Peritoneal mesothelioma can result from coughing up and swallowing inhaled asbestos fibers.

Since asbestos fibers remain in the body, the mesothelioma risk does not drop with time. The risk does depend on the level and duration of exposure. People exposed to high levels for a long period at a young age are most at risk.

If the cancer has spread beyond the mesothelium or is difficult to remove completely or if the patient is too ill for extensive surgery, palliative* surgery may be performed to relieve symptoms and control pain:

- A needle or thin tube is used to drain fluid from the chest, abdomen, or pericardium.
- Pleurectomy/decortication removes the pleura to prevent fluid buildup and ease pain and breathing.
- Pleurodesis inserts scar-forming talc or drugs into the space between the mesothelial layers to prevent the buildup of fluid.

Radiation therapy is sometimes used as the primary treatment, as an adjuvant (a support) to surgery or as palliative treatment. Chemotherapy* for mesothelioma is palliative and is usually administered intravenously* or directly into the chest or abdominal cavity.

Prognosis Mesothelioma is usually not diagnosed until the cancer is quite advanced. The average survival time at diagnosis is one year. The five-year-survival rate is about 10 percent, although this rate was slowly increasing in the early 2000s. Most patients die of complications related to mesothelioma, such as lung failure, heart problems, or stroke*.

Can Mesothelioma Be Prevented?

Although not all mesotheliomas have been connected to asbestos, avoiding such exposure is clearly the best prevention. Precautionary measures should be taken in performing any work that may involve asbestos exposure, particularly demolition of old buildings. It is often more dangerous to remove asbestos-containing materials than to leave them in place. If they are removed, the work should be performed by a qualified contractor.

* **diaphragm** (DY-a-fram) is the muscle that separates the chest and abdominal cavities. It is the chief muscle used in breathing.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **tumor** (TOO-mor) is an abnormal growth of body tissue that has no known cause or physiologic purpose. A tumor may or may not be cancerous.

* **radiation therapy** is a treatment that uses high-energy radiation from x-rays and other sources to kill cancer cells and shrink cancerous growths.

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

* **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

* **palliative** (PAL-ee-at-iv) means to ease or relieve without curing.

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

* **intravenously** (in-tra-VEE-nus-lee) means given or injected directly through a vein.

* **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

Metabolic Disease

A metabolic (met-a-BOLL-ik) disease is a condition that interferes with the body's chemical processes involved in growth, maintenance of healthy tissues, disposal of waste products, and production of energy to fuel body functions. As a result, a person may have too much or too little of certain substances (such as protein, fat, or carbohydrate) in the body. This imbalance often interferes with the normal function of various body tissues and organs.

Archibald Garrod and Inborn Errors of Metabolism

In the late 1800s and early 1900s, British scientist Archibald Garrod (1857–1936) suggested that people could inherit genes that cause problems with the body's metabolism, a collection of chemical processes that are critical to the normal growth and working of the human body. A gene is the unit of heredity that carries physical characteristics from parent to child. Usually, the parents of an affected child do not have the particular metabolic problem themselves. This is possible because each parent carries a "hidden" mutant (changed or abnormal) gene. If the mutant gene comes from both parents, the child will get the disorder.

The inheritance of the mutant gene from both parents creates problems when the child's body needs to metabolize (me-TAB-o-lize),

or process, certain nutrients and other substances properly. Garrod's hypothesis was revolutionary at the time, because no one had yet suggested that the body's chemical processes might somehow be related to heredity. Moreover, the scientific and medical communities generally believed that only foreign agents from outside the body, such as germs and bacteria, could cause disease.

In lectures delivered in 1908, Garrod described several hereditary diseases caused by too little or a complete lack of certain enzymes*. An enzyme is a protein that speeds up or controls certain chemical reactions in the body. Garrod described three diseases—alkaptonuria (al-cap-to-NYOOR-ee-a), cystinuria (sis-ti-NYOOR-ee-a), and pentosuria (pen-tos-YOOR-ee-a)—in which the patients experienced abnormally high levels of certain forms of acids and sugar in the urine. This sign showed that the body had not processed these substances correctly, because if it had, the body would have used those substances rather than discarding them in the urine, a waste product. The finding also suggested that the enzymes needed for processing them were either absent or not functioning properly. Garrod called these diseases “inborn errors of metabolism,” a name that persists to this day. He published *Inborn Errors of Metabolism* in 1909, a second edition of which appeared in 1923.

In the decades after Garrod made his discovery, scientists identified hundreds of genetic mutations that cause different metabolic disorders. Some of these disorders are fatal mere hours after birth, but others are treatable, particularly when diagnosed early, and patients may go on to have long and productive lives.

How Does Metabolism Normally Work?

People eat and drink every day, but few think about what happens to that food once the stomach and intestines begin digesting it. Once digestion breaks down food and drink into substances that the body can use, the process called metabolism begins. Metabolism is a series of chemical processes used by the body to put to work the nutrients in food. This process allows the body to carry out a variety of functions, such as growing, maintaining healthy tissues, disposing of wastes, and producing the energy needed for all activities. As a whole, metabolism is quite complex with hundreds of different reactions happening one after the other to convert nutrients into materials that the body needs for the functions of life. One way of thinking of metabolism is to consider it a kind of domino effect, with each chemical reaction, or domino, falling into place in sequence to create the end result. Metabolism involves two main phases: building up and breaking down.

Anabolism (building up) Anabolism (a-NA-bo-liz-um) is the building-up phase. It includes all the processes that occur when the body makes use of nutrients for the purpose of growing and building new tissues, which involves converting simple substances into more complex substances. For example, during digestion, the food releases important

* **enzymes** (EN-zimes) are proteins that help speed up a chemical reaction in a cell or organism.

- * **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.
- * **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.
- * **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.
- * **mutation** (myoo-TAY-shun) is a change in an organism's gene or genes.

compounds called amino (a-MEE-no) acids, which are the building blocks of proteins. Through anabolism, the body converts amino acids into proteins that are essential to the body's growth, development, and health. Protein is the main building material for all living tissue, including muscles, skin, and internal organs. It also is necessary to form hormones*, antibodies*, and enzymes, which are proteins that the body's cells produce to speed up or regulate chemical reactions. Hormones, antibodies, and enzymes are essential to the body's normal function.

Catabolism (breaking down) Catabolism (ca-TA-bo-liz-um) is the breaking-down phase. It involves processes that move in the opposite direction from anabolism: that is, they break down more complex substances into simpler forms, releasing energy that the body uses for work, movement, or heat production. For instance, the body's tissues store a carbohydrate called glycogen (GLY-ko-jen) in the liver* and the muscles. When the body needs energy, it breaks down the glycogen into glucose, a form of sugar. Metabolism continues when the glucose breaks down in the body's cells to release energy for fueling body functions.

Enzymes None of the processes involved in metabolism would be possible without enzymes. Because enzymes are proteins, they are made up of a string of amino acids. Each type of enzyme has its own string with certain amino acids lining up in a specific order. A person's genes are responsible for making sure the string of amino acids is correct. People who are born with metabolic diseases inherit a genetic* mutation* in a specific gene, and that mutation affects the amino acid string so that the body either fails to produce an enzyme at all or produces an enzyme that is inactive. As a result, that enzyme's activity in the body decreases or is completely absent.

One way to think of enzymes and amino acids is to consider enzymes as words and amino acids as letters of the alphabet. When a word is misspelled, its letters are ordered incorrectly and some may even be missing. This may cause its meaning to become confusing or unclear. When an enzyme is "misspelled," the amino acids are out of order and some may be missing altogether. Consequently, it cannot function properly, and this defect affects the particular step or steps in metabolism that the enzyme would have otherwise controlled.

Hundreds of such "misspellings" are possible, and they can cause many different kinds of metabolic disorders. Some are more serious than others. Doctors can treat many, but not all of them. When no treatment exists, the body does not properly process particular substances, such as carbohydrates, sugars, fats, or proteins. Depending on the particular enzyme and its function, they may cause too much or too little of these substances to be produced. In either case, the consequence is an imbalance that causes problems with the function and growth of many body tissues and organs, including the brain.

What Are Metabolic Diseases?

Metabolic diseases come in a very wide assortment. Some of the more common ones are discussed below.

Phenylketonuria Labels on diet soda and other food products containing the artificial sweetener aspartame (ASS-per-tame) feature a special warning: “Phenylketonurics: Contains Phenylalanine.” This is a warning for people with the metabolic disorder phenylketonuria (FEN-il-ke-to-NYOOR-ee-a) that aspartame contains the amino acid called phenylalanine (fen-il-AL-a-neen). People who have phenylketonuria (PKU) lack the enzyme (called phenylalanine hydroxylase) that is needed to convert this amino acid into another substance called tyrosine (TY-ro-seen). In other words, the body cannot process phenylalanine correctly. This amino acid is necessary for normal growth in infants and children and for normal protein production throughout life. However, if too much of it builds up, which is a problem for people with PKU, it poisons the brain tissue and eventually causes mental retardation. It also can cause the skin and urine to give off an unusual musty odor and lead to skin rashes.

Fortunately, doctors can determine whether an infant has PKU almost immediately after birth. In the 1960s scientists developed a PKU test medical professionals habitually perform on all newborns born in the United States. It involves taking a small blood sample—usually from the heel—from a two- or three-day-old newborn. Because PKU prevents processing of phenylalanine, the amino acid would appear at a high level in the child’s blood. Some doctors repeat this test when the child is a week to 10 days old. If the test indicates that the child may have PKU, the doctor will typically take another blood sample from a vein and run the test again to make sure. Only 1 out of every 13,500 to 19,000 babies born in the United States tests positive for PKU, which makes it a rare condition, but this adds up to about 250 or more babies each year.

If a baby tests positive for PKU, the doctor will put the patient on a special diet right away. With such a diet, the patient can avoid the mental retardation that was the certain result of PKU in the past. This diet cuts out high-protein foods, which are also high in phenylalanine. High-protein foods include meat, poultry, and fish; milk, eggs, cheese, ice cream; nuts; and many products containing regular flour. The particular dietary restrictions vary from person to person, depending on the severity of the condition in each individual. Medical professionals often recommend that children with PKU take a special artificial formula as a nutritional substitute for the foods they cannot eat. Patients, with the help of their parents when they are young, must adhere to the diet—even when they find it difficult—so they can remain healthy and avoid retardation.

With early diagnosis and careful dietary restrictions, children with PKU are able to grow up normally. They achieve in school, attend college,

THE DISCOVERY OF PHENYLKETONURIA

In Norway in 1934, a mother with two severely mentally retarded children went to see Asbjørn Følling (1888–1973), seeking an explanation for her children's condition. She also wondered about an unusual smell that her children always seemed to have. After testing urine samples, Følling discovered that the children excreted a substance not found in normal urine. Although he did not have access to the advanced chemical tests that would become available later in the 20th century, eventually Følling was able to identify the substance as a compound called phenylpyruvic (fee-nul-PY-roo-vik) acid. He immediately wondered whether the buildup of acid had something to do with the children's retardation.

Følling collected urine samples from hundreds of other mentally retarded patients and found that eight of these individuals excreted the same acid. He then published a paper that drew a connection between the acid levels and retardation in these 10 people. He also made the hypothesis (hy-PAH-the-sis) that these people are unable to break down another compound called phenylalanine, which is an amino acid (a building block of proteins), and this excess phenylalanine converted into an elevated amount of phenylpyruvic acid. Eventually, he confirmed his hypothesis when he and his colleague figured out a way to use bacteria to test for high levels of phenylalanine in the blood.

Følling had discovered phenylketonuria (PKU), and in so doing, he changed the lives of future generations of children who would be born with this condition. He showed that mental retardation could be avoided if medical professionals diagnosed the condition right away and if phenylalanine levels were controlled through dietary changes.

In 1962, President John F. Kennedy awarded Følling the Joseph P. Kennedy International Award in Mental Retardation for his achievements. At about the same time, scientist Robert Guthrie was using Følling's discoveries to develop an effective newborn screening test for PKU. The test became available in the early 1960s, and Guthrie worked diligently to establish screening programs in the United States and many other countries. In the early 2000s, doctors routinely screen all babies in the United States for PKU.

and enter a wide range of challenging professions as adults. With the exception of the special diet they must follow, children with PKU can do anything that children without PKU can do.

Maple syrup urine disease PKU is just one of several metabolic disorders that occur when the body lacks an enzyme needed to process amino acids. Another is maple syrup urine disease (MSUD), also sometimes called ketoacidemia or branched chain alpha-ketoacid dehydrogenase (BCKD). In this disease, patients lack the enzyme needed to process three other amino acids: valine (VAYL-eeen), leucine

(LOO-seen), and isoleucine (i-so-LOO-seen). These amino acids are present in milk, meat, eggs, and many other foods, and are essential for normal growth and function. When the body fails to metabolize them properly, the amino acids can build up in the body, causing the urine to smell like maple syrup or sweet, burnt sugar. If left untreated, MSUD can cause mental retardation, physical disability, and even death.

MSUD is even rarer than PKU. Only about one in 185,000 infants worldwide are born with MSUD. In addition to urine that smells like maple syrup, individuals with MSUD usually have little appetite and are extremely irritable. Some states require that all newborns be tested for MSUD, but as of 2009 some states did not. Unless medical professionals diagnose and begin to treat MSUD right away, the disease can cause seizures*, unconsciousness, brain damage, and even death. Treatment takes the form of a carefully controlled diet that cuts out certain high-protein foods containing the three amino acids the body cannot process. As for children who have PKU, medical professionals often give young patients with MSUD an artificial formula that supplies the necessary nutrients they might otherwise miss because of their restrictive diet.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

KING GEORGE III AND MENTAL ILLNESS

George III (1738–1820) was the king of England against whom the American colonists rebelled during the War of Independence. History books note that George III experienced violent fits of madness that eventually made him incapable of ruling. He suffered through bouts of agonizing pain, overactivity, paralysis, and delirium. These so-called nervous spells occurred during the last three or four decades of his life, which ended in 1820 when he was 81.

Some historians believe that the king's problem was physiological. When psychiatrists studied the king's letters and examined the notes made by his doctors, they discovered that King George's symptoms included dark red urine, a tell-tale symptom of the metabolic disease porphyria. In 1967 two British psychiatrists published a scientific paper, "A Clinical Reassessment of the Insanity of George III and Some of Its Historical Implications," in which they asserted that the king had porphyria. Further historical investigation suggested that other members of the royal family may have had the condition, too.

While George III was alive, medical science could not explain what was wrong with him. The body's chemical processes and their effect on the mind was not understood. In the early 2000s, however, much is known about this relationship. Porphyria is actually a problem in the blood that, in some cases, interferes with normal brain function and causes numerous mental symptoms.

Galactosemia For most babies and young children, mother's milk (or a formula like breast milk) and then cow's milk supply nutrients essential to the body's function and growth. Babies born with the metabolic disease galactosemia (ga-lak-to-SEE-me-a), however, do not have enough of the enzyme that breaks down the sugar (called galactose) in milk. This enzyme is usually produced by the liver, but if the liver does not produce enough, galactose builds up in the blood and can cause serious health problems if the condition is not diagnosed and treated.

Symptoms usually appear in the first few days of life, as soon as the baby starts drinking breast milk or formula. The baby often starts vomiting, the liver swells up, and the skin and eyes take on a yellow color (a condition called jaundice). Other symptoms might include infections, irritability, failure to gain weight, and diarrhea. If medical professionals fail to diagnose it quickly, galactosemia can cause severe damage to the liver, eyes, kidney, and brain. For this reason, many states require that all newborns have a blood test that can detect it. About one in 30,000 to 60,000 babies are born with the condition. Treatment involves removing all milk and milk-containing products from the diet. Doing so reduces the risk of permanent damage, but the child may still have problems with growth, speech, and mental function as he or she gets older.

Fructose intolerance Besides galactosemia, many other metabolic diseases cause patients to be unable to process sugars properly. One of these is fructose (FROOK-tose) intolerance, in which a person cannot metabolize fructose, which is a certain form of sugar found in fruit, fruit juices, powdered and table sugar, honey, corn syrup, and other foods. Like the treatment for galactosemia, the treatment for fructose intolerance involves excluding certain foods from the diet. The patient must strictly limit fructose to avoid possible damage to the liver and kidneys, and possible mental retardation.

Glycogen storage disease In a healthy person, the body takes a simple sugar called glucose from foods, converts it into a carbohydrate called glycogen, and stores it in the liver and muscles. When the body needs energy to fuel its activities, specific enzymes then reverse the process and break down the glycogen into sugar. People with certain metabolic diseases have problems with one or more of these enzymes, resulting in a condition known as glycogen storage disease.

Glycogen storage disease actually comes in nine different types, each involving different enzymes. One example is glucose-6-phosphatase (G6PD) deficiency, in which the patient has too little of the enzyme called glucose-6-phosphatase. Normally found in the liver, glucose-6-phosphatase helps to release glucose from the liver into the bloodstream so that the body can process it to produce energy. Deficiency of the enzyme can cause the levels of sugar in the blood to fall dangerously low if the patient does not get glucose in his or her diet every few hours.

In G6PD deficiency and other glycogen storage diseases, various parts of the body store excessive amounts of glycogen, which causes problems with the liver, muscles, blood cells, heart, brain, and/or other organs. Treatment for these conditions usually involves changes in diet.

Porphyria The body uses a special chemical called porphyrin (POE-fir-in) to make heme, which is the substance in the blood that carries oxygen to the tissues. Eight different enzymes are in charge of the metabolic process that uses porphyrin to make heme. When any of these enzymes are missing or do not function properly, too much porphyrin builds up in the body, and this excess eventually leaves the body in the urine or stool. It also causes the individual's body to produce too little heme to keep the person healthy. This enzyme deficiency is called porphyria (poor-FEER-ee-a).

People who have porphyria can experience symptoms that involve the skin, the nervous system, and/or other internal organs. When porphyria affects the skin, the person may have blisters, itching, swelling, or extreme sensitivity to the sun. When it affects the brain, it can cause hallucinations*, delirium*, seizures, depression, anxiety, and paranoia*. Other physical symptoms may include chest or stomach pain, muscle cramps, weakness, or urine that is dark purple or red.

Doctors can test someone's blood, urine, or stool to diagnose porphyria. They may prescribe various drugs to treat the illness. In some cases, they may also recommend that the patient take glucose or beta-carotene. In one form of porphyria, in which the patient's body has an excess of iron, patients often benefit from systematic draining of the blood, in which medical professionals remove a pint of blood from the patient's body once or twice a week for several weeks, until iron levels drop to normal.

How Does an Inherited Metabolic Disease Develop?

Many metabolic diseases exist beyond those described here. These few examples, however, illustrate the chain of events that happen in many inherited metabolic diseases:

1. A person inherits a genetic mutation, or abnormality.
2. Because of this inherited genetic mutation, the body either does not produce a certain enzyme or else it produces an enzyme that does not work as it should.
3. Consequently, a certain necessary step in metabolism does not occur normally.
4. The substance that should have been metabolized (broken down or changed into another form) builds up in the body and/or other important substances needed by the body are not available in adequate amounts.

As a result, the normal processes of a person's system no longer work properly, which can cause damage if the problem is not corrected with

* **hallucinations** (ha-LOO-sin-AY-shuns) occur when a person sees or hears things that are not really there. Hallucinations can result from nervous system abnormalities, mental disorders, or the use of certain drugs.

* **delirium** (dih-LEER-e-um) is a condition in which a person is confused, is unable to think clearly, and has a reduced level of consciousness.

* **paranoia** (pair-a-NOY-a) refers to either an unreasonable fear of harm by others (delusions of persecution) or an unrealistic sense of self-importance (delusions of grandeur).

diet or medication. In some cases, medical professionals cannot correct the problem, and it may cause permanent damage or even death. Many people with metabolic diseases, however, can go on to live healthy, productive lives if they follow their doctors' instructions precisely.

Metabolic Syndrome

Metabolic syndrome is the name given to a group or cluster of conditions that occur together and increase a person's risk of diabetes*, heart disease, and stroke*. A short definition of the syndrome is that it is a group of metabolic* risk factors in one individual. Metabolic syndrome is also known as insulin resistance syndrome, syndrome X, and Reaven's syndrome, after the California diabetes researcher who first described it in 1992.*

Enrique's Story

Enrique is a sixth-grade student in a California school whose family has a history of type 2 diabetes. Type 2 diabetes is a form of the disease that usually develops in adults whose bodies do not use the insulin* produced by their bodies effectively. This condition is called insulin resistance. Between 90 and 95 percent of American adults with diabetes have type 2, which has been linked to the metabolic syndrome, obesity*, high blood pressure, and abnormal levels of cholesterol* in the blood. The risk of developing type 2 diabetes is also related to a person's race or ethnic group.

Enrique was asked to participate in a study of overweight Hispanic children to find out whether the high risk of type 2 diabetes in Hispanic adults affects younger Hispanics. Doctors have known for some years that Hispanic Americans, particularly those whose families came from Mexico, have a higher rate of diabetes than either African Americans or Caucasian Americans. Although researchers had studied overweight African American and Caucasian American children, they had not yet looked at Hispanic youth. They also wanted to find out whether the definition of metabolic syndrome that was worked out from studies of adults can also be applied to children and teenagers.

Enrique was interested in finding out more about his health and the health of his relatives. He went with his parents to a clinic in the medical school nearby, where the doctors measured his height, weight, waistline, and blood pressure, and took samples of blood to see how well his body used insulin. They found that Enrique belonged in the 30 percent of overweight children who fit the pattern of metabolic syndrome and that he had a higher than average risk of developing type 2 diabetes as he grew into adulthood. The doctors gave Enrique and his parents some advice about nutrition and exercise to help Enrique lose weight, and some information about medications that can be given to children with insulin resistance. Enrique was not happy to have to cut down on some of his favorite foods, but he was glad that he learned more about his body, and that he helped the doctors learn more about his age group and ethnic community.

▲ Abdomen of a man with metabolic syndrome. GARO/Photo Researchers, Inc.

- * **syndrome** is a group or pattern of symptoms or signs that occur together.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.
- * **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

- * **metabolic** (meh-tuh-BALL-ik) pertains to the process in the body (metabolism) that converts food into energy and waste products.
- * **insulin** is a kind of hormone, or chemical produced in the body, that is crucial in controlling the level of glucose (sugar) in the blood and in helping the body use glucose to produce energy. When the body cannot produce or use insulin properly, a person must take insulin or other medications.
- * **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.
- * **cholesterol** (ko-LES-ter-ol) is a fatlike substance found in the blood and body tissues.
- * **pancreas** (PAN-kree-us) is a gland located behind the stomach that produces enzymes and hormones necessary for digestion and metabolism.
- * **triglycerides** (try-GLISS-eh-rides) are a type of fatty substances found in the blood.

What Is Metabolic Syndrome?

Changing Names and Definitions As the many names given to metabolic syndrome indicate, it has been defined somewhat differently by various public health organizations and medical societies since it was first named syndrome X by Gerald Reaven in 1992. Reaven was first concerned with the relationship of the syndrome to insulin resistance, a condition in which a person's body cannot use effectively the insulin produced by the pancreas*. Although insulin resistance is not considered a disease by itself, it is known to increase a person's risk of developing type 2 diabetes and heart disease. Reaven later wrote a book for the general public about the connection between syndrome X and heart disease.

In 1999 the World Health Organization published a set of guidelines for identifying the metabolic syndrome that included being diagnosed with type 2 diabetes (which includes insulin resistance), high blood pressure, and obesity. Subsequent definitions of the metabolic syndrome, however, did not require that a person be diagnosed with diabetes itself; instead, these definitions emphasized that metabolic syndrome is a group of conditions that increase a person's risk of serious illness rather than a disease in its own right. As of 2009, the definition of metabolic syndrome that was most widely used is the description published by the National Cholesterol Education Program (NCEP) and modified by the American Heart Association (AHA) in 2005. The two organizations distinguished between the metabolic risk factors of the syndrome itself—abnormally high levels of blood cholesterol, high blood pressure, and high levels of sugar in the blood—and what the two groups called the underlying risk factors. These risk factors include obesity, insulin resistance, aging, not getting enough exercise, and hormonal imbalances.

To be diagnosed as having metabolic syndrome, an adult must have three or more of the following conditions:

- A waist measurement of 40 inches or more in men or 35 inches or more in women
- A high level of triglycerides* in the blood or being treated for high levels of triglycerides
- A low level of HDL cholesterol ("good" cholesterol) or being treated for low levels of this type of cholesterol
- High blood pressure or being treated for high blood pressure
- A high level of blood sugar when measured after fasting (going without food for about 8 hours before the blood test, usually overnight) or being treated for this condition

Although it is possible for a person to have only one of these health problems, having any of them increases a person's risk of developing the others.

Metabolic syndrome in children and teenagers As Enrique's story indicates, doctors have asked whether children and adolescents can

METABOLIC SYNDROME AND TYPE 2 DIABETES

There is a circular relationship between the metabolic syndrome and type 2 diabetes. On the one hand, an adult with metabolic syndrome is five times as likely to develop type 2 diabetes in the future as a person without the condition. On the other hand, being already diagnosed with diabetes or coming from a family with a history of diabetes are risk factors for developing the metabolic syndrome. High levels of blood sugar have been shown in animal studies to lead to insulin resistance, a condition that can lead to the metabolic syndrome as well as diabetes itself.

In one study done in Japan in 2004, scientists fed laboratory rats a diet that was one-third sugar. The rats first developed high levels of triglycerides in their blood after four weeks on their sugary diet but remained at the same weight as rats on a normal diet. Next, the rats on the experimental diet developed large pads of fat around their abdomens. At the end of 20 weeks on the high-sugar diet, the rats had become obese, had high blood sugar levels as well as high levels of triglycerides, and had become insulin-resistant. The researchers think that the metabolic syndrome may develop in humans in the same series of stages.

develop the metabolic syndrome as well as adults. In early 2004 a group of researchers studied nearly 2,000 California youngsters over the age of 12 and found that two-thirds of the children had at least one abnormal metabolic measurement, and 10 percent had the metabolic syndrome. The rate of metabolic syndrome climbed to 30 percent in children who were overweight or obese; this figure concerned researchers because the rate of overweight and obesity in American children tripled between the mid-1970s and the early 2000s. The doctors found that the rates of metabolic syndrome in children from different racial and ethnic groups follow the same pattern as those for adults: Hispanic children have the highest rates of metabolic syndrome, followed by Caucasian and African American children.

How Common Is Metabolic Syndrome?

Using the standards proposed by the NCEP and AHA in 2005, some doctors estimated that about one-fifth (20%) of adults in the United States have metabolic syndrome. But because the risk of developing the syndrome increases as people get older, some researchers suspected the true rate among American adults may be as high as 25 percent, or 47 million people. Among Hispanic adults, it was thought to be as high as 31 percent. Researchers expected the rate to increase as the rate of obesity among children as well as adults continued to rise.

* **metabolism** (meh-TAB-o-liz-um) is the process in the body that converts foods into the energy necessary for body functions.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **gestational** (jes-TAY-shun-al) means relating to pregnancy.

Who Gets Metabolic Syndrome?

Causes The causes of metabolic syndrome are not fully understood, although there was as of 2009 wide agreement that it is the end result of a complicated series of changes in the body's metabolism*. Some doctors suspected that obesity was the basic cause of metabolic syndrome, while others thought that insulin resistance is the basic cause. A third group of doctors theorized that both obesity and insulin resistance are the results of a more general metabolic disturbance in a person's body caused by a combination of genetic* and environmental factors. As of 2009, research continued to explore possible causes of metabolic syndrome in general and insulin resistance in particular.

Risk factors Some people are more likely than others to develop metabolic syndrome. These risk factors include:

- Having a parent or sibling with diabetes
- Having a family history of high blood pressure and heart disease
- Being over age 45
- Having a family background that is African American, Alaska Native, American Indian, Asian American, Hispanic/Latino, or Pacific Islander
- Being overweight or obese, particularly if the fat is concentrated on the upper body. A high proportion of body fat on the upper body—sometimes called an apple-shaped figure—is a greater risk factor for metabolic syndrome than a high proportion of fat on the lower body (a pear-shaped figure). Upper-body obesity is thought to lead to increased fat deposits in muscle tissue and the liver, which in turn leads to insulin resistance and higher levels of triglycerides in the blood.
- Being inactive. Getting enough exercise makes it easier to keep weight at a healthy level. In addition, regular physical exercise helps the body respond better to insulin.
- Taking medications that cause weight gain or changes in blood pressure, cholesterol, and blood sugar levels. These types of drugs are most often prescribed for inflammation, allergies, HIV infection, depression, and other kinds of mental illnesses
- Being a woman who was diagnosed with diabetes during pregnancy, a condition known as gestational* diabetes
- Being a woman with polycystic (POL-ee-SISS-tik) ovary syndrome, or PCOS. PCOS is a metabolic disorder that affects a woman's hormone levels and reproductive organs.

How Do People Know They Have Metabolic Syndrome?

It is possible for people to develop metabolic syndrome over a period of years without any noticeable symptoms; this slow development is one reason why regular medical checkups are important to good health. In addition, some people develop metabolic syndrome without being obese or having a large

METABOLIC SYNDROME AND HEART DISEASE

According to the National Institutes of Health, an adult with metabolic syndrome has twice the risk of dying from heart disease and three times the risk of developing it as a person without metabolic syndrome. In the early 2000s, it was projected that soon metabolic syndrome might overtake smoking as the major cause of heart disease in American adults.

There are two conditions that are commonly found in people with metabolic syndrome, although whether these conditions help to cause the syndrome or only make it worse was not known as of 2009. The two conditions are: a tendency to form blood clots and a low-grade inflammation throughout the body. Both of these conditions contribute to heart disease by encouraging the buildup of plaque* in the coronary arteries.

* **plaque** (PLAK) is a raised patch or swelling on a body surface. Arterial plaque occurs on the inner surface of an artery and is produced by fatty deposits.

waist measurement. Most people with metabolic syndrome are diagnosed in the course of a medical checkup that includes a blood test.

In some cases, people with diabetes that has not yet been diagnosed may notice increased thirst; increased urination, especially at night; unusual tiredness; and blurred vision. High blood pressure usually develops without any symptoms; however, a few people may notice dull headaches, dizzy spells, or more nosebleeds than usual.

Some people are diagnosed with insulin resistance, one of the risk factors for metabolic syndrome, because they develop a skin condition called acanthosis nigricans (ah-can-THO-sis NEE-grih-cans). A person with acanthosis nigricans develops dark patches on the skin of the neck or on the elbows, knees, knuckles, or armpits. This skin discoloration is more common in Hispanics or African Americans with insulin resistance.

How Is Metabolic Syndrome Diagnosed and Treated?

Screening and diagnosis Because metabolic syndrome usually does not have the kinds of symptoms that lead people to see a doctor and because it is more likely to affect older adults, doctors recommend that adults be screened for the syndrome starting at age 45. If the results of blood tests and other measurements are normal, screening should be repeated only every three years. If the person has any risk factors in addition to age, screening should occur more frequently, the frequency depending on the number of other risk factors and their severity.

Screening for metabolic syndrome consists first of measuring the patient's waist, at the top of the upper edge of the hipbone just after the person has exhaled (breathed out). The doctor also weighs the patient,

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein

notes the distribution of body fat, and measure the patient's blood pressure. A sample of blood is taken and sent to a laboratory to measure the levels of triglycerides and cholesterol.

The patient's blood sugar level and possible insulin resistance can be tested in two ways. The first is a fasting blood glucose test. The person does not eat or drink anything (except water) after midnight the evening before the test and has a sample of blood drawn in the morning. The second test is called a glucose tolerance test and measures how quickly the body uses sugar. In this test, the person has one sample of blood drawn after fasting overnight and the second sample taken two hours after drinking a sugary liquid in the doctor's office or diagnostic laboratory. Blood sugar levels higher than normal but not high enough to indicate type 2 diabetes are considered a sign of pre-diabetes.

A pre-diabetes score on the fasting blood glucose test and the glucose tolerance test is considered indirect evidence of insulin resistance. To measure insulin resistance directly, a complicated test called the euglycemic (yoo-gly-SEEM-ik) clamp, which is usually done only in research laboratories, can be performed. The euglycemic clamp test takes about two hours. The patient is given an intravenous* solution of insulin and a solution of glucose (sugar). The patient's blood sugar level is measured every 5 to 10 minutes. The amount of intravenous glucose that the patient needs during the last 30 minutes of the test to maintain a normal level of blood sugar measures the person's sensitivity to insulin. Individuals who need high levels of additional glucose are insulin-sensitive. Very low levels indicate insulin resistance.

Treatment The metabolic syndrome is treated first with a combination of lifestyle changes. The goal is to lower the patient's risk of heart disease and type 2 diabetes by bringing blood pressure, blood sugar, and blood cholesterol down to healthier levels. If the patient has already been diagnosed with type 2 diabetes, treatment is focused on lowering the risk of heart disease. Specific lifestyle changes include:

- Quitting smoking, if the patient smokes. The nicotine in tobacco increases a person's risk of heart disease because it raises blood pressure and speeds up the heart rate. Smoking also raises the level of triglycerides in the blood and lowers the level of "good" cholesterol.
- Losing weight. This lifestyle change alone can significantly lower a person's risk of diabetes and heart disease. Most adults with metabolic syndrome need to cut their food intake by 500 to 1,000 calories per day in order to lose 7 to 10 percent of their body weight (the recommended amount) over a period of six months to a year.
- Getting at least 30 minutes of moderate-intensity exercise (like brisk walking) on most or all days of the week. Exercise combined with calorie cutting speeds up weight loss.
- Eating a healthier diet, which means cutting back on foods that are high in fat and cholesterol and adding more fruits, vegetables, fish, and whole grains to the diet. The Dietary Approaches to Stop

Hypertension (DASH) diet is a specific diet plan that is often given to patients with metabolic syndrome.

Some patients need medications in addition to lifestyle changes to treat specific health risks associated with the metabolic syndrome. The specific drugs prescribed and their dosages depend on the individual patient's test results:

- Drugs to lower the level of “bad” cholesterol and triglycerides
- Drugs to raise the level of “good” cholesterol
- Diuretics and drugs called ACE inhibitors. These are given to control high blood pressure. Diuretics cause the body to excrete extra fluid through the urine, whereas ACE inhibitors work to lower blood pressure by increasing the volume of blood pumped by the heart and keeping the blood vessels from tightening or narrowing.
- Drugs to lower insulin resistance. Metformin (met-FORM-in) is the drug most commonly prescribed for this purpose. Metformin can also be given to people diagnosed with diabetes or PCOS. In addition to controlling blood sugar levels, metformin also lowers triglyceride levels.
- Insulin. Insulin is given to control blood sugar levels in patients already diagnosed with diabetes.
- Low doses of aspirin. Aspirin is recommended to lower the risk of blood clots in patients with a high risk of heart disease.

Can Metabolic Syndrome Be Prevented?

Some risk factors for metabolic syndrome, such as age, race, and family history, cannot be changed. People can, however, lower their risk of developing metabolic syndrome by following guidelines from the National Heart, Lung, and Blood Institute:

- Following a healthy diet plan
- Keeping weight at a healthy level for one's age, sex, and height
- Getting at least 30 minutes of exercise every day
- Quitting smoking, or not starting in the first place
- Getting regular medical checkups for measuring blood pressure, cholesterol, and blood sugar levels

Self-care at home for metabolic syndrome involves following the same recommendations as for preventive care.

Mononucleosis, Infectious

Infectious mononucleosis (mah-no-nu-klee-O-sis), also known as mono, is an infectious illness usually caused by the Epstein-Barr (EP-steen BAR) virus (EBV). It often leads to fever, sore throat, swollen lymph nodes, and tiredness.*

What Is Mononucleosis?

By the time they are 40 years old, as many as 95 percent of all adults in the United States have evidence in their blood of a previous EBV infection. Many of these infections are never recognized, especially if they occur in early childhood, because the symptoms look like those of other childhood viral illnesses. Some people infected with EBV have no symptoms. This situation occurs in many parts of the world where most people are infected early in life. In the United States, EBV infection is most common during adolescence and early adulthood (ages 15–25). One-third to one-half of teens who come into contact with the virus for the first time develop symptoms of classic infectious mono: sore throat, swollen lymph nodes, fever, and extreme tiredness.

Mono most often is associated with acute* infection by EBV, but it is sometimes seen with acute cytomegalovirus* (CMV) infection, acute HIV* infection, and, rarely, other viruses.

Although the symptoms may be unpleasant, mono is generally a mild disease. After a person recovers, the virus remains dormant (inactive) in the body for life. It occasionally may reactivate, but it rarely causes symptoms again. When people have been infected with the virus, whether or not they had symptoms, they usually will be immune* to future EBV-related illness.

How Common Is Mononucleosis?

EBV is one of the most common human viruses in the world. In the United States, cases of mono with symptoms most often are found in teens between the ages of 15 and 17. The illness occurs in two out of every 1,000 adolescents and young adults and is less common in other age groups.

How Is Mononucleosis Spread?

Mono is contagious, although less so than the common cold. EBV passes from person to person primarily through contact with saliva. Kissing and sharing food, drinks, or utensils commonly spread the virus. Although EBV is present in the respiratory tract*, it usually is not transmitted by coughing or sneezing. Some people become sick and are able to spread the virus for weeks, especially those who are infected but do not feel sick and pass the virus to others without realizing it. The virus usually remains inactive after the first infection, but some people may spread it from time to time throughout their life.

How Do People Know They Have Mononucleosis?

Symptoms of mono develop between four and six weeks after infection and generally last two to four weeks. These include swollen lymph nodes, extreme tiredness, fever, sore muscles, and sore throat. Up to 50 percent of people with classic infectious mononucleosis have a swollen spleen, and some have an enlarged liver. Other symptoms may include loss of appetite, weakness, nausea (NAW-zee-uh), stiffness, headache, chest pain, and, rarely, jaundice*.

How Is Mononucleosis Diagnosed and Treated?

Symptoms of mono usually show up one to four weeks before the diagnosis is made. A physical exam, the patient's age, and sometimes a history of contact with an infected person help the doctor make the diagnosis. An adolescent patient with a lasting fever, sore throat, and swollen lymph nodes, with or without an enlarged spleen, is likely to have mono.

Blood tests can confirm the diagnosis. A blood count will show an increased number of lymphocytes*, and many of them will look unusual. A positive rapid screening test may confirm the diagnosis by revealing EBV in the blood, but this test can be negative, especially early in the illness. More accurate antibody* testing may be done to rule out other viruses that can cause mono-like illnesses. Antibody testing checks several antibodies to determine if there is a current infection or evidence of past infection.

There is no specific treatment for mono. Because it is a viral illness, antibiotics are not prescribed unless a secondary bacterial illness is present,

Kiss and Tell

Mono is often referred to as the “kissing disease” because the infection is spread primarily through direct contact with infected saliva.

* **immune** (ih-MYOON) means resistant to or not susceptible to a disease.

* **respiratory tract** includes the nose, mouth, throat, and lungs. It is the pathway through which air and gases are transported down into the lungs and back out of the body.

* **jaundice** (JON-dis) is a yellowing of the skin, and sometimes the whites of the eyes, caused by a buildup in the body of bilirubin, a chemical produced in and released by the liver. An increase in bilirubin may indicate disease of the liver or certain blood disorders.

* **lymphocytes** (LIM-fo-sites) are white blood cells, which play a part in the body's immune system, particularly the production of antibodies and other substances to fight infection.

* **antibody** (AN-tih-bah-dee) is a protein molecule produced by the body's immune system to help fight a specific infection caused by a microorganism, such as a bacterium or virus.

EBV and Cancer

EBV has been linked to the development later in life of Burkitt's lymphoma (a rare blood disease of the lymph nodes seen mainly in Africa) and nasopharyngeal carcinoma (nay-zo-fair-in-JEE-ul kar-sih-NO-muh, a cancer in the throat area seen mainly in China). EBV is also linked to lymphoma in the United States, most notably in people with weakened immune systems, such as people who have HIV.

- * **strep throat** is a contagious sore throat caused by a strain of bacteria known as *Streptococcus*.
- * **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.
- * **ibuprofen** (eye-bew-PRO-fin) is a nonsteroidal anti-inflammatory drug (NISAD) used to reduce fever and relieve pain or inflammation.
- * **tonsils** are paired clusters of lymphatic tissue in the throat that help protect the body from bacteria and viruses that enter through a person's nose or mouth.
- * **hepatitis** (heh-puh-TIE-tis) is an inflammation of the liver. Hepatitis can be caused by viruses, bacteria, and a number of other noninfectious medical conditions.
- * **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.

such as strep throat*. The best treatment for mono is rest. Over-the-counter medications such as acetaminophen* or ibuprofen* may be taken to relieve fever and pain.

Steroids, medications that reduce inflammation, may be given to decrease swelling in the tonsils* and lymph nodes in the neck if a patient is experiencing difficulty swallowing or breathing. Playing contact sports is prohibited for someone who has mono because when the spleen and liver enlarge, they are more vulnerable to injury. Patients with mono are advised not to play contact sports for at least one month and to be examined and get a doctor's permission before they start again.

Symptoms of mono usually clear up one to two months after they appear, but they can last as long as four months.

What Are Some Complications of Mononucleosis?

Recovery from mono is usually uneventful, but sometimes complications occur. An enlarged spleen may rupture, which is an emergency that needs surgery. Fifty percent of patients with infectious mononucleosis have some liver inflammation, but only a small number have significant inflammation, or hepatitis*. Blood problems that can result from the infection include anemia*, decreased white cells (cells that fight infection), and low numbers of platelets (cells that help the blood clot). Mononucleosis also can lead to encephalitis (en-seh-fuh-LYE-tis, inflammation of the brain), Guillain-Barré (GEE-yan bah-RAY) syndrome (an inflammation of the nerves, which causes muscle weakness and paralysis*), and Bell's palsy (PAWL-zee, a temporary weakness or paralysis of the muscles on one side of the face). Myocarditis (my-oh-kar-DYE-tis, an inflammation of the muscular walls of the heart) is a rare complication.

EBV has also been associated with cancers, such as lymphoma*, especially in patients with weak immune systems, such as people who have had organ transplants or who have HIV.

Can Mononucleosis Be Prevented?

There is nothing specific that a person can do to avoid contracting mono because EBV often is spread in the saliva of healthy people who have been infected in the past and who can still transmit the virus. Normal human behavior makes it practically impossible to prevent the spread of the disease.

Motion Sickness

Motion sickness occurs when people feel dizzy or nauseated because the motion their body senses and the motion their eyes perceive are not synchronized. The conflicting messages sent to the brain make them feel ill.

The Ruined Fishing Trip

Jon and his dad were very excited about their upcoming deep-sea fishing trip off the Florida coast. His father’s friend Bob had a boat and knew the right spots to look for fish. The sun was bright, and the sea was choppy that day. Bob traveled out about four miles from shore. Suddenly, his motor quit, and the boat vigorously bobbed up and down on the waves.

▲
A transdermal patch placed behind the ear can deliver medication to relieve motion sickness. *Van D. Bucher/Photo Researchers, Inc.*

The Patch

One of the most effective methods of preventing motion sickness is known as “the patch.” The patch is a small spot bandage that is usually worn behind the ear. The patch slowly releases scopolamine (sko-PALL-a-meen) through the skin. Scopolamine works by suppressing certain areas of the central nervous system, which decreases motion-induced nausea and vomiting. The patch provides lasting protection against motion sickness for about three days. The most common side effect of the patch is dryness of the mouth. Other less common side effects include drowsiness and dilation (widening) of the pupils of the eyes.

* **vertigo** (VER-ti-go) is the feeling that either the environment or one’s own body is revolving or spinning, even though they are not.

First Jon felt queasy in his stomach, and then he broke out in a cold sweat. He became nauseated and vomited over the side of the boat. When they got back to shore, Jon’s queasiness went away fairly rapidly. He felt frustrated that the pleasure of the fishing trip had been ruined by his bout of motion sickness.

What Causes Motion Sickness?

Dizziness, vertigo*, and motion sickness are all related to the sense of balance and equilibrium in the inner ear. Researchers in space and aeronautical medicine call this sense spatial orientation because it tells the brain where the body is in space.

The following sensors work together to maintain a sense of spatial orientation:

- The chamber of the inner ear known as the vestibular labyrinth (ves-TIB-u-lar LAB-e-rinth) consists of fluid-filled, interconnected tubes called semicircular canals that monitor the direction of motion.
- The eyes send signals to the brain about where the body is in space.
- Skin pressure receptors tell the brain what part of the body is touching the ground.
- Muscle and joint receptors tell the brain what parts of the body are moving.
- The brain processes all the information from these sensors and puts everything together. When information from the sensors appears to conflict, the brain is confused, and in many people motion sickness occurs. When the boat Jon was in was tossed about on the waves, information from Jon’s eyes did not match the information about the boat’s movement coming from other parts of his body. This confusion caused him to feel uncomfortable and to vomit. The sensitivity to mixed sensory messages about movement seems to be inherited; motion sickness tends to run in families.

What Are the Symptoms of Motion Sickness?

Almost everyone can get motion sickness at one time or another. Some people, especially children, become queasy when riding in a car or an airplane. Other people get seasick from the rocking motion of a boat on rough water. Some people feel sick from riding a roller coaster or a spinning carnival ride or even watching a jumpy, fast-moving scene in a movie. Poor ventilation, odors such as gas fumes or smoke, and drinking alcohol make a person more susceptible to motion sickness.

People who feel motion sick may do the following:

- become pale
- yawn
- act restless

- break out in a cold sweat
- feel queasy as if they will have to vomit
- vomit, sometimes repeatedly

How Can Motion Sickness Be Prevented?

Preventing motion sickness is easier than treating it once it has begun.

Travelers should sit wherever there is the least motion. In a car, sitting in the front seat and looking straight ahead may help. In an airplane, passengers feel the least motion in a seat over the wing. On a ship, remaining on the deck and looking at the far horizon rather than nearby objects may help. Eating only a light meal before traveling and avoiding alcohol also help a person avoid motion sickness.

Over-the-counter medications such as meclizine or dimenhydrinate (Dramamine) can be effective in preventing motion sickness. They work best if taken an hour or so before traveling. Although it is not a proven medical remedy, some people rely on ginger root, either sliced and chewed or brewed as tea, as a way to prevent motion sickness. In severe or prolonged cases of motion sickness, a doctor may prescribe a scopolamine patch.

Once the symptoms of motion sickness start, they are difficult to treat while the upsetting motion continues. For most people, the symptoms stop soon after the motion stops. If the symptoms persist, the person should consult a physician because another disorder may be causing the symptoms.

Multiple Sclerosis

Multiple sclerosis (MS) is an inflammatory autoimmune disease of the nervous system that disrupts communication between the brain and other parts of the body, resulting in episodes of weakness, paralysis, blindness, fatigue, and other symptoms.*

“She Played Like an Angel”

Jacqueline Du Pré (doo-PRAY) was born in England in 1945. On her fifth birthday, her parents gave her a cello, and she started lessons the next year. At 16, Jacqueline made her concert debut in London. In 1967 she married the pianist and conductor Daniel Barenboim, and together the young, talented couple charmed the musical world. Six years later, Jacqueline could no longer feel the strings of her cello. By the mid-1970s she was unable to dress herself or stand without help. In 1987, at the age of 42, she died of multiple sclerosis (MS). Many people with MS are mildly affected, but in the most severe cases, such as Jacqueline Du Pré's, a person may be unable to write, speak, or walk.

How Does the Body Communicate Information?

The nervous system allows the human body to receive information and react to the environment. The nervous system is divided into two parts: the central nervous system and the peripheral (pe-RIF-er-al) nervous system. The central nervous system consists of the brain and the bundle of nerves that is the spinal cord. The peripheral nervous system is made up of the nerves that branch out from the spinal cord and carry signals to and from the arms, legs, organs, and other parts of the body. The basic unit of the nervous system is the nerve cell, or neuron, and each human body has billions of them. Each neuron looks something like a kite. The top of the kite, or cell body, has many fingerlike extensions called dendrites. Dendrites send information in the form of electrical impulses toward the cell body. The tail of the kite, or axon, carries electrical messages away from the cell body. Axons, or nerve fibers, are sheathed (wrapped) in a protective substance called myelin (MY-a-lin). Myelin is made of fats

and proteins, and it acts to insulate nerve fibers and to keep the electrical impulses moving rapidly along the nerve fibers.

What Is Multiple Sclerosis?

MS is an inflammation* of the nerve fibers in the brain and spinal cord that results in the scarring of “white matter” (“sclerosis” means “scarring”). White matter (abundant in the brain and spinal cord) is made up of nerve fibers (axons) and their protective myelin sheaths. The scarred regions are called plaques. When the myelin covering the nerve fibers is damaged, signals passing through the neurons slow down or may stop completely. Some research has suggested that MS plaques represent not only damaged myelin, but also (in some cases) neurons that have been completely destroyed.

MS is not a common disease. Estimates of the number of people worldwide with MS vary, but in 2007 about 400,000 people in the United States were living with the disease and about 10,000 Americans were newly diagnosed with MS each year. The disease is most frequently diagnosed in people between 20 and 40 years of age, and it affects about twice as many women as men.

What Causes Multiple Sclerosis?

As of 2009, scientists did not know exactly what causes MS, but many thought that it is an autoimmune disease triggered by exposure to something in the environment in some individuals who have genes that make them susceptible to developing the MS plaques. In a healthy body, the immune system* is continually on guard to defend against foreign disease-causing invaders, such as bacteria, viruses, fungi, and parasites. Normally the body is able to distinguish its own cells from foreign cells and attack only foreign cells. Sometimes the mechanism for distinguishing self from non-self goes awry. Some scientists think that, with MS, the body no longer recognizes the myelin as “self”, and begins to attack it.

It is not clear what underlying changes occur that cause the body to attack the myelin in people with MS. Some scientists believe that a virus triggers a malfunction of the immune system. Because the incidence of MS is not spread evenly throughout the world, others believe that factors in the environment (colder temperatures, for instance) may trigger the disease. Both of these may play a role, as may other unknown environmental factors. Genes* appear to influence who gets MS. Generally, a person’s chances of getting MS are very low. If a member of a family has MS, then that member’s parents, children, and sisters and brothers still have a very low chance of getting the disease, but it is about 5 percent higher than in people who do not have family members with MS. It also seems likely that more than one gene is involved in a person’s susceptibility to MS. The understanding as of 2009 was that many different factors, both environmental and genetic, have to come together for a person to develop MS. Scientists continue to explore how genes interact with one another and with the environment, in relation to MS, in the hope of finding new ways to treat or cure it.

Word Origin

Sclerosis comes from the Greek word for “scarring” or “hardening.”

* **inflammation** (in-fla-MAY-shun) is the body’s reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person’s body structure and physical characteristics. Inherited from a person’s parents, genes are contained in the chromosomes found in the body’s cells.

* **incontinence** (in-KON-ti-nens)
is loss of control of urination or
bowel movement.

Are There Different Types of Multiple Sclerosis?

MS manifests differently in different cases, but usually the disease follows one of several patterns. The most common pattern is called relapsing-remitting MS, in which symptoms come and go, sometimes with periods of remission (when the affected person is fine). About three-fourths of all people diagnosed with MS have this type of the disease. In about half of all people with relapsing-remitting MS, the disease eventually returns permanently with no periods of relapse. When this happens, it is called secondary progressive MS. About 10 percent of people with MS have what is called primary progressive disease, which means that the disease does not go away after the first attack. Patients with primary progressive MS tend to be older (around 40 to 60 years old). A rare form of MS is called progressive-relapsing disease in which disease symptoms are always present, more or less at a constant level, however there are periods during which they worsen.

What Are the Signs and Symptoms of Multiple Sclerosis?

MS may begin abruptly, or the initial symptoms may be so mild and gradual that a person barely notices them. In the early stages of MS, people may find that simple motions such as opening a window or climbing a few stairs tire their arms and legs. Although everyone occasionally feels numbness or “pins and needles” in their hands and feet, these feelings are much more frequent in people with mild MS. Patients often experience blurring and double vision or they may lose vision in one eye or both eyes. Sometimes eye movement becomes painful. A person may become uncoordinated. In about 75 percent of patients with MS, many of these early symptoms disappear only to reappear months or years later.

Over time, as nerve damage increases, parts of the body may become stiff or paralyzed. Many patients with MS have difficulties related to urination and bowel movements, such as incontinence* and constipation. Walking or standing may become difficult or impossible. A person may become confused or forgetful owing to damage to the part of the brain that processes information. Some people with MS become depressed or have fits of laughing or crying uncontrollably, for no apparent reason. MS tends to vary in severity and the speed at which it progresses in different people; there is no single blueprint or timeline for how the disease develops.

How Is Multiple Sclerosis Diagnosed?

MS is often difficult to diagnose, because the symptoms are varied and not specific to the disease. Symptoms of MS can be confused with those that follow a viral infection or other disease. Diagnosis must be preceded by a complete neurological exam that tests functions of the nervous system such as reflexes, muscle tone, and perception of pain, heat, and touch. The accuracy of diagnosis improved with improvements in a diagnostic

THE FIRST DIAGNOSIS OF MULTIPLE SCLEROSIS

Jean-Martin Charcot (1825–1893) is known as the father of neurology, or the study of the nervous system. In 1868, a young woman came to his clinic with an unusual tremor and other neurological symptoms. She subsequently died, and in examining her brain, Charcot found the lesions* that people later recognized as brain and spinal cord plaques caused by MS.

Charcot was the discoverer of multiple sclerosis and the first person to describe the disease. He also gave the disease its name. His work established the foundation for the research that came later, and his definition of the disease remained in use in the early 2000s.

technique called magnetic resonance imaging*, or MRI, that is able to pinpoint locale(s) of damage that MS has caused in the brain. A spinal tap, also called a lumbar puncture, can also aid in diagnosis. This test removes a small amount of the fluid that surrounds the spinal cord so that it can be examined for certain abnormalities associated with MS. Also, an evoked potential test can be used to measure how strongly (or weakly) electrical impulses are transmitted from peripheral tissue, along nerve fibers, and to the brain. Abnormalities in this test also suggest MS.

What Is the Treatment for People with Multiple Sclerosis?

As of 2009, no cure existed for MS, and there was no way to prevent the disease. Treatment varies considerably because of the range and severity of MS symptoms. Some people do well for long periods with little or no treatment. Heat seems to make the symptoms of MS worse, but swimming or a cool bath may help to reduce symptoms. Several classes of drugs are used to treat MS and more were being developed and tested in the early 2000s. Some drugs are more effective for specific types of MS. However, many drugs used to treat MS have the potential to cause serious side effects.

Not all drugs are appropriate for all patients; however, several types of drugs are commonly used to treat MS. These include the following:

- Beta interferons. These are manmade versions of protein molecules produced naturally by cells of the immune system to fight infection. They are given by injection several times a week.
- Immune system blockers (or immunosuppressants). These drugs interfere with the immune system and slow its attack on myelin. They are given by injection.
- Corticosteroids* are used mainly in people with progressive MS. Long-term use of corticosteroids causes undesirable side effects.

The United States and the World

- In 2007 it was estimated that worldwide between 1.5 and 2.5 million people have MS.
- MS is more common in temperate regions north and south of the equator, such as the United States, Canada, northern Europe, and southern South America. MS is far less common in countries with tropical climates. No one knew why as of 2009.
- Caucasians, especially those of Northern European ancestry, get MS more often than Asians or Africans, and the disease is unknown among certain native peoples such as the Inuit (Native people of the Arctic) and Maori (Native people of New Zealand).
- Women get MS twice as often as men.

* **lesions** (LEE-zhuns) is a general term referring to a sore or a damaged or irregular area of tissue.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

* **corticosteroids** (kor-tih-ko-STIR-oyds) are chemical substances made by the adrenal glands that have several functions in the body, including maintaining blood pressure during stress and controlling inflammation. They can also be given to people as medication to treat certain illnesses.

- Muscle relaxants are used to treat muscle stiffening or muscle spasms that can be painful and interfere with daily activities.
- There are also drugs reduce fatigue, as exhaustion is a common symptom of MS.

In addition to drug treatment, people with MS often benefit from physical therapy and occupational therapy, which help them to better adapt to the difficulties they experience in performing daily tasks. Because MS takes a psychological toll as well as a physical one, counseling and support groups may also be helpful both to the patient and the patient's family.

Living with Multiple Sclerosis

About one-third of people with MS have very mild symptoms and are able to lead relatively normal lives. However, many people with MS gradually become seriously disabled, and their quality of life is severely diminished. The lifespan of people with MS is, on average, five to seven years shorter than that of persons without the disease. However, MS is rarely the cause of death in persons who have the disease; these individuals usually die of complications associated with the disease, such as paralysis, pneumonia, or some other infection, which are usually a consequence of their being bedridden.

The diagnosis of MS can be devastating because patients are often young adults. Suddenly plans for a career and family must take into account a disease whose course is uncertain. Yet many people with MS continue to lead productive lives. A woman who has MS may still become pregnant and bear a child safely, although she may be instructed to discontinue her MS medications during pregnancy, and the physical limitations of the disease may make it more difficult for her to care for her child.

More mature children who have a parent who has severe MS may find it hard to accept the changes they see happening in a person they remember as capable and independent and on whom they still depend. They may feel guilty about enjoying activities that the parent who has MS can no longer perform, or they may resent having to help with simple actions such as fetching a glass of water or turning on the radio or television for the parent. MS can take a tremendous emotional and financial toll on the entire family. Support groups and counseling can help MS patients and their families achieve the best possible quality of life given the limitations imposed by the disease.

Mumps

Mumps is a contagious viral infection that causes inflammation and swelling in the glands of the mouth that produce saliva.

What Is Mumps?

Mumps is an infection caused by a virus. The mumps virus can infect various parts of the human body, but typically it attacks the salivary glands. The mouth has three pairs of salivary glands: one pair under the mouth and lower jaw; a second pair under the tongue; and a third pair in the back of both cheeks between the ear and the jaw. In most cases, mumps affects the third pair, called the parotid glands*, causing them to swell painfully.

In some patients, the virus spreads to the central nervous system* and causes a condition called aseptic meningitis*. Up to 15 percent of patients who have mumps, most commonly adults, will develop cases of meningitis with symptoms (such as headache and stiff neck).

Before the introduction of the mumps vaccine in 1967, the infection was also a major cause of acquired (not present at birth) deafness in childhood. Deafness occurs in about one out of 20,000 cases of mumps, often in only one ear.

▲ Swelling of the neck and jaw is a sign of the mumps. *Andy Levin/Photo Researchers, Inc.*

* **parotid (puh-RAH-tid) gland** is the salivary gland located in the jaw just beneath and in front of each ear.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

* **aseptic meningitis** (a-SEP-tik meh-nin-JY-tis) is a milder, non-bacterial form of meningitis that is usually caused by a virus. Meningitis is an inflammation of the meninges, or the membranes that surround the brain and the spinal cord.

A Curious Outbreak

In 2006 an outbreak of more than 5,000 cases of mumps occurred in the United States. Most of the people affected were college students who had received one or more doses of the mumps vaccine. The illness was less severe than in non-vaccinated people. Analysis of this outbreak was expected to lead to new schedules of the vaccination.

* **epidemics** (eh-pih-DEH-miks) are outbreaks of diseases, especially infectious diseases, in which the number of cases suddenly becomes far greater than usual. Usually, epidemics that involve worldwide outbreaks are called pandemics.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

Is Mumps Common?

Mumps was a common childhood illness in the United States until 1967, when a vaccine was made available to the public. Before the vaccine, most mumps infections occurred in children under the age of 15, and 5- to 9-year-olds were the most frequently affected age group. In the early 2000s, many cases were diagnosed in young adults who had not been immunized.

After 1967, cases of mumps declined steadily. Statistics indicate the dramatic impact that the vaccine had. In 1964 approximately 212,000 cases of mumps were diagnosed in the United States. By 2001 that number had dropped to 231 cases, according to the Centers for Disease Control and Prevention.

Epidemics* of mumps are rare and usually break out among people who have not been vaccinated and who live in close quarters, such as army camps and college dormitories. For example, a small outbreak of the disease occurred between 1986 and 1987, mostly in older children and college-age students, because of insufficient immunization during a period from 1967 to 1977.

How Do People Contract Mumps?

Mumps is highly contagious. People infected with the mumps virus can spread it when they laugh, cough, or sneeze. Direct contact with saliva or fluid from an infected person's nose can also spread mumps. Patients are contagious from about one day before their glands become swollen to up to three days after the swelling has improved.

What Happens When People Have Mumps?

Signs and symptoms About one in five people who develop mumps have no symptoms. Many patients who do show signs of infection have only general symptoms such as a low fever, extreme tiredness, loss of appetite, muscle pain, and headache. Symptoms usually appear within 14 to 25 days after exposure to the virus.

Only 30 to 40 percent of people who become infected with the mumps virus have the swelling in the jaw area that most people associate with mumps. Earache and tenderness in the jaw are often the first signs of inflamed parotid glands. In two out of three cases of mumps, both parotid glands become swollen and painful, with one side swelling a few days before the other. Some patients also experience swelling in the other salivary glands. Talking, chewing, and swallowing can be painful, especially if the person eats or drinks acidic or sour food and beverages (such as lemonade and orange juice), which make the salivary glands squeeze out more saliva and increase discomfort.

Diagnosis and treatment A doctor typically diagnoses mumps by examining a person who has symptoms of the infection. Other infections can cause swelling in the salivary glands, too, so a doctor may take a sample of blood to look for antibodies* to the virus. Other tests that can

be used to diagnose mumps include culturing* samples of saliva or urine to find the mumps virus.

Most cases of mumps can be treated at home. Over-the-counter pain medication, such as acetaminophen*, can ease pain and fever, and warm or cold packs can soothe the pain of swollen, inflamed parotid glands. Resting and drinking plenty of non-acidic fluids help the body recover. The symptoms of mumps begin to clear up after one week and are usually gone within 10 days.

Complications Complications of mumps are rare but can be serious and may require additional treatment under a doctor's care or even hospitalization. The infection can lead to inflammation and swelling of the brain (encephalitis, en-seh-fuh-LYE-tis), as well as inflammation of the pancreas* (pancreatitis, pan-kree-uh-TIE-tis), other organs, or the membranes covering the brain and the spinal cord (meningitis). If symptoms of encephalitis or meningitis occur, it usually is within three to seven days after the swelling of the parotid glands begins. These symptoms include high fever, stiff neck, and headache. In some patients with mumps, an electrocardiogram* (EKG) will show signs of myocarditis*, but the condition rarely is severe enough to produce symptoms with mumps.

Up to half of all males who become infected with the mumps virus after puberty* experience painful swelling of the testicles* as a complication of the disease. Usually one testicle becomes swollen, but in some cases both do. High fever, chills, headache, nausea (NAW-zee-uh), and vomiting accompany the swelling, which generally goes away within a week after it appears, along with the fever and other symptoms. In rare cases, this swelling can permanently damage the testicle leading to infertility* due to the reduced ability to produce sperm cells. Only 5 percent of females who contract mumps after puberty develop inflammation of the ovaries*, which causes abdominal* pain and other symptoms similar to those of appendicitis*.

Can Mumps Be Prevented?

Immunization is the best way to prevent mumps, and the vaccine usually is administered during early childhood. The vaccine requires two doses and generally is given in the same shot with the vaccines for measles and rubella. This combination vaccine is known as the MMR (measles-mumps-rubella) vaccine. The first dose typically is given when an infant is between 12 and 15 months old and the second when the child is between four and five years old. Avoiding close contact with someone who has been diagnosed with mumps also reduces the risk of contracting the virus, particularly if the uninfected person has not been vaccinated.

* **culturing** (KUL-chur-ing) means being subjected to a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

* **pancreas** (PAN-kree-us) is a gland located behind the stomach that produces enzymes and hormones necessary for digestion and metabolism.

* **electrocardiogram** (e-lek-tro-KAR-dee-o-gram), also known as an EKG, is a test that records and displays the electrical activity of the heart.

* **myocarditis** (my-oh-kar-DYE-tis) is an inflammation of the muscular walls of the heart.

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

* **testicles** (TES-tih-kulz) are the paired male reproductive glands that produce sperm.

* **infertility** (in-fer-TIH-lih-tee) is the inability of females to become pregnant or of males to cause pregnancy.

* **ovaries** (O-vuh-reez) are the sexual glands from which ova, or eggs, are released in women.

* **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.

* **appendicitis** (ah-pen-dih-SY-tis) is an inflammation of the appendix, the narrow, finger-shaped organ that branches off the part of the large intestine in the lower right side of the abdomen.

* **factitious** means false. In this case it refers to an impression of illness produced falsely.

* **appendicitis** (ah-pen-dih-SY-tis) is an inflammation of the appendix, the narrow, finger-shaped organ that branches off the part of the large intestine in the lower right side of the abdomen.

* **dermatitis** is a skin condition characterized by a red, itchy rash. It may occur when the skin comes in contact with something to which it is sensitive.

* **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.

Munchausen Syndrome

Munchausen (MUNCH-how-zen) syndrome is a mental disorder in which a person pretends to be physically ill or produces the symptoms of illness in order to take on the role of a patient. The 1994 Diagnostic and Statistical Manual of Mental Disorders, known as the DSM-IV classified the condition as a “factitious disorder.” Factitious disorders include pretending to be mentally ill.*

How Did Munchausen Syndrome Get Its Name?

The disorder is named for Karl Friedrich Hieronymus, Baron von Münchhausen (1720–1797), a German nobleman, soldier, and huntsman who was known for making up exaggerated stories of his exploits and adventures. The disorder itself was not recognized and fully described until the twentieth century, however, the name “Munchausen,” was applied to it.

What Are the Signs of the Disorder?

There are a great many symptoms that may be faked or produced in Munchausen syndrome. For example, a person may complain of abdominal pain, fever, rashes, bleeding, irregular heartbeat, dizziness, fainting spells, or seizures. These symptoms may appear to be signs of such disorders as appendicitis*, dermatitis*, anemia*, a heart problem, or a brain tumor, even though the person never actually had the symptoms they complained of.

People with Munchausen syndrome often are knowledgeable about medicine and hospitals. They may pretend to have a disease by complaining of a symptom, such as pain, that they do not have. Sometimes they exaggerate or imitate a disorder, such as seizures, that they really do have. Some people may actually injure themselves to create a symptom. For example, they may make themselves bleed to produce anemia. They may also describe an elaborate but false medical history to their physicians and demand medical tests and treatment with drugs or even operations. If the faking of people with Munchausen syndrome is discovered and they are denied treatment, they may start all over again, attempting to fool another doctor at another hospital. In some cases, this process may be repeated throughout a person's life.

What Causes Munchausen Syndrome?

The basic cause for the behavior of people with Munchausen syndrome is believed to be an intense need for care and sympathy. Why people with the disorder have this driving need differs for each person. Often, the disorder begins in early adulthood, after hospitalization for a real medical condition. Other influencing factors may include an important past relationship with a physician, medical employment, or even ill will harbored toward the medical profession.

Diagnosis and Treatment

The two main tasks for a physician diagnosing Munchausen syndrome are to determine that the patient does not really have the illness that the described symptoms suggest and that he or she is not malingering. Malingering occurs when a person pretends to have an illness because of some life situation, such as wanting to avoid military duty, work, or school.

Munchausen syndrome is treated with psychotherapy. The therapist attempts to help patients understand why they have an excessive need for sympathy, care, and attention. Therapists also help patients find more honest and less destructive ways to satisfy their emotional needs. In the meantime, attempts are made to protect the patient from having unnecessary operations or other medical procedures.

Munchausen Syndrome by Proxy

A variation of Munchausen syndrome, called Munchausen syndrome by proxy, occurs when a caregiver (often the mother) falsely claims that a child is ill. (“By proxy” means acting as a substitute for another.) The caregiver may either pretend that the child is ill or do something to cause a symptom or illness. For example, the caregiver may give the child too much of a laxative, causing diarrhea. Sometimes, causing illness may seriously harm the child or even result in death.

It is believed that people with Munchausen syndrome by proxy seek to gain attention as devoted caregivers rather than for being sick patients, as in Munchausen syndrome. They often have troubled marriages or may have suffered some type of abuse as a child. Munchausen syndrome by proxy is considered a form of child abuse, and in most states suspicion of this disorder must be reported to a child protective agency.

Muscular Dystrophy

Muscular dystrophy (DIS-tro-fee) is a group of inherited disorders in which there is a gradual deterioration and weakening of muscles in the body.

What Is Muscular Dystrophy?

The term “muscular dystrophy” actually refers to a group of disorders that affect different muscles in the body and that may range from mild to severe. Although all of the muscular dystrophies are known to be caused by genes*, the way in which the genes produce the disorder was as of 2009 only partly understood.

The muscles that become weakened in muscular dystrophy are mostly the voluntary muscles, those that people can control when they want to move different parts of their body. Another name for voluntary muscle is skeletal muscle. The weakness is usually symmetrical; that is, it occurs more or less equally on both sides of the body. Muscle deterioration is also progressive, or gradually increasing over time. There is no pain connected with the weakening condition, although there may be some cramps and stiffness. Mental retardation sometimes accompanies this condition.

Who Gets Muscular Dystrophy?

All types of muscular dystrophy are uncommon. Still, numbers of individuals affected range in the tens of thousands. Many people have come to know something about muscular dystrophy through the efforts of

Normal, healthy musculature

Muscular dystrophy

Healthy muscle tissue (left). Muscular dystrophy (right). *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

American comedian and actor Jerry Lewis, who appeared on television on behalf of the Muscular Dystrophy Association. Similar media appeals, such as the Téléthon in France, have raised public awareness about the disease in other countries.

The most common and severe form of the disorder, called Duchenne (du-SHEN) muscular dystrophy, affects only boys at a rate of about one in every 3,500 to 5,000 boys. (Although girls can carry the gene that causes this disease, they usually have no symptoms.) In the United States, it has been estimated that 40,000 boys and young men are afflicted with this form. In western Europe, an estimated 70,000 are affected. The incidence* is believed to be comparable throughout the world. Muscular dystrophy affects all races, ethnic groups, and social classes equally.

What Causes Muscular Dystrophy?

Whether individuals have a form of muscular dystrophy has already been determined through hereditary factors by the time they are born (even though its effects are not apparent at birth). Because it is an inherited disorder, the disease is not in any way contagious, and it is not caused by anything that might happen in everyday life.

The defective gene that causes Duchenne muscular dystrophy is located on the X chromosome*. The disorder is, therefore, said to be sex-linked. It also is recessive, which means that females who inherit the defective gene

* **incidence** means rate of occurrence.

* **chromosome** (KRO-mo-zom) is a unit or strand of DNA, the chemical substance that contains the genetic code to build and maintain a living being. Humans have 23 pairs of chromosomes, for a total of 46.

will not usually develop the disease (because they need to have the defective gene on both X chromosomes) but are carriers of it. They can pass it on to the next generation. Affected males always inherit the gene for Duchenne muscular dystrophy from their mothers, and each male born to a woman who is a carrier for the disease has a 50-50 chance of inheriting the gene.

Myotonic (mi-o-TON-ik) dystrophy, an adult form of the disorder, is inherited as an autosomal dominant gene. Autosomal means that the gene that causes the disorder is not located on a sex chromosome. Dominant means that just one defective gene in a pair is able to produce the disease. Males and females are equally affected by the faulty gene, and both can transmit the disease to their children.

Other types of muscular dystrophy follow various different patterns of inheritance, and they can affect both children and adults.

Muscles under a Microscope

The gene responsible for the Duchenne form of muscular dystrophy was discovered in 1986. That was an important breakthrough, but scientists still needed to know how the gene caused muscle weakness. The following year, a protein that was named dystrophin (DIS-tro-fin) was found to be absent in the muscles of Duchenne patients and present in normal tissue. Therefore, the defective Duchenne gene does not produce dystrophin, whereas the same gene in its normal form does produce this protein. To understand why dystrophin is important in muscle function, a powerful microscope is needed.

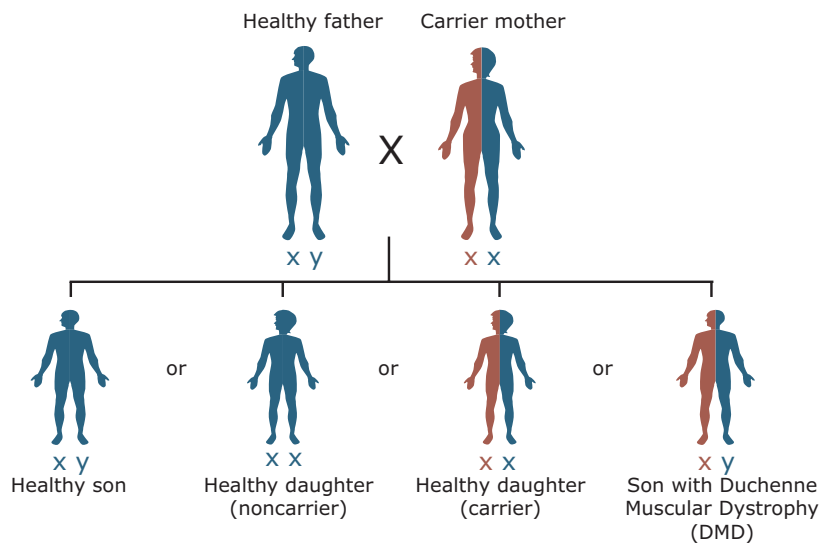

Seen under a microscope, muscles are made up of bundles of individual muscle fibers. Under greater magnification, each fiber is seen to have an outer membrane. Dystrophin is believed to be responsible for maintaining the structure of the muscle fiber membrane. Without it, the membrane tends to fall apart and become “leaky.” One of the substances that leaks out from inside the muscle fibers is creatine kinase (KREE-a-tin KI-naze), which is needed for the chemical reactions that produce energy for muscle contraction.

In other types of muscular dystrophy, the defect lies in an abnormality in another substance closely associated in function with dystrophin.

What Are the Symptoms of the Dystrophies?

There are several forms of muscular dystrophy. Some experts have listed as many as 20 types. Classification of types is based upon a person’s age at the start of the disease, the location of the muscles affected, the rate at which the disorder progresses, and the pattern of inheritance. The following are signs and symptoms of the more common and well-defined forms.

Duchenne muscular dystrophy The signs of Duchenne muscular dystrophy may not be noticed until ages three to seven, when the young boy is likely to start having difficulty walking. (Because of the way it is inherited, only boys usually have Duchenne muscular dystrophy.) Another characteristic sign is that the calf muscles, although becoming weaker, are enlarged partly because of accumulating deposits of fat in them.

Inheritance pattern of Duchenne muscular dystrophy (DMD). Sons have a 50-50 chance of inheriting the disorder from their mother if she carries the gene for it on one of her X chromosomes. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

Muscle weakness steadily advances from the lower to the upper body, and the boy needs a wheelchair usually by the time he is 12. Complications such as scoliosis (side-to-side curving of the spine) and lung infections commonly occur in the teen years, and the person may not live past his late teens or early twenties.

Becker muscular dystrophy In this form, the signs and symptoms are the same as those of Duchenne muscular dystrophy, but they begin later in life and progress more slowly. The same gene that causes the Duchenne form is responsible, but its defects are less damaging to muscle. Most affected men must eventually use a wheelchair, but some do not, and many live past middle age.

Myotonic dystrophy Myotonic dystrophy usually develops in adulthood, but it may occur as early as infancy. Males and females are affected equally. The characteristic symptom is myotonia, a delayed relaxation of muscle after it has contracted. Weakness commonly occurs in the muscles of the hands, face, neck, forearms, and lower legs.

Unlike other dystrophies, myotonic dystrophy may involve parts of the body other than the voluntary muscles. For example, the heart rate may be abnormally slowed. Cataracts may develop in the eyes. As in other dystrophies, mental retardation sometimes accompanies the condition. Nonetheless, people with mild forms of myotonic dystrophy may have relatively normal lives and survive beyond middle age.

Facioscapulohumeral muscular dystrophy Facioscapulohumeral (fay-she-o-skap-yoo-lo-HU-me-ral) muscular dystrophy gets its long name from the fact that it weakens the muscles of the face, shoulders (the scapula is the shoulder blade), and upper arms (the humerus is the upper arm bone). Facial expression is altered, and the shoulders tend to droop. Both males and females are affected, and the progression of

WHAT'S IN A NAME?

The word “dystrophy” comes originally from the Greek “dys,” which means “difficult” or “faulty,” and “trophe,” meaning “nourishment.” This word was chosen many years ago because it was at first believed that poor nourishment of the muscles was in some way to blame for muscular dystrophy. People later understood that muscle wasting in the disorder is caused by defective genes rather than poor nutrition.

The “Duchenne” in Duchenne muscular dystrophy may have been an unsuitable name as well. The French neurologist Guillaume Benjamin Amand Duchenne (1806–1875) described the disorder in detail in 1868. However, later research showed that the English physician Edward Meryon (1809–1880) had independently described the condition several years before Duchenne.

symptoms is usually slow. Symptoms often begin to appear between the ages of 10 and 40.

Limb girdle muscular dystrophy Muscle weakness in this form occurs mostly around the hips and shoulders (limb girdles). Symptoms may eventually extend to other muscles. Often, however, worsening of the condition is slow. Both sexes are affected, and symptoms may begin in late childhood or early adult life.

How Is Muscular Dystrophy Diagnosed?

A doctor may suspect that someone has muscular dystrophy just by observing certain signs of muscle weakness. If someone in the patient’s immediate family is known to have the disorder, the diagnosis becomes clearer.

To confirm the diagnosis, a blood test may be performed to look for high levels of creatine kinase, mentioned previously as a sign of Duchenne muscular dystrophy. Blood samples may also be analyzed for defective genes and can help determine the specific type of the disorder. Other tests can measure muscle activity, and a muscle biopsy, in which a tiny sample of muscle tissue is removed to be examined under the microscope, can show specific abnormalities.

How Is Muscular Dystrophy Treated?

In the early 2000s there was no cure for muscular dystrophy. Sometimes treatment with steroids was able to slow progress of muscular weakness. Treatment was aimed at maintaining general good health and mobility for as long as possible. An important goal is preventing scoliosis and often fatal lung infection. Moderate exercise, physical therapy, the use of braces, and sometimes surgery can assist walking.

Genetic counselors, using medical tests and family history, can help prospective parents make informed decisions about having children. The disease can be diagnosed in a baby before it is born; this is called prenatal testing.

Meanwhile, medical scientists in the laboratory have been working on ways to attack the cause of muscular dystrophy directly, through a technique called gene therapy.

Mushroom Poisoning

Mushroom poisoning is a type of food poisoning caused by eating wild mushrooms that contain natural substances that are toxic (poisonous) to humans. Mushroom poisoning is considered an emergency needing immediate medical care.

What Is Mushroom Poisoning?

Mushroom poisonings occur for one of three reasons:

- A collector of wild mushrooms accidentally confuses a poisonous species with an edible species, which can happen even to experts if they are hunting mushrooms in an unfamiliar area.
- A person experimentally eats a mushroom found in the wild, which commonly occurs when a curious child finds a mushroom growing in a lawn or woods.

Three views of the Death Cap mushroom (*Amanita phalloides*) one of the most dangerous natural poisons.

*Custom Medical Stock Photo, Inc.
Reproduced by permission.*

- A person intentionally eats hallucinogenic mushrooms as part of a spiritual or recreational experience. This type of poisoning is not fatal.

Of the more than 5,000 species of mushrooms growing wild in the United States, only about 100 contain compounds that are poisonous to humans, and only about twelve species can cause death. The degree to which a mushroom causes illness depends on the type of mushroom eaten, the amount eaten, and the size of the person poisoned. Toddlers and young children, because of their small size and tendency to put objects in their mouths, are the group most likely to be poisoned, followed by amateur foragers of wild mushrooms. Some poisonous North American mushrooms look like edible European and Asian mushrooms. Consequently, immigrants from Europe and Asia are the most likely foragers to be poisoned in North America.

Each year the American Poison Control Centers report about 10,000 exposures to wild mushrooms. Most years these result in fewer than 10 deaths. In about 90 percent of poisonings, the species of mushroom is never identified. Members of the genus *Amanita* account for the majority of identified mushroom poisonings. Mushroom poisoning happens more frequently in Eastern Europe and Asia where wild mushroom hunting is much more common, with most poisonings occurring in the spring or fall.

What Are the Symptoms of Mushroom Poisoning?

Mushroom poisoning symptoms can range from mild to deadly. There are two general patterns of symptoms depending on whether the mushrooms contain long-acting or short-acting toxins.

FATAL MYTHS ABOUT POISONOUS MUSHROOMS

Many myths describe edible from poisonous mushrooms. These myths can be deadly. All of the following are folklore sayings that are **not true**.

- If you cook a poisonous mushroom, it will no longer be poisonous. **False:** heating, boiling, canning, drying, pickling, or any other processing does not destroy the toxins in most poisonous mushrooms.
- If you cook poisonous mushrooms with a silver spoon, the spoon will turn black. **False:** some toxins have no effect on silver.
- Poisonous mushrooms when boiled with rice turn the rice red. **False:** many poisonous mushrooms have no effect on the color of rice.
- Poisonous mushrooms smell and taste bad. **False:** some are quite delicious.
- If an insect eats a mushroom, it is safe for a human to eat. **False:** many toxins affect humans and insects differently.
- White mushrooms are safe, brightly colored mushrooms are poisonous. **False:** the deadly *Amanita phalloides* or death cap is white, whereas many colorful mushrooms are safe to eat.
- Puffballs are always safe to eat. **False:** Some are safe, and others are not, but more importantly, an immature *A. phalloides* can look like a puffball.

Mushrooms containing long-acting toxins are more likely to cause permanent organ damage or death. The best known and most deadly poisonous mushroom in the United States and Europe is *Amanita phalloides*, also called the Death Cap. Two other members of the genus, *Amanita*, *A. virosa* (the Destroying or Death Angel), and *A. verna* (the Fool's Mushroom), and *Galerina autumnalis* (*Autumn Skullcap*) are also quite deadly. These mushrooms all produce a family of toxins called amanitins, which act by inhibiting an enzyme that is necessary for cells to reproduce. This effect eventually causes cell death.

Other species that cause severe, sometimes fatal illness through long-acting toxins include *Gyromitra esculenta* and *G. gigas* (both called False Morel), *Verpa bohemica* (Early False Morel), and *Cortinarius orellanus* (Sorrel Webcap).

Symptoms of mushroom poisoning caused by long-acting toxins fall into the a three-stage pattern.

- Stage 1: No symptoms occur for anywhere from 6 to 24 hours (except for *C. orellanus* where symptoms are delayed for 3 to 14 days). This is followed by painful abdominal cramping, vomiting, and passing

National Poison Control Center

Any time someone is suspected of having eaten a poisonous or unidentified mushroom (or been exposed to any other potentially poisonous substance), assistance can be found at the National Poison Control Center. The center can be called tollfree from anywhere in the United States at (800) 222-1222. A list of local poison control centers also can be found at <http://www.aapcc.org/DNN>.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **jaundice** (JON-dis) is a yellowing of the skin, and sometimes the whites of the eyes, caused by a buildup in the body of bilirubin, a chemical produced in and released by the liver. An increase in bilirubin may indicate disease of the liver or certain blood disorders.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

* **schizophrenia** (skit-so-FREE-nee-ah) is a serious mental disorder that causes people to experience hallucinations, delusions, and other confusing thoughts and behaviors, which distort their view of reality.

of a huge volume of watery diarrhea. Fluid loss is great enough to cause severe, sometimes fatal, dehydration*, especially among children and the elderly. This stage usually lasts about 24 hours.

- Stage 2: Diarrhea stops or slows, and the patient appears to be improving. Nevertheless, laboratory blood tests show that liver and kidney damage is occurring. This stage lasts two to three days.
- Stage 3: Liver and kidney damage become obvious. Laboratory blood and urine tests become more abnormal. Jaundice* develops as the liver fails. The kidneys may shut down. Coma* followed by death can occur in three to seven days. Death rates of between 10 and 60 percent have been reported. If recovery occurs, it can take a month or more, and some liver and kidney damage is permanent.

Mushrooms that contain short-acting toxins follow a different pattern of symptoms. Typically vomiting begins anywhere from 15 minutes to 2 hours after the mushrooms are eaten. This is often accompanied by heavy sweating, confusion, chills, tremor, loss of coordination, and sometimes breathing abnormalities. Because the person usually vomits soon after eating, fewer toxins are absorbed into the bloodstream. Generally eating a mushroom containing a short-acting gastrointestinal irritant is extremely unpleasant, but results in fairly rapid recovery and no lasting harm.

Hallucinogenic mushrooms, many of which contain psilocybin, have been used for centuries as part of mystical or spiritual experiences or for recreational purposes. These mushrooms, sometimes called magic mushrooms or little brown mushrooms (after their rather ordinary appearance), do not cause fatal reactions. They do, however, cause visual and other hallucinations. Some people experience euphoria, but others experience fear, agitation, and schizophrenia*-like symptoms. Symptoms usually wear off after a few hours. Hallucinogenic mushrooms are usually ingested intentionally. However, if children accidentally eat them, frightening and schizophrenic-like symptoms may continue for up to 72 hours.

How Is Mushroom Poisoning Diagnosed and Treated?

Diagnosis of mushroom poisoning is made on the basis of the patient's history; any samples of the mushrooms or vomit containing mushrooms, if available; and symptoms. Diagnosis is difficult if two or more types of poisonous mushrooms have been eaten at the same time, especially if one contains a short-acting and the other a long-acting toxin.

Mushroom poisoning cases in which symptoms suggest a short-acting toxin are generally treated by inducing vomiting and stomach washing, followed by dosing with activated charcoal, a product that absorbs some toxins. Patients are usually kept under observation for 24 hours to make sure there are no complications.

Treatment of long-acting toxins is more complicated. During the vomiting and diarrhea stage, intravenous fluids and electrolytes are

WHAT TO DO IF MUSHROOM POISONING IS SUSPECTED

Anyone who has eaten an unknown wild mushroom or who becomes ill after eating a wild mushroom needs a prompt medical evaluation. If mushroom poisoning is suspected, the following steps ought to be taken:

- Call the National Poison Control Center Helpline, the local poison control center, or the local emergency room and follow the advice given.
- If any of the suspect mushrooms are available, put all of them in a paper bag (not plastic) or paper towel. Do not refrigerate them. Take them along with the patient to the emergency room.
- If the patient's vomit contains bits of mushroom, save it and take to the emergency room. Sometimes experts can identify the mushroom from spores in the vomit.
- If the wild mushrooms were collected intentionally, find out which mushrooms the foragers thought they had collected. Doing so helps the experts narrow the field to look-alike species.

given to prevent dehydration and help stabilize body chemistry. Large intravenous* doses of the antibiotic penicillin G are also given. In Europe, *Amanita* poisoning is treated with silibnin, a product of the milk thistle plant that appears to reduce liver damage by limiting binding of toxin to liver cells. Because of the small number of identified *Amanita* poisonings in the United States, not enough data are available to satisfy the safety and effectiveness requirements of this treatment for its approval by the Food and Drug Administration. Silibnin is, however, sold in the United States as a dietary supplement.

When substantial kidney damage occurs, kidney dialysis* (either temporary or permanent) may be required. Survival after major liver damage requires a liver transplant.

How Can Mushroom Poisoning Be Prevented?

Mushroom poisoning can be prevented by not harvesting and eating wild mushrooms. Commercially grown mushrooms are safe. If one chooses to eat wild mushrooms, they should come from a known, reliable source. Other ways of reducing the chance of mushroom poisoning are to supervise young children and to clear the lawn of any mushrooms as they appear.

It is important for people to remember that many mushrooms which are poisonous in North America look almost identical to safe-to-eat mushrooms found in Europe and Asia, so much so that even experts are fooled. People should collect wild mushrooms in an unfamiliar area only under the supervision of a local expert.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

* **dialysis** (dye-AL-uh-sis) is a process that removes waste, toxins (poisons), and extra fluid from the blood. Usually dialysis is done when a person's kidneys are unable to perform these functions normally

Exposure to *Mycobacterium marinum* can lead to a rare infection known as “swimming pool granuloma” or “aquarium granuloma.” About 3 weeks after the bacteria enters through a break in the skin, usually on the hands, reddish bumps appear. This infection can be prevented by avoiding contact with contaminated water and wearing gloves or washing thoroughly when cleaning aquariums. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

* **mycobacteria** (my-ko-bak-TEER-e-uh) belong to a family of bacteria called “fungus bacteria” because they are found in wet environments.

* **tuberculosis** (too-ber-kyoo-LO-sis) is a bacterial infection that primarily attacks the lungs but can spread to other parts of the body.

* **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome).

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **opportunistic infections** are infections caused by infectious agents that usually do not produce disease in people with healthy immune systems but can cause widespread and severe illness in patients with weak or faulty immune systems.

Mycobacterial Infections, Atypical

Atypical mycobacterial (my-ko-bak-TEER-e-ul) infections are infections caused by mycobacteria other than those that cause tuberculosis*.*

What Are Atypical Mycobacterial Infections?

Atypical mycobacteria are commonly found in the environment, such as in soil and water, and in food. Most of the time they do not cause infection or illness in healthy people. When a person’s immune system is weakened, however, as occurs in people who have HIV* or AIDS*, several strains of mycobacteria can cause opportunistic infections*. Atypical mycobacteria are related to the bacterium that causes tuberculosis (TB), but they often are resistant to the drugs used to treat TB. These strains are called “mycobacteria other than tuberculosis,” or MOTT. Sometimes, they also called “nontuberculous mycobacteria,” or NTM.

Although some mycobacteria can live on human skin or in the nose, atypical mycobacterial infections are not known to spread from person to person. Rather, infection comes from direct contact with the bacteria in the environment.

Are Atypical Mycobacterial Infections Common?

Mycobacterial infections other than tuberculosis are uncommon. Most frequently they affect people with HIV or AIDS. As cases of HIV and AIDS increased from the 1980s into the early 2000s, so did instances of mycobacterium infections, and in the United States, these infections were more common than tuberculosis. People with seriously weakened immune systems or chronic lung disease are at greatest risk.

How Do People Know They Have an Atypical Mycobacterial Infection?

Signs and symptoms of atypical mycobacterial infections include fever, swollen lymph nodes, extreme tiredness, night sweats, weight loss, diarrhea (dye-uh-REE-uh), joint and bone pain, cough, shortness of breath, skin lesions*, general discomfort, and paleness. Many of these symptoms can be signs of less serious conditions, but in a person with a weakened immune system a combination of such symptoms suggests a MOTT infection. In children, lymphadenitis* is the most common type of MOTT infection, whereas lung infections, which occur less often in children, are the most common in adults.

What Are Some Specific Infections?

Mycobacterium avium complex (MAC) MAC includes the species *Mycobacterium avium* (A-vee-um) and *Mycobacterium intracellulare* (in-truh-sel-yoo-LAR-e). MAC most commonly causes lymphadenitis and lung disease in otherwise healthy people. Patients who have AIDS are particularly susceptible to MAC, and the infection often spreads to the blood, lungs, spleen, liver, bone marrow*, and intestines in people with HIV. MAC infection in an HIV-positive person can signal the start of full-blown AIDS. Such a so-called disseminated disease* rarely occurs in people with healthy immune systems.

Mycobacterium marinum This infection causes skin lesions, sometimes known as swimming pool granuloma* or fish tank granuloma. Infection with *M. marinum* (MAR-ih-num) is very rare, occurring in less than 1 in 100,000 people. Most at risk are people with weakened immune systems and people who handle fish, are exposed to contaminated water in aquariums, or swim in fresh or salt water that contains the mycobacterium. Several weeks after a person has contact with contaminated water, a bump appears on a hand, arm, or foot where there was a break in the skin. The lesion grows and drains over several weeks, leaving an ulcer*. Occasionally, a deep infection will cause tenderness and swelling in the nearby bone or joints.

Mycobacterium ulcerans Infection with *Mycobacterium ulcerans* (UL-sir-ans) occurs in tropical and subtropical regions in Asia, the Western Pacific, and Latin America, but it is most common in West Africa. The infection causes skin lesions known as Buruli (boo-REH-lee) ulcers, named for a region in Uganda in Africa. The ulcers develop mainly on the limbs, grow

* **lesions** (LEE-zhuns) is a general term referring to a sore or a damaged or irregular area of tissue.

* **lymphadenitis** (lim-fah-den-EYE-tis) is inflammation of the lymph nodes and channels of the lymphatic system.

* **bone marrow** is the soft tissue inside bones where blood cells are made.

* **disseminated disease** describes a disease that has spread widely in the body.

* **granuloma** (gran-yoo-LO-muh) is chronically inflamed and swollen tissue that often develops as the result of an infection.

* **ulcer** is an open sore on the skin or the lining of a hollow body organ, such as the stomach or intestine. It may or may not be painful.

Lady Windermere Syndrome

Lady Windermere Syndrome is a particular kind of atypical mycobacterial condition that causes chronic cough, fatigue, weight loss, and other less specific symptoms. It particularly affects older women who do not have an immune disorder or other lung disease. The syndrome is named for a character in Oscar Wilde's 1892 play *Lady Windermere's Fan*. In the play, Lady Windermere is a very fussy young woman who maintains her composure to the point of refusing to cough in public.

When the syndrome was named in 1992, it was proposed that this suppression of coughing may lead to an inflammation in part of the lungs, and this in turn makes the lungs more prone to a mycobacterial infection.

* **culture** (KUL-chur) is a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

* **sputum** (SPYOO-tum) is a substance that contains mucus and other matter coughed out from the lungs, bronchi, and trachea.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many X-rays of the body to create a three-dimensional picture.

* **endoscopy** (en-DOS-ko-pee) is a type of diagnostic test in which a lighted tube-like instrument is inserted into a part of the body.

slowly, and release a toxin (or poison) that damages the skin and underlying tissue. The infection is relatively painless, but if left untreated it can destroy massive amounts of skin and bone, leading to permanent deformities.

Mycobacterium kansasii Infection with *Mycobacterium kansasii* (kan-ZAS-e-eye) causes a lung disease similar to tuberculosis, although not as severe. Patients may experience fever and cough, and a doctor often hears wheezing and “crackling” when listening to the patient’s lungs. This infection can also involve the lymph nodes and cause skin lesions. In people with weak immune systems, the infection can erupt into widespread disease. This infection is rare in the United States, but people with chronic lung disease are especially susceptible. If left untreated, the disease frequently worsens and can be fatal.

How Do Doctors Diagnose and Treat Atypical Mycobacterial Infections?

A doctor can perform several tests to detect mycobacteria, including examination and culture* of samples of blood, sputum*, bowel movement, or bone marrow. Chest x-rays or computerized tomography* (CT) scans can show disease in the lungs. Some cases may require endoscopy* to collect a sample of lung or stomach tissue or biopsies* of skin or lymph node tissue. A quick diagnosis of mycobacterial infections is crucial, as treatment must begin as soon as possible.

A doctor may also order a PPD (purified protein derivative) skin test for tuberculosis. Because atypical mycobacteria are so similar to the bacterium that causes TB, this test will often be positive in patients with an atypical mycobacterial infection, although not as strongly positive as it would in patients with tuberculosis.

Treatment for mycobacterial infections depends on the type of bacterium, the location and severity of the infection, and on the status of the person’s immune system. Resistant and severe infections usually require treatment with a combination of antibiotics, and doctors may prescribe up to six medications to use at once. Surgery, sometimes along with medications, is the most effective way to treat lymph node infections and skin lesions.

Treatment for MOTT infections can take six months to two years. Antibiotics work during the growth stage of bacteria, and mycobacteria are slow-growing. If left untreated, MOTT infections can spread throughout the body, especially in people with weak immune systems. They can cause abscesses*, bone and joint infections, and infections of the lymph nodes, lungs, or soft tissue. Widespread infections can lead to serious illness and even death.

Can People Prevent Atypical Mycobacterial Infections?

Because mycobacteria are common in the environment, these infections are difficult to prevent, especially in people with weakened immune systems. Doctors may prescribe preventive medications for people who

are at risk, such as those with HIV or AIDS. Getting enough sleep and eating a healthy diet can also help these patients cope with and fight these infections.

Mycoplasma Infections

Mycoplasma (my-ko-PLAZ-muh) infections are caused by a type of very small bacteria. These infections usually involve the lungs or the urinary and genital tracts.

What Are Mycoplasma Infections?

Scientists have identified at least 16 species of these tiny bacteria; three have been linked to disease in humans, and researchers have explored possible relationships between other species and a variety of diseases.

Mycoplasma pneumoniae (my-ko-PLAZ-muh nu-MO-nye) is the cause of atypical or “walking” pneumonia (nu-MO-nyah, inflammation in the lungs), a form of pneumonia that is characterized by symptoms similar to those of the flu and is generally less serious than other types of pneumonia. Widespread outbreaks of mycoplasma pneumonia occur every four to eight years. Most people recover without lasting effects, but elderly patients and people with weak immune systems may experience complications from the infection.

Commonly found in the genital and urinary tracts of adults, *Mycoplasma hominis* (HAH-mih-nis) and *Ureaplasma urealyticum* (yoo-REE-uh-plaz-muh yoo-ree-uh-LIH-tih-kum) are known as the genital mycoplasmas. These organisms can cause urethritis* and contribute to vaginitis* in women. They have been associated with sexually transmitted diseases (STDs) and with chronic infections in people with weakened immune systems. Up to 50 percent of sexually active women are colonized* with *U. urealyticum*, which can spread to newborn babies

* **biopsies** (BI-op-seez) are tests in which small samples of skin or other body tissue are removed and examined for signs of disease.

* **abscesses** (AB-seh-sez) are localized or walled off accumulations of pus caused by infection that can occur anywhere within the body.

* **urethritis** (yoo-ree-THRY-tis) is inflammation of the urethra (yoo-REE-thra), which is the tube through which urine passes from the bladder out of the body.

* **vaginitis** (vah-jih-NYE-tis) is inflammation of the vagina (vah-JY-nah), which is the canal in a woman that leads from the uterus to the outside of the body.

* **colonized** means that a group of organisms, particularly bacteria, are living on or inside the body without causing symptoms of infection.

- * **sickle-cell disease** is a hereditary condition in which the red blood cells, which are usually round, take on an abnormal crescent shape and have a decreased ability to carry oxygen throughout the body.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.
- * **immunity** (ih-MYOON-uh-tee) is the condition of being protected against an infectious disease. Immunity often develops after a germ has entered the body. One type of immunity occurs when the body makes special protein molecules called antibodies to fight the disease-causing germ. The next time that germ enters the body, the antibodies quickly attack it, usually preventing the germ from causing disease.
- * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.
- * **cultures** (KUL-churz) are tests in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

during delivery. In premature infants, *U. urealyticum* may contribute to pneumonia and other infections, as well as to chronic lung disease.

Because these organisms are also found in healthy people and infants, their presence in someone who is sick does not necessarily mean mycoplasma is the culprit behind that particular infection. Although mycoplasma species such as *U. urealyticum* or *M. hominis* may be responsible for some infections, in many cases it appears that they help start or worsen an illness that is actually caused by another infectious organism.

Mycoplasma Pneumonia

The Centers for Disease Control and Prevention estimates that 2 million people contract mycoplasma pneumonia in the United States each year. Of these, 100,000 require hospitalization. Fatal cases are rare and usually occur in the elderly and in people with sickle-cell disease*.

Mycoplasma pneumonia most frequently affects people between the ages of 5 and 40; it is rarely seen in children under the age of 5. Outbreaks are common in groups of young adults, often in places where people are crowded together, such as in military facilities and college dormitories.

Mycoplasma is contagious, spreading through tiny drops of moisture from the nose and throats of infected people when they cough, sneeze, laugh, or talk. Sharing drinking glasses or eating utensils can spread the bacteria as well. Engaging in sexual activity without the use of a condom invites infection from sexually transmitted bacteria. In all cases, to become infected, someone must have close contact with the sick person.

The time between exposure and the appearance of symptoms is relatively long (1–4 weeks), so the disease can spread for months within a home without family members realizing they are passing along the same infection. After a bout of *Mycoplasma pneumoniae* infection, antibodies* will protect a person from re-infection, but this immunity* does not last for life.

Signs and symptoms Symptoms of mycoplasma pneumonia infection come on gradually. Many people have symptoms similar to those of the flu, such as sore throat, headache, weakness, fever, cough, and chills. Less common symptoms include earaches, eye pain, muscle aches, joint stiffness, skin rash, swollen lymph nodes* in the neck, and difficulty breathing. Some people have only a mild illness, whereas others develop the more full-blown classic walking pneumonia.

Diagnosis The physical exam is an important part of diagnosing mycoplasma pneumonia. A school-age child with fever, a cough, and wheezing or crackling sounds in the lungs may have mycoplasma. A chest x-ray helps confirm the diagnosis. Doctors do not usually order cultures* on samples of fluid from the nose or throat because the mycoplasma bacteria do not grow easily in cultures.

Although blood tests are not helpful in making a diagnosis early on, after about a week of illness, a blood test known as cold agglutinins (uh-GLOO-tuh-nins) is positive in half to three-fourths of all patients.

This test is not specific for *M. pneumoniae* (other infections can also give a positive test result), but information from it can help support a diagnosis of suspected walking pneumonia. Tests for specific antibodies produced by the body to mycoplasma require at least two blood samples over time to show the body's response to the infection.

Treatment Antibiotics, along with rest and fluids, help most patients recover. Some people get better without medicine, especially those who have only a mild illness. In severe cases, patients may need to be hospitalized so they can receive oxygen and other breathing support.

Symptoms usually last from one to four weeks, although the dry cough and extreme tiredness may linger for several more weeks.

Complications Few people die from mycoplasma pneumonia, but the elderly are most at risk. Complications are not common but can include acute respiratory distress (extreme difficulty in breathing) and respiratory failure.

Other complications are even rarer: pericarditis (per-ih-kar-DYE-tis, inflammation of the sac around the heart); anemia (uh-NEE-me-uh, a deficiency of red blood cells); and diseases of the central nervous system*, including Guillain-Barré syndrome (GEE-yah bah-RAY SIN-drome, a temporary inflammation of the nerves that causes muscle weakness and paralysis*), encephalitis (en-seh-fuh-LYE-tis, inflammation of the brain), and meningitis (meh-nin-JY-tis, inflammation of the membranes lining the brain and spinal cord).

Prevention The best defenses against mycoplasma pneumonia are frequent, thorough hand washing and not sharing food, drinks, or eating utensils.

Genital Mycoplasma Infection

Mycoplasma hominis infects up to 30 to 50 percent of sexually active men and women. *Ureaplasma urealyticum* may infect more than half of sexually active women and 5 to 20 percent of sexually active men. The habitual use of condoms during sexual activity helps prevent infection from these bacteria.

Twenty percent of newborns are colonized with these bacteria, but colonization rates drop significantly by three months of age. Premature infants have the greatest risk of colonization; up to half of all premature infants less than 34 weeks' gestational* whose mothers are colonized may pick up the bacteria during birth. Genital mycoplasmas spread through direct contact during all forms of sexual intercourse. Mothers also can pass the bacteria to their babies during pregnancy and delivery.

Signs and symptoms Most people with genital mycoplasma infection have no symptoms. Those who do may have a discharge (flow of fluid) from the urethra and pain or difficulty urinating. In rare cases, symptoms can include respiratory problems and joint pain, usually in people with weak immune systems.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

* **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.

* **gestational** (jes-TAY-shun-al) means relating to pregnancy.

- * **pelvic inflammatory disease** refers to an infection of a woman's internal reproductive organs, including the fallopian tubes, uterus, cervix, and ovaries.
- * **stillbirth** is the birth of a dead fetus.
- * **premature birth** (pre-ma-CHUR) means born too early. In humans, it means being born after a pregnancy term lasting less than 37 weeks.
- * **infertility** (in-fer-TIH-lih-tee) is the inability of females to become pregnant or of males to cause pregnancy

Occasionally, women develop urethritis from mycoplasma infection, and although genital mycoplasma does not cause vaginitis, it may contribute to infections caused by other vaginal organisms, resulting in vaginal discharge. Pelvic (lower belly) pain may be a symptom of pelvic inflammatory disease* brought on by mycoplasma, alone or with other STDs. In pregnant women, *U. urealyticum* can cause inflammation of the membranes and fluid surrounding the unborn baby called asymptomatic chorioamnionitis (a-simp-toh-MAH-tik kor-e-o-am-nee-ahn-EYE-tis), which has been linked to a greater risk of stillbirth* and premature birth*.

The symptoms of infection in newborns can be subtle. Fever, changes in blood pressure and heart rate, and difficulty breathing may be the first signs of a problem.

Diagnosis Samples are taken from the areas of suspected infection (such as a swab of discharge from the vagina), and the organism is grown with special culture techniques.

Treatment Antibiotics are prescribed to treat genital mycoplasma infections in people who have symptoms. In cases in which mycoplasma is found along with other disease-causing organisms, these other infections must be treated as well.

Genital mycoplasma infections generally respond to treatment within one to two weeks, although these infections commonly return.

Complications Complications are rare in healthy adults but may include inflammation of other parts of the genital tract. Some adults, especially those with weakened immune systems, may have bone and joint infections, skin infections, and lung disease. The bacteria also have been linked to infertility* in women. Infected newborns, especially premature babies, may develop pneumonia or chronic lung disease and are at risk for meningitis and for spread of the disease throughout their bodies.

Prevention Because many people carry genital mycoplasma bacteria but do not know they are infected, preventing their spread is difficult. Regular use of condoms helps prevent the spread of many genital infections, including this one. However, abstaining from all forms of sex (not having sex) is the only sure way to prevent infection.

Myocardial Infarction *See Heart Disease.*

Myocarditis and Pericarditis

Myocarditis (my-ob-kar-DYE-tis) is inflammation of the heart muscle, and pericarditis (per-ih-kar-DYE-tis) is inflammation of the smooth sac surrounding the heart.

What Are Myocarditis and Pericarditis?

Myocarditis, or inflammation of the muscular walls of the heart, is most commonly caused by viruses; however, it can also be caused by bacteria, parasites, and fungi. Other causes of the condition include radiation, chemicals, cocaine use, and prescription medications. Conditions that affect several parts of the body, such as autoimmune disease*, also can be associated with both myocarditis and pericarditis.

When the pericardium (per-ih-KAR-dee-um), the smooth, double-layered sac-like covering that surrounds the heart, becomes inflamed—known as pericarditis—fluid usually accumulates in the space between its layers. As the amount of fluid increases, the buildup puts pressure on the beating heart and can limit its ability to function. Many of the same infections that cause myocarditis can cause pericarditis as well, and the two can appear together. In addition to the infectious causes of pericarditis, heart surgery or a heart attack* can lead to an inflamed pericardium and accumulation of fluid around the heart.

How Common Are Myocarditis and Pericarditis?

Myocarditis and pericarditis are uncommon complications of many infectious diseases. Many cases of myocarditis are mild and go undetected when the person is sick. In fact, it is difficult to determine exactly how many people develop myocarditis or pericarditis. However, some evidence of myocarditis is found in 1 to 4 percent of autopsies*. In almost all of these cases, there were no symptoms of the disease while the person was alive.

Are Myocarditis and Pericarditis Contagious?

Neither myocarditis nor pericarditis is directly contagious. However, many of the organisms that cause infections that can lead to myocarditis or pericarditis are spread from person to person by coughing or sneezing. It is not clear why myocarditis or pericarditis develops in some people but not in others. A combination of the infection, a person's genes*, and an individual's immune response probably determines who will develop these conditions.

* **autoimmune disease** (aw-toh-ih-MYOON) is a disease in which the body's immune system attacks some of the body's own normal tissues and cells.

* **heart attack** is a general term that usually refers to a sudden, intense episode of heart injury. It is usually caused by a blockage of a coronary artery, which stops blood from supplying the heart muscle with oxygen.

* **autopsies** (AW-top-seez) are examinations of bodies after death to look for causes of death or the effects of diseases.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

- * **congestive heart failure** (kon-JES-tiv) or heart failure, is a condition in which a damaged or overworked heart cannot pump enough blood to meet the oxygen and nutrient needs of the body. People with heart failure may find it hard to exercise due to the insufficient blood flow, but many people live a long time with this condition.
- * **electrocardiogram** (e-lek-tro-KAR-dee-o-gram), also known as an EKG, is a test that records and displays the electrical activity of the heart.
- * **echocardiogram** (eh-ko-KAR-dee-uh-gram) is a diagnostic test that uses sound waves to produce images of the heart's chambers and valves and blood flow through the heart.
- * **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.
- * **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.
- * **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

What Are the Signs and Symptoms of Myocarditis and Pericarditis?

Because both conditions can seriously affect the heart's function, they may lead to signs and symptoms of heart failure. Patients with myocarditis may experience fever, rapid heartbeat, extreme tiredness, difficulty breathing, and chest pain—often described as “sharp” or “stabbing”—that can range from mild to severe, sometimes with heart attack-like intensity. In serious cases, congestive heart failure*, fainting, and, sometimes, sudden death can occur.

Pericarditis often is accompanied by chest pains that radiate from front to back, trouble breathing, and pain when taking a deep breath. These conditions usually improve when the patient is sitting and leaning forward or standing. They usually worsen if the patient is lying flat. Other symptoms may include dry cough, extreme tiredness, fever, rapid heartbeat, and chills.

How Are Myocarditis and Pericarditis Diagnosed?

A doctor suspects myocarditis based on symptoms and a physical exam. For instance, a rapid heartbeat, fluid in the lungs, and swollen ankles and feet may point to heart failure, which can occur with myocarditis. The history of the patient's illness is another important clue, as the patient often has had symptoms of a viral infection within the previous two weeks to six months.

To assess the heart's condition, the doctor may order any of a variety of tests. Although a chest x-ray often appears normal in the early stages of the illness, it may show an enlarged heart or fluid-filled lungs. An electrocardiogram* (EKG) may show evidence of heart inflammation and can help identify a heart attack as the possible cause of the symptoms. An echocardiogram* may show the decreased heart function seen in myocarditis. Blood tests that reveal inflammation of the heart muscle are often abnormal in people with myocarditis and can help in making the diagnosis. A biopsy* of a piece of heart muscle can provide a definitive diagnosis. Other tests may be done to identify a specific virus or other infectious organism, but in many cases the exact cause of the inflammation is never found.

To diagnose pericarditis, doctors look for signs of fluid around the heart. During a physical exam, physicians also listen for a rubbing sound that can be heard when the pericardial sac is inflamed. If enough fluid is present, the heart may appear enlarged on a chest x-ray. The fluid itself can be seen on an echocardiogram, a computerized tomography* (CT) scan, or a magnetic resonance imaging* (MRI) scan. An EKG can be helpful in making the diagnosis as well.

How Are Myocarditis and Pericarditis Treated?

Myocarditis and pericarditis may be difficult or impossible to prevent, but prompt recognition and treatment of these conditions will improve the chances of recovery. With both myocarditis and pericarditis, doctors strive to identify and treat the underlying cause, reduce the inflammation,

and improve the heart's function. These are serious conditions that usually require hospitalization once the patient has developed detectable symptoms.

Anti-inflammatory medicines such as aspirin, nonsteroidal anti-inflammatory medications, or corticosteroids* may be prescribed to reduce inflammation. Patients also may receive medicine to ease pain and diuretics* to remove excess fluid from the body. Depending on the cause and the complications of the inflammation, other treatments may be necessary as well, including antibiotics and medications that control heart rhythm problems and improve heart function.

Some cases of pericarditis may require pericardiocentesis (per-ih-KAR-dee-o-sen-tee-sis), or the removal of fluid from the pericardial sac with a needle. This procedure relieves pressure on the heart and collects fluid for tests. In chronic or recurrent cases, the doctor may recommend surgery to cut or remove part of the pericardium. During recovery, the patient's activity usually is restricted, and doctors typically recommend diet changes such as eating less salt. Cases of myocarditis and pericarditis may last from two weeks to three months, although some people never fully recover their prior heart function.

What Are Some Complications of Myocarditis and Pericarditis?

Complications of these conditions can be very serious. The heart muscle may become damaged and unable to pump effectively. Heart failure, irregular heartbeat, and death may occur. In some cases, if the heart muscle has been severely and permanently damaged, a heart transplant may be considered.

N

Narcolepsy

Narcolepsy (NAR-CO-lep-sy) is a serious, chronic sleep disorder characterized by excessive daytime sleepiness (EDS), fatigue, and sudden sleep attacks, due to the inability of the brain to regulate sleep-wake cycles normally.

What Is Narcolepsy?

The term “narcolepsy” was introduced by the French physician Jean-Baptiste-Édouard Gélinau (1859–1928) in 1876 and literally means a sleep attack (“narco” means “stupor”) and (“lepsy” means “attack”), and the condition is the result of a defect in the ability of the brain to regulate sleep-wake cycles.

How Common Is Narcolepsy?

Narcolepsy is the second most common sleep disorder, affects nearly 1 in 1,000 to 2,000 men and women or about 3 million people worldwide. Symptoms usually start in childhood and adolescence but are often not recognized until between age 35 and 45. Narcoleptic symptoms are often attributed to other conditions such as depression*, epilepsy*, or even laziness.

What Are the Effects of Narcolepsy?

Normally, there are four to six sleep cycles during eight hours of sleep. While falling asleep, brain waves slow down and enter into non-rapid eye movement (NREM) sleep. The purpose of NREM is restorative and refreshing sleep, and it lasts for up to 90 to 120 minutes. This period is followed by rapid eye movement (REM) sleep. REM sleep is characterized by complete paralysis* of all muscles except those of the eye, which leads to rapid eye movements and hence the name. Dreaming occurs most often during this stage, but due to muscle paralysis, dreams cannot be acted out. In narcolepsy, the NREM phase is abbreviated or absent with a quick onset of REM phase, which results in nighttime and daytime sleep attacks with accompanying muscle paralysis and vivid dreaming.

What Are the Symptoms and Signs of Narcolepsy?

There are four classic features of narcolepsy and only about one-third of patients have all symptoms.

▲ People with narcolepsy may fall asleep at any time even while driving. ©by Leitha Etheridge-Sims.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

* **epilepsy** (EP-i-lep-see) is a condition of the nervous system characterized by recurrent seizures that temporarily affect a person's awareness, movements, or sensations. Seizures occur when powerful, rapid bursts of electrical energy interrupt the normal electrical patterns of the brain.

* **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **genetic predisposition** is a tendency to get a certain disease that is inherited from a person's parents.

* **antigen** (AN-tih-jen) is a substance that is recognized as a threat by the body's immune system, which triggers the formation of specific antibodies against the substance.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

Excessive daytime sleepiness Narcoleptics have uncontrollable drowsiness during the day, which is the result of the brain trying to compensate for the lack of NREM sleep at night. It is seen in all patients and is often the first symptom to emerge and the most persistent. Onset of sleep can be unpredictable and physically irresistible. Each sleep period can last a few minutes or up to 30 minutes. In contrast to a person with sleep apnea, the narcoleptic wakes up feeling refreshed and alert. However, this alertness is often followed by another sleep attack at varying intervals. Such sleep behavior is quite disruptive to a person's daily life and can be quite dangerous if it happens during certain situations, such as while driving a car. In addition, narcoleptics can have "microsleep episodes," which last a few seconds and can be accompanied by "automatic behavior" where they continue to talk or act like they are awake but have no recollection of what transpires during these episodes.

Cataplexy The word "cataplexy" is Greek ("Kata" means "down") and ("plexy" means seizure*). It refers to a sudden loss of voluntary muscle control, often triggered by a strong feeling such as what one feels while laughing or when angry. About 70 percent of narcoleptics have experienced at least one episode of cataplexy. The severity of cataplexy can range from mild (slurred speech) to severe (knees buckling and falling down). The episode lasts a few seconds to a few minutes and the person is always conscious. The number of attacks varies from one per day to a few per year.

Sleep paralysis Sleep paralysis are brief (1–2 minute) episodes of inability to talk or move while awakening from sleep or while falling asleep. They are quite frightening, as the person can remember the episode but has no control over it and cannot prevent it. They are often associated with hypnagogic hallucinations. These attacks, however, do not cause any permanent damage, and people recover quickly.

Hallucinations Hallucinations are vivid and often frightening dream-like experiences that occur while falling into REM sleep (*hypnagogic*) or on awakening (*hypnapompic*). They occur due to the intrusion of REM associated dreaming into a wakeful state, resulting in fragmented and restless nighttime sleep with patients acting out their dreams sometimes.

Is Narcolepsy Hereditary?

Narcolepsy occurs sporadically and has some genetic predisposition*. About 50 to 90 percent of patients with narcolepsy and cataplexy have an antigen* on the surface of white blood cells, which is a marker for the disease, but is not the cause of it. For example, 20 percent of normal individuals also have this particular antigen. This specific antigen type is thought to predispose an individual to develop narcolepsy through a hitherto unknown immune system* disturbance. Some 8 to 12 percent of narcoleptics have a close family member with narcolepsy. Relatives of a narcoleptic have a 1 to 2 percent chance of having narcolepsy and a 4 percent chance of having excessive daytime sleepiness (EDS).

What Causes Narcolepsy?

The exact cause of narcolepsy was unknown as of 2009. It is thought that some sort of trigger (such as an infection) might activate the immune system of the individual to attack and destroy specific cells in a part of the brain called the hypothalamus* that normally secrete a chemical called hypocretin, leading to its reduction or complete absence. Hypocretin helps to stabilize wakefulness by stimulating certain alertness centers in the brain and prevents inappropriate transition to REM sleep. It also inhibits REM sleep and REM associated behavior, such as sleep paralysis and dreaming. The total lack or decrease of hypocretin results in the symptoms of narcolepsy. Rarely, patients may have a defect in a receptor leading to normal but ineffective levels of hypocretin. Narcolepsy can also be a manifestation of rare genetic* disorders such as Prader-Willi or Niemann-Pick.

How Is Narcolepsy Diagnosed?

The diagnosis of narcolepsy is usually made by a sleep specialist or in a sleep clinic. A detailed history is taken, including when the symptoms began, what exact symptoms are present and estimation of degree of sleepiness. The Epworth sleepiness scale rates the degree of sleepiness on a numbered scale from 0 (no chance of dozing) to 3 (high chance of dozing) depending on how likely a person is to doze off under eight circumstances, for example, in front of the television, in a public place, or in a car. The total of the responses is the patient's score. A score of 0 to 9 is normal, 10 or above indicates non-normal sleepiness. The sleep specialist may also ask the patient to keep a sleep diary to keep track of episodes of sleepiness and alertness. In addition, a small device called an actigraph 2 may be worn around the wrist like a watch, and it measures how and when a person sleeps.

Polysomnogram Polysomnogram consists of monitoring brain waves (electroencephalogram (EEG)*), muscle activity, breathing, and heart rhythm (electrocardiogram) by electrodes and monitors attached to the scalp, face, eyes, jaw, limbs, chest, and abdomen. The patient sleeps overnight in a monitored environment, such as a sleep clinic. Based on the pattern of NREM, REM and REM-associated behaviors, the diagnosis of narcolepsy is made, and other diagnoses such as sleep apnea are excluded. Narcoleptics fall asleep quickly, go into REM sleep rapidly, exhibit REM behaviors such as cataplexy and have frequent nighttime awakenings.

Multiple sleep latency test The multiple sleep latency test consists of four or five scheduled naps during the day, with naps spaced two hours apart. Based on the time it takes an individual to fall asleep, narcolepsy can be diagnosed. A normal person takes 15 to 20 minutes to fall asleep and gradually progresses through NREM to REM sleep, whereas a narcoleptic falls asleep within five minutes and enters rapidly into REM sleep.

* **hypothalamus** (hy-po-THAL-uh-mus) is a brain structure located deep within the brain that regulates automatic body functions such as heart rate, blood pressure, temperature, respiration, and the release of hormones.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **electroencephalogram** an instrument that records the electrical activity of the brain.

- * **cerebrospinal fluid** (seh-ree-bro-SPY-nuhl) is the fluid that surrounds the brain and spinal cord.
- * **antidepressant medications** are used for the treatment and prevention of depression.
- * **amphetamines** (am-FET-a-meenz) are stimulants, drugs that produce a temporary feeling of alertness, energy, and euphoria.
- * **palpitation** is the sensation of a rapid or irregular heartbeat.
- * **addiction** (a-DIK-shun) is a strong physical or psychological dependence on a physical substance.
- * **impotence** (IM-po-tens) is failure of a man to achieve or to maintain an erection.
- * **stem cell** an unspecialized cell that gives rise to differentiated cells.

Hypocretin and genetic analyses Levels of hypocretin can be measured in the cerebrospinal fluid*. A narcoleptic has low or absent hypocretin levels. Testing for the particular antigen can be done, but as discussed above it is not specific and does not prove that a person has narcolepsy. These research tests are available only at specialized centers.

How Is Narcolepsy Treated?

Narcolepsy is a chronic disorder like diabetes and cannot be cured. Treatment needs to be tailored to the most disturbing symptoms, may take several months to get to an appropriate regimen, and, even then, may result in only partial symptom relief.

Narcolepsy is often treated with medications, namely stimulants and antidepressant medications*.

Amphetamines Amphetamines* stimulate the brain and ensure alertness during the day. Side effects include palpitations*, nervousness, and feeling “high.” They also have abuse and addiction* potential.

Modafinil Modafinil is a non-amphetamine medication approved by the Food and Drug Administration (FDA) in 1999. It does not have addiction potential, but headache is the most common side effect.

Antidepressants Tricyclic antidepressants (Imipramine) and serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac) suppress REM sleep and REM sleep behavior. Side effects include impotence*, heart rhythm abnormalities, and high blood pressure.

Sodium oxybate Sodium oxybate (gamma hydroxy butyrate, Zyrem) is the only medication that controls cataplexy and EDS in patients with resistant narcolepsy. It was approved by FDA in 2002. It is an illegal drug in several countries and is popularly called the “date rape” drug. Side effects include breathing disturbances and bedwetting. Due to safety concerns and abuse potential, it is subject to FDA regulation.

Caution is to be exercised while taking any of the above medications as they can adversely interact with over-the-counter cough and cold remedies. As of 2009, experiments involving stem cell* transplantation and direct delivery of hypocretin into the brain were being conducted in animals, but this research was considered a long way away from human studies.

Lifestyle modifications and behavioral strategies Behavioral strategies include the following:

1. Regular sleep schedule
2. Taking short naps during the day
3. Avoiding alcohol, caffeine, and nicotine at night
4. Regular exercise four to five hours before sleeping
5. Sleeping in a comfortable environment

Narcoleptics should avoid engaging in activities that need long periods of alertness such as operating hazardous machinery or taking long drives. Narcoleptics can request reasonable workplace accommodations in accordance with the Americans with Disabilities Act. Children should work with their school personnel to facilitate modification of class schedules and to take medications. Finally, people around the patient should know about the condition, so they can be supportive and help with the emotional and physical aspects of the condition.

Nearsightedness

Nearsightedness, which is also called myopia (my-O-pee-ah), is an eye condition that causes objects that are not close to a person to appear out of focus or blurry.

Normal vision: far object is focused on the retina

Nearsightedness: far object is focused in front of the retina

Kate's Story

Kate noticed she was squinting when she needed to see the board from the back of her classroom. Squinting helped bring the words into focus. It seemed odd to her because she did not remember having to squint when she was younger. But now that she was in middle school, Kate was having trouble seeing things unless they were close.

Kate has a common eye condition known as nearsightedness. It affects more than 60 million people in the United States and often is not noticed until a child is between 8 and 12 years of age. Fortunately, nearsightedness is usually corrected easily with eyeglasses or contact lenses.

What Is Nearsightedness?

Nearsightedness means a person can see objects that are close but has trouble seeing distant objects clearly. The condition results when a person's eyeball is not shaped to focus properly when light passes through it. In most cases the eyeball is too long, but in some cases the front of the eye is curved abnormally.

The image passes through the front of the eyeball, as light does through the lens of a camera. As it does, the image is bent in order to focus it. The bending is known as refraction (re-FRAK-shun), and this process focuses the image on the retina at the rear inside of the eyeball. The retina functions little like the film in a camera. It receives the image. If a person's eyeball is not shaped properly, the light from the image is focused in front of the retina, which results in a blurred image for distant objects.

How Is Nearsightedness Diagnosed?

The first sign that a person is nearsighted usually occurs in childhood between the ages of 8 and 12. Often a teacher notices that a student is having trouble seeing the board. The teacher may notice the student squinting, which can help focus distant objects for nearsighted people. Sometimes the condition is discovered during a routine eye examination during childhood. Nearsightedness also is called myopia, which comes from a Greek word for "closed eyes," perhaps because squinting is common in nearsightedness.

What Are the Treatment Options for Nearsightedness?

Eyeglasses Prescription (pre-SKRIP-shun) eyeglasses are the most common solution for nearsightedness. The glasses change how the light passing through the eye is focused. Contact lenses worn on the eyeball also can help nearsightedness.

As a child passes through the teenage years, nearsightedness often gets worse because as the body grows, the shape of the eyeball changes too. Thus, people with nearsightedness may need to change prescription eyeglasses or contact lenses as they get older. By the time people reach their twenties, however, nearsightedness usually stabilizes and does not get worse.

Surgery Some people with mild or moderate nearsightedness may benefit from refractive surgery. A surgeon makes small incisions in the surface of the eye, known as the cornea, to flatten it. Doing so allows the image to be focused on the retina. Another type of surgery involves a laser that changes the shape of the cornea to achieve the same result. Many people who have the surgery no longer need glasses at all.

Nephrotic Syndrome

Nephrotic (ne-FRAH-tik) syndrome, or nephrosis (ne-FROH-sis), is a disorder of the filtering mechanism of the kidneys that causes the body to lose protein from the blood, which is then sent into the urine. Loss of protein results in such physical problems as excess body fluid, loss of appetite, and general tiredness. The syndrome is characterized by proteinuria (an excess amount of protein in the urine), hypoalbuminemia (an abnormally low level of albumin in the blood), and hyperlipidemia (an excess of fats, especially cholesterol in the blood), and edema. The blood filtering mechanism of the kidneys (glomerular membrane) may be damaged by infection, immune processes, toxins, and other factors. Nephrotic syndrome is a serious condition, but it can be treated effectively with medication and diet. Most children with the condition recover.*

Children—more likely boys—are at an increased risk from nephrosis, especially from minimal change nephrotic syndrome, when they are in the range of ages from eighteen months to four years. In adults, the risk from the disease, especially with regards to membranoproliferative glomerulonephritis, is about equal between men and women.

▲ The armpit of a five-year-old African HIV-positive boy shows swollen lymph glands due to nephrotic syndrome, caused by Kaposi's sarcoma. Dr. M.A. Ansary/Photo Researchers, Inc.

* **edema** (e-DEE-ma) means swelling in the body's tissues caused by excess fluids.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

Sally's Story

During the summer when Sally was seven years old, she stopped eating much of anything at meals, laid around the house all day, and seemed too tired to do her chores or play with friends. At first Sally's mother thought her daughter was just being lazy, but when Sally's whole body began to look puffy, especially her eyes, ankles, and abdomen, her mother began to worry.

The doctor identified Sally's puffiness as edema and asked Sally about how often she had been going to the bathroom. When Sally said she was urinating only about twice per day, the doctor suspected a kidney problem. The doctor ran several tests. An analysis of Sally's urine showed that it contained high levels of protein; and a blood test showed low levels of protein and high levels of cholesterol. These results made the doctor suspect nephrosis.

The doctor performed several additional tests to eliminate other diseases, then he confirmed the diagnosis with a kidney biopsy*. Ultimately, he could not figure out why Sally had developed nephrosis. He explained to Sally and her parents that her condition could not be cured but that medications and a low-fat, low-salt diet would help relieve the symptoms.

What Is Nephrosis?

The kidneys are a pair of bean-shaped organs located in the human abdomen just above the waist. Their chief role is to filter wastes and excess water out of the blood. The filtering units in the kidney are tiny blood vessels (or capillaries) called glomeruli (glom-ER-you-li), which remove body waste from the body as urine. Nephrosis is a kidney disease caused by a defect in the glomeruli.

When the glomeruli are damaged, the filtering mechanism does not work properly. Instead of keeping proteins in the blood—while allowing excess water, fluids, salt, and wastes to pass through the filter into collecting tubules where they become urine—the glomeruli filters leak. This action allows proteins to move out of the bloodstream along with the water, wastes, and other substances, and to be excreted in the urine. Loss of large amounts of protein from the blood allows fluid to leak out of the bloodstream into the body's tissues. The retention of fluid gives the body, especially the face and legs, a puffy and bloated appearance.

What Are the Symptoms of Nephrosis?

The earliest symptom of nephrosis is the observation of foamy looking urine when released into the toilet. Excess proteins in the urine often produce such an effect. The most common symptom of nephrosis is edema in the body, which often shows up as puffiness around the eyes, especially after first waking up from sleep. Puffiness in the hands, feet, ankles, and legs are often noticed, along with a temporary pitting of the skin at some locations. Excess fluid is also found in the pleural cavity (which is the space in the chest that surrounds the lungs) and in the peritoneal cavity

(the space in the abdomen that contains the stomach, liver, and intestines). The individual also feels increasingly fatigued and weak, with an associated reduction in weight due to a lessened appetite. Muscles become smaller and weaker. Abdominal pain, trouble breathing, headaches, fever, and skin sores can also occur. When the body becomes weakened, the hair and nails become brittle, and bones break easily as the body continues to lose nutrients.

What Causes Nephrosis?

Children as well as adults can develop nephrosis. But causes for the glomeruli defect that often results in nephrosis was unknown as of 2009. One facet known about nephrosis, however, is that it can develop as part of other diseases, including the following:

- Hypertension (high blood pressure)
- Infection
- Diabetes, a condition in which the body cannot produce sufficient amounts of the hormone insulin to regulate the amount of sugar in the blood
- Systemic lupus erythematosus (sis-TEM-ik LOO-pus er-i-them-a-TO-sus), sometimes just called lupus, which is a chronic inflammatory disease that can affect the kidneys and other organs
- Amyloidosis (am-i-loy-DO-sis), a condition in which a protein called amyloid collects in the tissues and organs
- Hereditary disorders
- Myeloma (my-e-LO-ma), a tumor derived from bone marrow cells, and multiple myeloma, which involves multiple sites of myeloma
- Glomerulonephritis (glom-er-u-lo-ne-FRY-tis), a condition in which the glomeruli become inflamed and scarred

In addition, overuse of some drugs (such as laxatives), exposure to certain chemicals (e.g., lead or carbon tetrachloride), and, in some people, exposure to certain allergens (such as poison ivy, poison oak, poison sumac, and insect stings) can affect the functioning of the kidneys and lead to nephrosis.

There are four primary types of nephrosis. The types are diagnosed based on the appearance of the kidney tissue in biopsies*. The most common type is minimal change nephrotic syndrome (MCNS), or minimal change disease. MCNS often occurs after upper respiratory infections, during the presence of cancerous tumors, and with adverse reactions to drugs (such as non-steroidal anti-inflammatory drugs [NSAIDs] such as aspirin, ibuprofen*, and naproxen) and bee stings. It occurs in children in about 90 percent of the nephrotic cases, but is found in only one in five adult cases of the condition.

The other three types of nephrosis are classified as membranoproliferative glomerulonephritis (MPGM), which is caused by groups of antigens and antibodies deposited in the glomerular basement membrane;

* **biopsies** (BI-op-seez) are tests in which small samples of skin or other body tissue are removed and examined for signs of disease.

* **ibuprofen** (eye-bew-PRO-fin) is a nonsteroidal anti-inflammatory drug (NISAD) used to reduce fever and relieve pain or inflammation.

* **diuretics** (dye-yoor-EH-tiks) are medications that increase the body's output of urine.

* **triglycerides** (try-GLISS-eh-rides) are a type of fatty substances found in the blood.

membranous glomerulopathy (membranous), which damages the glomerular basement membrane, the membrane that separates blood from urine; and focal segmental glomerulosclerosis (FSGS), which involves only some of the glomeruli, includes only portions of those affected glomeruli, and produces scarring within the affected glomeruli.

How Is Nephrosis Diagnosed?

Several tests are available to diagnose nephrosis. The most important is a urine test that shows the presence of proteinuria. When a person has nephrosis, the level of proteinuria in the urine is greater than two grams when measured over a twenty-four-hour urine collection period.

As a result of abundant proteinuria, the patient develops hypoalbuminemia, which is demonstrated by testing the blood for albumin. Levels generally below three grams per deciliter indicate a very low level of the water-soluble protein albumin in blood serum.

The condition called hypercholesterolemia shows that the body contains high levels of cholesterol in the blood. When nephrosis is present, test results indicate an elevated low-density lipoprotein (LDL), which transports cholesterol within the body, along with a higher-than-normal level of very low-density lipoprotein (VLDL). Both LDL and VLDL are commonly referred to as “bad cholesterol.”

Other tests include evaluating the plasma concentrations of electrolytes (such as calcium, potassium, and sodium), urea, and creatinine in order to test the efficiency of the kidneys to filter out waste products.

A kidney biopsy may also be performed. During the biopsy, a thin needle is inserted under the ribs and a tiny sample of the kidney is removed for examination with an electron microscope, which provides high quality images that are magnified millions of times for accurate analysis of the sample.

It is important to perform several tests because other diseases and conditions can act like nephrosis. Numerous tests help to eliminate the possibility of other problems so that nephrosis can be accurately diagnosed within patients.

What Is the Treatment for Nephrosis?

How nephrosis is treated depends on its cause. If it is caused by another disease, that underlying disease is treated. If the cause of nephrosis is not known, the symptoms may be treated with antibiotic drugs to reduce infections. Diuretics* are used to reduce edema. To reduce protein loss in the urine and hypertension, angiotensin converting enzyme (ACE) inhibitors are prescribed. Prednisone, by itself, or with immunosuppressive drugs are also often used to reduce protein loss. Medicines to reduce high blood pressure, cholesterol, and triglycerides* may be given. Corticosteroid is used to reduce signs of inflammation and allergic reactions. A diet low in fat (especially saturated fat), cholesterol, and salt might be recommended, and fluid intake might be restricted.

People with nephrosis, especially children, often recover when nephrosis is treated promptly and early. However, nephrotic patients may be at increased risk for complications from heart diseases and atherosclerosis, other kidney diseases, infections, and malnutrition. If the kidneys lose their ability to function, dialysis* may be necessary. Difficulties with blood pressure control may also occur.

Neural Tube Defects

Neural tube defects occur when the neural tube fails to close properly during gestation.

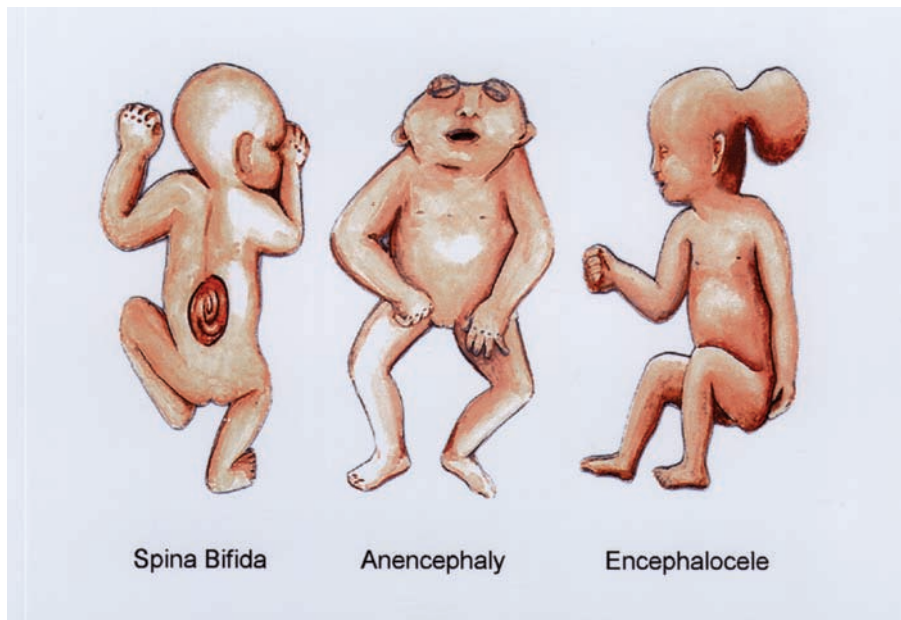

Neural Tube Defects: Overview

During fetal development, a structure known as the neural tube is formed. This tube later develops into the central nervous system* in the adult. The process of neural tube formation is called neurulation. The neural tube must close completely. However, the ends of it may be defective, and most neural tube defects involve the ends of the tube. Complete neurulation is essential to brain formation and function in the adult. Closure defects occur during pregnancy usually around 24 to 28 days after fertilization, or approximately three to four weeks into the pregnancy. Two of the most common neural tube defects are anencephaly and spina bifida. Anencephaly is caused by the improper closure of the anterior (upper) end of the neural tube, resulting in a fetus that is missing some or most of the brain. Spina bifida is caused by the improper closure of the posterior (lower) end of the neural tube, resulting in a lack or partial covering of the end of the spinal cord.

* **dialysis** (dye-AL-uh-sis) is a process that removes waste, toxins (poisons), and extra fluid from the blood. Usually dialysis is done when a person's kidneys are unable to perform these functions normally.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

Three common neural tube defects: Spina bifida (left) appears as a mass on the back/spine covered by skin or the meninges; Anencephaly (center) in which the brain is exposed; Encephalocele (right) in which a mass containing brain is located on the head. *Illustration by Greenwood Genetic Center. Reproduced by permission.*

* **incidence** means rate of occurrence.

How Common Are Neural Tube Defects?

In 2005 spina bifida occurred in nearly 18 individuals per 100,000 live births in the United States. This rate was significantly lower than in previous years. In 2005 the rate of anencephaly was nearly 12 individuals per 100,000 live births, also down from previous years. The overall incidence* of neural tube defects in live births declined through the previous several decades, perhaps due to better screening techniques and early pregnancy termination. The highest incidence in the United States is in the Appalachian regions, and the rate is higher overall in the East than in the West. In the United States, Hispanic people have three times as many neural tube defects as the rest of the population. Females are more likely than males to have anencephaly.

Internationally, neural tube defects are among the most common types of birth defects. Studies done on Caucasian populations show the lowest incidence of neural tube defects in mainland Europe. The highest rates among Caucasians occur in Great Britain, especially in Scotland and Ireland. The highest overall incidence of neural tube defects in the world occurs in Northern China, with a rate of 3.7 cases per 1,000 live births. Areas with high incidence specifically of anencephaly include Ireland, Scotland, Egypt, and New Zealand. Japan has the lowest incidence of anencephaly and other neural tube defects. Individuals of Celtic ethnic origin have the highest incidence of spina bifida.

What Are the Signs and Symptoms of Neural Tube Defects

Neural tube defects generally cause obvious physical features that are readily distinguished. Anencephaly is obvious at birth, because affected babies are missing a good portion of their brain and part of their skull. The

area of missing skull may or may not be covered by skin. Facial features are present and may appear relatively normal. Breathing and reflexes are present, but these babies are missing the portion of the brain responsible for consciousness and are also deaf and blind. Anencephaly causes death either during the pregnancy or shortly after birth. By contrast, symptoms of spina bifida may include a tuft of hair at the base of the spine and an obvious sac in which the spinal cord protrudes and is exposed.

Outcomes for cases of neural tube defect vary. Cases of anencephaly cause death shortly after birth. Other types of neural tube defects may cause progressive deterioration of the nervous system, resulting in a poor prognosis. Mental retardation occurs with some types of neural tube defects. Neural tube defects involving the posterior end of the neural tube may result in paralysis of the lower limbs, as well as bladder and bowel incontinence*. Babies with neural tube defects that are severe enough to expose portions of the central nervous system may have a complication known as meningitis, an infection of the lining of the brain and spinal cord. The type and severity of the neural tube defect determines whether the individual will survive to adulthood.

How Does Folic Acid Prevent Neural Tube Defects?

Folate is a form of folic acid, a type of B vitamin necessary for human health. Folate is found in some food groups and can also be taken as a vitamin supplement. It is a critical component of neural tube formation, although the exact mechanism by which it works in cell growth remained unclear as of 2009. Folic acid is necessary for the production of DNA*, the genetic building blocks of the human body. Cell growth and division requires the synthesis of DNA. Embryonic development, including the nervous system, is a period of rapid and intensive growth involving lots of DNA synthesis. Therefore, folic acid is an absolute requirement for the formation of what will be fetal organs and tissues early on in pregnancy. For this reason it is important to have adequate levels of folic acid in the body not only during pregnancy, but even in the time period right before it. Neural tube formation takes place in the third to fourth week of pregnancy. Many pregnant women are not aware of their pregnancy until after this time, and so they may engage in activities that harm neural tube formation without realizing it. In order to reduce the risk of neural tube defects, sexually active women of child-bearing age are encouraged by healthcare providers to take folic acid supplements.

Among women who have a pregnancy affected by a neural tube defect, the recurrence risk is approximately 2 to 4 percent for subsequent pregnancies. If there are multiple occurrences of neural tube defects within a family history, the risk is higher. These women ought to take even more folic acid than women without this history. Folic acid supplementation is responsible for preventing two-thirds of neural tube defects and is a critical component of prevention.

* **incontinence** (in-KON-ti-nens) is loss of control of urination or bowel movement.

* **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.

- * **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.
- * **antihistamines** (an-tie-HIS-tuh-meens) are drugs used to combat allergic reactions and relieve itching.
- * **anticonvulsants** (an-tie-kon-VUL-sents) are medications that affect the electrical activity in the brain and are given to prevent or stop seizures.
- * **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.
- * **cerebrospinal fluid** (seh-ree-bro-SPY-nuhl) is the fluid that surrounds the brain and spinal cord.

What Are Other Causes of Neural Tube Defects?

Many different environmental factors besides folic acid deficiency play a role in the development of neural tube defects. Maternal type 1 diabetes; maternal obesity*; environmental toxins, including some found in corn meal; poisons such as arsenic; and excessively high maternal body temperature may all contribute to neural tube defects during pregnancy. Hyperthermia, a term used to describe excessively high body temperature, may be caused by fever or recreational activities such as using a hot tub. Certain prescription drugs have been linked to the development of neural tube defects, including some antihistamines* and anticonvulsants*. Neural tube defects may also have a genetic component that predisposes certain individuals to respond more to environmental factors.

How Are Neural Tube Defects Diagnosed?

Alpha-fetoprotein (AFP) is a substance made in the liver of the fetus*. AFP can be measured in the blood and amniotic fluid of a pregnant woman. The level of AFP present is used to determine the likelihood of the presence of neural tube defects. In this manner, AFP measurement can generally be used as a screen for neural tube defects. Values of AFP approximately 2.5 times above normal are considered a sign of neural tube defects. If the mother has type 1 diabetes, the production of AFP during pregnancy is delayed and altered and so may be difficult to use as a screen.

How Are Neural Tube Defects Treated?

Neural tube defects may be open, meaning that a portion of the nervous system is exposed to the area outside the enclosed and protected central nervous system, placing the child at risk for infection. Because of this, some open neural tube defects such as spina bifida with an exposed spinal cord are treated with surgery to physically close the defect. In this case, surgical closure generally helps to prevent further complications of injury and infection, but it usually does not correct the other symptoms associated with the defect. Neural tube defects that affect the placement of structures of the brain may be treated surgically to reduce physical pressure on specific brain regions. If the neural tube defect causes blockage in the flow of cerebrospinal fluid* a shunt may be surgically placed in the brain, which allows fluid to drain away and thus prevents pressure build-up.

Neuroblastomas

Neuroblastomas are unusual cancers of immature or developing nerve cells in infants or young children. They often metastasize to other parts of the body.

What Are Neuroblastomas?

Neuroblastomas are malignant* tumors* of the autonomic nervous system*. They occur when primitive neurons* fail to mature normally and begin to divide uncontrollably. Neuroblastomas may release hormones* that cause changes in the body. They can also affect some brain functions.

About one-third of all neuroblastomas are diagnosed during the first year of life, and 90 percent are diagnosed by the age of five. Only about 2 percent of neuroblastomas occur in children over 10 years of age or in adults.

Two-thirds of neuroblastomas originate in the abdomen*. About one-half of these begin in the nerve-like cells in the medulla at the center of the adrenal glands* and one-half originate in clusters of nerves called ganglia in the abdomen. Other neuroblastomas may come from the chest or neck ganglia.

Sometimes, especially in very young infants, neuroblastoma cells die on their own and the tumor disappears. Other times the neuroblastoma cells spontaneously mature into ganglion cells that do not continue to divide and the tumor becomes a benign* ganglioneuroma. A ganglioneuroblastoma is a tumor that contains both malignant and non-malignant cells.

What Causes Neuroblastomas?

The causes of neuroblastomas are not well-understood. Nerve and adrenal medulla cells develop from fetal* cells called neuroblasts. Neuroblastomas are believed to occur when neuroblasts fail to mature due to mutations* in their DNA*. Instead the neuroblasts continue to grow and divide.

About 1 to 2 percent of neuroblastomas appear to have a hereditary component, with other family members having had the cancer as infants.

How Common Are Neuroblastomas?

Neuroblastomas are the most common cancer in infants and the fourth most common cancer in children. There are about 650 new cases in the United States every year.

- * **malignant** (ma-LIG-nant) refers to a condition that is severe and progressively worsening.
- * **tumors** (TOO-morz) are abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.
- * **autonomic nervous system** is a branch of the peripheral nervous system that controls various involuntary body activities, such as body temperature, metabolism, heart rate, blood pressure, breathing, and digestion. The autonomic nervous system has two parts—the sympathetic and parasympathetic branches.
- * **neurons** are nerve cells. Most neurons have extensions called axons and dendrites through which they send and receive signals from other neurons.
- * **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.
- * **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.
- * **adrenal glands** (α-DREEN-al glands) are the pair of endocrine organs located near the kidneys.

- * **benign** (be-NINE) means a condition is not cancerous or serious and will probably improve, go away, or not get worse.
- * **fetal** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.
- * **mutations** (mu-TAY-shuns) are changes in a chromosome or a gene.
- * **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.
- * **diarrhea** (di-ah-RE-a) refers to frequent, watery stools (bowel movements).
- * **high blood pressure** also called hypertension, is a condition in which the pressure of the blood in the arteries is above normal.
- * **spasms** (SPAH-zumz) are involuntary muscular tightenings or contractions.
- * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.
- * **bone marrow** is the soft tissue inside bones where blood cells are made.
- * **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.
- * **prenatal** (pre-NAY-tal) means existing or occurring before birth, with reference to the fetus.

Children with this familial form tend to be diagnosed at a younger age, and they often develop neuroblastomas in two or more organs.

What Are the Symptoms of Neuroblastomas?

The symptoms of neuroblastomas depend on the original location of the tumor and how far the cancer has metastasized (spread). The most common sign is a lump or mass, usually in the abdomen. The abdomen may swell, and the child may complain of a stomachache. The mass can be found elsewhere in the body, such as the neck or back of the eye. Depending on the location of the neuroblastoma, symptoms may include constipation or breathing, vision, or behavioral problems. Neuroblastomas frequently spread to the bones, and older children may complain of bone pain or have difficulty walking.

Paraneoplastic (caused by cancer located elsewhere in the body) syndromes are associated with less common symptoms caused by hormone-releasing neuroblastomas:

- Persistent diarrhea*
- High blood pressure* causing irritability
- Rapid heartbeat
- Flushing
- Sweating

Opsoclonus-myoclonus-ataxia syndrome, also known as “dancing eyes, dancing feet,” is an uncommon symptom characterized by irregular, rapid eye movements, muscle spasms*, and difficulty walking and possible difficulty in speaking. Surprisingly, neuroblastomas that cause this syndrome are less life-threatening than other forms.

How Are Neuroblastomas Diagnosed and Treated?

Diagnosis Because of their early age of onset, neuroblastomas can be difficult to diagnose. Up to 60 percent of cases are not diagnosed until they are already in the late stage when they have metastasized, especially to the lymph nodes*, bones, bone marrow*, liver*, or skin. Rarely, neuroblastomas are diagnosed during prenatal* ultrasound*. Sometimes neuroblastomas are discovered during tests for other childhood diseases. These cases usually have good outcomes and may not even require treatment.

About 90 percent of neuroblastomas overproduce chemicals called catecholamines* that can be detected in the blood or urine. Elevated levels of the hormones dopamine* or norepinephrine* in the blood can also be a sign of neuroblastoma. Additional tests measure blood-cell counts, liver and kidney* function, and salt balance.

Imaging tests used to diagnose and stage neuroblastomas include:

- Chest or head x-rays
- CT scans* of the abdomen, pelvis, or chest

HOW ARE NEUROBLASTOMAS STAGED?

The International Neuroblastoma Staging System may be used to measure the extent of the cancer, which helps determine the treatment and prognosis:

- Stage 1: The cancer has not spread, is on only one side of the body, and can be surgically removed.
- Stage 2: The cancer is localized, is on one side of the body, and may or may not be completely removed by surgery.
- Stage 3: The cancer cannot be completely removed surgically or is spreading to the other side of the body.
- Stage 4: The cancer has spread to distant sites or organs.
- Stage 4S (“special”): The child is less than one-year-old; the cancer is localized on one side of the body but may have spread to some lymph nodes, the liver, and skin; no more than 10 percent of bone-marrow cells are cancerous. 4S neuroblastomas often disappear spontaneously.
- Recurrent: The cancer has returned after treatment.

- MRI*
- Ultrasound
- Positron emission tomography*
- MIBG scans, which locate the tumor and metastasized cells. A radioisotope (MIBG, iodine-131-meta-iodobenzylguanidine) is injected into a vein. This compound attaches to specific tumor cells.
- Bone scans

A definitive diagnosis of neuroblastoma requires a biopsy*. The biopsied tissue may be tested with antibodies* against neuroblastoma cells.

About one-half of neuroblastomas spread to the bone marrow. Bone marrow is sampled by aspiration* and biopsy to diagnose and stage the cancer.

Treatment Treatment for neuroblastoma usually includes one or more of the following:

- Surgery to remove all or as much of the tumor as possible
- External-beam radiation therapy* before or after surgery
- A combination of several chemotherapy* drugs before or after surgery or as the primary treatment for metastasized tumors
- A highly radioactive form of MIBG for advanced neuroblastoma
- A treatment with 13-cis-retinoic acid usually for six months following primary treatment, to reduce the risk of recurrence in high-risk children

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **catecholamines** (kat-e-KO-la-meens) are hormones and neurotransmitters such as epinephrine, norepinephrine, and dopamine.

* **dopamine** (DOE-puh-meem) is a neurotransmitter in the brain that is involved in the brain structures that control motor activity (movement).

* **norepinephrine** (NOR-e-pi-nefrin) is a body chemical that can increase the arousal response, heart rate, and blood pressure.

* **kidney** is one of the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **MRI** which is short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

* **positron emission tomography** (POZ-i-tron i-MISH-en toe-MAH-gruh-fee) also called PET imaging or PET scanning, uses a radiotracer that accumulates in an area of the body and emits gamma rays that are detected as diagnostic images.

* **biopsy** (Bl-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.
- * **aspiration** (as-puh-RAY-shun) is the sucking of fluid or other material out of the body, such as the removal of a sample of joint fluid through a needle inserted into the joint.
- * **radiation therapy** is a treatment that uses high-energy radiation from x-rays and other sources to kill cancer cells and shrink cancerous growths.
- * **chemotherapy** (KEE-mo-THER-ah-pee) is the treatment of cancer with powerful drugs that kill cancer cells.
- * **transplants** (TRANS-plantz) are organs or tissues from another body used to replace a poorly functioning organ or tissue.
- * **metastases** (me-TAS-tah-seez) are new tumors formed when cancer cells from a tumor spread to other parts of the body.
- * **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.
- * **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.
- * **chromosome** (KRO-mo-zom) is a unit or strand of DNA, the chemical substance that contains the genetic code to build and maintain a living being. Humans have 23 pairs of chromosomes, for a total of 46.

Children who undergo bone-marrow-destroying chemotherapy receive bone-marrow transplants* with their own previously collected stem cells. This treatment has significantly increased the cure rate for neuroblastomas.

Prognosis Early-stage neuroblastomas—before metastases* occur—have a cure rate of over 90 percent. Later-stage neuroblastomas have a cure rate of only 30 percent, despite multimodal therapy.

Children are placed in risk groups based on the cancer stage and other factors:

- Low-risk children are usually cured by surgery alone.
- Intermediate-risk children have an 85–90 percent chance of surviving for five years.
- High-risk children have a five-year-survival of about 30 percent.

Other factors are considered in the prognosis:

- Children aged 12–18 months are more likely to be cured than older children.
- Many dying or dividing tumor cells indicates a less favorable prognosis.
- Fewer growing tumor cells and more mature nerve tissue indicates a better prognosis.
- The amount of DNA* in the tumor cells, the number of copies of certain cancer genes*, chromosome* abnormalities, certain receptors* on the cells, and various factors in the blood can all affect the prognosis.

Can Neuroblastomas Be Prevented?

As of 2009, there was no known prevention for neuroblastomas. Several countries, including Japan, Germany, and Canada, attempted to implement newborn-screening programs for neuroblastoma by measuring the levels of catecholamines in the urine, but these programs failed to improve the cure rate. However, a Canadian study found that eating foods fortified with folate (folic acid) during pregnancy cuts the risk of neuroblastoma by 60 percent. Folate fortification of grain products has been required in the United States since 1998.

Neurofibromatosis

Neurofibromatosis (noor-o-fy-bro-ma-TO-sis) is a genetic disorder that causes tumors to grow on nerves and that is also characterized by skin changes and deformities in bone.

What Is Neurofibromatosis?

The most common form, called neurofibromatosis type 1 or NF-1, mainly affects nerves in the skin, producing soft nodules or bumps. Neurofibromatosis type 2 (NF-2) is a very rare disorder that affects the auditory nerves

* **receptors** are cell structures that form a chemical bond with specific substances, such as neurotransmitters. This leads to a specific effect.

The characteristic skin changes and bone deformities of neurofibromatosis are often visible on the face and head. *AP Images.*

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

responsible for hearing and balance. Both types are caused by defective genes*.

Neurofibromatosis also is called Recklinghausen's disease, after the German physician Friedrich von Recklinghausen (1833–1910), who described it in 1882. The tumors he noted, called neurofibromas (noo-rof-y-BRO-mas), arise from the cells that make up the covering sheaths of the nerves.

NF-1 and NF-2 neurofibromatoses occur in both sexes and in all racial and ethnic groups. In the United States, NF-1 occurs in about 1 of 4,000 persons. NF-2 is ten times less common, occurring in about 1 in 40,000 people.

What Causes Neurofibromatosis?

Although many people who have neurofibromatosis inherited it from one of their parents, between 30 and 50 percent developed it spontaneously from a mutation (change) in their genes before birth.

Neurofibromatosis is inherited as an autosomal (non-sex-linked) dominant disorder, which means that each child born to a parent with neurofibromatosis has a 50 percent chance of inheriting the defective gene and developing the disease.

Genes produce proteins that determine a person's body physical and metabolic characteristics, everything from the color of a person's hair to how fast a person burns fat. Scientists have discovered that the neurofibromatosis genes, when normal, produce proteins that suppress tumors. This function suggests that when the genes are defective, they may fail to produce enough of these proteins, thus allowing the growth of tumors. Further research in the early 2000s was needed to confirm this theory, however.

What Are the Signs and Symptoms of Neurofibromatosis?

The signs and symptoms of neurofibromatosis vary greatly among individuals even in the same family. Many people do not know that they have NF-1 until it is diagnosed during a routine physical exam. The disease is usually mild.

NF-1 produces many soft, bumpy or stalk-like tumors under the skin. Another common sign of this disorder is light-brown patches on the skin called cafe-au-lait spots. Although these spots may appear in people who do not have NF-1, people with NF-1 usually have six or more of them. Signs may also include freckles in the armpits or groin areas, growths in the eye or on the optic nerve, deformation of bones, and scoliosis, a side-to-side curvature of the spine.

These signs first appear in infancy or early childhood and increase as a person grows older. Occasionally, tumors are massive or in rare cases become cancerous. They may also occur inside the body, squeezing or blocking internal organs.

The symptoms of NF-2 include tumors on the auditory (acoustic) nerves. These growths can cause loss of hearing and may damage nearby

nerves and structures in the brain. Tinnitus (ti-NY-tus; a ringing in the ears), balance disturbances, or headache can also occur. People with NF-2 may first notice these symptoms in their teen or early adult years.

It should be noted that the presence of significant high blood pressure in a patient with neurofibromatosis should cause the physician to search for an associated tumor of the adrenal gland called pheochromocytoma, which causes hypertension by the release of catecholamines*.

How Is Neurofibromatosis Treated?

The diagnosis of neurofibromatosis is made mainly by noting its outward signs. Internal viewing techniques, such as MRI (magnetic resonance imaging), are sometimes needed as well. Treatment is then designed to control symptoms.

Operations and braces may be needed to correct scoliosis. Surgery may also be performed to remove tumors that are exceptionally large, painful, or that press on organs. The tumors often grow back, however.

Various cancer treatments may be used in rare instances in which tumors become malignant*. Progress in biomedical research into the causes of neurofibromatosis in the late 1990s and early 2000s raised hopes that someday there would be treatment to slow or halt the growth of its tumors.

Some cases of neurofibromatosis can be severely debilitating, and its complications can be fatal. In most instances, however, symptoms are mild, and the person with the disorder can lead a normal, productive life.

Genetic tests and counseling are available for people with neurofibromatosis. These can help people learn more about their condition or that of a family member and can assist them in making decisions about having children of their own.

The Elephant Man

Neurofibromatosis has long been associated with the “Elephant Man,” the name given to the Englishman Joseph (John) Carey Merrick (1862–1890), who was exhibited in public as a medical freak because of his grotesque disfigurements. Merrick was thought to have had a severe form of neurofibromatosis, but accumulating evidence later indicated that he was suffering from a much rarer disease called Proteus syndrome. Nonetheless, public awareness of neurofibromatosis was greatly increased after the production of a play in 1979 and a film in 1980 on the life of Merrick.

* **catecholamines** (kat-e-KO-la-meens) are hormones and neurotransmitters such as epinephrine and dopamine.

* **malignant** (ma-LIG-nant) refers to a condition that is severe and progressively worsening.

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

Neurosis See *Psychosis*.

Newborn Infections See *Congenital Infections*.

Night Terrors/Nightmares See *Sleep Disorders*.

Nonspecific Urethritis

Nonspecific urethritis (NSU) is an inflammation or infection of the urethra (yoo-REE-thra), more often diagnosed in men, in which the cause is not defined. The urethra is the tube through which urine passes from the bladder to the outside of the body.*

What Is Nonspecific Urethritis?

Nonspecific urethritis (yoo-re-THRY-tis) is a common urinary tract infection. It is also called nongonococcal (non-gon-o-KOK-al) urethritis. “Nongonococcal” means that the urethritis is not caused by gonococcus,

The organs of the urinary tract.
Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.

the bacterium (bak-TEE-ree-um) that causes gonorrhea (gon-o-REE-a), a sexually transmitted disease (STD). However, nonspecific or nongonococcal urethritis is also considered to be an STD. It is most often caused by *Chlamydia* (kla-MID-ee-a), but other germs such as yeast*, herpesvirus*, intestinal bacteria*, or any of a number of other microorganisms. Although classified as an STD, nonspecific urethritis is not always caused by sexual activity. For example, it can be caused by an infection from intestinal bacteria that enters the urethra from skin around the anus*, or it may result from insertion of an object into the urethra. Although NSU is possible in either men or women and can affect individuals of all ages, this condition most commonly affects men.

What Are the Symptoms of Nonspecific Urethritis?

A common symptom of NSU is a tingling or burning sensation while urinating. Sometimes, there is also a slight, usually clear discharge. This discharge may be present only in the morning, before urination.

Signs and symptoms of NSU usually appear two to three weeks after infection. Sometimes, symptoms are mild or absent, especially in females.

How Is Nonspecific Urethritis Diagnosed and Treated?

The diagnosis of NSU is made by taking urine and discharge samples and conducting laboratory tests to identify the infecting organism. A direct swab of the urethra is usually performed and tested in an effort to demonstrate the causative organism. In many instances, however, the cause cannot be determined.

NSU is treated with antibiotics*. It is extremely important to finish the prescribed amount of these medications. Otherwise, the infecting organisms may not all be killed, and the disease can come back.

NSU is treated with antibiotics; several regimens are available, and treatment length depends on the specific antibiotic selected by the doctor. During this time, sexual activity must be avoided to keep from spreading the infection. Relapses are common, and follow-up visits may be needed to confirm a cure.

What Are the Complications of Nonspecific Urethritis?

Sometimes, treatment of NSU is unsuccessful, especially if the cause is not found. Possible complications may include chronic* urethritis and cystitis (sis-TY-tis), a bladder infection. The infection sometimes may reach the kidneys*.

How Can Nonspecific Urethritis Be Prevented?

General measures that can decrease the likelihood of NSU include frequent bathing. Especially good hygiene is needed in the genital area. Bubble baths should be avoided, because they can irritate the urethra.

* **yeast** (YEEST) is a general term describing single-celled fungi that reproduce by budding.

* **herpesvirus** (her-pee-z-VY-rus) is a member of a family of viruses that can store themselves permanently in the body. The family includes varicella virus, Epstein-Barr virus, and herpes simplex virus.

* **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.

* **anus** (A-nus) is the opening at the end of the digestive system, through which waste leaves the body.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **kidneys** are the pair of organs that filter blood and remove waste products and excess water from the body in the form of urine.

* **contagious** (kon-TAY-jus) means transmittable from one person to another, usually referring to an infection.

With regard to sexual transmission, as for any STD, not having sex is the only sure means of prevention. The risk of getting NSU is lowered by limiting the number of one's sexual partners. Condoms can decrease the rate of transmitting the infection.

NSU and other urinary tract infections are not contagious* in people who are not sexually active.

Nosebleeds

A nosebleed is bleeding that begins inside the nostrils. Its medical name is "epistaxis."

What Are Nosebleeds?

Most nosebleeds occur in children and older people and last for a short time. In rare cases, nosebleeds can be associated with other illnesses.

What Causes Nosebleeds?

Nosebleeds usually start after a bump to the nose or when the lining of the nostrils becomes irritated, crusted, or dry. This precondition often happens when someone has a cold, infection, or allergy that affects the amount of mucus secreted from the nose. A high fever can also dry out the lining of the nose. When a person removes the crusts that may appear in the nose, bleeding may occur.

Nosebleeds have other causes, too. People with systemic hypertension, which is high blood pressure, are prone to nosebleeds because their blood vessels do not function well. Hypertension is quite common among older adults, but not all of them have problems with nosebleeds. Another cause

Anatomical sideview of two types of nosebleeds. *Illustration by GGS Information Services, Inc. Reproduced by permission of Gale, a part of Cengage Learning.*

of nosebleed is the abuse of inhaled drugs, such as cocaine*, that irritate the lining of the nose.

What Is the Treatment for Nosebleeds?

Most nosebleeds are quite easy to treat. A person with a nosebleed should sit down, lean slightly forward, and breathe through the mouth while holding the nostrils firmly closed between the thumb and forefinger. After 10 to 15 minutes, sometimes less, the bleeding should have stopped. The person should avoid blowing the nose for 12 hours after a nosebleed, because doing so could restart the bleeding. If the nosebleed does not stop after a few attempts at pinching the nostrils closed for 10 to 15 minutes each time, then a doctor should be contacted. The doctor might put cotton gauze with medication into the nostril to stop the bleeding. In some cases, he or she may also prescribe nose drops to be used by the patient for a few days to help control further bleeding.

* **cocaine** (ko-KAYN) is a stimulant, a drug that produces a temporary feeling of alertness, energy, and euphoria.

* **hemophilia** (hee-mo-FIL-ee-a) is a hereditary disease that results in abnormal bleeding because the blood fails to clot. It occurs almost exclusively in males.

Prolonged nose bleeding may be a sign of serious injury to the head or an indication of an illness, such as hypertension or sinus blockage. A doctor will recommend treatment suited to the cause of the nosebleed.

Although rare, nosebleeds are sometimes the result of serious diseases. These include leukemia (cancer of the white blood cells), liver disease, atherosclerosis (also called hardening of the arteries), and some hereditary bleeding disorders such as hemophilia*, in which the blood fails to clot properly.

Can Nosebleeds Be Prevented?

The best way to prevent nosebleeds is to avoid bumping or picking the nose. People involved in contact sports, such as football or boxing, are more likely to receive bumps to the head or nose that result in nosebleeds. Medical professionals recommend wearing appropriate protective gear, such as face guards and masks, to help prevent these injuries. In general, humidifying (adding moisture to) the air indoors in the winter, when the air is very dry because of central heating, also helps protect individuals from nosebleeds.

O

Obesity

Obesity (o-BEE-si-tee) is a significant excess of body fat to the point where the ratio of body fat to total body mass is higher than accepted norms. Obese children are at higher risk for obesity as adults. People who are overweight or obese are at higher risk for high blood pressure, diabetes, joint pain, and other health problems. In cultures that value being thin, obese people may experience emotional distress and social stigmatization.

Karen's Story

Karen was a normal, healthy baby who grew into a very chubby child. By the time she was 12 years old, Karen was 50 pounds overweight. Because she was so heavy, she did not enjoy sports or other physical activities, so she spent much of her free time snacking in front of the television or chatting online with friends. As Karen gained weight, it became more difficult for her to catch her breath when she was active. She hated gym class and found it hard to deal with the teasing of classmates. Finally after talking to the mother of a friend who had lost weight, Karen decided she needed to make changes to lose weight. Because both of her parents were overweight, too, Karen enlisted them to make weight loss a family project. Karen and her parents began going to the local YMCA to exercise. They also slowly changed their eating habits and stopped buying so much snack food until they were eating a leaner, healthier diet. Even though it sometimes seemed difficult and took longer than she had hoped, Karen lost weight and began to enjoy a more active lifestyle.

What Is Obesity?

Obesity is an abnormal accumulation of body fat or approximately 20 percent or more over an individual's ideal body weight. The number of people, especially children, who are obese is increasing at an alarming rate in the United States and other parts of the developed world where lifestyles make it easy for people to take in more calories* than their bodies use. People can take in too many calories by eating too many burgers and fries, chips, dips, and nachos, and by drinking too many supersized sweetened soft drinks. They use too few calories by taking car rides instead of walking or riding a bike and by spending too much time seated in front of a television and video games instead of engaging in sports or other physical activities. Over time as the amount of calories from food is greater than

* **calories** (KAL-o-reez) are units of energy that are used to measure both the amount of energy in food and the amount of energy the body uses.

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

the amount of calories used by activity, people gain weight and become overweight or obese. Obesity is a health concern because it is associated with increased risk of illness, disability, and death.

Lifestyle is not the only cause of obesity. Researchers believe that genes* and heredity also play a role in the tendency to gain weight. People with a history of obesity in one or both parents are at higher risk of becoming obese themselves. Studies of adopted children confirm this relationship: The majority of adoptees followed a pattern of weight gain that more closely resembled that of their birth parents than their adoptive parents. Researchers think that people who have inherited "obesity genes" may use calories at a slower rate than others, or they may not have the same appetite shutoff control system that helps lean

BODY MASS INDEX

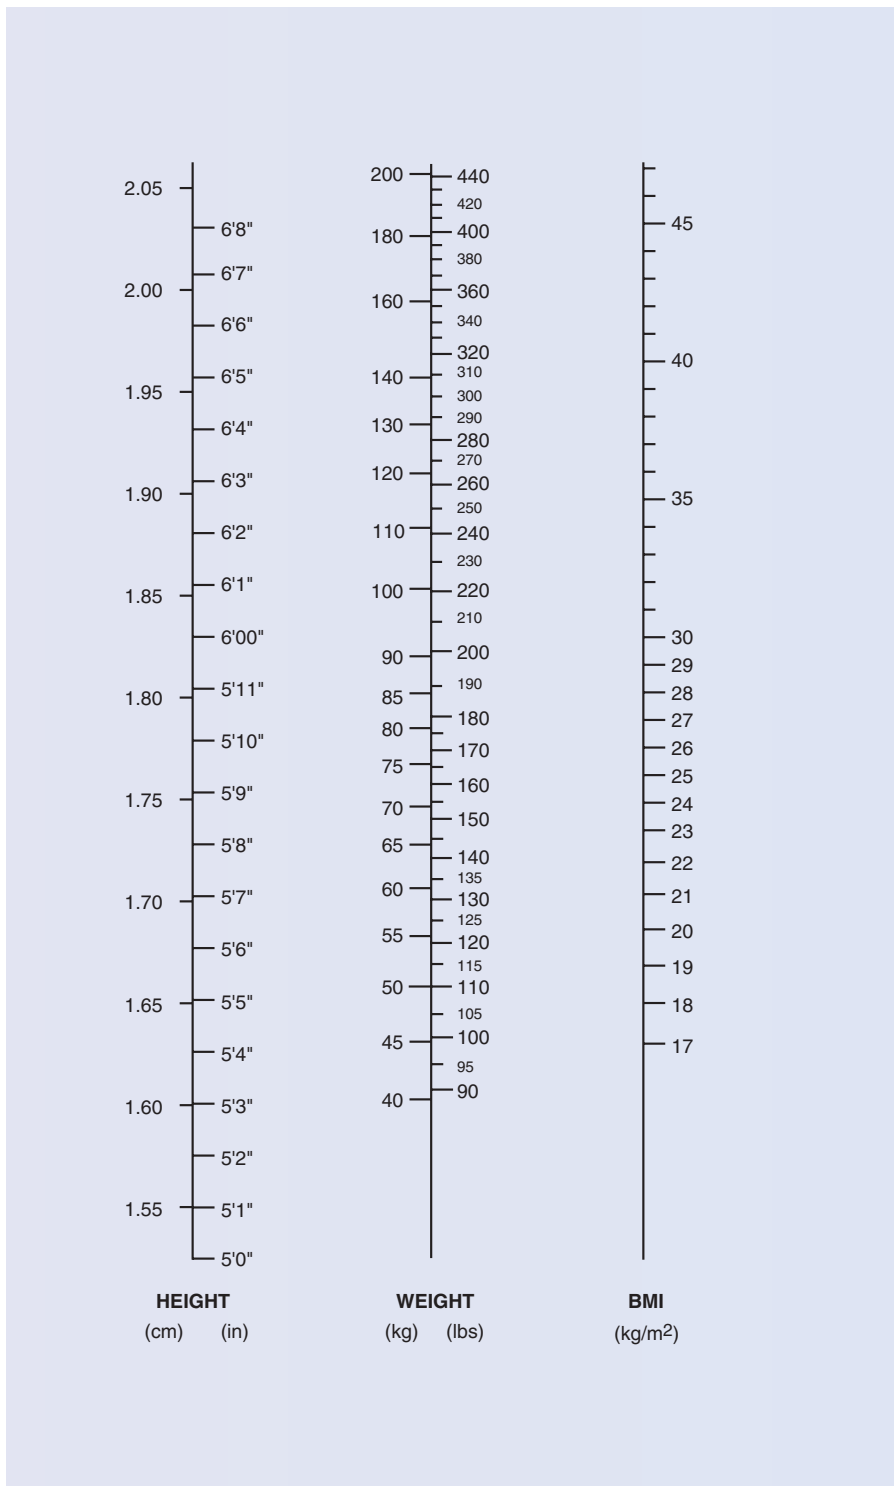

Obesity was traditionally defined as a weight at least 20 percent above the weight corresponding to the lowest death rate for individuals of a specific height, gender, and age. This weight was designated the ideal weight. Current guidelines for obesity use a measurement called the body mass index (BMI). BMI is a mathematical formula that uses height and weight to compare the ratio of body fat to total body mass. To calculate the BMI in metric units weight measured in kilograms and height measured in meters: $BMI = \text{kg}/\text{m}^2$. To calculate BMI in English units, weight in pounds (lb) is divided by height squared in inches (in) and then multiplied by 703. This calculation produces a number that is the individual's BMI. An online BMI calculator can be found at <http://www.nhlbisupport.com/bmi>

All adults age 20 and older are evaluated on the same BMI scale as follows:

- BMI below 18.5: underweight
- BMI 18.5–24.9: normal weight
- BMI 25.0–29.9: overweight
- BMI 30 and above: obese

The BMI of children is calculated in the same way as adults, but instead of assigning a child to a specific weight category based on his or her BMI, a child's BMI is compared to that of other children of the same age and sex. Children are then assigned a percentile based on their BMI. The percentile tells them how their weight compares to that of other children who are their age and gender as follows:

- Below the 5th percentile: underweight
- 5th percentile to less than the 85th percentile: healthy weight
- 85th percentile to less than the 95th percentile: at risk of overweight
- 95th percentile and above: overweight

Doctors use charts showing height, weight, and body mass index as guidelines for determining whether people are at a healthy weight or whether they are overweight. *Illustration by Argosy. Reproduced by permission of Gale, a part of Cengage Learning.*

people stop eating when they have taken in enough calories. Also, people who become obese as children may increase the total number of fat cells in their bodies, making it much more likely that they will be obese as adults. Nevertheless, a genetic predisposition to weight gain does not

* **cholesterol** (ko-LES-ter-ol) is a fatlike substance found in the blood and body tissues.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **eating disorders** are conditions in which a person's eating behaviors and food habits are so unbalanced that they cause physical and emotional problems.

automatically mean that a person will be obese. Eating habits and patterns of physical activity also play a significant role in the amount of weight a person gains.

According to the Centers for Disease Control and Prevention (CDC), between the mid-1970s and the early 2000s, the percentage of overweight and obese American adults ages 20 to 74 increased from 15.0 percent to 32.9 percent. During this same time, the percentage of overweight children two to five years of age increased from 5.0 percent to 13.9 percent and for children aged 6 to 11 years from 6.5 percent to 18.8 percent. Overweight and obesity in teens increased from 5.0 percent to 17.4 percent. In 2007, the World Health Organization (WHO) estimated that 1.6 billion people worldwide over age 15 were overweight and at least 400 million were obese.

What Are the Health Risks Related to Obesity?

Children Children who are in the 85th percentile or above are at risk for developing health problems related to obesity beginning in childhood. Children may have fewer visible health problems from being heavy than adults do. However, the more overweight the child is, the more likely he or she will develop high blood pressure, high levels of cholesterol*, and type 2 diabetes*. Often obese children and teens experience social and emotional difficulties because their weight sets them apart from their friends.

Childhood obesity can set the stage for a lifetime of weight control struggles. In childhood, excess calories are converted into new fat cells, while excess calories consumed in adulthood only expand existing fat cells. Because dieting and exercise can only reduce the size of fat cells, not eliminate them, people who are obese as children can have great difficulty losing weight as adults, because they may have up to five times more fat cells than someone who first becomes overweight as an adult.

Teens Obese teenagers may have the same problems as obese children, but they also may start having aches and pains as the extra fat in their bodies stresses their joints and overloads their muscles and tendons. Obese teens, as well as some younger children, may show the same health problems commonly seen in obese adults such as high blood pressure and type 2 diabetes. Socially, obesity tends to have an effect on the dating and social lives of teens. Overweight teens also may be at risk for eating disorders*.

Adults For adults, obesity is a serious health risk. Severe obesity is called "morbid" obesity because it is so frequently accompanied by serious health complications. On average, a BMI of greater than 40 (morbidly obese) reduces the lifespan of men by as much as 20 years and of women by 5 years. This is especially true in people who are obese and who also smoke. People who are obese for ten or more years are more likely to die earlier than people who maintain a healthy weight. The quality of life of an obese person is often diminished by a variety of serious health problems. Some of the risks of adult obesity are listed below.

HEART DISEASE AND STROKE The leading causes of death and disability in the United States are heart disease, heart attack, and stroke. Stroke is a disorder that occurs when a blood vessel to the brain is blocked or bursts. People who are obese are more likely to have high blood pressure (hypertension), which increases the risk of heart disease and stroke. Obesity is also linked to having higher levels of cholesterol and fats (triglycerides) in the blood, which can lead to heart disease.

DIABETES Type 2 diabetes is the most common form of diabetes. This disorder reduces the body's ability to use insulin to control blood sugar levels. It is a major cause of early death, heart disease, kidney disease, stroke, and blindness. Obese people are twice as likely as other people to develop type 2 diabetes. Of particular concern is the fact that type 2 diabetes is occurring with increased frequency among obese children and teens.

CANCER Men who are obese are more likely than other men to get cancer of the colon (main part of the large intestine), rectum (lower part of the large intestine), and prostate (PROS-tate; male gland in front of the rectum). Obese women are more likely than other women to get cancer of the colon, uterus, cervix (lower part of the uterus), ovaries (female glands where egg cells develop), gallbladder (small sac under the liver), and breast. For some types of cancer, such as colon and breast, it is not clear whether the greater risk is due to extra body fat or to a high-fat and high-calorie diet.

GALLBLADDER DISEASE Obese people are more likely than other people to develop gallbladder disease and gallstones, rock-like lumps that form in the gallbladder. Ironically, rapid weight loss itself can also lead to gallstones. Slower weight loss of about one pound a week is less likely to cause this problem.

OSTEOARTHRITIS Osteoarthritis (os-te-o-ar-THRY-tis) is a common disease that affects the joints (places where bones meet), especially those in the knees, hips, and lower back. Extra weight seems to promote osteoarthritis by putting extra pressure on these joints and wearing away the tissue that cushions and protects them.

GOUT Gout (GOWT) is a joint disease that can lead to problems with the kidneys (organs that filter blood and get rid of waste products and excess water as urine). Gout is more common in people with obesity. Some diets may cause an attack of gout in people who are prone to it. Such people should visit a doctor and ask if they need to be on a special diet.

SLEEP APNEA Sleep apnea (AP-nee-a) is a serious breathing disorder, which can cause a person to stop breathing for short periods during sleep and to snore heavily. It can lead to daytime sleepiness and sometimes heart failure. The more severe the obesity a person has, the greater their risk of getting sleep apnea.

Social and psychological conditions People who are obese may face discrimination when they apply for jobs or promotions, and studies

When Obesity Is Not Caused by Overeating

Obesity can also be a side effect of certain disorders and conditions, including the following:

- Cushing's syndrome, a disorder involving the excessive release of the hormone cortisol
- Hypothyroidism, a condition caused by an underactive thyroid gland
- Neurologic disturbances, such as damage to the hypothalamus, a structure located deep within the brain that helps regulate appetite
- Consumption of such drugs as steroids, antipsychotic medications, or antidepressants

Fad Diets

Fad diets are diets that claim to help people lose a lot of weight in a short time, often without making lifestyle changes. They become fads when they are widely advertised and reported in magazines, newspapers, television, and radio.

Fad diets often require eating a particular food or food group. Examples of fad diets include the cabbage soup diet, the grapefruit diet, the high fat, high protein, low carbohydrate diet, and the fat burning diet. These diets are not nutritionally balanced and can lead to serious health problems.

Realistic long-term expectations for weight loss from dieting are the loss of about one half pound (250 grams) of fat over one week. Any more weight lost than that probably will consist of water.

The best diets recommend exercising and eating controlled amounts of a balance of foods from all food groups. It is important to talk with a doctor before trying any diet.

have shown that they may be unfairly viewed by others as lazy or less intelligent. Obese adults often experience the inconvenience and frustration of needing large-size clothing, large-size movie seats and airplane seats, and large-size seat belts in a world designed by and for medium-size people. Depression, anger, frustration, and a feeling that their world is out of control are common among people who are obese.

Many people eat when they feel bored, sad, or angry. In general, though, most obese people are as mentally healthy as anyone else. However, about 30 percent of people who are treated for severe obesity have trouble with binge eating, which means that they eat large amounts of food in a short period while feeling that they cannot control how much they are eating.

How Is Obesity Treated?

Research shows that the best way for people of all ages to control their weight is through regular exercise and a portion-controlled balanced diet. Adults can improve their health by losing as little as 5 percent of their body weight. To lose weight, people must take in fewer calories than they use. They can do this by becoming more active and/or eating less. The best weight-loss programs combine both of these approaches and also teach people healthy habits that they can follow for the rest of their lives.

Exercise Studies show that regular physical activity, combined with a good diet, is the healthiest and most effective way to control weight. Even people who lose very little weight can improve their health by exercising and eating a nutritionally balanced diet. Exercise uses excess calories that would otherwise be stored as fat.

Aerobic (air-O-bik) exercises are any extended activities that make a person breathe harder while using the large muscles at a regular, even pace. Such exercises burn more calories than other activities. They also strengthen the heart and lungs. Examples include brisk walking, jogging, bicycling, lap swimming, aerobic dancing, and using a treadmill or stationary bike. For the best results, aerobic exercise should be done for 20 to 30 minutes at a time, three or more times a week. People who are out of shape should begin by exercising for briefer periods.

Muscle strengthening exercises, such as weight training, and stretching exercises should also be part of a balanced exercise program. In addition to burning calories, these activities strengthen the muscles and bones and help prevent injury. Such exercises should be done at least twice a week.

Diet Children should never go on a diet to lose weight unless a doctor tells them to do so for medical reasons. Limiting what children eat can interfere with their growth and may be harmful to their health. Instead, children should shift to eating better foods, with most coming from the grain, vegetable, and fruit groups. Some foods from the milk and the meat and bean groups should also be included. Junk foods, which provide

few vitamins and minerals but are full of fat and sugar, should be eaten sparingly or avoided altogether. Fat should not be restricted in the diet of very young children. By the time children are five years old, however, they should get no more than 30 percent of their total calories from fat. Simple ways to cut back on fat include eating low-fat or nonfat dairy products, lean meats, and other low-fat or fat-free foods.

Adults who are trying to lose weight often go on low-calorie diets. Such diets typically contain 1,000 to 1,500 calories per day. The exact number of calories that is right depends on a person's size and activity level. The goal should be to lose no more than one pound a week while still eating a varied diet that includes plenty of grains, vegetables, fruits, and other healthful foods.

A doctor may prescribe a medically supervised, very low-calorie diet for severely obese individuals. These specially formulated diets contain no more than 800 calories a day. Such diets can lead to faster weight loss than ordinary low-calorie diets. Because serious side effects can develop, very-low-calorie diets should always be supervised by a physician and/or nutritionist.

Drugs Appetite-suppressant drugs are sometimes prescribed to aid in weight loss. These drugs work by increasing levels of brain chemicals that control feelings of fullness. Appetite suppressants, though, are rarely truly effective, because most of the weight lost while taking them is regained after stopping them. Also, suppressants containing amphetamines can be potentially abused by patients. These drugs may have potentially harmful side effects. Two appetite-suppressant drugs, dexfenfluramine hydrochloride (Redux) and fenfluramine (Pondimin) as well as a combination fenfluramine-phentermine (Fen/Phen) drug, were taken off the market when they were shown to cause potentially fatal heart defects.

The Food and Drug Administration (FDA) approved weight-loss drugs include sibutramine (Meridia), diethylpropion (Tenuate, Tenuate dospan), mazindol (Mazanor, Sanorex), phendimetrazine (Bontril, Plegine, Prelu-2, X-Trozone), orlistat (Xenical), and phentermine (Adipex-P, Fastin, Ionamin, Oby-trim). These drugs are available only with a doctor's prescription. All of them have significant side effects and should be taken only under medical supervision. Alli is a version of orlistat approved by the FDA for sale without a prescription. Some doctors have also found that antidepressant medications* help obese people gain control over their eating habits.

Surgery Obesity surgery, also called bariatric surgery, reduces or bypasses the stomach or a portion of the small intestine so that severely overweight people can achieve significant and permanent weight loss by taking in or absorbing fewer calories. Surgery is generally performed only on severely obese people who have tried and failed at losing weight using other methods.

Surgical procedures reduce the size of the stomach through stapling or banding so that the person feels full quickly. The exit to the stomach

Weight-loss Supplements

The weight-loss supplement industry is a big business. Dietary supplements that claim to suppress appetite, burn more calories, and produce dramatic weight loss are sold over-the-counter (without a prescription) and are not subject to the same rigor testing for safety and effectiveness as over-the-counter or prescription drugs.

Many heavily promoted weight-loss products are based on fads or gimmicks that create false hopes but rarely produce long-term weight loss. Some of these products, even ones promoted as natural or herbal, can actually endanger health, especially in people who have other chronic illness (e.g., diabetes, heart disease). Individuals should consult a physician before taking any weight-loss product.

* **antidepressant medications** are used for the treatment and prevention of depression.

may also be relocated to bypass part of the small intestine so that fewer calories are absorbed into the blood. Weight-loss surgery has some major risks and side effects. It is only performed after extensive medical tests and psychological, behavioral, and nutritional counseling on people for whom the benefits outweigh the risks. The cost of this surgery is sometimes covered by insurance.

Controlling Weight

Weight control is not easy and requires a long-term effort. It does not help much for a person to lose lots of weight only to regain it. Keeping weight off is the toughest part of a weight-loss program for most people. The key to keeping pounds off or stopping obesity before it starts is to learn healthy habits that last a lifetime. Here are some hints:

- Get moving. Turn off the television, computer, and video games in favor of physical activities. Have fun with friends and family by sharing activities that are good exercise, such as walking, dancing, or bicycling. In addition, look for other ways to become more active throughout the day. For example, walk around during school breaks and take the stairs instead of the elevator.
- Eat slowly. This makes it easier for a person to recognize feelings of fullness. One way for a person to slow down at meals is to make the meals as pleasant as possible. If meals are stressful, a person is tempted to eat faster in order to leave the table sooner.
- Snack wisely. Unplanned snacking often leads to overeating. Planned snacks at particular times of the day can be part of a balanced diet without spoiling the appetite at mealtimes. It is also important to choose healthy snacks, such as fresh fruit, raw vegetables, and low-fat yogurt.
- Avoid unconscious eating in front of the television or computer. People who are paying attention to a television or a computer are less likely to pay attention to feelings of fullness and, therefore, may eat too much.

Obsessive-Compulsive Disorder

Obsessive-compulsive (ob-SES-iv-kom-PUL-siv) disorder (OCD) causes people to become trapped in a pattern of repeated, unwanted thoughts, called obsessions (ob-SESH-unz), and a pattern of repetitive behavior, called compulsions (kom-PUL-shunz). Thoughts that feel impossible to control cause distress and anxiety (ang-ZY-e-tee) that is often neutralized, or temporarily relieved, by a particular compulsive behavior.

Melvin and Adrian

In the 1997 movie *As Good as It Gets*, actor Jack Nicholson portrays Melvin Udall, a man who acts in ways that seem odd to others. He feels as if he has to eat lunch at the same table each day, and he always brings his own plastic utensils. He follows a complicated procedure to lock his front door. Much of what he does, from the way he walks around cracks to the way he talks and thinks, make his life difficult. This character has obsessive-compulsive disorder. Adrian Monk, the main character on the television series *Monk* (played by Tony Shalhoub), also has OCD. According to the National Institute of Mental Health, in 2007 about 2.2 million Americans over age 18 were living with OCD.

What Is Obsessive-Compulsive Disorder?

Many people knock on wood to ward off bad luck. Others may walk around, rather than under, ladders, or they may step over, rather than on, cracks in the sidewalk. These are familiar examples of superstitions and rituals. Superstitions are irrational beliefs resulting from false ideas, fear of

These PANDAS Are a Bear

PANDAS (Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infections) is a term for unusual, OCD-like symptoms that arise in a small number of children after strep throat, a common throat infection caused by bacteria. The behavior of the children usually changes quite suddenly. Almost overnight, they develop obsessions, compulsions, tics, uncontrollable muscle twitches, or verbal outbursts. As of 2009, the cause remained unknown. One theory, though, suggested that a strep infection in childhood prompts the body to form antibodies (AN-ti-bo-deez), substances in the blood that fight bacteria and other foreign matter. The next time strep develops, the body is ready to fight back. It releases a barrage of antibodies, but some miss their mark and head for the part of the brain that is thought to affect behavior and movement, resulting in OCD symptoms.

* **nervous system** is a network of specialized tissue made of nerve cells, or neurons, that processes messages to and from different parts of the human body.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

the unknown, or trust in magic or chance. Superstitions are common in everyday life and generally are harmless. People with obsessive-compulsive disorder, however, go much further, to the point of becoming trapped in a pattern of repeated, unwanted behaviors and thoughts that are senseless and upsetting but that seem impossible to control. The behaviors and thoughts can take up so much time and energy that they interfere with the individual's daily life.

OCD usually begins with an obsession. Obsessions are repeated thoughts, urges, or images that intrude into a person's mind and seem senseless and distressing. People then go through repeated rituals, called compulsions, in an effort to prevent these thoughts or make the anxiety and distress they cause go away. For example, people may wash their hands, check to make sure the stove is turned off, or check a door lock over and over again. For people with OCD, there is no pleasure in doing these acts. There is only short-lived relief from the upsetting thoughts (for example, that their hands are contaminated, the house will catch on fire, or a thief will come in the door), which all too soon return. Most people have a few repetitive habits. The difference between a harmless ritual or superstition and obsessive-compulsive disorder is that with OCD the thoughts and behaviors disrupt the lives of people with the disorder. People with OCD are aware that their thoughts and actions make little sense are abnormal, but they cannot control their obsessions and compulsions.

What Causes Obsessive-Compulsive Disorder?

Scientists do not know exactly why some people develop OCD. About 2 percent of adults in the United States have OCD in any given year. The disorder usually begins during childhood or the teenage years, and it affects men and women equally. In the past, it was believed that OCD was due mainly to family problems or attitudes learned as children. Later, researchers stressed the interaction between biological factors and life experiences. Brain imaging studies (special brain x-rays) have shown that people with OCD have patterns of brain activity that differ from the patterns of people with other mental disorders and of people with no disorders at all.

OCD occurs more often than average in people with certain other conditions that affect the brain and nervous system*. For example, there is an increased risk of OCD in people with Tourette's (tu-RETZ) syndrome, an inherited nervous system disorder that causes repeated, uncontrollable muscle twitches and verbal outbursts. Researchers have thought there may be a genetic* factor in the development of both OCD and Tourette's syndrome.

What Are the Symptoms of Obsessive-Compulsive Disorder?

The first signs of obsessive-compulsive disorder typically appear between the ages of 10 and 24. An obsession, or intrusive thought, creates constant worry and fear that the person tries to hold in check with a repeated

behavior or compulsion. People who do not experience OCD believe that the worry is silly or strange. People with OCD can also agree that the worry is needless; however, they cannot stop feeling the worry that comes with the thought. Interestingly, obsessions and compulsions do not have to be related. The thought “I might get sick” could be followed by the behavior of counting to seven rather than repeated hand washing. Compulsions also include a wide variety of checking rituals, such as returning often to check a door lock, even though each time the person finds it locked. Another common compulsion is the need to order or arrange precisely certain objects such as stuffed animals or action figures or to count certain objects. Some people with obsessive-compulsive disorder have violent thoughts. They may fear that they or someone they love will die in a horrible accident or that they will harm someone. For example, a driver with OCD may fear that he or she has run over someone and return to the spot over and over to check that no one has been harmed.

How Is Obsessive-Compulsive Disorder Treated?

OCD is a mental health disorder that is diagnosed by a psychiatrist*. It is a type of anxiety disorder and can be present alone or with other mental health disorders. Diagnosis involves a patient history, looking for symptoms, and ruling out other physical and mental conditions, including other anxiety disorders*.

Medications Studies have shown that medicines that affect a brain chemical called serotonin* can reduce the symptoms of OCD. Whereas medicines may help control OCD, the symptoms may return once people stop taking medication. For this reason, doctors often recommend a combination of prescription medication and visits to a behavior therapist. Some individuals whose OCD is not significantly debilitating* might choose behavior therapy alone as the preferred treatment.

Behavioral therapy Behavioral (be-HAY-vyor-al) therapy seeks to help people change specific unwanted behaviors. For OCD, doing so entails using an approach called exposure and response prevention. In this approach, people purposely are exposed to a feared object or idea, either directly or through imagination. Then they prevent themselves from carrying out the usual response (the compulsion), instead using other methods to manage the anxiety they feel. For example, people with a hand-washing compulsion might be encouraged to touch objects that they believe to be dirty. Then with the therapist’s help, they resist the compulsion to wash for several hours. During this time, the anxiety associated with the obsession decreases and so does the compulsion to wash. Research has shown that this approach can be effective for treating OCD. People who remain in therapy may gradually learn to worry less about their obsessive thoughts, and eventually they may learn to go for long periods without falling back on their old compulsive actions. With exposure and response prevention, thoughts and compulsions frequently (and sometimes quickly) disappear or become manageable.

* **psychiatrist** (sy-KY-uh-trist) is a medical doctor who has completed specialized training in the diagnosis and treatment of mental illness. Psychiatrists can diagnose mental illnesses, provide mental health counseling, and prescribe medications.

* **anxiety disorders** (ang-ZY-e-tee dis-OR-derz) are a group of conditions that cause people to feel extreme fear or worry that sometimes is accompanied by symptoms such as dizziness, chest pain, or difficulty sleeping or concentrating.

* **serotonin** (ser-o-TO-nin) is a neurotransmitter, a substance that helps transmit information from one nerve cell to another.

* **debilitating** (de-BI-li-tay-ting) means making weak or sapping strength.

Oncogenic Infections

Oncogenic (on-ko-JEH-nik) infections are those that may increase a person's risk for developing a certain type or types of cancer.

What Are Oncogenic Infections?

Cancer often is linked to lifestyle choices (such as smoking), a person's genetic* makeup, and environmental influences. However, connections between the development of certain types of cancer and specific viral,

bacterial, and parasitic infections also exist. These infections are referred to as oncogenic, or tumor-producing, infections.

An oncogenic virus* transfers its genetic material to other cells and then remains in the body for a long time as a latent infection (meaning dormant, or inactive, but not dead) or as a chronic (KRAH-nik) infection (meaning that the infection continues for a long time). For example, Epstein-Barr (EP-steen BAR) virus remains in the body for life, occasionally flaring up and being subdued by the body’s immune system*. Chronic infections such as hepatitis (heh-puh-TIE-tis) B or C often damage the body slowly, over many years.

Another characteristic of oncogenic infections is that they seem to encourage cells to reproduce at an unusually fast rate, which may damage the genetic material in those cells. Additional factors, such as smoking or exposure to other carcinogens*, may be needed to trigger the final change of a normal cell into a cancer cell. These exposures, along with each person’s individual genetic makeup, may explain why cancer develops in some people who have had oncogenic infections but not others.

What Are Specific Oncogenic Infections and Their Treatment?

Several infections have been linked to the development of cancer. Human papillomavirus (pah-pih-LO-muh-vy-rus), or HPV, is a family of more than 70 different types of viruses that can produce warts* on various parts of the body. Some strains* of HPV are spread sexually and cause genital* warts. Certain sexually transmitted HPVs are linked to the development

- * **virus** (VY-rus) is a tiny infectious agent that can cause infectious diseases. A virus can only reproduce within the cells it infects.
- * **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.
- * **carcinogens** (kar-SIH-no-jenz) are substances or agents that can cause cancer.
- * **warts** are small, hard growths on the skin or inner linings of the body that are caused by a type of virus.
- * **strains** are various subtypes of organisms, such as viruses or bacteria.
- * **genital** (JEH-nih-tul) refers to the external sexual organs.

Oncogenic Infections	Associated Cancers
Human papilloma virus (HPV) infection	Cervical and penile cancers
Epstein-Barr virus (EBV) infection	Lymphomas and nasopharyngeal cancer
Hepatitis B and C virus (HBV or HCV) infection	Liver cancer
<i>Helicobacter pylori</i> infection	Stomach cancer
Human lymphotropic virus type 1 (HLTV-1) infection	Lymphomas

Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.

- * **cervical** refers to the cervix (SIR-viks), the lower, narrow end of the uterus that opens into the vagina.
- * **penile** (PEE-nile) refers to the penis, the external male sexual organ.
- * **anal** refers to the anus, the opening at the end of the digestive system through which waste leaves the body.
- * **Pap smear** is a common diagnostic test used to look for cancerous cells in the tissue of the cervix.
- * **mononucleosis** (mah-no-nu-kee-O-sis) is an infectious illness caused by a virus with symptoms that typically include fever, sore throat, swollen glands, and tiredness.
- * **lymphocytes** (LIM-fo-sites) are white blood cells, which play a part in the body's immune system, particularly the production of antibodies and other substances to fight infection.
- * **lymphoma** (lim-FO-muh) refers to a cancerous tumor of lymphocytes, cells that normally help the body fight infection.
- * **lymphatic system** (lim-FAH-tik) is a system that contains lymph nodes and a network of channels that carry fluid and cells of the immune system through the body.
- * **nasopharyngeal** (nay-zo-fair-in-JEE-ul) refers to the nose and pharynx (FAIR-inks), or throat.
- * **carcinoma** (kar-sih-NO-muh) is a cancerous tumor that arises in the epithelium (eh-puh-THÉE-lee-um), the sheets of cells that line body surfaces, such as the insides of hollow organs and cavities.
- * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

of cervical*, penile*, and anal* cancer. (Anal and penile cancers are rare in the United States.)

According to the American Cancer Society, the most important risk factor for a woman in the development of cervical cancer is HPV infection. HPV is found in 90 percent of cervical cancer cases. Its presence may make a woman more likely to have cervical dysplasia (SIR-vih-kul dis-PLAY-zhuh), or precancerous cells in the cervix. This condition can lead to cancer if it is left untreated. Just having one of the oncogenic strains of HPV, however, does not mean cancer will eventually develop. Early discovery and treatment can lessen a woman's risk of cervical cancer, and doctors advise women diagnosed with HPV to have frequent Pap smears*. HPV is the most common sexually transmitted disease in the United States, with five million new infections diagnosed each year. Although there is no cure for HPV, there are treatment options aimed at controlling the infection. Prevention of HPV infection is possible, thanks to the HPV vaccine. The American College of Obstetrics and Gynecology and the federal Advisory Committee on Immunization Practices recommend that girls receive this three-immunization series prior to becoming sexually active. The target age range for administration is age 11 or 12, although it can be given at any point between ages 9 and 26. Research has demonstrated that the HPV vaccine can prevent more than 70 percent of all cervical cancers.

Epstein-Barr virus (EBV) is commonly known as the virus that causes infectious mononucleosis*. Up to 95 percent of adults in the United States have been infected with the virus by the time they are 40 years old. EBV is transmitted through contact with saliva of someone who is infected. Children who contract EBV rarely have symptoms, and when they do, the symptoms typically are the same as those of common viral infections. When adolescents or adults are infected with EBV, they can have infectious mononucleosis.

EBV remains in the body, primarily in the lymphocytes*, for the rest of a person's life. It is dormant for much of the time, although it occasionally flares up without causing any real harm. People with weakened immune systems are at particular risk that EBV will flare up and cause illness. EBV is associated primarily with the development of Hodgkin's disease and non-Hodgkin's lymphoma* (both cancers of the lymphatic system*), nasopharyngeal* carcinoma*, and Burkitt's lymphoma, a rare cancer arising in the lymph nodes* that is a common type of childhood tumor in some parts of the world, primarily central Africa.

Hepatitis B and C virus (HBV and HCV) infections primarily affect the liver. They are spread through contact with infected blood, such as through the sharing of needles (including needles for tattooing, body piercing, and drug use). HBV can also spread through contact with the body fluids of an infected person during sexual intercourse. Some people with hepatitis have no symptoms at all, but in others the infection can eventually result in liver cancer or liver damage from cirrhosis (sir-O-sis), a condition in which liver cells die and are replaced with scar tissue.

Because HBV and HCV infections generally are chronic, the viruses are present in the body for a long time and can do significant damage. As the body tries to overcome this damage, new cells are created at a faster rate, increasing the risk of cell mutation* and liver cancer. Hepatitis B can be treated with a 4-month series of injections of interferon (in-ter-FEER-on) alpha-2b, a drug that strengthens the immune system to fight the virus; a once-a-day oral pill called lamivudine, given for about a year; or a once-a-day oral pill called adefovir dipivoxil, given for about one year. If HBV infection affects the liver severely, shutting it down, a liver transplant may be necessary. HBV infection can be prevented by vaccination* against the infection. HCV infection can be treated with a specialized form of interferon called pegylated interferon or peginterferon. This type of interferon only requires weekly administration, whereas infusions of standard interferon would be required multiple times per week. This treatment is usually given in conjunction with an oral treatment, ribavirin. Giving two drugs together is called combination therapy. Combination therapy is much more effective than monotherapy and is usually administered for about 48 weeks. Most infections with HBV or HCV do not result in liver cancer.

The *Helicobacter pylori** bacterium is linked to most cases of gastric (stomach) and duodenal* ulcers*. The infection can be treated with antibiotics. People infected with *H. pylori* are at higher risk of stomach cancers, such as gastric lymphoma and adenocarcinoma (ah-deh-no-kar-sin-O-muh). Gastric cancer has been diagnosed more often in countries where *H. pylori* infection is common, such as China and Colombia, and it is believed that the combination of infection, diet, and other factors contributes to these cancers. The bacteria may spread through contact with feces (FEE-seez), or bowel movements, found in contaminated water sources or on hands that have not been washed thoroughly.

Human lymphotropic (lim-fo-TRO-fik) virus type 1 is a virus that has been linked to the development of certain types of leukemia* and lymphoma primarily in people from Japan, the southern Pacific islands, the Caribbean, parts of central Asia, and central and western Africa. Infection with the virus often occurs at birth, but it can remain inactive for years and sometimes decades before cancer develops. The virus usually is spread through contact with contaminated blood, from prolonged exposure to an infected sexual partner, or from mother to child through breast milk. The earlier a person contracts the infection, the higher the risk for lymphoma. Most people who are infected with this virus, however, do not develop a cancer. This virus is related to the human immunodeficiency (ih-myoo-no-dih-FIH-shen-see) virus (HIV), the cause of acquired immunodeficiency syndrome (AIDS). HIV itself is an oncogenic virus that has been linked to several types of cancer, including Kaposi's sarcoma (a tumor that originates in cells that line the blood and lymph vessels), and non-Hodgkin's lymphoma (cancer of the immune system).

- * **mutation** (myoo-TAY-shun) is a change in an organism's gene or genes.
- * **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.
- * ***Helicobacter pylori*** (HEEL-ih-ko-bak-ter pie-LOR-eye) is a bacterium that causes inflammation and ulcers, or sores, in the lining of the stomach and the upper part of the small intestine, also known as peptic ulcer disease.
- * **duodenal** (do-uh-DEE-nul) refers to the upper part of the small intestine.
- * **ulcers** are open sores on the skin or the lining of a hollow body organ, such as the stomach or intestine. They may or may not be painful.
- * **leukemia** (loo-KEE-me-uh) is a form of cancer characterized by the body's uncontrolled production of abnormal white blood cells.

▲ Nerve paralysis caused this man to lose control of his eye movements. When the man looks to the right, the left eye does not move, giving him a cross-eyed appearance. ©Chris Barry/Phototake. Reproduced by permission.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

* **syndrome** is a group or pattern of symptoms or signs that occur together.

* **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.

How Can Oncogenic Infections Be Prevented?

Exposure to oncogenic infections does not mean that individuals will get cancer. Many people contract such infections and never get cancer. Many factors play a role in the development of cancer, and these infectious agents increase the risk only for some people. Nonetheless, avoiding exposure to these infections can lower the risk of certain types of cancer. People can avoid HIV infection, as well as human lymphotropic virus type 1 and HPV infection, by limiting the number of their sexual partners and practicing abstinence (not having sex) or safe sex. To prevent hepatitis B and C, it is essential to avoid poorly sanitized needles for tattoos, piercing, or illegal intravenous* drug use. Thorough hand washing, particularly after using a bathroom or changing a diaper, can lessen the risk of infection with *H. pylori*. It is almost impossible to avoid exposure to Epstein-Barr virus.

Ophthalmoplegic Syndromes

Ophthalmoplegic syndromes are conditions in which there is complete weakness or paralysis of one or more of the muscles controlling eye movement.

What Is an Ophthalmoplegic Syndrome?

An ophthalmoplegic (off-thal-mo-ple-gik) syndrome* refers to a condition in which there is complete weakness or paralysis* of one or more of the muscles controlling eye movement. (“Ophtho” means “eye” and “plegia” means “paralysis”).

How Are Eye Movements Controlled?

The control of eye movements is complex and involves muscles, nerves, and interconnecting pathways. Three pairs of muscles are involved: the superior and inferior oblique, superior and inferior recti, and lateral and medial recti. “Recti” is the plural of “rectus,” the name for any of the four muscles of the eyeball that begin at the border of the optic opening and run forward to insert into the sclera (tissue) of the eyeball. The three nerves that originate

from the brain stem* and supply the extraocular muscles are the oculomotor (third cranial nerve), trochlear (fourth cranial nerve), and abducens (sixth cranial nerve). The medial longitudinal fasciculus (MLF) is a fiber tract that connects the third and sixth nerve nuclei of opposite sides. Various other pathways connect the cranial nerve nuclei to other parts of the brain. A disturbance in any of these components leads to ophthalmoplegia.

What Are the Symptoms for Ophthalmoplegic Syndromes?

The most common symptom is *diplopia* or double vision*. Depending on which muscle or muscles are involved, the double vision can be either in the horizontal, vertical, or slanted axis. Diplopia can involve one or both eyes, can be painful or painless, can come on suddenly or gradually, and can be congenital* or acquired. In ophthalmoplegic syndromes, besides diplopia, other neurological* symptoms and signs are also present depending on the particular syndrome (e.g., headache, limb weakness, eye swelling, lack of coordination, and numbness).

What Are Some of the Common Ophthalmoplegic Syndromes?

Congenital ophthalmoplegia

Congenital ophthalmoplegia is a rare non-progressive syndrome due to fibrosis (increased fibrous tissue) of one or several of the muscles supplied by the third nerve, leading to restriction of upward gaze.

Acquired ophthalmoplegic syndromes Acquired ophthalmoplegic syndromes can be classified by the part of the eye movement control apparatus that is involved.

Orbit In Graves' disease, in which there is too much functioning of the thyroid gland*, the extraocular muscles become bulky due to fat and connective tissue* deposits leading to a "staring look" with restriction of eye movements. Orbital fractures, direct trauma* to the eye, or tumors* may lead to muscle entrapment and ophthalmoplegia.

Extraocular muscles Progressive external ophthalmoplegia develops in late childhood or adolescence with paralysis of the extraocular muscles, droopy eyelids (ptosis), hearing loss, cataracts*, neuropathy, lack of coordination (ataxia), and sexual dysfunction.

Kearns-Sayre syndrome starts in the first or second decade with ophthalmoplegia, retinal* degeneration, ataxia, deafness, muscle weakness (face and swallowing), and heart rhythm abnormalities. These disorders are due to DNA mutation and are either inherited or occur sporadically.

Neuromuscular junction The typical disorder is myasthenia gravis, which is characterized by ptosis and extraocular, skeletal, and respiratory* muscle weakness that typically worsens with activity and improves with rest. It occurs at any age from childhood to adulthood and is due to an

* **brain stem** is the part of the brain that connects to the spinal cord. The brain stem controls the basic functions of life, such as breathing and blood pressure.

* **double vision** is a vision problem in which a person sees two images of a single object.

* **congenital** (kon-JEH-nih-tul) means present at birth.

* **neurological** (nur-a-LAH-je-kal) refers to the nervous system, which includes the brain, spinal cord, and the nerves that control the senses, movement, and organ functions throughout the body.

* **thyroid gland** (THY-roid GLAND) is located in the lower part of the front of the neck. The thyroid produces hormones that regulate the body's metabolism (me-TAB-o-LIZ-um), the processes the body uses to produce energy, to grow, and to maintain body tissues.

* **connective tissue** helps hold the body together, is found in skin, joints and bones.

* **trauma** refers to a wound or injury, whether psychological or physical. Psychological trauma refers to an emotional shock that leads to lasting psychological damage.

* **tumors** (TOO-morz) are abnormal growths of body tissue that have no known cause or physiologic purpose. Tumors may or may not be cancerous.

* **cataracts** (KAH-tuh-rakts) are areas of cloudiness of the lens of the eye that can interfere with vision.

* **retina** (RET-i-na) is the tissue that forms the inner surface of the back of the eyeballs; it receives the light that enters the eye and transmits it through the optic nerves to the brain to produce visual images.

* **respiratory** (RES-pi-ra-tor-ee) refers to the breathing passages and lungs.

- * **immune** (ih-MYOON) means resistant to or not susceptible to a disease.
- * **receptors** are cell structures that form a chemical bond with specific substances, such as neurotransmitters. This leads to a specific effect.
- * **toxin** is a substance that causes harm to the body.
- * **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.
- * **strokes** are events that occur when a blood vessel bringing oxygen and nutrients to the brain bursts or becomes clogged by a blood clot or other particle. As a result, nerve cells in the affected area of the brain cannot function properly.
- * **multiple sclerosis** (skluh-RO-sis), or MS, is an inflammatory disease of the nervous system that disrupts communication between the brain and other parts of the body. MS can result in paralysis, loss of vision, and other symptoms.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.
- * **dementia** (dih-MEN-sha) is a loss of mental abilities, including memory, understanding, and judgment.
- * **Parkinson's disease** is a disorder of the nervous system that causes shaking, rigid muscles, slow movements, and poor balance.

immune* attack on acetylcholine (a chemical involved in neuromuscular transmission) receptors*.

Another disorder is botulism, in which the botulinum toxin* from certain bacteria* leads to pupil dilatation and ophthalmoplegia.

Cranial nerves or their nuclei in the brainstem A tumor, aneurysm, or clot located behind the eye can lead to painful, puffy, and paralyzed eyes. Tolosa-Hunt syndrome is an inflammatory condition of the same region that causes painful ophthalmoplegia. Various infections or infiltration of cancer cells can affect the cranial nerves, resulting in ophthalmoplegia. In the brainstem, strokes*, tumors, and multiple sclerosis* can all result in it. **Ophthalmoplegic migraine** is a type of headache that causes transient paralysis of the extraocular muscles. In diabetes*, due to interruption of blood supply, painful paralysis of one or more muscles supplied by that cranial nerve occurs.

Brainstem pathways In internuclear ophthalmoplegia, the MLF is affected by multiple sclerosis, tumor, or stroke, leading to a disturbance in conjugate (paired or parallel) eye movements.

Supranuclear structures Progressive supranuclear palsy is a rare neurodegenerative disorder affecting certain parts of the brain that exert control over the nuclei involved in eye movement, resulting in restricted upgaze, gait imbalance, dementia* and Parkinson's disease* like features. Neurodegenerative diseases such as Huntington's disease*, Wilson's disease due to impaired copper metabolism and Wernicke's disease due to thiamine deficiency from chronic alcohol use also cause impaired upward gaze.

Higher brain structures Injury to various parts of the cerebral cortex* due to tumors, strokes, and trauma can also result in ophthalmoplegia.

Medications Intoxication with antipsychotics* such as phenothiazines, antidepressants used for treating depression, and anticonvulsants* such as phenytoin can result in ophthalmoplegia. Deficiency of thiamine and vitamin E can also cause it.

How Is an Ophthalmoplegic Syndrome Diagnosed?

Diagnosis is made by a neurologist*, an ophthalmologist*, or by a neurologist who specializes in eye disorders (neuro-ophthalmologist). Diagnosis is made by a combination of thorough history taking, physical exam, and laboratory tests.

History Taking a thorough medical history requires asking such questions as the following:

- How did the diplopia start?
- How long has it been present? Is there any fluctuation in the diplopia?

- In which direction is the diplopia worst? Does it get better by covering one eye or by tilting the head?
- Is there any pain?
- Was there any trauma?
- Are there other family members with diplopia?
- Are there other eye symptoms, such as ptosis, decreased vision, or uncontrollable jerking of eyes?
- Are there other symptoms, such as headache, muscle weakness, or numbness?
- Is there any history of diabetes, stroke, migraine, or thyroid problems?

Physical examination Eyes are examined for protrusion, redness, ptosis, and tenderness. Then, eye movements are examined separately in each eye and together in both eyes. A red glass or prism in front of each eye helps to pinpoint the eye and the muscle that is responsible for the false image leading to diplopia. Pupils are examined with respect to their reaction to light. A dilated eye exam is done to examine other structures, such as the retina. Finally a thorough neurological* exam includes systematic tests of how well various parts of the nervous system are functioning. A general physical exam is performed also.

Laboratory testing Laboratory testing includes a complete blood count, blood chemistry profile, and thyroid testing. Based on the history and physical exam, one or more of the following tests may be performed:

1. Brain imaging by computerized tomography* (CT scan) or magnetic resonance imaging* (MRI) to rule out stroke, cancer, aneurysm, or multiple sclerosis
2. Electromyogram to determine muscle electrical activity
3. Nerve conduction or evoked potential testing for determining nerve activity and response for conditions such as diabetes and multiple sclerosis respectively
4. Cerebrospinal fluid* analysis by spinal tap for infections, multiple sclerosis, and cancer
5. Tests for electrical activity of the heart (electrocardiogram) and hearing (audiogram)
6. Muscle biopsy* in conditions such as muscular dystrophy*.
7. In myasthenia, testing for acetylcholine activity (Tensilon test) or detecting acetylcholine receptor antibodies
8. Genetic analysis for DNA* mutation*

How Is Ophthalmoplegia Treated?

Specific treatment depends on the syndrome. Myasthenia gravis is treated with corticosteroids*; diabetes with insulin* or medications; and multiple sclerosis with immunosuppressants*. Vitamin E has been tried in

* **Huntington's disease** is a genetic condition that leads to involuntary twitching or jerking of the muscles in the face, arms, and legs along with a gradual loss of mental abilities.

* **cerebral cortex** (suh-REE-brul KOR-tek) is the part of the brain that controls functions such as conscious thought, listening, and speaking.

* **antipsychotics** describes a type of medication that counteracts or reduces the symptoms of a severe mental disorder such as schizophrenia.

* **anticonvulsants** (an-tie-kon-VUL-sents) are medications that affect the electrical activity in the brain and are given to prevent or stop seizures.

* **neurologist** (new-RHAL-eh-jist) a physician who specializes in diagnosing and treating diseases of the nervous system.

* **ophthalmologist** (off-thal-MOLL-o-jist) is a medical doctor who specializes in treating diseases of the eye.

* **neurological** (nur-a-LAH-je-kal) refers to the nervous system, which includes the brain, spinal cord, and the nerves that control the senses, movement, and organ functions throughout the body.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

* **cerebrospinal fluid** (seh-ree-bro-SPY-nuhl) is the fluid that surrounds the brain and spinal cord.

- * **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.
- * **muscular dystrophy** (DIS-tro-fee) is a group of inherited disorders that causes muscle weakening that worsens over time.
- * **DNA** or deoxyribonucleic acid (dee-OX-see-ry-bo-nyoo-klay-ik AH-sid), is the specialized chemical substance that contains the genetic code necessary to build and maintain the structures and functions of living organisms.
- * **mutation** (myoo-TAY-shun) is a change in an organism's gene or genes.
- * **corticosteroids** (kor-tih-ko-STIR-oyds) are chemical substances made by the adrenal glands that have several functions in the body, including maintaining blood pressure during stress and controlling inflammation. They can also be given to people as medication to treat certain illnesses.
- * **insulin** is a kind of hormone, or chemical produced in the body, that is crucial in controlling the level of glucose (sugar) in the blood and in helping the body use glucose to produce energy. When the body cannot produce or use insulin properly, a person must take insulin or other medications.
- * **immunosuppressants** (im-yoo-no-su-PRES-ants) are substances that weaken the body's immune system.
- * **pacemaker** a device whose function is to send electrical signals that control the heartbeat. The heart's natural pacemaker is the sinoatrial node, a special group of cells. Sometimes it is necessary to implant a battery-powered pacemaker that sends small electrical charges through an electrode placed next to the wall of the heart.

Kearns-Sayre syndrome and Coenzyme Q in progressive external ophthalmoplegia, but there is no definitive treatment for these. A pacemaker* may be needed in Kearns-Sayre syndrome. All syndromes benefit from symptomatic treatment for alleviating diplopia. The basic principle is to abolish the abnormal image from the eye with the weak muscle by using an eye patch, special glasses with prisms, or by surgery for ptosis.

What Is the Prognosis for Ophthalmoplegic Syndromes?

The prognosis depends to a large part on the underlying condition that produced the ophthalmoplegia and the presence of additional organ or neurological dysfunction. Several ophthalmoplegic syndromes resolve with time, such as those due to diabetes and mild trauma. Kearns-Sayre syndrome is disabling and shortens life expectancy. Patients with multiple sclerosis have significant disability from other neurological complications and have a slightly shortened life expectancy.

Oppositional Defiant Disorder

A child whose behavior is overly hostile, negative, and purposefully disobedient much of the time for a period of more than six months may have oppositional (op-po-ZI-shun-al) defiant* (dee-FY-ent) disorder.*

What Is Oppositional Defiant Disorder?

Oppositional defiant disorder (ODD) is a type of disruptive behavior problem in children. Children with ODD often lose their temper, act stubborn and willful, argue, and refuse to follow rules, and they may annoy others on purpose. Some oppositional behavior is quite common

and normal in children. Examples of oppositional behavior are refusing to follow rules, directions, or requests given by adults in charge. While all children may act in these ways occasionally, ODD is diagnosed in those children who act in these ways frequently and whose oppositional behavior seriously interferes with their ability to get along with others in school, on the playground, or at home. ODD can start as early as the preschool years and can be diagnosed in children and adolescents of any age whose defiant behavior is the cause of problems at home, in school, or with peers. Children with ODD have at least four of the following problem behaviors to a greater degree than expected for their age for at least six months:

- Become easily annoyed
- Lose temper often
- Feel and act angry and resentful
- Argue with adults
- Refuse to do what adults request
- Actively defy the rules of behavior at home or in the classroom
- Blame others for their own mistakes
- Deliberately annoy others

Children with ODD are often set in their ways (inflexible) and stubborn. They may have other problems as well, such as hyperactivity*, anxiety*, or depression*. ODD is sometimes an early sign of another behavioral disorder called conduct disorder*. Some, but not all, children with ODD go on to show signs of conduct disorder when they are older. While there are some similarities between ODD and conduct disorder, children and adolescents with ODD do not demonstrate the physical aggression or property destruction that is typical of those with conduct disorder.

What Causes Oppositional Defiant Disorder?

There is no single cause of ODD. Some experts believe that certain children may develop oppositional problems because they are less adaptable and overly sensitive by nature. For example, some children seem to find it especially hard to handle frustration and who become easily upset even by minor situations or disappointments. When they are frustrated, such children have extreme difficulty coping and adapting. They may act stubborn, defiant, and inflexible. Some children are more irritable and touchy by nature. They may be particularly upset by the way certain clothing feels or by tastes or smells, and they may act even more cranky, oppositional, and defiant when they are tired or hungry.

Family environment also can contribute to oppositional defiant disorder. In families in which there is much conflict, harsh discipline, aggressive behavior, or inconsistent rules for behavior, children are more likely to develop oppositional defiant disorder because they are learning to relate to others in hostile, argumentative ways.

* **oppositional** (op-po-ZI-shun-al) is an attitude of going against something or refusing in a combative way.

* **defiant** (dee-FY-ent) is an attitude of challenging the rules in a hostile way or of being disobedient on purpose.

* **hyperactivity** (hy-per-ak-TI-vi-tee) is overly active behavior, which makes it hard for a person to sit still.

* **anxiety** (ang-ZY-e-tee) can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person's physical or mental well-being.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

* **conduct disorder** is diagnosed in children and adolescents who have had serious problems with lying, stealing, and aggressive behavior for at least 6 months.

* **salivary glands** (SAL-i-var-ee glands) are the three pairs of glands that produce the liquid called saliva, which aids in the digestion of food.

* **mucous membranes** are the thin layers of tissue found inside the nose, ears, cervix (SER-viks) and uterus, stomach, colon and rectum, on the vocal cords, and in other parts of the body.

How Is Oppositional Defiant Disorder Treated?

Children with oppositional defiant disorder may work with a mental health expert. Often children with ODD are referred by their parents or by school personnel because their behavior is so difficult to manage. Treatment involves helping the child learn to handle frustration, develop more cooperative forms of behavior, and acquire more skills for solving problems and adapting to situations. Parents may be coached to make clear and simple rules for the child, to reward the child's positive behavior patterns, and to enforce consequences for the oppositional ones. When oppositional defiant disorder is treated early, more serious problems with conduct disorder may be prevented.

Oral Cancer

Oral cancer (also known as mouth cancer) occurs when cells in the tissues of the mouth or throat divide without control or order, forming abnormal growths.

What Is Oral Cancer?

Oral cancer usually begins in the tissues that make up the lips, tongue, or cheek lining, but it also can affect the gums, the floor or the roof of the mouth, or the salivary glands*. In almost all cases, it is caused by the use of substances that irritate the mucous membranes* in the mouth: spit

tobacco (also called chewing tobacco or snuff), cigarettes, cigars, pipes, or alcohol. Over time, this constant irritation takes its toll, and some of the tissue takes on an abnormal appearance and eventually turns cancerous. Oral cancer most commonly appears in men over the age of 45 who have been longtime users of tobacco and alcohol.

Many oral cancers begin as whitish or reddish patches in the mouth, called leukoplakia (loo-ko-PLAY-kee-a) or erythroplakia (e-rith-row-PLAY-kee-a). Other symptoms may include the following:

- a sore on the lip or in the mouth that does not heal
- a lump on the lip or in the mouth or throat
- unusual bleeding, pain, or numbness in the mouth
- a sore throat that does not go away or a feeling that something is caught in the throat
- difficulty or pain with chewing or swallowing
- swelling of the jaw
- pain in the ear
- a change in the voice

Most dentists check for signs of oral cancer as part of a usual dental examination. Early detection is the key to treating it successfully.

▲ A polyp, or mucocele (MU-ko-seel), formed inside the mouth's mucous membrane is a common sign of oral cancer. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

A MAJOR LEAGUE FIGHT AGAINST SPIT TOBACCO

For many years, baseball great Joe Garagiola (b. 1926) waged a one-man battle against the prevalent use of spit tobacco, also called chewing tobacco, snuff, or chew, by major league baseball players. A former user of spit tobacco, Garagiola was concerned both about the players' health and about the effect their behavior was having on young fans. He wanted to convey the message that just because spit tobacco is smokeless does not mean it is safe. To the contrary, it is a major cause of oral cancer.

In 1996, Garagiola collaborated with the group Oral Health America to found the National Spit Tobacco Education Program (NSTEP) and get other players involved with the cause. Bill Tuttle, who started using spit tobacco as an outfielder in the 1950s and 1960s, gave talks based on his own experiences with oral cancer. NSTEP recruited players Lenny Dykstra, Mike Piazza, Tino Martinez, Alex Rodriguez, and Paul Molitor to do anti-tobacco spots that were broadcast during games. In 2009 Garagiola continued his involvement with NSTEP and served as one of their speakers.

The mission of the National Spit Tobacco Education Program is to prevent people, especially young people, from starting to use spit tobacco and to help all users quit.

* **lymphatic system** (lim-FAH-tik) is a system that contains lymph nodes and a network of channels that carry fluid and cells of the immune system through the body.

* **radiation** is energy that is transmitted in the form of rays, waves, or particles. Only high-energy radiation, such as that found in x-rays and the sun's ultraviolet rays, has been proven to cause human cancer.

* **gum disease** is an infection caused by bacteria that affect the tissues surrounding and supporting the teeth.

* **lesions** (LEE-zhuns) is a general term referring to a sore or a damaged or irregular area of tissue.

Otherwise, it can spread throughout the mouth, throat, neck, and even to distant parts of the body through the lymphatic system*.

How Is Oral Cancer Diagnosed and Treated?

When dentists or doctors find a suspicious-looking area in the mouth, they may order a biopsy. During this procedure, a surgeon removes part or all of the suspect tissue. Examination under a microscope determines whether cancer cells are present. Once oral cancer is diagnosed, doctors then need to find out whether the cancer has spread.

The first course of treatment is to remove the tumor and any cancerous tissue in the mouth. If there is evidence that the cancer has spread, the surgeon may also remove lymph nodes in the neck as well as part or all of the tongue, cheek, or jaw.

Doctors may also order radiation* therapy, either before the surgery to shrink the tumors, or afterward to destroy any remaining cancer cells. In some cases, surgeons may place tiny "seeds" containing radioactive material directly into or near the tumor. Generally, this implant is left in place for several days, and the patient stays in the hospital.

ORAL CANCER AND TOBACCO

The Centers for Disease Control and Prevention and the National Association of Health Education Centers have compiled statistics about spit tobacco use.

- In the United States, about one out of ten boys and one out of fifty girls in high school use smokeless or spit tobacco.
- According to a 2005 survey, an estimated 3 percent of adults in the United States were currently smokeless tobacco users. Smokeless tobacco use is much higher among men (6%) than women (0.4%). Smokeless tobacco use is most common among young adults ages 18 to 25.
- Another 2005 survey found that an estimated 8 percent of high school students were currently smokeless tobacco users. Smokeless tobacco is more common among males (13.6%) than female high school students (2.2%). Estimates by race/ethnicity are 10.2% for white, 5.1% for Hispanic, and 1.7% for African-American high school students.
- Smokeless tobacco contains 28 cancer-causing agents (carcinogens).
- Spit tobacco use by adolescents is associated with early indicators of gum disease* and unusual lesions* in oral tissue.

A 2008 study from the WHO International Agency for Research on Cancer concluded that smokeless tobacco users have an 80 percent higher risk of developing oral cancer and a 60 percent higher risk of developing pancreatic and esophageal cancer.

Chemotherapy is another possible treatment for oral cancer, especially when it has spread beyond the mouth. It involves taking anti-cancer drugs by injection or in pill form.

Life after Oral Cancer

People who are treated for large or widely spread oral tumors often experience permanent changes that are challenging to deal with, both emotionally and physically. If they lose part of their jaw, tongue, cheek, or palate (the roof of the mouth), they need reconstructive and plastic surgery. If surgery is not possible, they may need to use an artificial dental or facial part called a prosthesis*. In either case, their appearance will be changed permanently.

These people are also likely to have some difficulty chewing and swallowing, and they may lose their sense of taste. For these reasons, weight loss can be a problem after treatment for oral cancer.

Many patients have trouble speaking after losing part of their mouth or tongue. Speech therapists work with them both during and after their hospital stay to help them get back to speaking as normally as possible.

How Is Oral Cancer Prevented?

People can prevent oral cancer by not using spit tobacco or smoking cigarettes, cigars, or pipes, or quitting if they already do. If they drink alcohol, they should not have more than one or two drinks per day.

Oral Infections

Oral infections are infections that occur in or around the mouth.

What Are Oral Infections?

Bacteria and viruses usually cause oral infections. They can affect the teeth, gums, palate (PAL-it, the roof of the mouth), tongue, lips, and inside of the cheeks. Simple oral infections are limited to the mouth and are different from oral lesions*, which are non-infectious and may be a sign of an illness that involves other parts of the body.

Oral infections are very common. Tooth decay is the second most common infectious condition, after the common cold.

Many oral infections are not contagious because bacteria that exist naturally in every person's mouth cause them. However, herpangina (herpan-JY-na) and recurrent herpes labialis (HER-pee-z lay-be-AL-us) are contagious and spread through contact with fluid from an infected person's mouth and nose.

What Are Some Common Oral Infections?

Canker sores Canker sores, also called aphthous (AF-thus) ulcers, are painful but benign* sores that occur on the tongue, inside of the lips and cheeks, gums, and palate. There is no evidence that canker sores are caused by an infectious organism. However, they are very common and can be confused with the sores that appear with some mouth infections. The ulcers may appear one at a time or in groups. They are small, pale, shallow, gray-white, and usually surrounded by bright red tissue.

These sores most frequently affect children and young adults. Sometimes they erupt when people accidentally bite the inside of their mouth or at the spot where braces rub the inside of the cheek. Stress, sensitivity to a particular food, not getting enough iron or B vitamins, and changes in hormones*, like those that occur during women's normal menstrual cycle*, also may trigger canker sores. Often there is no apparent

Healthy gums (left) with no pockets or redness; gingivitis (center) with inflamed gum and pocket; and periodontitis (right) with infected pockets, plaque and tartar. *Illustration by Argosy. Reproduced by permission of Gale, a part of Cengage Learning.*

reason why a person develops a canker sore, although some people may be more likely to have them, especially if other people in their family have had canker sores. Canker sores were once thought to result from infection, but no infectious agent was identified. Later it was suspected that something triggers the immune system, and the cells that normally fight infection “attack” the body’s own tissue, leading to a canker sore.

Someone who has a canker sore may feel a tingling or burning sensation before a sore, reddish spot appears. The pain from a canker sore lasts up to 10 days, and the sore heals completely in one to three weeks. Canker sores usually come and go throughout a person’s life. Occasionally, a person who develops a severe outbreak of canker sores may have a fever or a generally ill feeling.

A doctor (or dentist) usually diagnoses canker sores simply by examining the sore. Rarely, a biopsy* may be taken if the sore is unusually large or is not healing as expected; such a test can distinguish the canker sore from other types of mouth ulcers. These sores heal without treatment, but over-the-counter medicines for canker sores can ease pain. People with more serious sores may be prescribed medication to apply to them. Experts advise anyone with a canker sore to avoid acidic, hot, or spicy foods and to rinse the mouth and gargle with warm saltwater to relieve pain. There is no known way to prevent the sores.

Cavities Dental caries (KARE-eez), also known as tooth decay and cavities, are areas where the hard enamel of a tooth has been destroyed, leaving small holes that are susceptible to further decay. Tooth decay occurs most frequently in children and teens and is the leading cause of tooth loss in younger people. Up to 80 percent of teens have had cavities by the time they finish high school, although tooth decay is much less common in the early 2000s than it was before fluoride supplements and regular dental care were available to most people.

Bacteria that live in the mouth, especially certain kinds of streptococcus (strep-tuh-KAH-kus), cause tooth decay. The bacteria change food, particularly sweet and starchy foods, into acid, which eats away at the enamel of teeth. The acid, bacteria, and bits of food in the mouth combine into a thin film called plaque (PLAK), which coats the teeth and collects in their grooves. A person with dental caries may experience pain or sensitivity in the affected tooth, usually when eating cold, hot, or sweet foods. Some people may not feel anything at all until the cavity extends into the middle part of the tooth, which houses the tooth’s blood vessels and nerves. If left untreated, caries can lead to long-term tooth sensitivity, abscesses*, weakened teeth that can break easily, and even tooth loss.

Sugary foods and drinks and other foods contain carbohydrates* that increase the risk of tooth decay. Frequent meals and snacks also give the bacteria more chances to produce acid. Infants and young children who sip milk or juice throughout the day or go to bed with a bottle may develop bottle caries, a pattern of tooth decay that can damage baby teeth extensively.

* **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **abscesses** (AB-seh-sez) are localized or walled off accumulations of pus caused by infection that can occur anywhere within the body.

* **carbohydrates** are nutrients in food that help provide energy to the body.

* **ligaments** (LIG-a-ments) are bands of fibrous tissue that connect bones or cartilage, supporting and strengthening the joints. Ligaments in the mouth hold the roots of teeth in the tooth sockets.

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

* **periodontal** (pare-e-o-DON-tul) means located around a tooth.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **tonsils** are paired clusters of lymphatic tissue in the throat that help protect the body from bacteria and viruses that enter through a person's nose or mouth.

Tooth decay usually is diagnosed during regular dental visits, and, depending on how badly the tooth has decayed, it may be treated with a filling, crown, or root canal (surgery to remove the pulp of the tooth). A dentist can apply a protective sealant to the molars or use fluoride to help prevent caries. Limiting sweets and frequent snacks; good dental hygiene (brushing and flossing); getting fluoride from drinking water, toothpaste, or other supplements; and regular dental visits are the best ways to prevent tooth decay.

Gingivitis Gingivitis (jin-juh-VY-tis) is inflammation of the gums, also known as the gingiva. It is caused by plaque that coats the teeth along the gum line. The bacteria and acid inflame and irritate the gums, making them red, swollen, and tender. If the plaque is not removed by brushing, flossing, and regular dental visits, it hardens into tartar at the base of the teeth and at the gum line, which further irritates the gums. As gingivitis progresses, the buildup of plaque and tartar causes the gums to recede and affects the ligaments* and bones supporting the teeth. Gingivitis often appears during puberty* or early adulthood, and it is the first stage of periodontal* disease.

Causes of gum irritation, which can lead to gingivitis, include the following:

- poor dental care and habits
- dental devices or appliances (such as bridges or braces) that have rough, irritating edges
- extremely vigorous tooth brushing or flossing
- teeth that are not aligned properly
- pregnancy
- poorly controlled diabetes* or certain other long-lasting illnesses

Swollen, bright red, tender gums that bleed easily and mouth sores are signs of gingivitis. It is diagnosed by examining the gums during a dental visit, and dental x-rays may be taken to determine how much damage has been done to underlying structures in the mouth. People with gingivitis are treated with a thorough dental cleaning, followed by careful and regular at-home cleaning of the teeth and gums. Antibacterial mouthwash also may be prescribed. Gingivitis will not clear up on its own and can progress to serious periodontal disease that eventually affects the ligaments that hold the teeth in the gums and the tooth sockets, leading to tooth loss. Untreated gingivitis also may cause abscesses or a condition known as trench mouth, which is a severe and painful form of gum disease.

Herpangina Herpangina is an infection marked by painful sores on the roof of the mouth, the tonsils*, and sometimes the inside of the cheeks. The lesions start as small bumps but become whitish sores with a red border. Herpangina usually is caused by coxsackievirus (kok-SAH-kee-vy-rus), which also causes hand, foot, and mouth disease; in hand,

foot, and mouth disease, small blisters are found on the palms and the soles as well as in the mouth. A day or two before the sores of herpangina appear, a person may have a fever, sore throat, and headache. Symptoms last less than a week.

Herpangina tends to affect young children and occurs most frequently in summer and fall. Like many other infections from common viruses, it is difficult to prevent. A doctor diagnoses herpangina by examining the appearance and location of the patient's lesions. Treatment includes drinking enough fluid and using over-the-counter medication such as acetaminophen* for pain and fever relief. A person may also apply numbing cream to the lesions to ease discomfort.

Gingivostomatitis Gingivostomatitis (jin-juh-vo-sto-muh-TY-tis) is an infection of the gums and mouth caused by herpes simplex virus type 1 (genital* herpes is caused by herpes simplex virus type 2) and other common childhood viruses. As with herpangina, fever and illness appear before the mouth sores do. The lesions begin as blisters that pop soon after they form, leaving the base of the blister. When this covering peels off, a tender ulcer is formed. It looks grayish or yellowish with a red border. These painful sores often make it difficult to eat.

The diagnosis of gingivostomatitis is based on the presence of mouth sores, usually accompanied by other symptoms of a viral illness. Gingivostomatitis caused by herpes virus has a distinctive appearance and usually does not require more tests. Cultures* or biopsies* rarely are done. Treatment for gingivostomatitis includes easing pain and preventing dehydration*. Over-the-counter pain medicine, medicated mouthwash or saltwater gargles, or numbing cream may provide some relief. Brushing teeth and gums gently helps prevent bacterial infection of the sores. Fluids and a bland diet are recommended as well.

Herpes Recurrent herpes labialis, also known as cold sores or fever blisters, is a condition caused by herpes simplex virus type 1. Cold sores are extremely common. Most Americans are infected with the virus by age 20. The virus stays in the body for life, although it usually causes no disease or only an occasional cold sore in most people. Many factors can trigger a reactivation of the herpes virus and recurrent cold sores, such as fever, sun exposure, and stress.

Burning, tingling, or itching may occur a day or two before a small, sometimes painful blister appears on the gums, lips, inside of the mouth, or around the mouth. The blister is filled with clear or yellowish fluid. Shortly after it forms, the sore crusts over, and the crust eventually falls off. Sometimes a person also develops a mild fever or feels ill.

A doctor diagnoses herpes labialis based on the appearance of the cold sores, although fluid from a blister may be examined or cultured to confirm the diagnosis. Patients with cold sores often report having had them before. The blisters usually disappear on their own after one to two weeks, but if a person has frequent or severe cold sores, a doctor may prescribe

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

* **genital** (JEH-nih-tul) refers to the external sexual organs.

* **cultures** (KUL-churz) are tests in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

* **biopsies** (Bl-op-seez) are tests in which small samples of skin or other body tissue are removed and examined for signs of disease.

* **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.

* **vaginal** (VAH-jih-nul) refers to the canal in a woman that leads from the uterus to the outside of the body.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

antiviral medication to shorten the outbreak. However, the medicine does not get rid of the virus. When cold sores appear, ice or warm compresses may ease any discomfort or pain.

Cold sores are contagious. Kissing spreads the virus by direct contact, but the virus may spread indirectly by sharing food, drinks, lipstick, or utensils. It is difficult to prevent this infection because it can spread when no sores are visible.

Thrush Thrush, or candidiasis (kan-dih-DYE-uh-sis), is an overgrowth of *Candida*, a yeast-like fungus that can thrive in moist areas around body openings such as the mouth. Candidiasis can cause cracks in the corners of the mouth, and the lips, tongue, palate, and inside of the cheeks can have crusty whitish or yellowish patches. *Candida* also can cause other conditions, such as diaper rash and vaginal* yeast infections.

Thrush generally is not contagious, but newborns may come in contact with the fungus during birth if the mother has a vaginal yeast infection. People with weakened immune systems, such as those with AIDS* or cancer, may be more susceptible to thrush.

How Can People Prevent Oral Infections?

Frequent hand washing and avoiding exposure to people who are sick whenever possible helps prevent the spread of viral infections. Taking care of the teeth and mouth also goes a long way toward preventing oral infections. Tips for good oral hygiene include the following:

- Visiting a dentist regularly (every six months) for teeth cleanings and check-ups, and brushing teeth twice daily. Fluoride toothpaste is recommended for children; anti-tartar toothpaste is recommended for adults.
- Brushing the gums and tongue gently.
- Flossing daily.
- Brushing teeth after eating sugary or starchy foods.
- Wearing a helmet, and possibly a mouth guard, when playing certain sports, such as football or hockey, to protect teeth from injury.
- Not using tobacco products.

Osgood-Schlatter Disease

Osgood-Schlatter disease is a condition that causes knee pain in some children during their adolescent growth spurt.

Danny's Story

Danny's twelfth birthday marked the beginning of soccer season, a four-inch growth spurt, and a lot of pain in his right knee. When Danny's coach asked him why he was limping, Danny told him that his knee hurt, especially when climbing stairs, kneeling, or jumping. His coach called his parents and suggested they take Danny to the doctor.

Danny's doctor examined the tender, swollen knee. When she gently pressed the area just below the kneecap, Danny grimaced in pain. The results from the rest of the examination were normal. Danny was diagnosed as having Osgood-Schlatter (OZ-good SHLAT-er) disease.

This diagnosis scared Danny at first, but quickly the doctor eased his mind by explaining that Osgood-Schlatter disease is a condition in adolescents that almost always goes away on its own. It was named for an American surgeon, Robert Bayley Osgood (1873–1956), and a Swiss surgeon, Carl Schlatter (1864–1934), hence the long, serious-sounding name.

What Is Osgood-Schlatter Disease?

Osgood-Schlatter disease refers to pain that occurs at the bump on the shin bone, or tibia (TIB-e-a), just below the knee. At this spot a tendon* from the muscles of the thigh attaches to the shin after passing over the kneecap. Sometimes, especially during the adolescent growth spurt, the place where the shin bone is actively growing partially detaches from the rest of the bone, resulting in pain and swelling. This problem most often occurs in children between the ages of 10 and 15, especially those who are active in sports, and it affects more boys than girls.

Osgood-Schlatter disease usually goes away after the growth spurt ends. To treat the symptoms, doctors suggest taking over-the-counter pain medicine such as ibuprofen* or acetaminophen*, stretching well before exercising, and cutting back on sports that require contraction of the quadriceps (KWOD-riseps) muscle of the thigh, such as squat thrusts or running. Some doctors put a cast on the leg to limit a child's activity. Continuing to play sports usually does not make the condition worse, but it can delay the healing process. In a few cases, the problem does not go away on its own because abnormal bony structures form or small pieces of bone become detached. In these cases, surgery may be required to remove the bone fragments.

Remember R-I-C-E

When treating pain from sprains, strains, or other limb-related conditions, it's helpful to remember the "RICE" treatment.

R = Rest the injury from the painful activity.

I = Ice the affected area for 20 minutes, 3 times a day.

C = Compress the painful area with an elastic bandage.

E = Elevate the leg.

* **tendon** (TEN-don) is a fibrous cord of connective tissue that attaches a muscle to a bone or other structure.

* **ibuprofen** (eye-bew-PRO-fin) is a nonsteroidal anti-inflammatory drug (NISAD) used to reduce fever and relieve pain or inflammation.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

Osteoarthritis *See Arthritis.*

Osteomyelitis

Osteomyelitis (ah-stee-o-my-uh-LYE-tis) is a bone infection that is usually caused by bacteria. It can involve any bone in the body, but it most commonly affects the long bones of the arms and legs.

Special bone scans are used to diagnose osteomyelitis. The affected areas of bone “light up” on these scans. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

What is Osteomyelitis?

Osteomyelitis usually is caused by infection with bacteria. *Staphylococcus aureus* (stah-fih-lo-KAH-kus ARE-ree-us), streptococcal (strep-tuh-KAH-kul) species of bacteria, and *Pseudomonas aeruginosa* (su-doe-MO-nas-air-ew-jih-NO-suh) are the major organisms associated with osteomyelitis. These bacterial intruders can travel from other parts of the body, such as the ear, throat, or intestines*, through the bloodstream and to a bone, where they can start an infection. Bones that have been weakened or damaged, such as one that has been injured recently, are more susceptible to bacterial invasion. When there is trauma* to the bone, such as a puncture wound from stepping on a nail, bacteria can infect the bone directly. Rarely, fungi may cause osteomyelitis and the spread through the body of tuberculosis (too-ber-kyoo-LO-sis), a contagious disease caused by another bacteria mycobacterium tuberculosis, that typically affects the lungs, also can lead to bone infection, usually in the spine.

In children, osteomyelitis occurs most often in the long bones of the leg, such as the femur (FEE-mur) and tibia (TIH-be-uh). Adults tend to have the infection in the hipbones and vertebrae*, where it may occur following surgery on a bone or from an infection that has spread from the skin. People with diabetes* can have osteomyelitis in the foot bones from ulcerations* ulcers* on their feet.

Acute versus Chronic Osteomyelitis

Osteomyelitis that evolves rapidly is called acute* osteomyelitis. If a bone infection persists because it is not treated or it does not respond to treatment, it is known as chronic* osteomyelitis.

When the bone becomes infected in acute osteomyelitis, the skin that covers the bone usually becomes inflamed and swollen. The condition is diagnosed by a blood culture, by a biopsy* (tissue sample), or by an x-ray or bone scan examination. If acute osteomyelitis is confirmed, antibiotic treatment begins immediately, often with an excellent chance of complete recovery.

When osteomyelitis is not treated or does not respond to treatment, it may become a chronic, or long-term, condition. In its chronic stages, osteomyelitis can be very painful and cause considerable damage to the infected bones. Sometimes this chronic form develops from compound fractures (in which case the broken bone punctures the skin and is exposed). Antibiotics are used to treat chronic osteomyelitis, but sometimes surgery is also required to remove infected areas of bone because over time, the infection may interfere with the blood supply to the bone, causing the bone tissue to die.

In rare cases, tuberculosis, an infection of the lungs and sometimes other parts of the body, can spread to bones (especially the spine), causing a form of osteomyelitis. When tuberculosis is involved, drugs to combat tuberculosis are used to treat both conditions.

- * **intestines** are the muscular tubes that food passes through during digestion after it exits the stomach.
- * **trauma** refers to a wound or injury, whether psychological or physical. Psychological trauma refers to an emotional shock that leads to lasting psychological damage.
- * **vertebrae** (VER-tuh-bray) are the bones that form a column surrounding the spinal cord; there are 39 vertebrae in the spine.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.
- * **ulcerations** are open sores on the skin or tissue lining a body part.
- * **ulcers** are open sores on the skin or the lining of a hollow body organ, such as the stomach or intestine. They may or may not be painful.
- * **acute** describes an infection or other illness that comes on suddenly and usually does not last very long.
- * **chronic** (KRAH-nik) lasting a long time or recurring frequently.
- * **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

* **pus** is a thick, creamy fluid, usually yellow or ivory in color, that forms at the site of an infection. Pus contains infection-fighting white cells and other substances.

How Common Is Osteomyelitis?

Chronic osteomyelitis occurs in about 2 in 10,000 adults. Children have the acute form of the disease more often than adults do, at a rate of about 1 in 5,000. Children commonly have blood stream spread of infection to long bones because actively growing bones are quite vascular. Adults in whom the long bones are not growing and are less vascular have blood stream spread to the bones of the spine. People who have diabetes, who have had a traumatic injury recently, or who use intravenous* drugs are at greatest risk for chronic infection.

Is It Contagious?

Bone infections are not contagious. However, some types of bacteria that cause the infections that can progress to osteomyelitis are passed from person to person.

What Are the Signs and Symptoms of Osteomyelitis?

The first sign of acute infection may be a fever that begins suddenly. The area over the infected bone may become warm, red, and swollen, and the joints next to the bone may swell as well. As the infection progresses, it can cause pain in the affected bone and may limit the person's movement in that area. Individuals with acute osteomyelitis may feel irritable, nauseated, and generally, very ill. They usually respond to intravenous antibiotic treatment; however, the medication is often irritating at the site of infusion.

Patients with chronic bone infection may experience drainage of pus* through the skin covering the affected bone. Due to local pain and drainage caused by the infection, individuals having chronic osteomyelitis usually require surgical removal of dead infected bone.

A HISTORIC INFECTION

Some cases of osteomyelitis last for years, even a lifetime. Joshua Lawrence Chamberlain (1828–1914) rose to the rank of general during the American Civil War and was a hero in the Battle of Gettysburg. General Ulysses S. Grant selected Chamberlain to receive the official surrender of the Confederate Army's weapons at Appomattox, Virginia, in 1865. Chamberlain later served as governor of Maine and president of Bowdoin College. Before he reached that lofty standing, Confederate soldiers had shot him in the groin in a battle at Petersburg, Virginia, in 1864. The ball pierced both hipbones, but despite the crude battlefield surgery of the time he survived his injury. His wound never healed completely, though, and Chamberlain lived another 50 years with chronic osteomyelitis. He died in 1914, at the age of 85, from complications of that long-lasting wound.

How Is the Disease Diagnosed?

To help make the diagnosis, a doctor may order an x-ray of the suspect area to look for signs of bone inflammation or damage, but changes in the bone may not show up for weeks after the infection begins. Magnetic resonance imaging* (MRI) or a computerized tomography* (CT) scan may show changes that reflect osteomyelitis sooner than x-rays will. Radionuclide scans* may help pinpoint the location of the infection early in the course of the disease. Blood cultures* or, less commonly, a bone biopsy may identify the infectious agent.

What Is the Treatment for Osteomyelitis?

Patients with osteomyelitis usually need to be hospitalized. They typically receive antibiotics for four to six weeks to combat the infection. At first, the medication is given intravenously, but patients may be switched to oral (by mouth) medicine as the treatment continues and their condition improves. In more serious and chronic cases, patients may need an operation to remove bits of bone that have died. To help new bone grow, surgeons may perform a bone graft, in which bone from another part of the body is placed in the spot where dead bone has been removed; doctors may use packing material to fill in the open area temporarily.

How Long Does the Disease Last?

Patients with osteomyelitis often need several weeks or months of treatment before the infection clears up. Acute cases may resolve after as little as one month of antibiotic therapy, but chronic cases can linger much longer.

What Are the Complications?

In children, osteomyelitis can damage growing bones permanently, especially if it is not promptly and adequately treated. Infection may spread to the blood, overlying skin, or nearby joints. Bones may be weakened and break more easily. Movement of nearby joints or limbs may become limited. Occasionally in chronic cases, severe infection or damage to the bone may result in the need to amputate, or remove, part or all of a limb.

How Can Osteomyelitis Be Prevented?

Quick, thorough treatment of any infection, particularly those from deep wounds, can lower the risk of osteomyelitis. Skin is the most common initial site of infection (spreading to the bones via the blood stream), so proper treatment of all breaks in the skin is an important first step in preventing this bone infection. It is recommended that patients who are more susceptible to osteomyelitis, such as those with diabetes, contact a doctor promptly if they notice signs of infection.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **radionuclide (ray-dee-o-NU-klide) scans** are tests that begin by giving a patient a small amount of a radioactive substance. The radioactive substance shows up on a scan, producing a view of the structure or function of the part of the body being studied.

* **cultures** (KUL-churz) are tests in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

Osteoporosis

Osteoporosis (os-te-o-po-RO-sis), which literally means “porous bones,” is a disease that occurs when there is loss of bone density, which increases the likelihood of a bone fracture from even a minor fall or bump.

What Is Bone?

Bone is living tissue. There are two general types of bone tissue: cortical and spongy. Cortical bone is dense and compact and generally forms the outer layer of bones. Spongy, or cancellous, bone generally forms

A normal bone (left) and one with osteoporosis (right). ©PHOTOTAKE Inc./Alamy.

the inner layer. Spongy bone is mesh-like and contains bone marrow* within its meshwork. Osteoporosis is more common in bones with a large percentage of spongy bone. These include the vertebrae (bones of the spine), the hips, and the wrists. These bones are more fragile and are especially prone to fracture when they have been affected by osteoporosis.

Because bone is living tissue, old bone is constantly being broken down (bone resorption) and new bone is constantly being deposited (bone formation). Until late adolescence, bone mass and density increase because more bone is formed than is resorbed. When people are in their mid-twenties to their mid-thirties their bones are at their maximum mass and strength. After that, more bone is resorbed than is formed, and bone mass and strength are gradually lost. Osteoporosis develops gradually over time, although rates vary among individuals.

How Many People Have Osteoporosis?

Osteoporosis is a serious public health problem, costing approximately \$20 billion each year in the United States. In 2008 the National Osteoporosis Foundation estimated that 10 million people in the United States over age 50 had osteoporosis and another 34 million were at risk for developing the disease. Women with osteoporosis outnumber men by a ratio of four to one. Although persons of either sex and people of any ethnic background can develop osteoporosis, it is especially common among white and Asian women over age 50. Many persons do not become aware that they have osteoporosis until they fracture (break) a bone. Typically, in persons who have osteoporosis, fracture is the result of a simple fall that would not have caused a fracture in a young adult.

In the United States, osteoporosis is responsible for approximately 2 million bone fractures annually. These fractures, which are often the first evidence of the disease, can occur in any bone, but the most common locations are the hip (annually about 300,000 fractures), spine (700,000 fractures), and wrist (250,000 fractures). Breaks in the hip and spine are of special concern because they usually require hospitalization and major surgery. Because many people with osteoporosis-related fractures are elderly, the fractures often lead to other serious consequences, including permanent disability and even death. Only about 15 percent of people who fracture a hip are able to walk across a room unaided six months later and about one-fourth of people over age 50 who fracture a hip die within one year.

Types and Causes of Osteoporosis

Osteoporosis is classified as primary or secondary. Primary osteoporosis is part of the aging process and is not associated with any other disease process. Secondary osteoporosis is a result of another disease, treatment, or abnormality.

Primary osteoporosis Primary osteoporosis is associated with aging. It is the most common form of the disease, accounting for about 95 percent of osteoporosis in women and at least 80 percent in men.

* **bone marrow** is the soft tissue inside bones where blood cells are made.

* **menopause** (MEN-o-pawz) is the end of menstruation.

* **genes** (JEENS) are the functional units of heredity that are composed of deoxyribonucleic acid (DNA) and help to determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are segments of chromosomes found in the nuclei of the body's cells.

* **endocrine** (EN-do-krin) refers to a group of glands, such as the thyroid, adrenal, and pituitary glands, and the hormones they produce. The endocrine glands secrete their hormones into the bloodstream, and the hormones travel to the cells that have receptors for them. Certain hormones have effects on mood and sometimes cause emotional swings.

* **anorexia nervosa** (an-o-REK-se-a ner-VO-sa) is a psychiatric illness characterized by a distorted body image and a fear of gaining weight, which usually lead to self-starvation and dangerous weight loss and malnutrition.

* **bulimia** (bu-LEE-me-a) is characterized by episodes of out-of-control eating, or binge eating, and by self-induced vomiting the use of laxatives.

In women, primary osteoporosis is often referred to as “postmenopausal osteoporosis,” which results from the accelerated bone loss that occurs in women during and after menopause*. After menopause, ovaries produce very little estrogen, a hormone that helps to maintain bone mass.

Several factors influence whether a person develops primary osteoporosis. These include:

- **Sex.** Women are smaller, start out with less bone mass, and lose bone mass more rapidly as they age.
- **Figure type.** People with small bones and those who are thin are more likely to have osteoporosis.
- **Early menopause.** Women who stop menstruating early lose large amounts of bone tissue fairly early in life. The female sex hormone estrogen helps to protect bone mass. When women stop menstruating, the level of estrogen in their bodies drops, and the protective effect is lost.
- **Lifestyle.** People who smoke, use alcohol heavily, and/or exercise little have an increased chance of developing osteoporosis.
- **Diet.** Those who do not get enough calcium or protein may be more likely to have osteoporosis.
- **Genetics.** The amount of bone formation that occurs during adolescence and rate at which it is broken down later in life appears to be influenced by genes* (heredity). Researchers believe that they may have identified a few specific genes and gene variations that play a role in the development of osteoporosis.

Secondary osteoporosis Secondary osteoporosis is osteoporosis that results from another, underlying medical condition or the result of taking medication. Secondary osteoporosis can have many causes. Confinement to a wheelchair or bed can cause the bones to lose mass and density. This effect also has been observed in astronauts who have undergone prolonged periods of weightlessness in space, as it is impossible to get proper exercise when there is no gravity to work against. Cancer, some endocrine* diseases, and some liver and digestive diseases can also lead to secondary osteoporosis, as can the eating disorders anorexia nervosa* and bulimia*.

Signs and Symptoms

Osteoporosis does not always produce obvious symptoms. Often an older person first learns of his or her condition after breaking a bone in a fall, when an x-ray reveals decreased bone density. Although falls are the most common cause of fractures, the thinning vertebrae in a person with osteoporosis may actually collapse under the weight of the upper body. Called compression fractures, these fractures can cause severe pain, usually in the mid or lower back. Chronic, or long-lasting, pain may develop after several such fractures have occurred. The person may gradually lose inches of height, and the upper back may curve forward, creating the hunchback appearance that one sees in many elderly women.

Diagnosing Osteoporosis

If a doctor suspects the presence of osteoporosis, he or she will take a complete medical history, conduct a physical examination, and order x-rays, as well as blood and urine tests, in an effort to rule out other diseases that can cause loss of bone mass. However, the only way to confirm a diagnosis of osteoporosis is to measure bone density. A standard x-ray may reveal that the bones are less dense than normal, but osteoporosis is usually advanced by the time it is evident on an x-ray.

Special imaging techniques may be conducted, including a computerized tomography* scan and bone density scan, also called bone photon densitometry (FO-ton den-si-TOM-e-tree), which is an enhanced form of x-ray technology that is used to measure degrees of bone loss. Bone density scanning is painless and exposes the patient to only a small amount of radiation—about one-fiftieth that of a chest x-ray.

In some instances, a blood test and bone biopsy (removal of a tiny sample of bone for examination) may be used to rule out the possibility of osteomalacia (OS-te-o-ma-LAY-she-a), a closely related condition, known as rickets when it affects children, that usually results from a lack of vitamin D.

Treating Osteoporosis

Osteoporosis cannot be cured, but it can be treated. Treatment usually is multi-sided and is aimed primarily at stopping or slowing bone loss.

Lifestyle Changes The lifestyle changes that help slow bone loss are beneficial to people of all ages, including the elderly, in whom there is going to be at least some measure of osteoporosis. Exercise, especially weight bearing exercise or strength training, is important to the maintenance of bone strength. Even frail individuals with chronic health problems can exercise with weights under the supervision of a physical therapist or health professional familiar with the American College of Sports Medicine strength-training guidelines for older people. Exercise that improves flexibility and balance can also improve coordination and help to prevent falls and fractures.

A diet that includes enough calcium and vitamin D also helps slow osteoporosis. Calcium is the main mineral in bones, and very few people get enough of it in their diet. Experts recommend 1,500 mg of calcium per day for adolescents, pregnant or breast-feeding women, post-menopausal women, and adults over age 65. All others should get at least 1,000 mg per day. Foods are the best source for this important mineral. Milk, cheese, and yogurt have the highest amounts. Other foods that are high in calcium are green leafy vegetables, tofu, shellfish, Brazil nuts, sardines, and almonds.

People who do not get enough calcium from food may need to take calcium supplements. Calcium supplements vary in calcium content and absorbability. Calcium carbonate is the most common and least expensive calcium supplement. Five- or six-hundred mg calcium tablets can

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of a region of the body to put together a cross-sectional picture.

be taken one to three times daily. It is recommended that individuals, in addition to getting enough calcium, get 800 to 1,000 international units (IU) of vitamin D daily. Vitamin D helps the body absorb calcium in the digestive tract.

Other lifestyle choices include not smoking and not drinking alcohol. Older people should assess their homes for hazards that might cause falls. Protecting against falls might include removing small, loose rugs; installing grab bars in showers; improving lighting on stairs; marking the final stair with reflective tape; avoiding loose, floppy footwear; and placing often-used kitchen supplies where they can be reached without climbing on a stool or chair.

Drugs In the past, women often received estrogen/progesterone hormone replacement therapy (HRT) to ease the symptoms of menopause. Because HRT artificially increased the amount of estrogen in the body, it had the added effect of slowing or preventing bone loss. However, large studies have shown that HRT can also increase the risks of heart disease and breast cancer. In the early 2000s, under most circumstances, HRT was used sparingly and only for a short time.

Several drugs belonging to a group called bisphosphonates have been approved in the United States for treatment and/or prevention of osteoporosis. These drugs slow the breakdown of bone. Some are approved exclusively for use in women, whereas others can also be taken by men. Drugs in this category include alendronate, ibandronate, and risedronate. Another drug calcitonin is produced by the thyroid gland and suppresses bone resorption; it is approved for the treatment of osteoporosis. Raloxifene has effects on bone similar to those of estrogen and is used in the treatment of osteoporosis. Teriparatide, a form of human parathyroid hormone, has been shown to actually stimulate bone growth. Patients should discuss with their doctor the risks and benefits of these drugs based on their individual situation, as they should for all drugs.

Preventing Osteoporosis

The best time to take steps to promote bone growth (and make osteoporosis less likely in later years) is during the childhood and teen years. This is particularly so for young women with small frames and who have close relatives with osteoporosis. For young people, just as for the elderly, getting plenty of regular exercise is important, as is calcium in the diet. It is estimated that more than 70 percent of children and teenagers fail to consume adequate amounts of calcium. The aim is to achieve full bone density in the skeleton by the time individuals have reached their early twenties.

Beginning in adolescence, not smoking and not drinking alcohol are important. Fad diets that promise rapid weight loss need to be avoided. While exercise, particularly supervised weight training, is important in the prevention of osteoporosis, extreme exercise, especially when combined with dieting and weight loss, can stop menstrual periods and reduce estrogen levels in young women. This decreased estrogen can cause significant bone loss.

Otitis (Ear Infections)

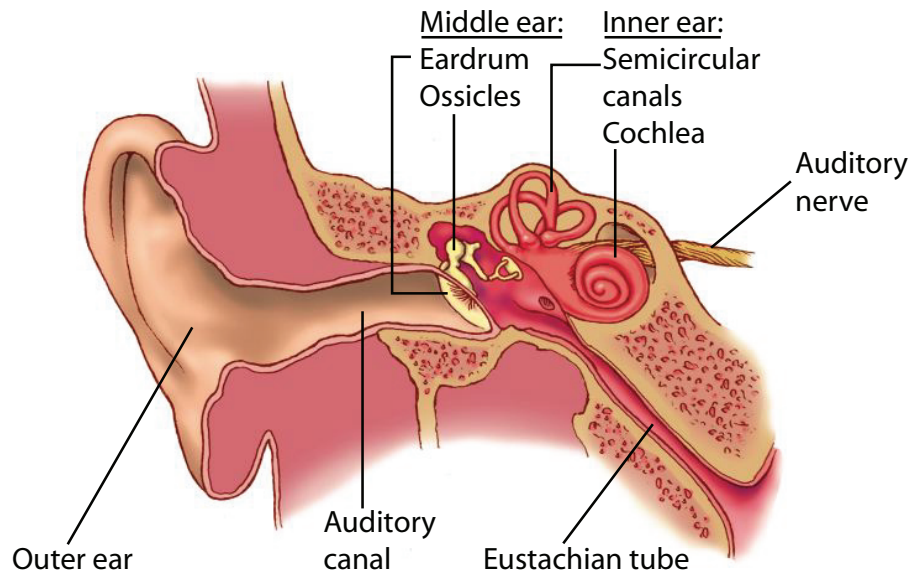

Otitis (o-TIE-tis) is an inflammation of the internal or external parts of the ear, usually caused by infection.

The Anatomy of the Ear

The ear has three main parts: outer, middle, and inner. The outer ear consists of the pinna, or visible tissue attached to the head, and the external auditory canal, which is the visible entrance into the ear. Earwax made in the outer ear lubricates the tissue, keeps it from itching, and helps prevent bacteria from entering the middle ear. The middle ear consists of the eardrum (tympanum) and three small bones (the malleus, incus, and stapes). The Eustachian tube* connects the middle ear to the throat. The inner ear contains fluid and sensitive hairs that vibrate in response to sound and send information to the brain. When the ear becomes infected, an

* **acute** describes an infection or other illness that comes on suddenly and usually does not last very long.

* **pus** is a thick, creamy fluid, usually yellow or ivory in color, that forms at the site of an infection. Pus contains infection-fighting white cells and other substances.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **effusion** (ih-FYOO-zhun) is an excessive accumulation of body fluid in a body space or cavity, such as the middle ear.

* **respiratory tract** includes the nose, mouth, throat, and lungs. It is the pathway through which air and gases are transported down into the lungs and back out of the body.

earache may occur. There are two common types of ear infection: otitis media and otitis externa.

What Is Otitis Media (Middle Ear Infection)?

Otitis media or middle ear infection is extremely common, especially in young children. It occurs when the eustachian tube becomes blocked and fluid collects in the middle ear. This condition occurs when a person has a cold or other upper respiratory symptoms, such as those caused by allergies. The fluid that accumulates in the middle ear provides a warm, moist place for bacteria to grow, which results in an infection of the middle ear that usually becomes apparent when the ear begins to ache. In acute* otitis media, the middle ear becomes inflamed and fills with fluid or pus*.

Chronic* otitis media results when the infection does not go away (with or without treatment) within a few weeks. In more severe or long-lasting cases of chronic otitis media, the eardrum may become permanently damaged or the infection may spread to surrounding structures. More often in chronic otitis media, the infection clears up, but fluid remains and the eardrum cannot move freely to transmit sound waves. This condition is known as chronic otitis media with effusion*, and it can cause a temporary hearing loss in the affected ear. Otitis media is labeled recurrent when a person has repeated ear infections but gets better between infections.

Otitis media is not contagious, but common colds and other infections of the respiratory tract* that can lead to it are. When people cough, sneeze, laugh, or talk, they can spread the viruses or bacteria that cause colds and respiratory illnesses to their hands, to the surfaces around them, and into the air. Other people can touch contaminated surfaces with their hands or can breathe in these germs and spread the germs to their noses and mouths. If the conditions are right, the germs enter the middle ear

through the eustachian tube or cause a blockage in the eustachian tube, setting the stage for an ear infection to develop.

Adults can get otitis media, but it is much more common in children, especially those under three years of age. The eustachian tubes of children are narrower, shorter, and more horizontal than those in adults, making it easier for germs to enter and fluid to build up. Young children also have more frequent respiratory infections than adults.

What Are the Signs and Symptoms of Otitis Media?

Signs and symptoms of otitis media include the following:

- In babies, irritability, fussiness, or tugging on the ear
- Ear pain or a feeling of pressure in the ear
- Buzzing or ringing sounds in the ear
- Pus draining from or bleeding from the ear (if the eardrum has ruptured)
- Mild hearing loss
- Fever

Complications of otitis media include a ruptured eardrum due to high-pressure fluid buildup in the middle ear. Hearing loss may also occur. Hearing loss is usually temporary, except in long-standing chronic cases. Occasionally an ear infection develops into mastoiditis*, and, rarely, the infection spreads to the brain.

What Is Otitis Externa (Swimmer's Ear)?

Otitis externa, often called swimmer's ear, is an inflammation or infection of the outer ear canal. It is not contagious but occurs when bacteria or fungi enter through a break in the skin inside the ear.

Otitis externa often occurs after swimming or diving when moisture breaks down the protective wax and skin in the ear canal. Although it is called swimmer's ear, otitis externa can occur if these barriers are broken in other ways, such as by frequent cleaning with cotton swabs or scratching inside the ear too roughly. Once the skin is broken, bacteria can enter and cause infection. The ear becomes red, swollen, and painful to the touch. Otitis externa is common. It affects mostly teens and young adults. People who spend a lot of time swimming or diving are most susceptible.

Occasionally otitis externa can have complications. In about 1 percent of cases, the infection persists and results in chronic otitis externa. Rarely, this condition can lead to malignant* otitis externa, a serious condition in which the infection spreads to the bones and nerves of the ear, skull, and brain; this condition occurs almost exclusively among elderly people with diabetes*. Malignant otitis is a serious condition that requires hospitalization, treatment with intravenous* antibiotics, and sometimes surgery to remove the infected tissue.

Three by Three

According to the American Academy of Otolaryngology, one-third of all children experience three or more ear infections by the time they are three years of age. Otitis media is the most frequent diagnosis among children for sick visits to the doctor, and it is the leading cause of hearing loss in children.

* **mastoiditis** (mas-toy-DYE-tis) is an infection of the mastoid bone, located behind the ear.

* **malignant** (ma-LIG-nant) refers to a condition that is severe and progressively worsening.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

What Are the Signs and Symptoms of Swimmer's Ear?

Signs and symptoms of otitis externa include:

- Ear pain that usually worsens if the ear is touched or pulled
- Red, swollen outer ear canal
- Green or yellow pus draining from the ear
- Mild loss of hearing

Other Ear Infections

Malignant otitis is a serious condition that rarely occurs in children but does occasionally occur in the elderly, especially in those people with diabetes or other chronic diseases that weaken the immune system. Bacteria invade the cartilage and bone of the head in this rare but serious condition. Treatment involves hospitalization, intravenous antibiotics, and sometimes surgery to remove the infected tissue.

How Are Ear Infections Diagnosed?

A doctor examines a person's ears, inside and out, checking for redness, swelling, and abnormal collections of fluid. The doctor takes a close look at the eardrum by using a lighted instrument called an otoscope (O-toh-sko-pe). With an otoscope, the doctor can see if there is fluid in the middle ear making the eardrum bulge. In the case of chronic middle ear infections, an audiogram may be performed to test the person's hearing, and a tympanogram (tim-PAH-no-gram) may be done to check for normal vibration of the eardrum and pressure levels in the middle ear. In cases that do not respond to treatment, samples of fluid, pus, and blood from inside the ear may be tested to discover whether a bacterium, virus, or fungus is causing the infection. If the doctor thinks the infection has spread to surrounding bone or cartilage, an x-ray or computerized tomography* (CT) scan of the head may be performed.

How Do Doctors Treat Ear Infections?

Over-the-counter, non-aspirin painkillers such as acetaminophen* and warm heating pads can be used to ease the throbbing pain of earaches. Antibiotic eardrops are used to treat otitis externa. Oral (by mouth) antibiotics may be prescribed to treat otitis media and in more severe cases of otitis externa. However, the medical community is concerned about the overuse of antibiotics. Antibiotics may not always be necessary to treat otitis media. Some cases of otitis media are caused by viruses, which do not respond to antibiotic treatment, but it is often difficult to tell the difference. Even if bacteria are the cause of an ear infection, most people will get better on their own, although antibiotic treatment lowers the risk of the infection spreading and clears up symptoms sooner. Typically, the symptoms of acute otitis media improve within the first two to three days of antibiotic treatment. Chronic infections, however, can last several

weeks or months. In children with chronic otitis media, it may be helpful to surgically insert a small plastic tube in the eardrum that allows air to flow into the middle ear and prevent fluid buildup that can interfere with hearing.

In cases of external otitis, doctors recommend that water be kept out of the ear canal during recovery; earplugs or shower caps can help keep out water while bathing, and swimming should be avoided.

How Can Ear Infections Be Prevented?

Frequent hand washing can help prevent spread of the germs that cause colds and other respiratory illnesses, which often lead to ear infections, especially in young children. Toys should be washed often to keep infections from spreading among babies and young children in daycare settings.

To prevent fluid from pooling in eustachian tubes, experts recommend that bottle-fed babies be held in an upright position. Babies should not be put to sleep with a bottle. Breastfeeding also can help prevent otitis media in babies, as can avoiding exposure to cigarette smoke. The use of pacifiers may also contribute to ear infections.

Vaccination* of children with the pneumococcal conjugate vaccine (PCV) protects against infection by 23 types of bacteria, including *Streptococcus pneumoniae* (strep-tuh-KAH-kus nu-MO-nye), a common cause of otitis media. The American Academy of Family Physicians estimates that widespread use of PCV has reduced the number of ear infections in young children by at least 5 million each year. Vaccination against influenza* also can reduce the likelihood of contracting otitis media. Treating allergies or removing enlarged adenoids* that block the eustachian tubes may decrease the chances of having recurrent or chronic ear infection in some patients.

After swimming or bathing, thoroughly drying ears with a towel can help get rid of water and lower the risk of contracting otitis externa. For avid swimmers, preventive eardrops can be used after swimming. Nothing should be inserted into the ears because of the risk of injuring the skin of the ear canal or damaging the eardrum. Ear wax serves a protective function and should be removed only when it builds up and clogs the external auditory canal.

Ovarian Cancer

Ovarian cancer occurs when cells in the ovaries, the reproductive glands from which a woman's eggs are released, begin to grow rapidly and out of control, forming a tumor.*

Anatomical view of the pelvis, ovaries, and fallopian tubes with a tumor on an ovary. *Illustration by GGS Information Services, Inc. Reproduced by permission of Gale, a part of Cengage Learning.*

What Are the Ovaries?

The ovaries* are the two glands located on opposite sides of a woman's uterus*. They are responsible for producing the hormones estrogen and progesterone. During the childbearing years, they are also responsible for releasing eggs for fertilization every month. After the eggs are released by the ovaries, they travel through the fallopian tubes* to the uterus where they can be fertilized by sperm. After a woman reaches menopause*, the ovaries no longer produce eggs, and they produce a much lower level of hormones.

What Are Ovarian Cysts?

Cysts are fluid-filled sacs that can form in any structure in the body. Ovarian cysts are fairly common, especially during the childbearing years. They can cause discomfort, swelling, or pressure in the abdomen, pain during sex, difficulty urinating, and weight gain. Ovarian cysts often resolve spontaneously. If they do not resolve, they are removed surgically. Ovarian cysts are usually not cancerous and are not life threatening.

What Is Ovarian Cancer?

Ovarian cancer occurs when cells divide and multiply too rapidly. Normally, when old cells die, the body gets rid of them to make room for new cells. These new replacement cells divide and multiply rapidly. This is only a problem when the body cannot rid itself of the old cells, and there are too many cells. This buildup of cells forms a mass called a tumor. There are two kinds of tumors. Benign* tumors are not cancerous, and malignant* tumors are. While they can both be removed, malignant tumors sometimes grow back. Malignant cells can grow rapidly in the tumor, and they can spread to other parts of the body. This spreading is called metastasis. As a cancer metastasizes, the patient's prognosis becomes bleaker, which is why early detection of cancer is so important.

What Are the Symptoms of Ovarian Cancer?

Because its symptoms are often nonspecific, ovarian cancer can be very difficult to detect. Women often mistake its symptoms for another condition and do not seek treatment until after the cancer has metastasized.

The most common symptoms of ovarian cancer include abdominal discomfort and/or swelling; pressure in the back, abdomen, pelvis, or legs; nausea; indigestion; pain during sexual intercourse; and fatigue.

How Is Ovarian Cancer Diagnosed?

Physicians may use several tests to diagnose ovarian cancer. These include:

- A physical exam, which helps physicians to determine a person's overall health by measuring blood pressure, weight, and temperature.
- A pelvic exam, which allows the physician to feel the ovaries and determine if there is any change in their size or shape. He or she may also be able to feel any growths that may be present on the ovaries.

- * **ovaries** (O-vuh-reez) are the sexual glands from which ova, or eggs, are released in women.
- * **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.
- * **fallopian tubes** (fa-LO-pee-an tubes) are the two slender tubes that connect the ovaries and the uterus in females. They carry the ova, or eggs, from the ovaries to the uterus.
- * **menopause** (MEN-o-pawz) is the end of menstruation.
- * **benign** (be-NINE) means a condition is not cancerous or serious and will probably improve, go away, or not get worse.
- * **malignant** (ma-LIG-nant) refers to a condition that is severe and progressively worsening.

- * **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.
- * **MRI** which is short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.
- * **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.
- * **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.
- * **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.
- * **cervix** (SIR-viks) is the lower, narrow end of the uterus that opens into the vagina.

GILDA'S CLUB

In 1989 Gilda Radner, one of *Saturday Night Live's* most beloved stars, died from ovarian cancer. She was just 42 years old. Radner had first been diagnosed with ovarian cancer in 1986 after experiencing fatigue and leg pain. After chemotherapy and radiation treatment, Radner went into remission, only to have her cancer return just a few years later. After undergoing a routine procedure, Radner slipped into a coma and never regained consciousness.

In 1991 Radner's husband Gene Wilder, along with Joanna Bull and Joel Siegel, established Gilda's Club in her memory. Upon being diagnosed with ovarian cancer, Radner had been quoted as saying, "Having cancer gave me membership in an elite club I'd rather not belong to." The mission of Gilda's Club is to create welcoming communities of free support for everyone living with cancer—men, women, teens, and children—along with their families and friends (more information available at www.gildasclub.org).

- Imaging tests, which allow the physician to see a picture of the ovaries to determine whether there are any abnormal changes. These include ultrasound*, MRI*, and CT scans*.
- Blood tests, which let the physician see the levels of certain hormones and proteins in the blood that may or may not indicate cancer

In order to confirm a diagnosis of ovarian cancer, physicians will perform a laparotomy so that they may perform a biopsy* on the tumor. A small incision in the abdomen so that the doctor can explore the abdominal cavity. The physician will usually remove a small tissue sample for biopsy. The information from examining the biopsied tissue is used to stage the cancer and determine an appropriate treatment plan.

How Is Ovarian Cancer Treated?

Treatment for ovarian cancer depends on the stage of the cancer when the cancer is detected. In early stage of ovarian cancer, the most common treatment is the surgical removal of all visible signs of cancer, including the affected ovary and its fallopian tube, the adjoining lymph nodes*, and attached fatty tissue. Biopsy of any suspected tissues is performed. In these cases for women of childbearing age, the uterus, healthy ovary, and healthy fallopian tube remain, leaving open the possibility for future pregnancies.

In more advanced stages of ovarian cancer, women often undergo a complete hysterectomy, which involves the removal of the uterus, cervix*, fallopian tubes, and ovaries. Any visible signs of cancer in the nearby lymph nodes and attached fatty tissue are also removed. Physicians perform a biopsy on any tissue that appears abnormal. In the event of total hysterectomy, there is no possibility for future pregnancy.

For most women, physicians recommend chemotherapy* following surgery. Chemotherapy is treatment with drugs that are meant to kill remaining cancer cells anywhere in the body. Chemotherapy can cause side effects such as pain, nausea, and vomiting. Immunotherapy, which works by boosting the immune system, also showed promise as of 2009.

In addition to these treatments, a healthy diet, plenty of exercise, and a strong support system are also important for women who are battling ovarian cancer.

Ovarian Cysts

Any ovarian follicle, a small hollow sphere-shaped group of cells in the ovary that contains a single ovum or egg, that is larger than 0.8 inches (2 centimeters) is considered an ovarian cyst. Ovarian cysts can be as small as a pea or as large as an orange or cantaloupe.

Tanya's Story

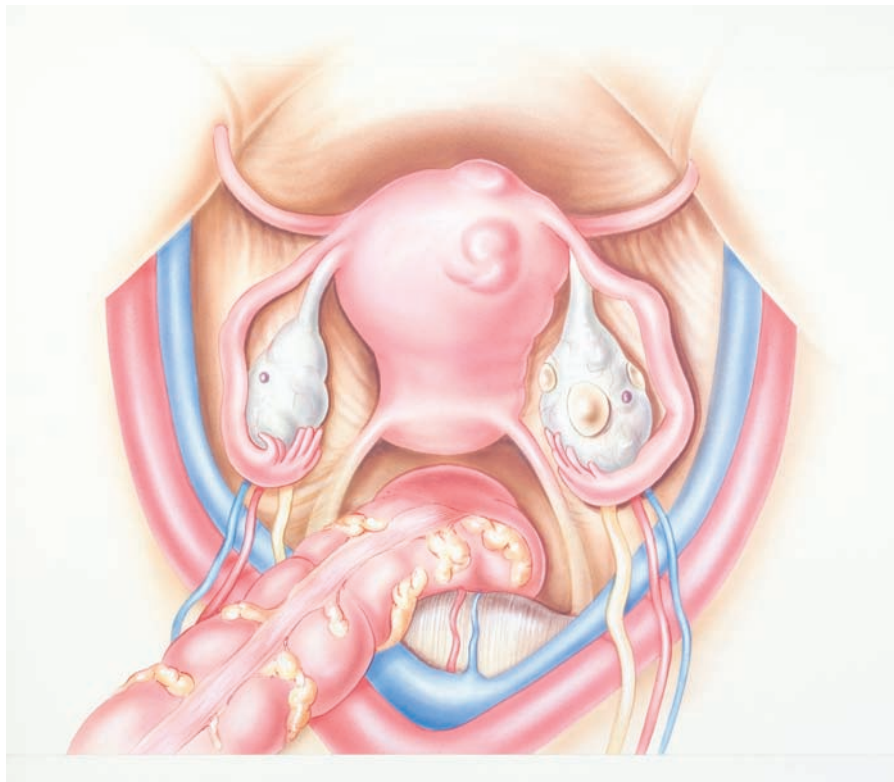

Tanya is an eighth-grader who had her first menstrual* period shortly after her twelfth birthday. Her periods were irregular for the first several months, which she knew is normal for girls in early puberty*. After her periods became more regular, however, Tanya noticed a sharp cramping pain on one side of her abdomen between periods. At first she did not think much

* **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.

* **menstrual** (MEN-stroo-al) refers to menstruation (men-stroo-AY-shun), the discharging through the vagina of blood and tissue from the uterus that recurs each month in women of reproductive age.

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

Illustration of a human uterus and ovaries. Shown is a comparison of a normal ovary (left) to an ovary with small ovarian cysts (right). * **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **mittelschmerz** (MITT-el-shmairts) a cramping pain that some women experience at the midpoint in their menstrual cycle when one of their ovaries releases an egg.

about the cramps because they went away after a few hours. The cramps got worse with each month, however, and one month they were so bad that Tanya's parents thought she might have appendicitis. They took their daughter to the emergency room because she was in great pain.

The doctors in the emergency room checked Tanya right away because they knew that appendicitis is not unusual in teenagers and must be treated as soon as possible. They gave her an ultrasound* test to get a clearer picture of the organs in her abdomen. The doctors found that Tanya did not have appendicitis; instead, she had some simple ovarian cysts that looked like bubbles on the ultrasound image of her ovaries. The doctors explained to Tanya and her parents that this type of cyst occurs when the follicle in the ovary that releases an egg each month ruptures. It was the bursting of the follicle that caused the sharp cramps that Tanya felt halfway between her periods. This type of pain is called mittelschmerz* from two German words that combined mean "middle pain." About 20 percent of women experience mittelschmerz during their childbearing years; it is usually only mildly uncomfortable, but once in a while it produces pain severe enough to send the woman to the emergency room.

Tanya was relieved to find out that her cramps did not indicate a serious health problem and that she could treat them at home with an over-the-counter pain reliever. She was surprised, though, to learn that teenagers and even young girls can develop ovarian cysts.

What Is an Ovarian Cyst?

An ovarian cyst is any collection of fluid larger than 0.8 inch that develops inside a thin wall of tissue in the ovary. Ovarian cysts can occur in young girls and older women after menopause*, although they are most common in women of childbearing age. Most ovarian cysts are harmless, do not produce any noticeable symptoms, and are related to the normal functions of a woman's body during the menstrual cycle*. Some cysts, however, are malignant* and need to be removed by surgery, whereas others may need to be removed because they are causing pain or bleeding even though they are benign*.

Functional ovarian cysts The majority of ovarian cysts are functional, which means that they result from the normal functioning of a woman's ovaries. This type of cyst is also called a simple cyst. To better understand how functional cysts develop, it is useful to review the process of ovulation*.

Women have two ovaries*, one on each side of the uterus*. One of the ovaries produces an egg each month that lies within a sac called a follicle. As the egg matures, the hormone estrogen signals the uterus to prepare for a possible pregnancy by thickening its lining, which is called the endometrium (en-doe-MEE-tree-um). If the egg is not fertilized, the extra tissue added to the lining of the uterus is shed from the body. The result is a normal menstrual period.

In most cases, the follicle that released the egg eventually shrinks without causing any symptoms. Functional cysts, however, can develop when the egg is not released normally or the follicle collects fluid or blood after the egg is released. Functional cysts usually look like air bubbles on the ovary when the doctor performs an ultrasound test. There are three basic types of functional cysts:

- **Follicular cysts.** Sometimes called Graafian (GRAY-fee-un) follicle cysts, this type of functional cyst develops when the follicle does not release the mature egg or when it collapses in on itself. Follicular cysts contain a clear fluid and can grow to become as large as 2.5 inches in diameter. The follicular cyst can burst, causing the pain of mittelschmerz, or it can remain in the ovary for several months and then gradually disappear.
- **Corpus luteum cyst.** The corpus luteum (KOR-pus LOO-tee-um) is the name given to the structure that develops in the ovary after a follicle has released its egg. It has two layers of cells and secretes two hormones* that are necessary to maintain a pregnancy if the egg is fertilized. If the egg is not fertilized, the corpus luteum stops producing hormones after about 14 days, breaks down, and gradually disappears. It can, however, also fill with blood or tissue fluid and grow to form a cyst. In most cases, corpus luteum cysts do not cause health problems. They can, however, grow to be as big as four inches in diameter and cause the ovary to twist inside the

* **menopause** (MEN-o-pawz) is the end of menstruation.

* **menstrual cycle** (MEN-stroo-al SYkul) culminates in menstruation (men-stroo-AY-shun), the discharging through the vagina of blood, secretions, and tissue debris from the uterus that recurs at approximately monthly intervals in females of reproductive age.

* **malignant** (ma-LIG-nant) refers to a condition that is severe and progressively worsening.

* **benign** (be-NINE) means a condition is not cancerous or serious and will probably improve, go away, or not get worse.

* **ovulation** (ov-yoo-LAY-shun) is the release of a mature egg from the ovary.

* **ovaries** (O-vuh-reez) are the sexual glands from which ova, or eggs, are released in women.

* **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.

* **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

abdomen, causing sudden severe pain. Corpus luteum cysts can also fill with blood and burst during the second half of the menstrual cycle, releasing their blood inside the abdomen and causing severe pain.

- **Hemorrhagic** (*hem-uh-RAGE-ik*) *cyst*. Also called a blood cyst, this type of functional cyst develops when a blood vessel in the wall of a cyst breaks and leaks into the cyst. The bleeding may occur rapidly and stretch the wall of the cyst until it bursts, causing pain on one side of the body. The blood in a hemorrhagic cyst forms clots that can be seen on an ultrasound image. If the cyst bursts, the blood is released into the abdominal cavity.

Other types of benign ovarian cysts There are two other categories of ovarian cysts that are not related to the menstrual cycle but are still considered benign (noncancerous). The first type, dermoid (DER-moyd) cysts (also called ovarian teratomas) are strange-looking swellings that develop from a cell in the ovary that can give rise to other types of body tissues such as teeth, hair, fatty material, and bone. A dermoid cyst typically contains samples of these other tissues inside its wall. Almost all (98%) dermoid cysts are not cancerous; however, they can cause trouble if they become large enough to cause the ovary to twist and lose its blood supply or if they burst and spill their contents into the abdomen. Dermoid cysts may be as small as one-half inch or as large as 17 inches.

The second type endometrioid (en-do-MEET-ree-oid) cysts results from endometriosis (en-do-meet-ree-OH-sis), a condition that develops when a small patch of tissue from the endometrium—the tissue that lines the uterus—grows inside the ovaries instead of its normal location. The blood in the endometrioid cyst builds up inside the walls of the cyst and eventually turns brown, which is why these cysts are sometimes called chocolate cysts. Like other types of ovarian cysts, endometrioid cysts can grow to the point where they rupture and spill their contents onto other abdominal organs. They range in size from three-fourths of an inch to seven or eight inches.

Pathological ovarian cysts Pathological (path-oh-LAW-gih-kul) ovarian cysts are caused by some kind of disease process. There are two types of pathological cysts. The first type is a malignant cyst caused by cancer of the ovary. Cancerous ovarian cysts can cause nausea, vomiting, intestinal blockage, loss of appetite, and swelling of the abdomen as well as abdominal pain.

The second type of pathological ovarian cyst develops in a polycystic (pol-ee-SISS-tik)-appearing ovary. This condition is not the same as polycystic ovary syndrome even though the names are similar. The word *polycystic* means “many cysts” and refers to the appearance of the ovary on an ultrasound image. A polycystic-appearing ovary is about twice the size of a normal ovary (which is the size of a large olive) and has a number of small cysts that can be seen around the outside of the ovary. The cysts are

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS) is an endocrine disorder that affects between 4 and 7 percent of women in the United States. It is the most common hormonal disorder in women of childbearing age. The most significant features of PCOS are the absence of ovulation and menstruation; acne; abnormal production of androgens (male hormones); growth of hair on the face, chest, and legs; and obesity. The disorder gets its name from the fact that most women with PCOS have polycystic ovaries. It is possible, however, for a woman with normal-appearing ovaries to have PCOS, just as a woman can have a polycystic-appearing ovary without having the disorder.

The cause of PCOS was not completely known as of 2009, although insulin resistance appeared to be a factor. Women with PCOS cannot have children unless they are treated, and they have an increased risk of type 2 diabetes, high blood pressure, heart disease, and cancer of the uterus. The condition is treated with medications to increase the patient's sensitivity to insulin, to restore ovulation, and to bring on regular menstrual periods.

* **endocrine** (EN-do-krin) refers to a group of glands, such as the thyroid, adrenal, and pituitary glands, and the hormones they produce. The endocrine glands secrete their hormones into the bloodstream, and the hormones travel to the cells that have receptors for them. Certain hormones have effects on mood and sometimes cause emotional swings.

usually one-half inch in size or smaller and may look like a string of pearls. This type of ovary can be found in some normal women and in some women with various endocrine* disorders. The main difference between a polycystic-appearing ovary and polycystic ovary syndrome (PCOS) is that a woman with PCOS will have other symptoms and abnormalities.

How Common Are Ovarian Cysts?

Ovarian cysts in general are common in American women; 95 percent are benign. They can be detected in almost all women of childbearing years on an ultrasound test, and in 14 to 17 percent of women after menopause. Most ovarian cysts are functional cysts. Another 10 percent are dermoid cysts. Cancerous ovarian cysts are diagnosed in about 22,000 women in the United States each year. Between 4 and 7 percent of women of childbearing age in the United States are diagnosed with polycystic ovary syndrome.

Different types of ovarian cysts are more common in different age groups, however. Ovarian cysts in women over 50 or in girls before puberty are more likely to be cancerous than those in women of childbearing age. Dermoid cysts are most common in women in their late twenties or early thirties. Women who take certain types of fertility drugs are more likely to develop corpus luteum cysts than those who do not.

Who Gets Ovarian Cysts?

Women from all races and ethnic backgrounds appear equally likely to develop functional ovarian cysts, although Caucasian women are more likely to develop cancerous cysts than women of other races. Some

* **hypothyroidism** (hi-po-THY-royd-ih-zum) is an impairment of the functioning of the thyroid gland that causes too little thyroid hormone to be produced by the body. Symptoms of hypothyroidism can include tiredness, paleness, dry skin, and in children, delayed growth and mental and sexual development.

* **infertility** (in-fer-TIH-lih-tee) is the inability of females to become pregnant or of males to cause pregnancy.

other risk factors for ovarian cysts have been identified; they include the following:

- A family history of ovarian cysts
- A large amount of fat on the upper body
- Hypothyroidism*
- Early menstruation; first period at age 11 or younger
- A history of irregular menstrual cycles
- Infertility*
- Being treated for breast cancer with a drug called tamoxifen
- A history of heavy smoking

One factor that appears to lower a woman's risk of ovarian cysts is taking birth control pills. The pills work to prevent pregnancy by preventing the production of eggs during ovulation.

How Do Women Know They Have Ovarian Cysts?

Most ovarian cysts, including early-stage cancerous cysts, do not cause any noticeable symptoms and are usually found in the course of an ultrasound test performed for other reasons. The most common single symptom that women report is pain in the lower abdomen. The pain is usually described as sharp or stabbing, sudden, and severe. Other symptoms that women may have with ovarian cysts are as follows:

- Irregular menstrual periods
- A feeling of pressure, bloating, or fullness in the abdomen
- Pain during sexual intercourse or vigorous exercise
- A need to urinate more frequently or difficulty in emptying the bladder
- Pain in the vagina or spots of blood from the vagina
- Pain during bowel movements
- Weight gain
- Nausea and vomiting
- Indigestion, heartburn or feeling full before the end of a meal
- Pain in the lower back or pelvis shortly before or after the end of the menstrual period
- Unusually heavy menstrual periods

How Serious Are Ovarian Cysts?

Most functional ovarian cysts are not a danger to health even though they sometimes cause mittelschmerz or cramping pain in the second half of the menstrual cycle. Functional cysts that continue to grow rather than shrinking after a few months may need to be removed to prevent torsion (twisting) of the ovary or to make sure that the cyst is not malignant. In

general, cysts that last beyond two to three menstrual cycles or grow larger than 2.5 to 5 inches are removed by surgery. The doctor may also recommend surgery if the cyst is causing severe pain.

Cancerous ovarian cysts are dangerous, partly because they can grow and develop for some time before causing any obvious symptoms. Although they occur in only 15 women per 100,000 in the United States each year, they cause 16,000 deaths. The five-year survival rate for women diagnosed with the most aggressive type of ovarian cancer is only 41 percent.

Women who are having any of the following symptoms with ovarian cysts should see their doctor at once:

- Weakness, dizziness, or fainting
- A fever that does not go away
- A mass in the abdomen that is large enough to be felt
- Extreme thirst or urination
- Sudden swelling of the abdomen
- Extreme abdominal pain
- Nausea and vomiting that does not stop
- Cold, moist skin, a sudden drop in blood pressure, or other symptoms of shock*
- Vaginal bleeding in a woman who has completed menopause

How Are Ovarian Cysts Diagnosed and Treated?

Diagnosis Some ovarian cysts are large enough to be felt when the doctor examines a patient's abdomen in the office or emergency room. Most, however, are too small to be felt during a physical examination but are identified through ultrasound imaging. To perform an ultrasound of the ovaries, the doctor places a thin wand into the vagina and points it in the direction of the uterus and ovaries. This type of ultrasound gives a clearer image of the cyst than an ultrasound performed through the abdomen. The doctor can tell whether the cyst is filled with fluid, is a solid mass, or is a mixture of fluid and solid tissue.

The doctor may also order magnetic resonance imaging* to confirm the results of the ultrasound or CT scans* to get a clearer picture of the extent of the cyst.

There are no laboratory tests that can detect ovarian cysts. The doctor may, however, order a urine test to rule out the possibility that the patient has an ectopic pregnancy*, and a blood test if the patient has a fever and may have an infection.

A postmenopausal woman with an ovarian cyst will be given a blood test to look for a tumor marker* called CA125, a substance in the blood whose level can be measured to evaluate whether a cyst in the ovary is benign or cancerous. It is, however, possible for conditions other than cancer to cause a rise in the level of CA125 in a woman's blood.

* **shock** is a serious condition in which blood pressure is very low and not enough blood flows to the body's organs and tissues. Untreated, shock may result in death.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **ectopic pregnancy** (ek-TAH-pik) is an abnormal pregnancy in which the fertilized egg develops outside the uterus, usually within one of the fallopian tubes.

* **tumor marker** (TOO-mer MARK-er) is a substance found in blood, urine, or body tissues whose level rises when a person has cancer. Tumor markers can be used to detect possible cancer.

* **laparoscopy** (lap-uh-ROS-kuh-pee) a type of surgery in which a small fiberoptic instrument is inserted through a very small incision to examine the inside of the abdomen or remove small amounts of tissue. It is also called minimally invasive surgery.

* **ibuprofen** (eye-bew-PRO-fin) is a nonsteroidal anti-inflammatory drug (NISAD) used to reduce fever and relieve pain or inflammation.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

Treatment Small benign ovarian cysts that are not causing any symptoms are usually treated first by watchful waiting. Because most functional cysts go away by themselves after a few months, the doctor usually recommends that a woman with a functional cyst return in one to three months for a follow-up ultrasound to see whether the cyst has changed in size. Women who are through menopause are also treated with watchful waiting if the cyst is smaller than an inch, is fluid-filled, and is not causing any other symptoms.

If ultrasound and other tests indicate that the cyst is very large, is growing, or may be cancerous, the doctor may perform a type of surgery called a laparoscopy* to remove the cyst or a part of it from the ovary for examination under a microscope.

If the cyst is very large, if it is found to be cancerous, or if the woman has completed menopause, the doctor will usually recommend abdominal surgery to remove one or both ovaries. If the cyst is cancerous and the woman is postmenopausal, the doctor may recommend surgical removal of the uterus as well as both ovaries to prevent the cancer from recurring or spreading.

In some cases the doctor may prescribe birth control pills to regulate the woman's menstrual cycle, to keep follicles from developing into functional cysts, and to stop or slow down the growth of existing functional cysts. Birth control pills also lower the risk of developing ovarian cancer in the future.

Self-Care at Home Women who have mittelschmerz or mild pain in the lower back or abdomen from ovarian cysts can take over-the-counter pain relievers such as ibuprofen* or acetaminophen*. The doctor may also prescribe pain relievers that contain codeine or oxycodone if the cramps are very bad. Warm baths and heating pads are helpful to many women, and some find that cutting back on coffee and other beverages containing caffeine helps to relieve cramps.

Can Ovarian Cysts Be Prevented?

As of 2009 there was no known way to prevent the development of ovarian cysts except for surgical removal of both ovaries. Regular medical checkups can, however, help in diagnosing ovarian cysts as soon as possible. Women should keep track of the frequency and heaviness of their periods and tell their doctors if they notice any changes in their usual pattern that last for more than two cycles.

* **incontinence** (in-KON-ti-nens) is loss of control of urination or bowel movement.

Overactive Bladder

Overactive bladder causes an abrupt and hard to control need to urinate.

What Is Overactive Bladder?

An overactive bladder is caused by a sudden, involuntary contraction of the muscle in the wall of the urinary bladder. Overactive bladder causes an abrupt and hard to control need to urinate referred to as urinary urgency. Overactive bladder is also known as urge incontinence* and is a form of

◀ Anatomy of the kidneys and urinary tract. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

urinary incontinence (unintentional loss of urine). Overactive bladder is most common in older adults. It affects approximately one in 11 adults in the United States.

What Causes Overactive Bladder?

The bladder functions by filling with urine and then emptying. This process requires a complex interaction between the kidneys, nerve impulses, and muscular activity. When defective, various parts of this process can contribute to overactive bladder and urge incontinence.

How Does a Normal Bladder Function? The kidneys are responsible for filtering waste from the blood and producing urine. The urine then travels down a pair of tubes called the ureters from the kidneys to the bladder. The bladder fills with urine but holds the urine until it is time to void (release) it by going to the bathroom. During voiding, urine drains from the bladder through an opening (called the neck) and flows out of the body through a short tube called the urethra. In women, the urethral opening is located just above the opening to the vagina, whereas in men it is at the tip of the penis.

As the bladder fills with urine, it expands. When the bladder is approximately half full, nerve impulses are sent to the brain. The need to urinate normally occurs when the bladder is approximately three-fourths full. In order to release the urine it has been holding, the bladder relies on specialized muscle. During voiding, nerve signals coordinate the relaxation of the pelvic floor muscles and the urinary sphincter muscles (muscles surrounding the neck of the bladder and upper portion of the urethra). The relaxation of these muscles allows the urine to escape the bladder while muscles of the bladder contract, forcing urine out.

Abnormal bladder function Often overactive bladder symptoms occur because the muscles of the bladder involuntarily contract. The contraction of the bladder muscles creates urinary urgency. If the urinary sphincter remains constricted, it will prevent the bladder from leaking. However, if the urinary sphincter is overwhelmed by the bladder muscle contraction, involuntary urination occurs.

What Are the Symptoms of Overactive Bladder?

Symptoms associated with overactive bladder include frequent urination, usually at least eight times per day. Awakening to urinate at night usually occurs at least twice. There is a sense of urinary urgency, and an involuntary loss of urine immediately following the urgent need to urinate (urge incontinence). Some individuals may also have what is called mixed incontinence, when both urge incontinence and stress incontinence occur. Stress incontinence is an involuntary loss of urine in response to the pressure caused by physical stressors such as coughing or laughing, which increase the pressure within the abdomen and pelvis.

Although an individual with overactive bladder may be able to get to the bathroom in time when they experience urinary urgency, the frequency with which they must urinate both day and night, combined with the need to suddenly go to the bathroom, is disruptive at work and social activities, and affects their quality of life. For this reason, overactive bladder may cause significant social, psychological, occupational, and sexual problems.

What Risk Factors Make People Likely to Develop an Overactive Bladder?

Overactive bladder is not considered a normal part of aging. However, the risk of experiencing overactive bladder increases with age. As people get older they have increased risk of developing overactive bladder and are more likely to get diseases that cause problems with bladder function, such as enlarged prostate and diabetes. Neurological disorders such as Parkinson's disease*, stroke*, and multiple sclerosis* have been associated with overactive bladder. Lifestyle decisions that may reduce risk of overactive bladder include getting regular exercise, eating a high-fiber diet, and limiting caffeine and alcohol. Individuals who have an overactive bladder and whose lives are severely disrupted are at increased risk for depression.

How Is Overactive Bladder Diagnosed?

In the initial stages of an overactive bladder diagnosis, other medical issues that may be causing symptoms need to be ruled out. Medical history and a physical exam focusing on the abdomen and genitals are necessary. A urine test may be performed in order to rule out urinary tract infection. Once other, more common causes of urinary urgency have been ruled out, three specialized tests may be performed.

Urodynamic tests assess bladder function, including the ability to empty completely. This aspect of bladder function is assessed by measuring the urine left in the bladder after voiding is complete. Failure of the bladder to empty completely may cause symptoms similar to overactive bladder.

Cystometry is performed to measure the pressure inside the bladder and assess bladder function. In this test, two catheters* are used. The first enters the bladder and fills the bladder with water. The second catheter is attached to a pressure-measuring sensor and placed near the bladder in the vagina or rectum. Cystometry can identify involuntary muscle contractions, indicate the level of pressure that causes urge incontinence, and measure the pressure required for the bladder to empty.

Electromyography examines the muscles of the bladder to assess its ability to coordinate impulses in the muscles of the bladder with impulses in the urinary sphincter. If these muscles are not coordinated, the process of normal urination is affected. Also cystoscopy can be performed, which involves running a tiny lens through the urethra to check for abnormalities such as tumors in the bladder.

* **Parkinson's disease** is a disorder of the nervous system that causes shaking, rigid muscles, slow movements, and poor balance.

* **stroke** is a brain-damaging event usually caused by interference with blood flow to the brain. A stroke may occur when a blood vessel supplying the brain becomes clogged or bursts, depriving brain tissue of oxygen. As a result, nerve cells in the affected area of the brain, and the specific body parts they control, do not properly function.

* **multiple sclerosis** (skluh-RO-sis), or MS, is an inflammatory disease of the nervous system that disrupts communication between the brain and other parts of the body. MS can result in paralysis, loss of vision, and other symptoms.

* **catheters** (KAH-thuh-ters) are small plastic tubes placed through a body opening into an organ (such as the bladder) or through the skin directly into a blood vessel. They are used to give fluids to or drain fluids from a person.

How Is Overactive Bladder Treated?

Pelvic muscle rehabilitation is one treatment used to relieve the symptoms of overactive bladder. This treatment improves pelvic muscle tone and prevents involuntary leakage of urine. Pelvic muscle rehabilitation includes doing Kegel exercises, which are sets of voluntary muscle contractions of the pelvic muscles and urinary sphincter, designed to improve their strength and help prevent urinary incontinence. Electrical stimulation of the muscles of the pelvic floor may also be performed in conjunction with Kegel exercises. Behavioral therapies such as scheduled bathroom appointments every two to three hours may help some people with incontinence. Caffeine and alcohol may be avoided because they increase the frequency of urination. Double voiding is a technique that involves emptying the bladder, waiting a few minutes, and then attempting to fully empty the bladder a second time. This technique may help people who have difficulty emptying their bladder completely during urination. At home occasional catheterization may also improve bladder emptying and increase dryness. Patients may learn how to periodically insert a catheter into their bladder to empty it. Maintaining a healthy weight is also important for overactive bladder patients. Being overweight increases incidents of incontinence. Medications that relax the bladder are used to alleviate symptoms of overactive bladder and reduce episodes of urge incontinence. These drugs include tolterodine, oxybutynin, an oxybutynin skin patch, trospium, solifenacin, and darifenacin. Common side effects include dry eyes and dry mouth.

Surgery to treat overactive bladder is only used on severe cases that do not respond to other treatments. Surgery may be performed to improve the storage ability of the bladder and reduce pressure. One type of surgical intervention is nerve stimulation of specific nerves involved in bladder function. Stimulation of the nerves of the bladder is analogous to stimulation of the heart by a pacemaker. A thin nerve stimulation wire attached to a small battery may be inserted under the skin.

P

Pain

Pain is a signal from the body that something is wrong.

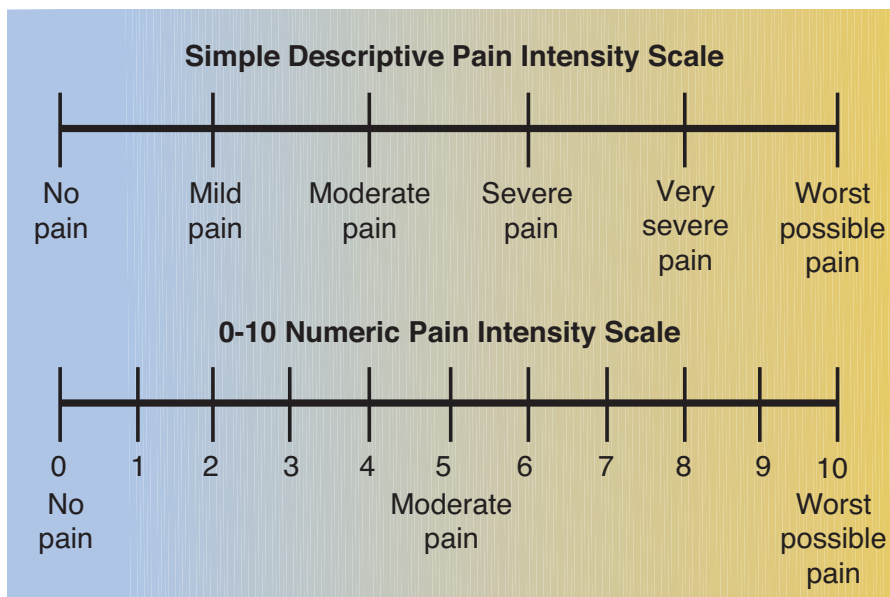

Sarah's Story

Sarah woke up Monday morning with pain in her throat. She did not mention it to her mother before heading for school, and the pain continued to worsen during the day. By evening Sarah could barely swallow, and when her mother looked into her mouth, she saw that Sarah's tonsils were red and inflamed.

The pain did not go away, and on Thursday morning, her mother took Sarah to the doctor. After taking a history and examining Sarah's throat, the doctor used a swab to collect a culture*. The culture indicated that Sarah had strep throat (a contagious infection caused by bacteria called Group A beta-hemolytic *Streptococcus pyogenes*), and the doctor prescribed a course of antibiotics as treatment. After a few days on the antibiotics, the pain went away, and after 10 days, Sarah's strep throat was healed.

* **culture** (KUL-chur) is a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

Pain Intensity Scales

Medical professionals use pain intensity scales to help determine the level of pain a person is suffering. *Public Domain.*

* **nervous system** is a network of specialized tissue made of nerve cells, or neurons, that processes messages to and from different parts of the human body.

* **neurotransmitter** (NUR-o-tranz-mit-er) is a chemical substance that transmits nerve impulses, or messages, throughout the brain and nervous system and is involved in the control of thought, movement, and other body functions.

Without the pain that accompanied her sore throat, Sarah and her mother might not have realized that Sarah had an infection that, if left untreated, could have made her seriously ill.

What Is Pain?

Pain is one of the body's signals that something is wrong. In Sarah's case, the pain of a sore throat was the harbinger of a strep infection. Pain is an unpleasant, uncomfortable feeling conducted from the site of an injury by the nervous system* to the brain. Pain serves several functions: as a warning of an injury; as a means of preventing further injury; and as a cause of reduced activity to allow healing to proceed.

In the brain, the pain messages first enter the thalamus, a part of the brain that diverts nerve impulses to the proper areas of the brain. Pain signals are routed to three areas of the brain: the frontal cortex, the thinking and reasoning part of the brain; the somatosensory cortex, the part of the brain that handles physical sensations; and the limbic system, the part of the brain that controls the emotions.

The body releases natural chemicals that can intensify the perception of pain, such as prostaglandins, compounds that have many functions in the body, including to sensitize the nerve cells in the spinal cord to pain. The analgesic (pain-killing) aspirin blocks the receptors on the cells that are keyed to receive prostaglandins and thus interfere with its effect, relieving pain. Endorphin, another neurotransmitter*, blocks the perception of pain naturally, and because the brain may release a high level of endorphin during an exciting or stressful situation, a person who is injured in such a situation—such as a traffic accident—may not even be aware of being injured until later.

Each person experiences pain in a unique way. How pain is interpreted and handled is affected by a variety of factors, such as age, gender, emotional state, previous experiences of pain, and attitude. Upbringing and social or cultural background can also affect a person's experience of pain, such as the famous British "stiff upper lip" expectation that a person would not show a reaction to pain.

What Are the Two Main Types of Pain?

The human body can experience acute pain, which strikes quickly and leaves quickly (usually within six weeks), such as after a fall, or chronic pain, which can also strike quickly but lingers, sometimes for years.

An example of acute pain is the pain of a sprained ankle. After the stretching of the ankle's ligaments, the pain receptors in the area signal the brain. The brain responds by not putting weight on the injured joint so as not to cause additional damage.

Acute pain can often be successfully treated with over-the-counter pain medications called analgesics. Some analgesics not only relieve pain but also reduce inflammation.

However, intense pain can be the sign of a life-threatening condition. A feeling of pressure, fullness, squeezing, or pain in the center of the chest

or pain that is radiating down one or both arms or into the jaw may signal a myocardial infarction (heart attack). Someone experiencing such symptoms should seek medical help immediately.

A doctor will ask the patient to describe the location of the pain and indicate its severity, perhaps by using a scale from 0 to 10 (0 being no pain, 10 being worst), words (such as no pain, mild, moderate, and severe), or faces that by their expressions show the extent of the pain. The doctor may order tests or procedures, such as x-rays, MRIs*, or laboratory tests, to determine if the pain is the result of an injury, such as fractured bone, or an infection or a heart attack. Once the underlying cause is treated, pain usually disappears.

Chronic pain may come and go or be a constant lingering ache, but it occurs over a period of six months or more. For people who suffer from migraine headache, the pain comes on suddenly and can be incapacitating. On the other hand, people with fibromyalgia* experience a constant pain throughout the body. Approximately 76 million Americans live with chronic pain, and 58 percent of chronic-pain sufferers report experiencing anxiety or depression. Chronic pain affects people's quality of life.

The most common types of chronic pain are lower back pain, migraine headaches, neck pain, and facial pain. Arthritis*, fibromyalgia, and cancer all cause chronic pain, as can diabetes* and shingles (a painful contagious rash). Chronic pain can result from an initial injury, such as a back injury suffered during car accident, but for an unknown reason the central nervous system continues to send pain messages after the injury heals.

How Is Pain Treated?

Pain can be relieved by medications called analgesics. There are two main groups of analgesics that are available without prescription: nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen*. Although they are available over the counter (OTC), both groups must be taken with caution; excessive doses of acetaminophen can cause liver damage, and NSAIDs can damage the stomach.

Stronger pain relievers, such as narcotics, are available only with a prescription because they can cause physical and psychological dependence. They may be administered by mouth or intravenously.

The pain of childbirth is acute but can be relieved in a number of ways. A woman in labor may opt for an epidural or a spinal block, in which a local anesthetic is injected into the lower part of the body to block pain signals. A woman may control pain with behavioral techniques such as relaxation exercises and controlled, rhythmic breathing.

Like acute pain, chronic pain can be treated with pain relievers. In some cases, such as fibromyalgia, antidepressant medications* can be helpful. Exercise and alternative therapies such as acupuncture (a technique to relieve pain by inserting and manipulating fine needles in the skin) can also help to relieve chronic pain. Research continues to explore ways to relieve the suffering of people who experience chronic pain.

* **MRI** which is short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

* **fibromyalgia** (fi-bro-my-AL-ja) is a group of disorders that are characterized by aching, tender, and stiff muscles.

* **arthritis** (ar-THRY-tis) refers to any of several disorders characterized by inflammation of the joints.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

* **antidepressant medications** are used for the treatment and prevention of depression.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

* **enzymes** (EN-zimes) are proteins that help speed up a chemical reaction in a cell or organism.

Pancreatic Cancer

Pancreatic (pan-kree-AT-ik) cancer is a condition in which the cells in the pancreas (PAN-kree-us), a digestive gland located behind the stomach, divide without control or order, forming tumors that frequently spread to other parts of the body. The disease is usually fatal.

What Is Pancreatic Cancer?

The pancreas is a six-inch-long gland in the abdomen* that is surrounded by the stomach, intestine, and other digestive organs. It is shaped like a long, flattened pear, wide at one end and narrow at the other.

This gland produces fluids that contain digestive enzymes* (EN-zymes), proteins that help break down food for use in the body. These fluids travel through a series of ducts, or tubes, into a main pancreatic duct that joins the common bile duct coming from the liver and gallbladder. Along with

the bile, which helps the body digest fat, the pancreatic juices empty into the small intestine.

Besides secreting enzymes, the pancreas has islet (EYE-let) cells that manufacture and release hormones directly into the blood. These hormones help the body store or use the energy that comes from food. Insulin and glucagons are created this way, and these hormones help control the amount of sugar in the blood.

Cancer usually begins in the juice-carrying ducts, but in rare cases it may start in the islet cells. A tumor* forms and eventually grows into the surrounding organs. Cancer cells may also break away from the tumor and spread to other parts of the body, such as the lymph nodes*, liver, lungs, and bones.

Finding cancer early is the key to treating it successfully, but with pancreatic cancer, a patient typically does not notice the symptoms until the cancer has spread to other parts of the body. By then, it is usually too late for treatment to be successful.

What Are the Symptoms of Pancreatic Cancer?

People with cancer of the pancreas eventually develop pain in the upper abdomen that sometimes spreads to the back and may become worse after eating or lying down. They also may experience nausea*, loss of appetite, weight loss, and weakness. If the tumor blocks the common bile duct so that bile cannot pass into the small intestine, they develop jaundice (JAWN-dis), a condition in which the skin and whites of the eyes turn yellow. Islet-cell cancer can cause the pancreas to make too much insulin or other hormones. As a result, the person may feel weak or dizzy and experience chills, muscle spasms, or diarrhea*.

How Is Cancer of the Pancreas Diagnosed?

When doctors suspect pancreatic cancer, they perform x-rays and other imaging tests that produce pictures of the pancreas and the areas surrounding it. These tests can help doctors rule out other, less serious conditions that may cause the same symptoms. While these visual tests are helpful in diagnosing pancreatic cancer, the only way to know for sure is to do a biopsy (BY-op-see), the removal of a tissue sample that is then viewed under a microscope. Surgeons can obtain this tissue in different ways. They can get it with a needle that is inserted through the abdomen into the pancreas or through a thin, flexible tube passed down the throat and into the stomach region.

How Is Pancreatic Cancer Treated?

Pancreatic cancer has the highest mortality rate of all cancers: between 95 and 99 percent. The best chance for survival occurs when the tumor is confined to the pancreas and the immediate surrounding area. More commonly, treating the disease aims at lessening the pain and improving the person's quality of life.

* **tumor** (TOO-mor) usually refers to an abnormal growth of body tissue that has no known cause or physiologic purpose and is not an inflammation.

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **nausea** (NAW-zha) refers to a feeling of being sick to one's stomach or needing to vomit.

* **diarrhea** (di-ah-RE-a) refers to frequent, watery stools (bowel movements).

- * **radiation therapy** is a treatment that uses high-energy radiation from x-rays and other sources to kill cancer cells and shrink cancerous growths.
- * **chemotherapy** (KEE-mo-THER-a-pee) is the treatment of cancer with powerful drugs that kill cancer cells.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

In either case, the most common forms of treatment are surgery, radiation therapy*, and chemotherapy* (kee-mo-THER-a-pee), or a combination of them. Surgery involves removing part or all of the pancreas in a procedure called pancreatectomy (pan-kree-a-TEK-to-mee). Radiation therapy uses high-energy rays to damage cancer cells and stop them from growing and dividing. Chemotherapy is the use of anticancer drugs that are fed into a vein or given in pill form.

Who Develops Cancer of the Pancreas and Why?

As with most other types of cancer, pancreatic cancer is usually diagnosed in middle-aged and older people. It rarely occurs in people younger than 40 years of age, and most people who develop it are around 70 years of age. Cancer of the pancreas is the fourth most common kind of cancer, affecting about 37,000 Americans every year.

Doctors are not sure what causes this type of cancer. Research shows that people are more likely to develop it if they smoke cigarettes or they have diabetes*. Some studies suggest that a fatty diet that is low in fruits and vegetables contributes to pancreatic cancer, whereas others indicate that people who are exposed to certain harsh chemicals in their jobs are at higher risk. Heredity is another possible factor: About 10 percent of people who have pancreatic cancer have a family history of the disease. In the early 2000s research was under way to help pinpoint specific causes of pancreatic cancer, particularly in those people who have none of the risk factors.

Pancreatitis

Pancreatitis (pan-kree-a-TY-tis) is a painful inflammation of the pancreas.*

What Is Pancreatitis?

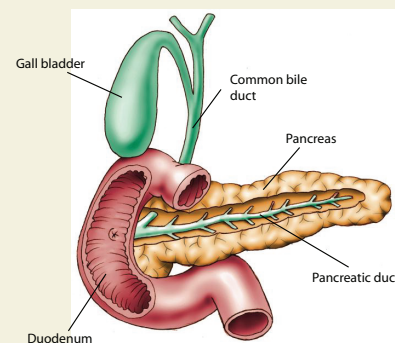

The pancreas (PAN-kree-us) is part of the digestive system. It is a gland that is about six inches long and shaped like a flattened pear. It lies next to the stomach with its wider end near the duodenum (doo-o-DEE-num), the first part of the small intestine. The pancreas produces insulin and glucagon (GLOO-ka-gon), which are chemical messengers called hormones*, which control the use of sugar in the body. The pancreas is also one of the organs in the digestive system that helps to break down food. The pancreas does this by secreting enzymes* that allow the body to digest proteins, sugars, and fats. These digestive juices from the pancreas travel into a tube, called the pancreatic duct. Other digestive juices, known as bile, also enter the pancreatic duct. Bile comes from the gall bladder, which is a small muscular sac that stores juices produced by another organ, the liver. Another tube, called the common bile duct, leads from the bladder to the pancreatic duct. From the pancreatic duct, this combination of digestive juices empties from the pancreatic duct into the small intestine, where it can then start digesting food.

Normally, the powerful digestive enzymes of the pancreas are inactive until they reach the small intestine. When the pancreas becomes inflamed, however, its enzymes leak out, become activated, and begin to digest the tissues they contact, so they begin to eat away at the pancreas and surrounding tissues. The resulting damage can cause swelling of tissues and blood vessels.

There are two forms of pancreatitis: acute and chronic. Acute* pancreatitis occurs when the pancreas suddenly becomes inflamed and destruction of the pancreas with attendant biochemical and functional abnormalities occur. Chronic* pancreatitis is persistent inflammation of the pancreas or a combination of persistent inflammation with repeated attacks of acute pancreatitis. Over time, the damage caused by chronic pancreatitis can lead to malabsorption (when the body cannot absorb the nutrients and calories it needs). People who have advanced cases may also develop diabetes*. This occurs because pancreatitis can damage the cells in the pancreas that produce insulin and glucagon.

Insulin and glucagon work opposite to one another. Glucagon tells the liver to turn a chemical called glycogen into another, called glucose. Glucose is a form of sugar that the liver then releases into the bloodstream. Insulin, by contrast, tells the liver to turn the glucose into glycogen, and the glycogen is then stored in the liver. Together, these two hormones regulate blood sugar. This regulation is important because blood sugar levels that are too high or too low can cause numerous health problems, including death.

Because advanced chronic pancreatitis can affect both insulin and glucagon production, doctors must be very careful in treating this condition.

▲ Anatomy of the pancreas, gallbladder, and duodenum. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

- * **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.
- * **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.
- * **enzymes** (EN-zimes) are proteins that help speed up a chemical reaction in a cell or organism.
- * **acute** describes an infection or other illness that comes on suddenly and usually does not last very long.
- * **chronic** (KRAH-nik) lasting a long time or recurring frequently.
- * **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **gallstones** (GAWL-stonz) are hard masses that form in the gallbladder or bile duct.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **cancer** is a condition characterized by abnormal overgrowth of certain cells, which may be fatal.

For example, people who have diabetes usually have high blood sugar, and doctors may order an infusion of insulin to treat it. If a patient's glucagon production is low, however, the additional insulin can lead to an overly decreased blood-sugar level (called hypoglycemia), which can be fatal.

What Causes Pancreatitis?

Pancreatitis has many causes, but most cases of acute pancreatitis result from alcohol abuse or gallstones*. A patient usually feels severe pain in the upper abdomen* that may last for hours or for a few days. The abdomen may be swollen and tender. Other symptoms may include nausea, vomiting, fever, and an increased pulse rate.

How Is Pancreatitis Diagnosed?

In addition to pain, patients with chronic pancreatitis usually show signs of long-term damage such as malabsorption or diabetes. Because acute pancreatitis causes an increase in certain levels of digestive enzymes in the blood, a blood test may confirm a diagnosis of the condition. Sometimes, a doctor may order x-rays or CT scans* to make the diagnosis.

How Is Pancreatitis Treated?

Treatment for pancreatitis depends on the type, cause, and severity of the condition. Although acute pancreatitis usually gets better on its own, a patient may spend time in the hospital during the attack. If the patient has gallstones, surgery to remove them may be needed.

Patients with chronic pancreatitis will begin a strict diet that limits fat and protein, because the damaged pancreas can no longer digest these substances properly. Patients sometimes receive replacement enzymes to help digest their food, and a doctor may prescribe medication to relieve pain. Because alcohol is often the cause of both acute and chronic pancreatitis, the best way to prevent the disease is to avoid drinking alcohol.

With treatment, the outlook for chronic pancreatitis often is good, but patients must stop drinking alcohol. Other less common causes of pancreatitis, such as infections, cancer*, and reactions to medicines or chemicals, require a proper diagnosis in order to be treated the best way possible.

Panic Disorder

Panic (PA-nik) is a sudden surge of overwhelming fear that causes both psychological (sy-ko-LAH-je-kal) and physical symptoms. Panic disorder is a condition that leads to repeated attacks of panic that can strike often and without warning.

Karla's Story

Karla was riding her bicycle to school when a speeding car ran a stop sign. The driver slammed on the brakes, but the car kept skidding toward Karla with a sickening squeal. As Karla watched the car bearing down on her, she felt her heart racing, she broke into a sweat, and could not catch her breath, and everything seemed to be moving in slow motion. For a moment before the car finally came to a stop, Karla feared she was going to die.

What Are Panic Attacks and Panic Disorder?

Karla was feeling panic, a sudden surge of overwhelming terror that causes both psychological symptoms, such as feeling that things are unreal or fearing that death is approaching, and physical symptoms, such as a racing heart, sweating, trembling, shortness of breath, chest pain, upset stomach, and dizziness. These feelings are the body's natural response to danger or stress. For some people, though, the feelings seem to arise from nowhere. They can occur in seemingly harmless situations, such as while taking a quiet walk or sitting in class. Panic attacks are bursts of intense fear or discomfort that happen, often for no obvious reason. They are part of many anxiety (ang-ZY-e-tee) disorders, in which needless fear becomes so intense and long-lasting that it causes problems at home, in school, at play, or elsewhere.

Panic disorder is a particular type of anxiety disorder in which people have panic attacks that strike often and usually without warning. The attacks are so unpleasant that many people live in constant dread of the next one. People may develop phobias (FO-bee-as), intense, unrealistic fears of certain objects or situations, about things linked to past panic attacks. For example, a boy who has had a panic attack during basketball practice might develop a phobia of the gym. As the problem gets worse, people may start to avoid situations where they believe they might have another panic attack. This avoidance may even turn into agoraphobia (a-gor-a-FO-be e-a), a condition

* **genetics** (juh-NEH-tiks) is the branch of science that deals with heredity and the ways in which genes control the development and maintenance of organisms.

* **identical twins** are twins produced when a single egg from the mother is fertilized and divides to form two separate embryos of the same sex with nearly identical DNA.

* **fraternal** twins are born at the same time but develop from two separate fertilized eggs. Unlike identical twins, who develop from only one fertilized egg that splits into two and who look exactly alike, fraternal twins may not look the same at all or be the same gender. Identical twins have the same genes, but fraternal twins are no more likely to share genes than non-twin siblings.

* **nervous system** is a network of specialized tissue made of nerve cells, or neurons, that processes messages to and from different parts of the human body.

that makes people find it hard to go beyond familiar places or even leave their homes. People with agoraphobia are terrified of having a panic attack in a situation where it would be hard to escape or get help.

How Common Is Panic Disorder?

About one in every 63 adults in the United States will have panic disorder at some point in his or her life. The problem usually begins during the late teen or early adult years, but children and older adults can have panic disorder, too. Women are affected twice as often as men. People with panic disorder often have other conditions as well, such as other anxiety disorders or depression.

What Causes Panic Disorder?

Genetics There are probably several causes of panic disorder. Genetics* may play a role in some cases, because panic disorder and other forms of anxiety can run in families. Also, research has shown that identical twins* are more likely to have panic disorder than fraternal* twins.

Physical factors People with panic disorder may not be able to use the natural substances made by the body to reduce feelings of anxiety. Such people may have flaws in nerve cell structures in the nervous system* that bind to these substances.

Psychological factors Other research suggests that it takes very little to set off the body's danger alarm in people with panic disorder. These people may have learned to overreact to normal body changes, giving rise to frequent false alarms. Some scientists speculate that the faulty learning may be the result of repeated stress. Once people have learned to react this way, a stressful event may trigger full-blown panic disorder.

THE MYTHOLOGICAL ROOTS OF PANIC

The word "panic" comes from the Greek term "panikos," which means "of Pan." Pan, the son of Hermes, was the Greek god of nature, of shepherds and their flocks (both goats and sheep), and of music. He was not an especially handsome Greek god, having the upper body of a man and the hindquarters and horns of a goat. Nonetheless, within the woods where he made his home, Pan was known for chasing the ladies. The beautiful nymph Syrinx, in an effort to escape him, was changed into a stand of reeds. Pan plucked one of the reeds and made a musical instrument called a panpipe. When lonely travelers wandered through the wild woods at night, it was said that they heard the pipes of Pan in the wind whistling through the trees and were struck with dread and deep fear. This fear of Pan came to be known as panic.

What Are the Symptoms of a Panic Attack?

Panic disorder starts with panic attacks that can seem to come without a reason. People can be struck suddenly by intense feelings of fear and vulnerability or of losing control. These symptoms usually last several seconds, but they may go on for several minutes or longer. Confused by the unexpected rush of feelings, people may worry that they are going crazy or suffering from a disease. Even when the most intense symptoms of panic have stopped, anxiety and nervousness may last for a while.

Symptoms of a panic attack may include the following:

- pounding or racing heart
- sweating
- trembling
- shortness of breath
- a choking feeling
- chest pain
- upset stomach
- dizziness
- faintness
- feeling as if things are unreal
- fear of losing control
- fear of dying
- numbness or tingling

Initial panic attacks may occur when people are under great stress, such as when they are trying to do too much or when they have just lost a loved one through moving away, divorce, or death. A panic attack may also follow surgery or a serious accident or illness. In addition, overuse of caffeine or abuse of cocaine and certain other drugs may trigger panic attacks. Whatever the situation, though, first panic attacks usually take people completely by surprise, which is one reason they are so terrifying and so clearly remembered.

What Are the Symptoms of Panic Disorder?

Some people have a single panic attack or occasional attacks, but they never have a problem serious enough to affect their lives. For others, however, panic attacks can continue and cause much misery. People with panic disorder have attacks so often that they start to live in constant fear of the next one. This “fear of fear” can become so intense and last so long that it greatly interferes with people’s lives. Panic disorder tends to get worse over time if it is not properly treated.

How Is Panic Disorder Treated?

Early treatment helps keep panic disorder from reaching the stage where people experience severe problems in everyday life. With proper care, 70 to 90 percent of people with panic disorder can feel much better.

Calming Down

Three strategies for coping with a panic attack are:

- Focusing on the fact that the feelings are frightening but not dangerous
- Rating one’s fear from 0 to 10 and noticing how it begins to fall from the highest level after just a few seconds or minutes
- Distracting oneself by counting backward from 100 by threes or by snapping a rubber band on one’s wrist. Distracting oneself from the panic allows the feelings to disappear on their own after a few seconds or minutes, whereas focusing on the panicky feelings intensifies them.

* **thyroid gland** (THY-roid GLAND) is located in the lower part of the front of the neck. The thyroid produces hormones that regulate the body's metabolism (me-TAB-o-LIZ-um), the processes the body uses to produce energy, to grow, and to maintain body tissues.

* **epilepsy** (EP-i-lep-see) is a condition of the nervous system characterized by recurrent seizures that temporarily affect a person's awareness, movements, or sensations. Seizures occur when powerful, rapid bursts of electrical energy interrupt the normal electrical patterns of the brain.

Before treatment starts, a medical checkup can determine if there are other possible causes for the person's physical symptoms, such as an over-active thyroid gland*, certain types of epilepsy*, or problems with the rhythm of the heartbeat.

Medications Certain medications can prevent or lessen the severity of panic attacks. When people find that their panic attacks are less frequent or less severe, they may worry less about future attacks, and they may be able to face situations they have been avoiding. There are several different kinds of medications doctors may use to treat panic disorder, depending on the person's age and condition.

Therapy A treatment that often works well for panic disorder is cognitive-behavioral (COG-ni-tiv-bee-HAY-vyor-al) therapy, which helps people change specific unwanted behaviors and faulty thinking patterns. People are taught that statements such as "I am going to have a panic attack" can be replaced with statements such as "This is only uneasiness. It will pass." They also may learn to use slow, deep breathing to help ward off the rapid, shallow breathing that many people experience during panic attacks. In another technique, the therapist may have people intentionally bring on some of the sensations of a panic attack. For example, people may exercise to raise the heart rate. Then the therapist can teach them how to cope better with these physical sensations. For example, instead of thinking, "I am having a heart attack," a person may be taught to think, "It is only my heart beating fast. I can handle it."

In this way, cognitive-behavioral therapy focuses on helping people learn to relax when they feel panic. People are taught to understand the thought processes behind their panicky feelings and the way the body physically reacts to stress. Then the therapist can help individuals find ways to respond better when they feel the symptoms of a panic attack.

Paralysis

Paralysis (pa-RAL-i-sis) is the inability to consciously control the movement of the muscles.

Sang Lan's Story

As she was warming up for her routine at the July 1998 Goodwill Games, 17-year-old Chinese gymnast Sang Lan prepared for a vault, a move she had performed thousands of times. But Sang flung herself too forcefully into the vault and landed on her head instead of her feet. The impact snapped the sixth and seventh vertebrae (VER-te-bray) in her neck, damaging her spinal cord and leaving her unable to move from the chest

* **brain stem** is the part of the brain that connects to the spinal cord. The brain stem controls the basic functions of life, such as breathing and blood pressure.

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

down. Sang's disability is probably permanent. This type of injury is one of the causes of the condition called paralysis.

What Is Paralysis?

Muscle is a special kind of tissue that enables bodies to move. It is under the control of the nervous system, which processes messages to and from all parts of the body. To understand paralysis, it is important to understand certain terms. Motor neurons are those nerve cells that stimulate the muscles that are under conscious control, such as those for walking, swallowing, breathing, talking. The usual pathway through which nervous signals are sent involves transmission of impulses from the upper motor neurons of the brain to the lower motor neurons of the brain stem* and the spinal cord and then onto the actual muscles. Paralysis occurs when either the upper or the lower motor neurons are irrevocably damaged through either disease or injury, and the individual loses the ability to move the muscles voluntarily.

Paralysis of the muscles of the face, arm, and leg on one side of the body is called hemiplegia ("hemi" means "half") and usually results from damage to the opposite side of the brain, which occurs because the upper motor neurons cross from one side of the brain to the other within the brain stem. Damage to the nerves of the spinal cord affects different parts of the body, depending on the amount of damage and where it occurred. Paralysis of both lower limbs is called paraplegia, and paralysis of both arms and both legs is called quadriplegia. Paralysis may be temporary or permanent, depending on the disease or injury. Because paralysis can affect any muscle in the body, a person may lose not only the ability to move but also the ability to talk or to breathe unaided. Spastic paralysis refers to a form of paralysis which often occurs due to upper motor neuron disease or injury. In spastic paralysis, the muscles are continuously contracted and tight. The individual may experience twitches and muscle spasms. Flaccid paralysis refers to a form of paralysis that often occurs due to lower motor neuron disease or injury. In flaccid paralysis, the muscles get no input from the central nervous system*, and they remain floppy, loose, and limp.

How Does a Person Become Paralyzed?

Physical injury (e.g., sports or car accidents) poisoning, infection, blocked blood vessels, and tumors can all cause paralysis. Defects in the developing brain of the fetus* or brain injury during birth can cause a paralytic condition known as cerebral palsy. In diseases such as multiple sclerosis, inflammation scars the nerves, interrupting communication between the brain and the muscles. Sometimes the muscle tissue itself is affected. In muscular dystrophy, deterioration of the muscle tissue of the arms and legs causes increasing weakness.

Guillain-Barré (gee-YAN ba-RAY) syndrome is an autoimmune disorder in which the body's own cells attack the insulation and core of the

nerve fibers, beginning in the hands and feet. In myasthenia gravis (my-es-THEE-nee-a GRA-vis), another autoimmune disorder, a chemical malfunction disrupts the communication needed for muscles to contract.

In rare cases, no physical cause for paralysis can be found. Psychologists call this condition a conversion disorder; that is, a person converts his or her psychological anxiety into physical symptoms of paralysis, but nerve and muscle function are still intact.

Signs and Symptoms

The signs and symptoms of paralysis vary. When the spinal cord is crushed, as in Sang Lan's injury, a person is immediately paralyzed and loses feeling in the affected limbs. When damage to the muscles or central nervous system is caused by a progressive disease or disorder, such as muscular dystrophy or multiple sclerosis, symptoms are gradual and often start with muscle fatigue and weakness. With poliomyelitis (PO-le-o-my-e-LY-tis) and stroke, paralysis comes on suddenly, with little or no warning.

Diagnosis

Information about symptoms and their onset helps the doctor pinpoint the cause of paralysis. With certain genetic* diseases that are inherited, such as muscular dystrophy, family medical history provides important clues. A careful physical examination with attention to presence or absence of voluntary movement and/or reflexes and characteristics of muscle tone can quickly, accurately, and cheaply establish the general location of the lesion or injury. Confirmation of the diagnosis usually requires other testing, including electromyography, and computerized tomography* CAT or MRI* scans.

Is Paralysis Treatable?

Aside from poliomyelitis (which can be prevented by vaccination*) and brain and spinal cord injuries (which in some cases can be prevented by using appropriate safety measures), it is usually not possible to prevent the conditions that cause paralysis, and most of the time there is no specific treatment. Steroid medications are sometimes given at the time of spinal cord injury to reduce inflammation in an attempt to limit the amount of damage to the spinal nerves. For people with paralysis who must use wheelchairs, treatment emphasizes exercises and special care to avoid infections and pressure sores. Patients with myasthenia gravis may be offered a drug that helps their muscles contract. Most people with Guillain-Barré syndrome recover on their own. Conversion disorder can be difficult to treat; the underlying psychological problem must be addressed.

Living with Paralysis

Many people with paralysis have normal life spans, even when the condition is the result of progressive disease. People who are confined to wheelchairs can still drive, swim, fly planes, and even ski. But being paralyzed requires major adjustments to daily living, because the muscles a person usually relies on to do certain actions no longer work. For example, for

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **MRI** which is short for magnetic resonance imaging, produces computerized images of internal body tissues based on the magnetic properties of atoms within the body.

* **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.

“Like a Mind in a Jar”

Jean-Dominique Bauby (1952–1997), editor of the magazine *Elle*, was 43 and had a wife and two young children when he suffered a stroke that left him with a condition called locked-in syndrome. Bauby was able to think, but he could not speak or move a single muscle in his body except for his left eye. He began to communicate by blinking his eye in a kind of code that a friend painstakingly transcribed letter by letter, first into words and then into sentences. The sentences became a book titled *The Diving Bell and the Butterfly*. The book was an instant bestseller in France and later inspired readers worldwide.

people with severe paralysis, ordinary body functions such as urinating and having bowel movements may be difficult tasks. In extreme cases, a person may not even be able to breathe without assistance. Help is available to cope with most cases of paralysis, and people with this condition can often hold jobs, raise families, and participate in various activities.

Will There Ever Be a Cure?

In the mid-1990s, no one would have imagined that badly injured nerves could heal. But in the 21st century, people may be able to regain the function they have lost through injury to their motor nerves. For example, experiments with rats and cats have shown that it is possible to repair damaged nerves and that severed spinal cord tissue can be made to grow back. Of course, many questions need to be answered before these approaches can be applied to humans.

Stem cells are generic or archetypal cells that can differentiate into any number of specific kinds of cells, given the right chemical environment. A great deal of hope rests on the theory that stem cell technology may induce stem cells to differentiate into cells that could be transplanted in order to repair injuries to the spinal cord, or to upper or lower motor neurons.

Parasitic Diseases: Overview

Parasitic diseases are caused by infection with parasites such as protozoa (one-celled animals), worms, or insects. These diseases are widespread in Africa, Southeast Asia, and Central and South America, especially among children. They include malaria and schistosomiasis, the world's most common serious parasitic infectious diseases.*

What Are Parasitic Diseases?

Most of the world's nearly 7 billion people are infected with parasites, which are primitive animals that live in or on the bodies of humans, animals, or insects. Often the parasites do little damage, and people may be unaware that they have them. In any given year, however, more than 1 billion people, many of them children, fall sick with parasitic diseases, and millions of them die.

Where Do Parasitic Illnesses Occur?

Parasites live everywhere, but they thrive in warm, moist environments. So they are most common in sub-Saharan Africa, the Indian subcontinent, Southeast Asia, and Central and South America. Some regions and some nations in these parts of the world are too poor to take measures that could prevent many parasitic infections—such as building water and sewage treatment plants, controlling mosquito populations, and providing adequate medical care. Furthermore, in many of these places, parasitic diseases make so many people weak, ill, and unable to work that they slow economic development and help keep regions impoverished.

Travelers from industrialized nations may pick up parasitic infections in tropical areas where they visit. In addition, parasites can infect people who live in industrialized nations if they eat food that was produced in tropical areas. Examples of such parasites are cyclospora and cryptosporidia (both protozoans).

Some parasites are found worldwide, even in cooler climates and in wealthier nations, including the United States. These include pinworms, whipworms, and such protozoa as *Giardia lamblia* (which causes intestinal problems), several *Babesia* species (which spread via ticks and cause fever and chills), *Trichomonas vaginalis* (which infects the genitals of men and women), and *Cryptosporidium parvum* (which has caused outbreaks of diarrheal illness in some cities of the United States).

What Are the Most Common Parasitic Diseases?

The intestinal roundworm *Ascaris lumbricoides* causes ascariasis, estimated to infect more than 1 billion people, although it often does little damage. Malaria (a disease caused by a protozoan, transmitted to humans

▲ The *Giardia lamblia* protozoan that causes giardiasis. Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.

* **malaria** (mah-LAIR-e-uh) is a disease spread to humans by the bite of an infected mosquito.

▲
A skin rash on the upper arm caused by the burrowing of hookworm larvae. *St. Bartholomew's Hospital/Photo Researchers, Inc.*

Ectoparasites

“Ecto-” means “outer.” Ectoparasites live on the outer surface of humans. They include lice and the mites that cause scabies (SKAY-beez).

by mosquitoes) has a much greater impact. According to the Centers for Disease Control (CDC), the malaria-causing agent is responsible for 300 million to 500 million illnesses per year worldwide and more than 1 million deaths. About half of those deaths occur in children under five years of age. *Schistosoma* blood flukes cause schistosomiasis (shis-to-so-MY-a-sis), which results in 120 million illnesses, 20 million of them severe, according to the CDC.

Other parasitic diseases are estimated to afflict 1 million or more persons per year are filariasis, amebiasis, Chagas' disease, leishmaniasis, and African sleeping sickness (trypanosomiasis).

How Do Parasitic Diseases Spread?

In many cases, people get parasitic infections as a result of bathing in, swimming in, or drinking water that contains parasites; by eating food that has not been cooked thoroughly; or by coming into contact with untreated sewage, which can happen when human waste is used to fertilize fields. It also can happen when people who handle food do not wash their hands thoroughly after using the bathroom.

Many impoverished nations are undergoing rapid urbanization, meaning that many people are crowded together into fast-growing cities that may lack sewage treatment facilities. Raw (untreated) sewage may be dumped into rivers whose water is also used for drinking, bathing, washing, and cooking. Parasitic diseases spread easily in such conditions.

Insects and animals spread some parasitic diseases. Mosquitoes, for instance, spread the protozoan that causes malaria. Tsetse flies spread the protozoan that causes African trypanosomiasis (tri-pan-o-so-MY-a-sis), also called African sleeping sickness. Domestic animals spread beef and pork tapeworms.

What Happens When People Get Parasitic Diseases?

Symptoms The symptoms of parasitic diseases vary widely depending on the parasite. Parasitic infections may cause symptoms including (but not limited to) the following:

- fever
- listlessness
- joint and muscle aches and pains
- intestinal problems including diarrhea, constipation, gas and bloating, and other gastrointestinal symptoms
- skin conditions including hives, rash, swelling, and sores
- weight gain or loss

Diagnosis Parasitic diseases can be difficult to diagnose because evidence of the presence of many parasites does not show up in the routine blood tests that doctors perform. In addition, people with parasites are

prone to getting bacterial infections as well, which may give doctors the impression that the bacteria alone are the cause of the illness.

Certain blood tests, however, can help with diagnosis. In addition, medical professionals can sometimes see parasites if they examine samples of stool or blood under a microscope.

Treatment There are a variety of medications that can kill most parasites, although not all parasites can be treated with medication. Because different parasites respond best to different medications, individuals should consult a medical professional to assure proper treatment.

How Can Parasitic Diseases Be Prevented?

Public authorities that build sewage and water treatment systems play a major part in preventing these diseases. Disease prevention is also achieved by controlling insect populations that spread some parasitic diseases and by teaching people always to wash their hands thoroughly after using the bathroom and before handling food. To control many parasitic infections effectively, a combination of medications and sanitary improvements are necessary.

Parkinson's Disease

Parkinson's disease is a disorder of the central nervous system that causes shaking, rigid muscles, slow movements, and poor balance. The disease is progressive, meaning it tends to get worse over time.

Sleeping Sickness

African trypanosomiasis (tri-pan-o-so-MY-a-sis) is also called African sleeping sickness. Protozoa (single-cell animals) of the genus *Trypanosoma* cause the disease. African trypanosomiasis, in which the disease-causing agent is transmitted by the bite of an infected tsetse (TZEET-ze) fly, occurs only in Africa. Treatment for African trypanosomiasis is composed of drug regimens administered under a doctor's care over a period of weeks. Left untreated, death eventually occurs.

▲ Actor Michael J. Fox waits for his turn to testify before the Senate Appropriations Subcommittee on September 28, 1999, in Washington, DC. The committee heard testimony from Fox and others suffering from Parkinson's disease. *AP Images.*

* **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.

Michael J. Fox's Story

Actor Michael J. Fox first noticed the twitch in his left little finger in 1991 while filming the movie *Doc Hollywood*. He remembers looking at the shaking finger and thinking, "Geez, what's that?"

Within six months, Fox's whole left hand started to twitch uncontrollably, and parts of his body started to feel stiff. Fox was concerned, so he visited a doctor.

Fox was only 30 years old and appeared to be in excellent health. His roles often required physical stunts that he performed with ease. He never expected to find out that his shaking hand and rigid muscles meant he had Parkinson's disease, a condition that is more common among people over 50 years of age.

What Is Parkinson's Disease?

Parkinson's disease is a movement disorder. It results from chemical imbalances in a small area deep within the middle of the brain that controls muscle movements, coordination, and balance.

For many people, their first symptoms are an involuntary twitching of a finger or hand, perhaps with a motion like rolling a small ball between the fingers. Doctors call this type of twitching "pill-rolling." Often, other people barely notice the motion.

Slowly over months and years, the twitching gets worse. Although it often starts in a limb, the tremors can affect the neck, face, and head. Sometimes, it affects only one part or side of the body.

Muscles also become rigid and do not respond normally, because the brain is unable to send the proper messages through the central nervous system* to get the body to act the way a person wants. At times, the person seems to freeze in the middle of an action, such as reaching for a book or walking.

The person starts to shuffle the feet and walk slowly. The arms do not swing back and forth normally. It can become difficult to sit or walk without rolling forward and sometimes falling. As talking becomes difficult, the person speaks slowly and in a monotone.

Eventually, the symptoms become so severe the person needs help with simple activities of living, such as walking and eating. The person's ability to think also can be affected late in the disease.

Not all people develop all the symptoms. Sometimes the disease progresses quickly, from the slight tremors to incapacity within a few years. Often and especially with treatment, however, a person can live well for many years.

The disease affects more than 1.5 million Americans. About 10 percent of the cases involve people younger than age 40, like Fox. Most men and women who get the disease, however, first show signs of it when they are between 50 and 75 years of age.

The disease is named for a British doctor, James Parkinson, who first described the disease's symptoms in 1817. He called it "Shaking Palsy." In the 1960s scientists began to understand how the chemical changes in the

brain caused the symptoms. Eventually, research led to medications and other treatments to help control the disease.

What Imbalance in the Brain Causes Parkinson's Disease?

People with Parkinson's lack enough of the chemical dopamine* in their brain. Dopamine (DO-pa-meen) is a neurotransmitter, a chemical that helps nerve cells send messages to each other. Dopamine receives assistance in sending these messages from other chemicals.

For some reason, the production of dopamine and the other chemicals is disturbed in the brains of people with Parkinson's. When that happens, the messages cannot transmit as well between one nerve cell and the next. Shaking, rigid muscles and other problems result.

What Causes Parkinson's Disease?

As of the early 2000s, no one knew exactly what causes the chemical imbalances. Scientists suspected a number of causes that might, in some cases, trigger the disease. Possible causes include a head injury (especially like those received during a boxing match), some medicines given for other serious conditions, abuse of certain drugs, exposure to toxic levels of carbon monoxide and other pollutants, and small strokes in the brain. Parkinson's disease is not contagious and, therefore, cannot pass from one person to another, like a cold can.

Parkinson's does run in some families, which has led researchers to look for a gene* that might trigger the disease. They studied a large number of Parkinson's cases among two large European families that appeared to share a defective gene, but as of 2009 the scientists had not been able to find the same abnormal gene in many others with the disease. In addition, researchers were interested in a particular area of the brain called the substantia nigra. When this part of the brain is not working properly because its nerve cells have died off, Parkinson's results. By learning more about the substantia nigra, they hoped to be able to fight the disease.

How Is Parkinson's Disease Diagnosed?

Parkinson's is a difficult disease to diagnose. No single test can determine if a person has it. Instead, doctors often rule out other causes of the shaking, such as a brain tumor or other brain disorder to arrive at their diagnosis.

How Is Parkinson's Disease Treated?

Hope is available for people with Parkinson's, because several prescription drugs can help. For most people, doctors prescribe a combination of drugs that help the brain make dopamine, the chemical needed to help nerve cells communicate in the brain. Other medications act like dopamine in the brain, improving the ability of the brain to control movements.

The drugs do not cure the disease, but they do treat its symptoms. People are able to perform many of the same activities they did before the

* **dopamine** (DOE-puh-meen) is a neurotransmitter in the brain that is involved in the brain structures that control motor activity (movement).

* **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

Did You Know?

Actor Michael J. Fox is not the only famous person with Parkinson's disease who has continued to maintain an active life. Janet Reno, the U.S. attorney general during the Clinton administration, and boxer Muhammad Ali have the disease.

Ali created a dramatic moment at the 1996 Olympics when he carried the torch in Atlanta. In 1998, Ali joined others in promoting more research that involves people of African, Hispanic, and Asian ancestry.

WHO WAS JAMES PARKINSON?

Parkinson's disease was first identified and named *paralysis agitans* (pa-RAL-i-sis AJ-i-tans) by the British physician James Parkinson (1755–1824). His classic description of its symptoms appeared in "Essay on the Shaking Palsy." Other physicians, as ancient as Galen (138–201 C.E.) and as many years later as Parkinson's contemporary Gerard van Swieten (1700–1772), had noted tremors like those characteristic of Parkinson's, but Parkinson's observations of the disorder were among the earliest to interpret those symptoms as a well-defined clinical syndrome. Not long after Parkinson's essay was published, the French neurologist Jean-Martin Charcot (1825–1893) began using the term "Parkinson's disease" to describe the condition.

disease developed, which is why Michael J. Fox has been able to continue taking some acting roles.

Besides drug treatment, doctors sometimes recommend brain surgery to destroy tiny areas of the brain that are malfunctioning. Fox had this surgery. The elimination of these cells can improve the trembling in some people with Parkinson's.

Experimental treatments were available in the early 2000s. These included transplanting brain tissue from human fetuses into the part of the brain where the dopamine is in short supply. Early results showed that this surgery might benefit some people, but the technique was controversial because the fetal tissue often becomes available as the result of an abortion or infertility treatments. Researchers experimented with animal cells and cells they grew in the laboratory in attempts to achieve the same results as using fetal cells. Many were especially interested in stem cells, which are unspecialized cells that can develop into any kind of cell, including nerve cells, and may be important in treating and perhaps one day curing Parkinson's disease.

Pedophilia

The term “pedophilia” (ped-uh-FIL-ee-uh) is derived from the Greek words for “child” and “love.” Pedophilia is a sexual perversion in which an adult prefers sexual encounters with children. Such a person is known as a pedophile. The term “pedophile” has medical and legal meanings. Medically, a pedophile is an adult who experiences sexual urges towards prepubescent children; this person may or may not engage in the act of child sexual abuse. In law enforcement, the term usually refers to someone accused or convicted of sexual abuse involving a prepubescent child or a minor (below the age of legal consent).

Two Victims of Sexual Abuse

Twelve-year-old Valerie was at a family reunion where she met many relatives whom she had not seen in a long time. She realized she was not likely to remember aunts and uncles whom she met when she was very young. When she was walking alone down a narrow corridor, an uncle whom she hardly knew approached her. “Valerie,” he said. “Look how you have grown. Give me a hug!” She hugged him, but she was surprised that he did not let go when she thought he would. Next she felt him touching her low below her hips.

She yelled, “Stop it!” Then she ran to her parents. The uncle had drunk too much alcohol. When he sobered up, he was sorry for his actions. Although there were legal consequences for his actions, he would not be considered a pedophile by psychiatrists. This incident made him realize that he needed help with his alcoholism. He was even grateful that Valerie reported him.

Ten-year-old Cindy needed a babysitter when her parents went out. She liked to have teenaged Conrad babysit because he always made her chocolate

* **psychoactive** (sy-ko-AK-tiv) affecting a person's mood, behavior, perceptions, or consciousness.

sundaes, which her parents did not like her to have. "This is our little secret," he would say. Another little secret was a game called "Lifeguard," which Conrad made up. They played it in their underwear pretending they were at the beach. Cindy never told her parents about the game because Conrad told her it was all right, and she could see that her parents trusted Conrad. Because she kept the sundaes a secret, it was easier to keep the game a secret. One day her parents came home early and saw them playing the game. They called the police on Conrad and Cindy had to tell many law enforcement people all of the details about the game. Her parents assured her that she should not feel ashamed. They took special care to spend more time with her. When Conrad was arrested, many other young girls came forward to say he had abused them also, some more than he had Cindy.

What Is Pedophilia?

Pedophilia is the deviant (abnormal) sexual preference for prepubescent children by an adult over the age of 16. According to the guidelines established by the American Psychiatric Association (APA), the offender has to be at least five years older than the victim. The preference may or may not be exclusive, which means the offender may also enjoy adult sexual relationships. The APA guidelines do not recognize as a pedophile an adolescent who is sexually involved with a younger adolescent in a long-term relationship. Also, an isolated event, which is not part of a pattern of behavior, is not considered pedophilia. This distinction includes an adult who acts sexually toward a child while under the influence of alcohol or other psychoactive* drugs. The APA also avoids classifying as pedophiles those persons who may have the predisposition for pedophilia but who are not likely to act out by initiating a sexual act with a child.

How Common Is Pedophilia?

Rates of pedophilia in the general population are undetermined. Numbers of reported sex acts against children necessarily differ from any estimate of how many people are predisposed to pedophilia. An estimate given in *Time* magazine (2002) was as low as 4 percent of the population; whereas Gordon Hall of the University of Oregon found up to 25 percent of the population has an inclination. Of course, these sources relied on different methods for evaluating someone as a pedophile. Also, being aroused by pedophilic stimuli does not indicate necessarily the urge to commit sexual abuse against children.

Who Becomes a Pedophile?

Some data regarding the nature of pedophiles comes from those who have been incarcerated for their sexual offense. Using this population introduces variables into the research. For this reason, findings tend to be disputed. Identifying who is most likely to be a pedophile is difficult to establish with any certainty. As of 2009, the causes of pedophilia were not fully understood. In the past, it was widely believed that most male pedophiles

were victims of childhood sexual abuse themselves; however, subsequent research found this to be true in only a small percentage of cases.

Most pedophiles are men; however, there are female pedophiles, and they differ in many ways from the males. Kathryn Jennings at the University of Toronto conducted a study of female pedophiles. She found that over half of the women studied were forced into the act by a male partner or spouse. Many of these women reported being victims of abuse themselves when they were young. Also, most male pedophiles tend to rely on certain excuses for their behavior, such as claiming their desire is uncontrollable or that children are sexual beings. However, Jennings found that the women did not try to justify their actions by these kinds of explanations.

Some research was underway in 2009 to determine predisposing factors in pedophilia. Other research sought to describe common factors in neurological, cognitive, and behavioral traits of pedophiles; some results suggested that lower IQ, school failure, and childhood head injuries resulting in loss of consciousness were common traits. Research sponsored by the Canadian Institutes for Health Research found evidence for a link between low IQ and pedophilia. The researchers divided data into three groups of offenders: non-sexual, sexual against adults, and sexual against children. The measured intelligence of the pedophiles was significantly lower than the IQ of other offenders. The researchers suggested that something in the offenders' development contributed to both the low IQ and the pedophilia. These findings may be relevant only to the incarcerated pedophile. Moreover, they do not explain pedophiles among groups that tend to have normal or above average IQs.

Pedophiles commonly exhibit sociopathic tendencies, impaired interpersonal functioning, increased introversion, and cognitive distortions. Studies have shown that treating offenders with selective serotonin reuptake inhibitor (SSRI) has had some success on reducing recidivism (relapse into criminal activity), which suggests that pedophilia is related to a disturbance in the neural system relating to impulse control. This therapy is often used in treating impulsive shopping, aggression, and anger. A study reported by the APA found similarities in measured personality traits among pedophiles. These personality traits correlated defiance of authority and sexual deviance. However, there are many people with these same personality measures who are not pedophiles.

Many pedophiles have a history of substance abuse. While intoxication may facilitate the pedophile's acting on sexual urges against children, it is not the cause of pedophilia.

How Is Pedophilia Diagnosed and Treated?

If a psychiatrist is trying to diagnose someone as a pedophile, most likely that person has already committed an offense against a child. Any prescribed treatment would be negotiated in relation to court action by which the person is bound. However, individuals who suspect they have pedophilic impulses could turn to a psychiatrist for a diagnosis.

* **puberty** (PU-ber-tee) is the period during which sexual maturity is attained.

* **behavior therapy** is a type of counseling that works to help people change their actions.

Diagnosis The main way to diagnose the condition of pedophilia is through following the guidelines of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*. These guidelines specify that individuals must be at least 16 years old before they can be considered a pedophile. The child who stimulates sexual desire has to be at least five years younger than the person, and the child has to be prepubescent, meaning not yet experiencing puberty*. The guidelines also define what constitutes a sexual reaction to children. These reactions or feelings have to have some manifestation such as intense fantasies that arouse the person sexually, sexual urges that seem to be uncontrollable, or definite sexual behaviors involving a child. These feelings have to be recurrent and continuing over a period of at least six months. Another key component of the diagnosis is that these feelings have led to actual behavioral or affective changes; the person has acted on these feelings or has allowed these feelings to deteriorate his lifestyle. Thus, persons for whom such feelings do not interfere with their daily life do not classify as pedophiles. The *DSM-IV* emphasizes a diagnosis has to take into consideration long-term behavior, personal distress, or interpersonal difficulty.

Treatment As of 2009 there were no reliable methods to cure pedophilia. Treatment is generally performed in collaboration with law enforcement in order to prevent further occurrence of child sexual abuse. Incarceration and/or public monitoring are common methods for preventing pedophiles from abusing children again.

Several therapies that combine behavior therapy* with medication have shown some success in deterring repeat offenses. Most drugs used in treating pedophiles suppress testosterone in men, with the goal of reducing the pedophile's sexual urges. Another method in drug treatment involves drugs that actually increase the secretion of testosterone so that the supply is dissipated. Thus, the level is never high enough to allow a sexual drive.

Can Pedophilia Be Prevented?

There are many therapists who believe that someone with pedophilic tendencies might volunteer for diagnosis and treatment if the social stigma was not so severe. A campaign to bring awareness of the types of support available might help prevent a young person from developing and acting on these deviant urges. Unfortunately, the available help was limited, and the methods were not fully validated as of 2009.

The most important aim when dealing with pedophilia is preventing harm to children. Parents have to be aware of the many elaborate ways that pedophiles use to get access to children and to obtain their trust. Children who are too young to understand how people can disguise their true intentions can be fooled in ways that their parents may not suspect. Parents may think that they have educated their children to be wary of strangers, but the pedophiles can be very creative in their deceit. Once abuse has happened, most pedophiles will use either direct threats or complex persuasive techniques to keep the child from reporting sexual abuse.

The Internet provides a pedophile with various ways to meet and tempt young children. The pedophile pretends online to be a young person who is sincerely interested in the child. Children who assume they are chatting online with a peer may open up about personal issues, including clues that the pedophile can use to find the child in real life. Parents need to be aware of the contacts their children have online. Parents should be aware of and use whatever solutions are available to them for controlling Internet use by their children.

- * **cervix** (SIR-viks) is the lower, narrow end of the uterus that opens into the vagina.
- * **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.
- * **ovaries** (O-vuh-reez) are the sexual glands from which ova, or eggs, are released in women.
- * **fallopian tubes** (fa-LO-pee-an tubes) are the two slender tubes that connect the ovaries and the uterus in females. They carry the ova, or eggs, from the ovaries to the uterus.

Pelvic Inflammatory Disease (PID)

Pelvic inflammatory disease (PID) is an infection of the female reproductive system, including the cervix, uterus*, ovaries*, and especially the fallopian tubes*. PID usually is the result of an untreated or poorly treated sexually transmitted bacterial infection. It can cause scarring and reduce or eliminate a woman's ability to get pregnant.*

Illustration by Corey Light. Reproduced by permission of Gale, a part of Cengage Learning.

- * **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.
- * **vagina** (vah-JY-nah) is the canal, or passageway, in a woman that leads from the uterus to the outside of the body.

Pelvic inflammatory disease (PID) risk factors

Age: the rate of infection in women drops as they get older. Risk is highest for sexually active women under 25 years of age.

Ethnicity: the rate of infection is higher in nonwhite groups.

Socioeconomic status: the rate of infection is higher in women of lower socioeconomic status.

IUD: the rate of infection is higher with the use of IUDs, and frequent douching.

Barrier contraception: consistent use of barrier contraceptives protects against PID, although they may not protect against other STDs, such as HPV.

Lifestyle: the rate of infection is higher in women who abuse drugs and alcohol, have had intercourse for the first time at an early age, and have had a higher number of sexual partners.

STDs: the rate of infection is higher in women who have had sexually transmitted diseases.

Carrie and Reg's Story

Two years after Carrie and Reg got married, they decided to start a family. Carrie began looking at the ads for strollers and baby clothes. But after a year, she had not gotten pregnant. She was sure she did not have a medical problem. After another six months of trying, Carrie and Reg decided to see a doctor who specializes in fertility problems.

The doctor asked Carrie if she had ever had pelvic inflammatory disease (PID). She said no, she had not even heard of it. But in a series of tests, her body told a different story. Carrie's fallopian tubes (the place where egg meets sperm in conception) had been scarred by PID. After trying laser surgery to remove the scar tissue, the blocked passageways were opened, and Carrie finally got pregnant.

When healthy young women have difficulty getting pregnant, damage from PID is one of the many possible causes. In most cases, the women do not know they had the disease and never got treated. Quick treatment of PID can reduce the chances that it will cause infertility.

What Causes Pelvic Inflammatory Disease?

Most often, women get PID as a result of having a sexually transmitted bacterial* infection that was not treated, often because it was not noticed. The bacteria *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are the most common bacteria involved in PID. The infections they cause are called a chlamydial (kla-MID-e-al) infection and gonorrhea (gon-o-REE-a). PID can involve more than one type of bacteria. In many cases, doctors do not identify the bacteria involved.

Most often, bacteria enter the vagina* during sexual activity and then move up into the cervix, uterus, and other parts of the reproductive system where they rapidly reproduce. PID also can develop after a woman gives birth or has an abortion in unsanitary conditions. In rare cases, certain medical procedures done on reproductive organs, such as injecting dye for special x-rays, can lead to PID.

What Effect Does Pelvic Inflammatory Disease Have?

To understand the effect of PID, one has to understand the basic facts about conception. The ovary releases an egg into one of a woman's two fallopian tubes, where it meets with the sperm*. The newly formed embryo* travels through the tube to the uterus, an expandable sac where it attaches to the wall and grows into a fetus*.

In PID, bacteria infect the cervix and then travel upward and infect the fallopian tubes, a condition called salpingitis (sal-pin-JY-tis). Doctors sometimes use that name as a synonym for PID; however, PID can also involve the uterus and the ovaries. In severe cases, a collection of pus can form in the ovaries and fallopian tubes, (a tubo-ovarian abscess), or the infection can spread to the membrane* around the reproductive organs, a condition called pelvic peritonitis (per-i-to-NY-tis).

The body usually fights off the infection, but in the course of fighting the infection, tissues can be damaged and scar tissue may form. Scar tissue can block the delicate fallopian tubes. That means the egg and sperm may not be able to meet, or, if they do, the fertilized embryo may not be able to reach the uterus.

Of women who have PID one time, about 10 percent become infertile. Each repeat episode of PID doubles the chance of becoming infertile. In 2007 the Centers for Disease Control and Prevention estimated that about 100,000 American women become unable to conceive children each year as a result of PID. Prompt treatment within three days of symptoms can help prevent infertility and other complications.

Women who have had PID are also more likely than other women to have an ectopic (ek-TOP-ik) pregnancy. That means the embryo starts growing outside the uterus, usually in the fallopian tubes. Such a pregnancy cannot produce a baby and, if it is not ended, poses a very serious risk to the woman because the growing embryo will rupture the fallopian tubes and cause life-threatening hemorrhage*.

Who Is at Risk for Acquiring Pelvic Inflammatory Disease?

About one million American women have a case of PID each year of which about 200,000 are hospitalized due to complications of their infection. PID is rare among women who do not engage in sex. Sexually active teenagers are at the highest risk by far, followed by women in their early twenties. The risk increases if a woman has many sexual partners, has sex with a man who has many sexual partners, or has sexual intercourse very frequently even with a single partner. Frequent douching (inserting fluid into the vagina supposedly to clean it) also increases the risk of PID. Women who use an intrauterine device (IUD) for birth control have a slightly increased risk of developing PID for a short time after the IUD has been inserted.

- * **sperm** are the tiny, tadpole-like cells males produce in their testicles. Sperm can unite with a female's egg to result eventually in conception.
- * **embryo** (EM-bree-o), in humans, is the developing organism from the end of the second week after fertilization to the end of the eighth week.
- * **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.
- * **membrane** (MEM-brain) is a thin layer of tissue that covers a surface, lines a cavity, or divides a space or organ.
- * **hemorrhage** (HEH-muh-rij) is uncontrolled or abnormal bleeding.

The United States and the World

- In the United States, it is estimated that more than one million women get PID each year. Almost all U.S. cases are caused by a sexually transmitted disease.
- With its complications of infertility and ectopic pregnancy, PID is estimated to cost the U.S. economy more than \$4 billion a year.
- In developing nations of Africa and Asia, PID is far more common, with many infections caused by childbirth or abortions occurring in unsanitary settings.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **ectopic pregnancy** (ek-TAH-pik) is an abnormal pregnancy in which the fertilized egg develops outside the uterus, usually within one of the fallopian tubes.

* **syphilis** (SIH-fih-lis) is a sexually transmitted disease that, if untreated, can lead to serious life-long problems throughout the body, including blindness and paralysis.

* **HIV** or human immunodeficiency virus (HYOO-mun ih-myoo-no-dih-FIH-shen-see), is the virus that causes AIDS (acquired immunodeficiency syndrome) infection.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

What Are the Symptoms of Pelvic Inflammatory Disease?

About 60 percent of all cases of PID have symptoms so mild that they go unnoticed. At the other extreme, symptoms can be quite severe. Noticeable symptoms are not specific to PID. They include the following:

- Pain in the lower abdomen* or pelvis
- Sharp pain when the doctor performs a pelvic examination
- Fever of over 100 degrees Fahrenheit (38 degrees Celsius)
- Discharge of pus or irregular bleeding from the vagina
- Pain during urination or intercourse

Sometimes, long after an untreated PID infection occurs, women have chronic* (persistent) pain in the pelvis, which is sometimes called chronic PID.

How Is Pelvic Inflammatory Disease Diagnosed?

PID can be difficult to diagnose. Many conditions cause similar symptoms, and no one test can tell for sure if a woman has PID. Because it is so important to treat PID promptly, doctors usually start treatment if the symptoms even suggest PID.

To try to confirm the diagnosis, doctors can administer blood tests and take pelvic cultures to look for general evidence of infection. They test for chlamydial infection and gonorrhea, and they do a pregnancy test to determine whether the symptoms are being caused by an ectopic pregnancy*. All women with PID also should be tested for syphilis* and offered the opportunity to be tested for HIV*.

Ultrasound*, a painless procedure that uses sound waves to create an image of the organs, can help doctors look for a tubo-ovarian abscess.

The most definitive test for PID is laparoscopy (la-pa-ROS-ko-pee), a surgical procedure in which a narrow device is inserted through a small incision into the abdomen so the doctor can look inside the belly. Laparoscopy usually is done only if treatment is not working or if the doctor suspects the woman may have another condition, such as appendicitis*(a-pen-di-SY-tis), that requires emergency surgery.

How Is Pelvic Inflammatory Disease Treated?

Since it is difficult to determine exactly which bacteria are causing PID, combinations of two or three different antibiotics (an-ty-by-OT-iks) that fight a wide range of bacteria are given for at least two weeks, usually in pills to be taken at home. If a woman is pregnant or particularly ill, she usually is hospitalized for at least a few days and given antibiotics intravenously*.

If a woman has an abscess, it may need to be drained through a tube or catheter* inserted into the abdomen. If an abscess ruptures, or breaks open, immediate surgery is necessary.

If a woman has PID, any man who had sex with her in the previous two months should be treated for possible chlamydial infection

and gonorrhea. Even if he has no symptoms, chances are high that he is infected and could reinfect the woman or other partners.

How Can Pelvic Inflammatory Disease Be Prevented?

Like chlamydial infections and gonorrhea, PID most surely is prevented by not having sex. A sexually active woman is most protected if she has sex only with one faithful partner, that is, a partner who has sex only with her. Short of that, a woman should limit her sexual partners. Latex condoms worn by the man during sexual activity can prevent PID if they are used correctly at all times.

A woman should seek immediate treatment if she suspects that she, or a sexual partner, has a sexually transmitted disease. Because these diseases often cause no symptoms, health officials recommend that all sexually active young women, especially teenagers, get tested routinely for chlamydial infections and gonorrhea. When chlamydial infection screening of young women was tried as an experiment, it reduced the number of cases of PID.

Peptic Ulcer

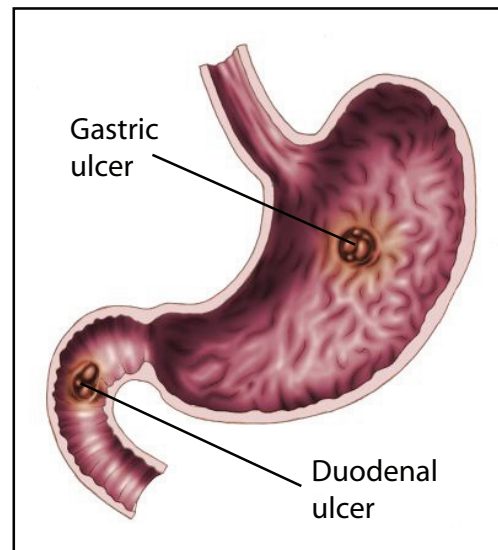

A peptic ulcer is a painful sore that forms in the stomach or the duodenum (doo-o-DEE-num), the first part of the small intestine. Peptic ulcers found in the stomach are sometimes called gastric or stomach ulcers. Those found in the duodenum are sometimes called duodenal ulcers.

* **appendicitis** (ah-pen-dih-SY-tis) is an inflammation of the appendix, the narrow, finger-shaped organ that branches off the part of the large intestine in the lower right side of the abdomen.

* **intravenously** (in-tra-VEE-nus-lee) means given or injected directly through a vein.

* **catheter** (KAH-thuh-ter) is a small plastic tube placed through a body opening into an organ (such as the bladder) or through the skin directly into a blood vessel. It is used to give fluids to or drain fluids from a person.

Peptic ulcers may occur in the stomach (gastric ulcers) or in the first part of the small intestine (duodenal ulcers). Many peptic ulcers are the result of infection with *H. pylori* bacteria. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **enzyme** (EN-zime) is a protein that helps speed up a chemical reaction in cells or organisms.

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

What Is a Peptic Ulcer?

Digestive juices in the stomach contain hydrochloric acid, a very strong acid that is produced by parietal cells and secreted into the stomach. This acid helps to kill bacteria and viruses found in food and water and, along with the enzyme* pepsin, begins the process of digestion, or break down of food so that it can be absorbed into the bloodstream and used by the body. The inside of the stomach and duodenum are lined with a heavy layer of mucus. This mucus protects the stomach tissue from being destroyed by stomach acid. Peptic ulcers develop when there is damage to the mucus lining. Stomach acid then erodes (eats away at), the stomach tissue and/or duodenal. This condition causes inflammation* and can result in a peptic ulcer.

Who Gets Peptic Ulcers?

Peptic ulcers are common in adults, but rare in children and teenagers. Duodenal ulcers are most likely to develop in people between 30 and 50 years of age, whereas most stomach ulcers occur in people over age 60. People living in the United States have about a 10 percent chance of developing a peptic ulcer in their lifetime. In 2008, about 4.5 million Americans had peptic ulcers. Peptic ulcers cause about 1 million hospitalizations and 6,000 deaths each year.

Why Do People Get Peptic Ulcers?

Peptic ulcers form because the mucus in the stomach and duodenum is unable to protect the tissue underneath it from destruction by stomach acid. Several conditions can upset the balance between mucus and stomach acid and make it likely that an ulcer will form.

Helicobacter pylori *Helicobacter pylori* (hel-i-ko-BAK-ter pi-LOR-ee) is a spiral-shaped bacterium that has adapted to living in the very acidic

environment of the stomach. In order to survive, *H. pylori* burrows into the mucus lining the stomach. Once it gets into the mucus, it uses an enzyme to cause a chemical reaction that produces bicarbonate and ammonia. Both of these are strong bases that neutralize any stomach acid that reaches the bacterium. The immune system responds to the presence of *H. pylori*. Eventually the mucous lining is weakened and stomach acid can eat away at the tissue underneath, forming an ulcer or open sore.

In the United States, about 10 percent of children under age 12 are infected with *H. pylori*. This number increases with age until about half of all Americans over age 60 have the infection. The rate of infection is much higher in the developing world. Scientists are not exactly sure how the infection is passed from person to person, although they think that it is transmitted through contact with feces* from infected people or through drinking contaminated water. Some researchers also believe that *H. pylori* can be transmitted through kissing an infected person.

As of 2009, researchers do not fully understand the relationship between *H. pylori*, gastric inflammation, and peptic ulcers. For example, about 90 percent of people who have peptic ulcers are infected with *H. pylori*, but only a small number of those who are infected develop an ulcer, and 10 percent of people with ulcers do not have *H. pylori* infections. Also, antibiotic treatment to rid the body of *H. pylori* does not, by itself, cure most ulcers.

Nonsteroidal anti-inflammatory drugs Nonsteroidal anti-inflammatory drugs (NSAIDs) are medications used to reduce inflammation and treat the pain it causes. Familiar NSAIDs are aspirin, ibuprofen (Advil, Motrin), and naproxen (Aleve). Long-term use of NSAIDs, for example to treat arthritis, can cause the mucous lining to weaken and allow an ulcer to form.

Other causes Certain lifestyle choices also make it more likely that a person will develop a peptic ulcer. These include heavy alcohol use, cigarette smoking, and heavy caffeine consumption.

People who experience severe injuries, burns, or who undergo major surgery are more likely to develop an ulcer. Some researchers also believe that extreme anxiety and emotional distress can promote ulcer formation.

What Are the Symptoms of Peptic Ulcer?

The most common symptom of a peptic ulcer is a gnawing or burning pain in the stomach. This pain comes and goes over a period of days or weeks, most often when the stomach is empty, for example, three or four hours after a meal or in the middle of the night. Eating may help relieve the pain. Other possible symptoms include weight loss, poor appetite, bloating, burping, nausea, and vomiting.

How Are Ulcers Diagnosed?

If a person has lasting abdominal pain or other symptoms of peptic ulcer disease, there are several methods a doctor can use to make a diagnosis.

* **feces** (FEE-seez) is the excreted waste from the gastrointestinal tract.

* **gastrointestinal** (gas-tro-in-TESS-tih-nuhl) means having to do with the organs of the digestive system, the system that processes food. It includes the mouth, esophagus, stomach, intestines, colon, and rectum and other organs involved in digestion, including the liver and pancreas.

* **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

* **culture** (KUL-chur) is a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.

* **antagonist** (an-TAG-oh-nist) a chemical that acts within the body to reduce or oppose the effects of another chemical.

One of the most common ways to check for ulcers is with endoscopy (en-DOS-ko-pee). For this procedure, a person is given medication to relax and numb the throat. Then a doctor gently inserts an endoscope (a thin, flexible tube with a camera and light on the end) down the throat, through the esophagus, and into the stomach and intestines. The camera on the end of the endoscope allows the doctor to view the digestive system and take pictures of it. In addition, the doctor can perform a biopsy, removing a small amount of tissue for study under a microscope.

Although it is less helpful than endoscopy, another test that may be used to check for ulcers is an upper gastrointestinal* (GI) series. This is a set of x-rays of the gastrointestinal system. A person taking the test first drinks a white, chalky liquid called barium to help highlight the ulcer and makes it visible on the x-ray.

A person suspected of having *H. pylori* infection may undergo a breath test. During a breath test, a person drinks a liquid containing a carbon marker known as carbon-13 (^{13}C). The person then provides a breath sample by blowing up a balloon or blowing bubbles. The sample is checked for the presence of the ^{13}C marker. If the person has *H. pylori* infection, there will be traces of ^{13}C present in the carbon dioxide gas molecules of the person's breath. A person's blood also can be checked for the presence of antibodies* to *H. pylori*, indicating infection. However, the presence of the antibody in the blood does not indicate current infection and may be due to prior infection. Another diagnostic measure is to take a culture* of the *H. pylori*. This is the most accurate means of detection.

How Are Peptic Ulcers Treated?

People with peptic ulcers and infected with *H. pylori* are treated for 10 to 14 days with what is called triple therapy. This consists of a combination of two or three antibiotic medicines that kill *H. pylori* bacteria and a drug that reduces acid production in the stomach. But the mainstay of peptic ulcer treatment is the reduction or abolition of gastric acid secretion. Two classes of drugs reduce acid production: histamine type 2 receptor antagonists* and proton pump inhibitors. Alternatively, patients may take an antacid that neutralizes the acid. Some of these drugs are available over-the-counter, meaning without a prescription. In addition, patients are encouraged to make lifestyle changes such as limiting alcohol and caffeine consumption and quitting smoking.

If left untreated, ulcers can lead to serious complications. In some cases, the ulcer can make a hole all the way through the stomach or duodenum wall. In other cases, the ulcer or acid breaks a blood vessel and causes serious internal bleeding. Peptic ulceration may obstruct the passage of stomach contents into the duodenum. It is important to get medical help promptly for the following symptoms, which may signal a peptic ulcer or other serious problem:

- Sharp, sudden, or long-lasting stomach pain
- Bloody or black stools (bowel movements)
- Bloody vomit or vomit that looks like coffee grounds

Can Ulcers Be Prevented?

Ulcers that developed in response to medications such as NSAIDs or stressful situations such as severe burns and other conditions that are often associated with peptic ulcerations can be prevented by taking drugs known as prophylactic H2 blockers or proton pump inhibitors.

Peritonitis

Peritonitis (per-i-to-NY-tis) is an inflammation of the peritoneum (per-i-to-NEE-um), which is the lining of the abdominal (ab-DOM-i-nal) cavity. Peritonitis typically results from a hole or slit in one of the hollow organs of the abdomen, which include the stomach, small intestine, colon, and gallbladder. This hole can allow the contents of the organ, often including billions of bacteria to escape into the abdominal cavity. Peritonitis can be life-threatening.*

* **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.

* **ulcer** is an open sore on the skin or the lining of a hollow body organ, such as the stomach or intestine. It may or may not be painful.

* **Crohn's disease** (KRONZ) an often inherited, chronic inflammatory disease that typically affects the small and/or large intestine but which can affect any part of the digestive system. The disease causes crater-like ulcers or sores in the inner surface of the bowel. Mild cases may be treated with medication; serious cases may be treated with surgery.

* **colitis, ulcerative** (ko-LIE-tis, UL-sir-ah-tiv) a common form of inflammatory bowel disease that causes inflammation with sore spots or breaks in the inner lining of the large intestine (colon). Symptoms include cramping, bleeding from the rectum, and diarrhea.

* **gallbladder** is a small pear-shaped organ on the right side of the abdomen that stores bile, a liquid that helps the body digest fat.

* **bacteria** (bak-TEER-ee-a) are single-celled microorganisms, which typically reproduce by cell division. Some, but not all, types of bacteria can cause disease in humans. Many types can live in the body without causing harm.

* **cirrhosis** (sir-O-sis) is a condition that affects the liver, involving long-term inflammation and scarring, which can lead to problems with liver function.

* **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

What Is Peritonitis?

Peritonitis (per-i-to-NY-tis) is an inflammation of the peritoneum, the thin, slippery, abdominal lining that covers the organs in the abdomen. While peritonitis may not sound serious, it is very dangerous if it is not identified and treated right away. Anyone with symptoms of peritonitis needs emergency medical attention immediately.

Usually, the cause of peritonitis is a perforation (per-fo-RAY-shun), or a hole, in the stomach, intestines, appendix, or one of the other organs covered by the lining. The perforation can come from a disease process such as stomach or intestinal ulcer*, Crohn's disease*, or ulcerative colitis, ulcerative* gallbladder* disease, a knife or gunshot wound to the abdomen, or from a cut during surgery. When such a perforation occurs, bacteria* can quickly invade the abdominal cavity. For example, a puncture in the colon (the part of the intestine that stores feces before it leaves the body) can send billions and even trillions of bacteria and bacterium-like cells flooding into the abdomen. The peritoneum mounts a defense against the onslaught, and peritonitis results.

People can also get peritonitis from complications of a wide variety of other illnesses, including the following.

- Burst appendix
- Diverticulitis (dy-ver-tik-yoo-LY-tis), the inflammation and possible rupture of pouches that form on the colon
- Perforated ulcer
- Cholecystitis (ko-li-sis-TIE-tis), which typically results when a gallstone blocks and inflames the bile duct and can lead to rupture of the gallbladder
- Pelvic inflammatory disease

In all of these cases, bacteria can inflame the peritoneum. People with cirrhosis* (si-RO-sis) of the liver* sometimes get spontaneous bacterial peritonitis, which means that they have no rupture or obvious source for the infection.

What Happens When People Get Peritonitis?

Symptoms The symptoms of peritonitis range from mild to excruciating pain in the stomach area, and while the pain may start in one area, it often extends throughout the abdomen within a matter of hours. Movement and/or touching the abdomen typically make the pain worse. A person with peritonitis usually loses his or her appetite and may quickly become nauseated. Some may begin vomiting. Peritonitis often causes a muscle spasm in the abdominal wall, making the abdomen* feel hard and immobile, as if it were a wooden board. The stomach may also become distended (puffed out).

Diagnosis A doctor often can diagnose peritonitis through a physical examination of the patient. Doing so may include gently touching the abdomen both to determine the level of pain and tenderness (typically very

severe) and to check for hardness (called rigidity)). To confirm the diagnosis, the doctor may also order blood tests, abdominal x-rays, or CT scans*.

Treatment The treatment of peritonitis usually includes surgery and antibiotics*. Surgery repairs any ruptured organ that caused the inflammation, and also washes and drains the infectious fluids from the abdominal cavity. Antibiotics treat the bacterial infection. Most people who get peritonitis recover fully after treatment. Without prompt treatment, however, peritonitis can be fatal, so people who have symptoms of peritonitis should receive immediate medical attention.

Personality and Personality Disorders

The term “personality” refers collectively to all traits or characteristics that determine how people usually think and feel about themselves, relate to others, and react to the world around them. A personality disorder may be present when a person’s usual way of relating to others, thinking about the world, and reacting to events causes him or her to have problems that interfere with important areas of life, including relationships with other people.

Three Neighbors

Renée is a warmhearted, energetic woman who knows everyone in the neighborhood. She is always ready to lend a hand or a tool from her well-stocked garage. She loves to organize neighborhood activities. Renée hosts backyard cookouts, plans the yearly spring cleanup and planting of the neighborhood park, and serves mugs of hot chocolate when neighbors shovel snow from the walks in winter. People say that Renée is friendly, outgoing, and enthusiastic.

* **CT scans** or CAT scans are the shortened name for computerized axial tomography (to-MOG-ra-fee), which uses computers to view structures inside the body.

* **antibiotics** (an-tie-by-AH-tiks) are drugs that kill or slow the growth of bacteria.

* **psychologists** (sy-KOL-o-jists) are mental health professionals who treat mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth. Psychologists also study the brain, behavior, emotions, and learning.

Pradeep, her next-door neighbor, has a quiet nature and prefers to keep to himself. Pradeep is always on time and well organized. He keeps to a set routine every day. He walks his dog at 6:30 a.m., has coffee and reads the morning paper at 7:00, and then heads off to work at 7:30. At 5:30 every weekday evening, he pulls into his driveway again. Early on Saturdays he shops for groceries for himself and for Mrs. Dunn, a neighbor who cares for her elderly mother. People say that Pradeep is shy, reliable, and thoughtful.

Rudy, who lives at the end of the block, annoys everyone with his grouchy mood and self-centered attitude. He scowls at the neighborhood kids who walk past his house, warning them not to step on his lawn and scolding them to keep the noise down as they get off the school bus on his corner. People say Rudy is selfish, impatient, and bad tempered.

What Is Personality?

The brief descriptions of these three neighbors highlight some of the ways they are different from one another. They capture a few of the main characteristics of each person. These characteristics are what psychologists* (sy-KOL-o-jists) call personality traits.

Personality traits shape or label the ways people usually think and feel about themselves (such as insecure, self-centered, or humble), how they relate to others (such as suspicious, critical, or friendly), and how they react to events (such as accepting, encouraged, or short-tempered). Personality is a person's own special blend of these traits. Although each person has a unique personality, there are some groups of personality traits that produce common personality styles.

Some normal and common personality styles have been described with terms such as self-confident, dramatic, sensitive, leisurely, adventurous, solitary, and aggressive. Personality style influences how someone thinks, feels, and behaves in most situations. Well-adjusted people tend to be able to adapt to situations that call for a way of thinking or reacting that is different from their usual personality style.

Some individuals have a personality style that causes them to have serious problems in most areas of their lives. Such individuals are often set in their ways and inflexible. They tend to be unable to adjust to the demands of a situation that calls for a different way of responding. Such a problematic personality style may qualify as a personality disorder. There are 10 different personality disorders that mental health professionals may diagnose. A personality disorder has a harmful effect on most aspects of the person's life, leading to long-term difficulties in relationships with other people.

What Are Personality Disorders?

Personality, or personality style, describes someone's usual pattern of thinking, feeling, and behaving. Personality style is made up of a number of personality traits or characteristics. A personality disorder is a problematic personality style that negatively affects most areas of a person's life.

Personality disorders are generally diagnosed only in adults, but they reflect difficult personality styles that have been present since adolescence or young adulthood. Personality disorders can only be diagnosed in those under 18 years of age when the features have been present for a least one year and appear to be pervasive, persistent, and unlikely to be part of a particular developmental phase. Antisocial personality disorder cannot be diagnosed in someone under 18 years of age (similar symptoms in someone under age 18 labeled as conduct disorder).

Personality disorders can cause lifelong psychological problems and difficulty in relating to others.

There are 10 different personality disorders that mental health experts may diagnose. Each has its own set of characteristics, and each causes problems of a certain nature. The 10 personality disorders fall into three groups, called clusters, based on similarities in the personality traits of the disorders in each group.

One cluster includes personality disorders that feature unusual points of view or odd or eccentric behavior of various sorts. In this cluster are the following disorders:

- **Paranoid:** People with paranoid (PAIR-a-noyd) personality disorder distrust other people and may become overly suspicious, believing that other people's actions are always meant to harm them. Someone with paranoid personality disorder may find it difficult to form friendships and may be overly guarded, argumentative, or cold toward others.
- **Schizoid:** Individuals with schizoid (SKIT-zoyd) personality disorder are typically loners and do not often show emotion. Such people do not make friends easily and do not even care to spend time with their families. A person with this disorder usually chooses a solitary job and activities and has very little, if any, social life.
- **Schizotypal:** People who have schizotypal (skit-zo-TIE-pal) disorder can be fearful and distrustful of others. They are usually unable to make friends outside their own families. They also can have strange beliefs and superstitions. They tend to dress oddly or act in a peculiar way that does not seem to fit in with those around them.

Another cluster includes personality disorders that feature personality styles that are overly dramatic, overly emotional, overly reactive, or unpredictable. In this cluster are the following disorders:

- **Antisocial:** Individuals with antisocial personality disorder are typically in trouble with the law and have no respect for the rights of other people. Such people frequently lie and cheat, and they try to take advantage of others for their own profit or enjoyment. They can be irritable and often get into fights or even attack others. They also may be quite reckless and put themselves or others in danger, and they frequently do not understand or care that they have done something wrong or hurt another person.

- **Borderline:** Individuals with borderline personality disorder have difficulty being in relationships. People with this disorder fear that they will be abandoned, and the fear can become so strong that it makes them try to hurt or even kill themselves. Their relationships are often overly intense, and they may be extremely demanding of the time and attention of anyone who is close to them. They may abruptly end relationships and can quickly and drastically change their views about their friends if they think their friends have let them down.
- **Histrionic:** Histrionic (his-tree-AH-nik) personality disorder makes people want to be the center of attention. To draw attention, people with this disorder can be highly dramatic, often making up exaggerated stories about themselves. They flirt to attract people, and they may dress and act in a showy or overly sexy way. They may publicly exaggerate their emotions, perhaps through temper tantrums or fits of crying. People with this disorder can be too trusting of other people and too easily influenced by them.
- **Narcissistic:** People who have narcissistic (nar-se-SIS-tik) personality disorder are overly self-concerned. They often exaggerate their talents and accomplishments. They think of themselves as superior to others, and they tend to imagine themselves as very wealthy or powerful or beautiful or intelligent. Because they feel that they are unique, they also need other people to admire them and to treat them as special. They usually do not care much about the feelings or needs of other people. In fact, they often take advantage of other people to get what they want.

A third cluster includes difficult personalities that feature anxious, fearful, or extremely cautious behavior. In this cluster are the following disorders:

▶ The ancient Greek myth of Narcissus tells the story of a young man who fell in love with his own reflection. Entranced by his image reflected in the water, he threw himself into the pool and drowned. The term “narcissistic,” or conceited and self-centered, derives from this myth. (*Echo and Narcissus*, oil on canvas, by John William Waterhouse). ©Walker Art Gallery, National Museums Liverpool/The Bridgeman Art Library International.

- **Avoidant:** People with avoidant personality disorder fear criticism and disapproval, and for this reason they tend to steer clear of jobs or activities where they must work together with other people. They do not make new friends easily, and they typically are quiet and shy because they fear that other people will embarrass and make fun of them. They often feel out of place in social situations.
- **Dependent:** Individuals who have dependent personality disorder have a difficult time making even small, everyday decisions, for example, about what to wear. People with this disorder often rely on others to take care of them and make all their choices in life. When they are alone, they feel helpless, and they typically look around for someone to care for and support them.
- **Obsessive-Compulsive:** People with obsessive-compulsive (ob-SES-iv-kom-PUL-siv) personality disorder have a deep need for order and control. They pay close attention to rules, lists, and schedules, and they can be very hard on themselves when they do not meet their own high standards of perfection. Some may be incredibly neat and orderly, but others may tend to be pack rats, hoarding money or even saving worthless or unnecessary objects just in case they might need them one day. (Obsessive-compulsive personality disorder is not the same as obsessive-compulsive disorder.)

* **inborn** means present from birth, or inherited.

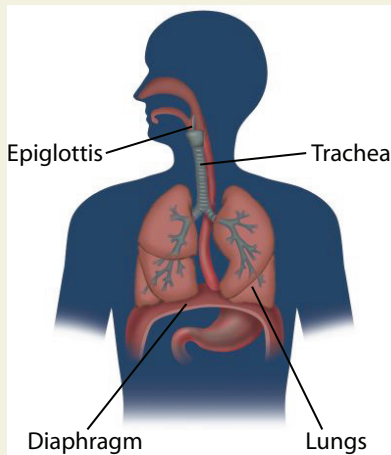

How Are Personality Disorders Diagnosed?

Personality disorders are difficult to diagnose because many, if not all, of these sorts of traits are also found in normal personalities. A personality disorder is diagnosed only when a personality trait, or a set of traits, is present to such an extreme that it causes an individual to have problems almost every day in almost all interactions.

Several of the personality disorders have traits that overlap, making it difficult to distinguish them. Evaluating personality styles can be subjective, and different people may have different ideas about each personality style. Even experts may not agree about whether a certain trait in an individual is extreme or simply a variation of normal. Also, when some people have problems as a result of trauma or other difficult events in their lives, they may appear to have problems affecting most parts of their lives. Generally, however, these problems are temporary. Researchers have continued to work on finding new ways of classifying and diagnosing personality disorders that will be more reliable and accurate.

What Causes Personality Disorders?

Because each personality disorder is different, there are separate theories about how each one may develop. There is still much to learn about the factors involved in each of these disorders. Most theories focus on a combination of inborn* traits and early experiences that influence and shape how someone begins to think, feel, and act. Research has shown that being

▲
Pertussis can cause quick short coughs due to spasms of the glottis as the air leaves the lungs. This makes the distinctive “whooping” sound associated with the disease. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

* **respiratory tract** includes the nose, mouth, throat, and lungs. It is the pathway through which air and gases are transported down into the lungs and back out of the body.

a victim of child abuse or neglect increases the risk of that individual's developing a personality disorder in adulthood.

How Are Personality Disorders Treated?

Because personality disorders can be so deeply ingrained and so long-standing, they are among the most difficult conditions to treat. People with personality disorders often resist change. Although some treatment methods can be effective, change may be slow. Treatment for personality disorders usually involves long-term talk therapy aimed at helping people understand how their particular pattern causes them trouble and then learning new ways to approach and solve specific problems. Medications are sometimes used to help treat problems that may be associated with the personality disorder, such as depression or anxiety.

Pertussis (Whooping Cough)

Pertussis (per-TUH-sis), also called whooping cough, is a bacterial infection of the respiratory tract that causes severe coughing.*

What Is Pertussis?

Pertussis is a respiratory disease found only in humans that is caused by the bacterium *Bordetella pertussis*. The first account of the infection was recorded in the sixteenth century, but it was not until the early twentieth century that *B. pertussis* was identified as the cause.

The infection causes a violent series of coughing fits usually ending in a high-pitched intake of breath that sounds like a “whoop,” giving the disease its other name, whooping cough. These coughing fits can be so severe that patients may vomit, lose consciousness, break a rib, or turn blue from lack of oxygen.

Do Many People Contract Pertussis?

Pertussis occurs throughout the world in all age groups, with at least 50 million cases and 300,000 deaths reported each year. In the early twentieth century, it was a common childhood disease and a leading cause of infant death. With the widespread use of a vaccine* starting in the mid-1940s, infection rates in children in the United States declined by 99 percent until the 1980s when they began to rise again. In 2005 there were 25,616 cases of whooping cough reported in the United States. However, experts at the Centers for Disease Control and Prevention assumed that only 5 to 10 percent of cases were being recognized and reported.

The increase in whooping cough cases is thought to be attributable to two main factors. Because previously deadly childhood diseases have been controlled by immunization, some parents feel less urgency to vaccinate their children. The vaccination* rate for children ages 19 to 35 months in the United States in 2006 was only 85 percent, and many states give liberal exemptions to parents who do not wish their children to be vaccinated. In addition, vaccination, or even having the pertussis, does not provide lifelong immunity*. Unless teens and adults have booster shots to renew their immunity, they can develop the disease and pass it on to children who have not been immunized or who are too young to have completed the required series of vaccinations.

How do People Get Pertussis?

Pertussis is an extremely contagious infection. The bacteria can spread through the air in drops of fluid released from the mouth and nose of a coughing or sneezing person who is infected. Inhaling those airborne drops can lead to disease, as can direct contact with the drops, such as touching them and transferring bacteria from a hand to the mouth or nose. Pertussis is different from most other contagious respiratory illnesses because children generally do not infect adults. Instead, adults usually have a mild case of the disease first and unknowingly pass the bacteria to their children, who develop a more serious form of the illness. Up to 90 percent of susceptible (non-immune) people living in the same house with someone who has whooping cough become infected as well.

Bordetella pertussis bacteria seen under a microscope. ©Peter Arnold/Alamy.

* **vaccine** (vak-SEEN) is a preparation of killed or weakened germs, or a part of a germ or product it produces, given to prevent or lessen the severity of the disease that can result if a person is exposed to the germ itself. Use of vaccines for this purpose is called immunization.

* **vaccination** (vak-sih-NAY-shun), also called immunization, is giving, usually by an injection, a preparation of killed or weakened germs, or a part of a germ or product it produces, to prevent or lessen the severity of the disease caused by that germ.

* **immunity** (ih-MYOON-uh-tee) is the condition of being protected against an infectious disease. Immunity often develops after a germ has entered the body. One type of immunity occurs when the body makes special protein molecules called antibodies to fight the disease-causing germ. The next time that germ enters the body, the antibodies quickly attack it, usually preventing the germ from causing disease.

- * **incubation** (ing-kyoo-BAY-shun) is the period of time between infection by a germ and when symptoms first appear. Depending on the germ, this period can be from hours to months.
- * **toxins** are substances that cause harm to the body.
- * **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.
- * **lymphocytes** (LIM-fo-sites) are white blood cells, which play a part in the body's immune system, particularly the production of antibodies and other substances to fight infection.
- * **antibodies** (AN-tih-bah-deez) are protein molecules produced by the body's immune system to help fight specific infections caused by microorganisms, such as bacteria and viruses.

What Happens When People Have Pertussis?

Following exposure to the bacteria, an incubation* period begins and generally lasts 7 to 10 days but occasionally stretches to as long as a month. During this time, the bacteria settle in the lungs where they produce toxins* that cause inflammation and make it difficult to clear out the mucus* that forms in the respiratory tract.

After the incubation period, there are three distinct stages of pertussis infection: the catarrhal (kah-TAR-hul), paroxysmal (PAIR-ok-siz-mul), and convalescent (kon-vuh-LEH-sent) stages. In the catarrhal stage, the first symptoms of the disease appear and often are mistaken for those of a common cold or the flu. They include runny nose, sneezing, mild fever, and a cough that gradually worsens. This stage typically lasts one to two weeks.

In the paroxysmal stage, the characteristic symptoms of whooping cough become obvious. The occasional cough develops into sudden violent attacks, or paroxysms, of rapid coughing ending with the whooping noise. Spasms of coughing are due to the buildup of mucus in the respiratory tract and occur frequently at night. Babies under six months of age may not have the strength to make the whooping sound that older children do, and the characteristic whoop may be absent in adults. It is difficult to breathe during these fits, and many patients turn blue from lack of oxygen. The severe coughing also can lead to vomiting and extreme tiredness. Between these bouts, patients look normal. The paroxysmal stage generally lasts from one to six weeks but can linger for up to 10 weeks.

In the final, convalescent stage, coughing slowly subsides over two to three weeks.

How Is Pertussis Diagnosed?

In some cases, the doctor can make the diagnosis of whooping cough based solely on hearing the cough. However, other infections (specifically with chlamydia pneumoniae) can produce a syndrome with a cough very much like the whoop in classic whooping cough, so careful examination of the offending bacteria is necessary. A definitive diagnosis requires an examination of fluid from the nose or throat. Samples of this fluid are checked for bacteria. Blood tests can look for the increased number of lymphocytes* commonly seen with this disease and for antibodies* to the bacterium. Experts suspect that many cases of adult whooping cough go undiagnosed.

How Is Pertussis Treated?

Doctors commonly prescribe a two-week course of antibiotics to keep the disease from spreading to other people. Antibiotics can also be prescribed for other people living in the same household with the patient to prevent these people from contracting the infection. However, antibiotics can do little to improve the illness if they are not prescribed until after the characteristic whooping cough symptoms appear. Cough medicines do not

ease the cough significantly, but using a cool-mist vaporizer and avoiding irritants such as smoke or fumes can help.

Children 18 months of age and younger who contract whooping cough need to be watched carefully because they may choke or stop breathing during a coughing spasm. Infants younger than six months of age usually are hospitalized and given oxygen and intravenous* fluids, and their mouth and nose may need to be suctioned to keep their breathing passages clear of mucus.

Whooping cough usually lasts between six weeks and two months, but it can take even longer for a patient to recover completely. The coughing spasms may continue on and off for several months.

Complications

Complications of whooping cough include bacterial infections such as ear infections or pneumonia*; dehydration* due to poor fluid intake and vomiting after coughing; broken blood vessels in the eyes, nose, and brain from forceful coughing; problems associated with lack of oxygen such as seizures* or, rarely, brain damage and, particularly among young infants, death. Adults may cough hard enough to break a rib.

Can Pertussis Be Prevented?

Vaccination (vak-sih-NAY-shun) is the best way to prevent pertussis in children. The vaccine for pertussis is given in a combined vaccine, including those for diphtheria* and tetanus*. The DTaP vaccine (made with acellular pertussis, which contains only parts of the pertussis bacterium and does not cause as many side effects as the vaccine made with the whole bacterium) is given in five doses: at two, four, and six months, between 15 and 18 months, and between four and six years of age. At least three doses are required to stimulate immunity, and four or all five doses are preferred.

Teens and adults who have completed the childhood series of vaccinations for pertussis can receive a booster shot to renew their immunity. This is especially important for people who work with young children and those who travel to parts of the world where pertussis is common. Adults can also reduce their chances of spreading the disease by practicing good hygiene, such as regularly washing their hands; not sharing food, silverware, or drinking glasses; and covering their mouth when they sneeze or cough.

Pervasive Developmental Disorders, Overview

Pervasive (per-VAY-siv) developmental disorders are various conditions in which the brain fails to develop normally, resulting in serious problems with communication, social interaction, and behavioral development.

What are Pervasive Developmental Disorders?

Pervasive developmental disorders (PDDs) are conditions that prevent children from developing normal communication and normal social abilities. Parents may note symptoms of PDDs as early as infancy, and signs of these conditions begin to appear in the earliest years of childhood. Some forms of PDD are milder and other forms are more severe. Most children with these conditions have very limited interests and activities, and some engage in unusual behavior, such as rocking, flapping their hands, or even behavior that causes self-injury.

PDDs include autism (AW-tizm), Asperger's (AS-per-gerz) syndrome, Rett's syndrome, and childhood disintegrative disorder. The term "pervasive developmental disorder" refers to the whole group of conditions, but it sometimes is used to refer to milder forms of autism. The word "pervasive" means that the condition affects all aspects of something. It is used to describe these conditions because these conditions affect all aspects of a person's life.

What Are the Types of Pervasive Developmental Disorders?

Autism is a brain disorder that affects children within the first three years of life. Sometimes these children appear to develop normally for a time in early infancy. The word "autism" comes from the Greek word meaning "self." It was chosen for the disorder due to the characteristic self-absorption of people who have this problem. Indeed, children with autism appear to live in a world of their own, often seeming not even to notice members of their own family around them. They seldom make eye contact with other people or share the interests of others.

Children with autism are socially isolated. Their social problems are made worse by the fact that their language skills usually do not develop normally. Some children may never learn to talk. Others may talk, but they use language inappropriately, perhaps simply repeating the words of others or reversing the meanings of “I” and “you.” They may persist in certain behavior, such as hand-flapping or body-rocking, for no apparent purpose.

Asperger’s syndrome is generally thought to be a milder form of pervasive developmental disorder, and it shares with autism the features of social isolation and lack of responsiveness to other people. The difference between Asperger’s syndrome and what is called “classic” autism is that a child with Asperger’s syndrome has the intellectual function and language skills of a normal child of the same age. In fact, children with this syndrome often have excellent vocabularies but do not use their language skills for appropriate conversation. Socially, they often lack good give-and-take interactions. They may memorize and then recite timetables or lists (for example, facts from almanacs) or have intense and highly focused interests (for example, on mechanical devices). A child with Asperger’s syndrome may know the names and numbers of every Amtrak engine or be an expert on the town’s fire stations. Also, their social interactions often revolve around their overly focused interests (“Which fire station is near your house?” may be a way to say “Hello”).

Rett’s syndrome is a severe genetic* developmental condition that affects only girls. At first, the child develops normally, usually during the first and second year. She may even begin to walk and talk. Then she starts to lose these skills and may show signs of a stiff-legged walk. Losing the ability to use words to communicate, she may also lose interest in making friends. A typical physical sign of Rett’s syndrome is that the child’s head stops growing at the normal rate.

Childhood disintegrative disorder has signs that are in many ways similar to those of autism. An important difference is that in childhood disintegrative disorder a child may develop normally for two to 10 years. Then the child may begin to lose some combination of social or communicative skills, bowel or bladder control, or motor skills (physical coordination).

What Causes Pervasive Developmental Disorders?

Rett’s syndrome is caused primarily by a faulty gene. The causes of most cases of autism, Asperger’s syndrome, and childhood disintegrative disorder were not known as of 2009. Because autism and Asperger’s syndrome tend to run in families, it was believed that they were at least partly caused by faulty genes. Some authorities have speculated that childhood disintegrative disorder may be the result of damage to the developing brain, but as of the early 2000s, it was not known how this damage occurs.

How Are Pervasive Developmental Disorders Diagnosed and Treated?

In order to diagnose a developmental disorder, a doctor or psychologist first asks the child’s parents questions about the child’s early development

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **hyperactivity** (hy-per-ak-TI-vi-tee) is overly active behavior, which makes it hard for a person to sit still.

and then carefully observes the child to identify possible signs of impairment in social activities, behavior, and communication.

There are no cures for pervasive developmental disorders, but many children improve over time. Early intervention is essential to developing social and language skills. Therefore, prompt and proper diagnosis is important, so that well-planned special training and education can begin. Children are taught how to overcome the effects of certain impairments and how to build on the skills they have. Medication may be used to treat special problems, such as seizures* or hyperactivity*. One key to treatment is the development of a communication system that can help children with their social skills. One communication system that has proven to be effective uses picture exchanges. For example, if a child wants a drink, he hands the teacher a picture (symbol) of a drink. Pictures are gradually added together (picture of orange + picture of drink) and paired with words. Often, words then begin to replace the picture exchange system.

Often, children with these disorders can learn to attend to their basic needs such as self-feeding, dressing, and personal care. Many individuals with milder developmental problems learn to use language effectively and learn to relate well enough to gain some degree of independence (have a job, live in a group home) as adults. Some people with autism and Asperger's syndrome make rapid developmental progress in school and eventually may live by themselves.

Many individuals with PDDs, however, never learn to relate socially, never develop a communication system to express their needs, and never rid themselves of unusual behaviors such as rocking or hand-flapping.

Phenylketonuria (PKU)

Phenylketonuria (fen-il-kee-to-NU-ree-a), or PKU, is an inherited metabolic disease in which the body cannot change one essential amino acid, phenylalanine (fen-il-AL-a-noon), into another needed amino acid, tyrosine (TY-ro-seen). Untreated, PKU often results in severe mental retardation, but if it is detected at birth and these children are put on a special diet, they can lead normal lives.

Children with a Strange Smell

In 1934 a mother with two children with mental retardation went to a Norwegian medical doctor, Asbjørn Følling (1888–1973). Følling became interested in the children's condition when the mother described the children's odd musty odor. The children, four and six years of age, had severe mental retardation. The younger child could not speak or walk and still wore diapers. The older child could speak only a few words and had problems walking.

Følling examined the children's urine and found no protein or glucose in it, but he was puzzled when their urine turned a deep green, instead of staying brownish, after he added the chemical compound ferric chloride to it. Følling expanded his study to other children whose urine produced the same kind of reaction and concluded that the unusual quality of the urine seemed to be connected with mental retardation. Thus, he discovered PKU, which he concluded was a genetic error in the children's metabolism*.

What Causes Phenylketonuria?

PKU is a disruption in normal metabolism. Normally, an enzyme* in the body called phenylalanine hydroxylase (fen-il-AL-a-noon hy-DROK-si-lase) changes the essential amino acids* phenylalanine to another needed amino acid called tyrosine (TY-ro-seen). If phenylalanine hydroxylase is missing, as it is in PKU, phenylalanine builds up in the blood and passes out of the body in urine.

▲ A package of artificial sweetener alerts people with PKU that the product contains phenylalanine. ©Leonard Lessin/ Peter Arnold, Inc.

- * **metabolism** (meh-TAB-o-liz-um) is the process in the body that converts foods into the energy necessary for body functions.
- * **enzyme** (EN-zime) is a protein that helps speed up a chemical reaction in cells or organisms.
- * **amino acids** (α-MEE-no acids) are the chief building blocks of proteins. In humans, certain amino acids are required to sustain life.

* **eczema** (EG-ze-mah) an inflammatory skin condition characterized by redness, itchiness, and oozing blisters that become crusty and hard.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **hyperactivity** (hy-per-ak-TI-vi-tee) is overly active behavior, which makes it hard for a person to sit still.

* **formula** is a prepared, nutritious drink or a dry drink mix designed specifically for infants.

PKU affects on average 1 out of every 10,000 to 15,000 babies in the United States. Because PKU is an inherited disorder, there is considerable variation among different ethnic and racial groups. The condition is found less often in people of African descent (1 in every 50,000 babies) and in Ashkenazic Jews.

What Are the Signs and Symptoms of Phenylketonuria?

Infants with PKU usually have lighter skin, hair, and eyes than the rest of their families, but symptoms do not appear until they are about three to six months old. These may include the following:

- An eczema*-like rash
- Seizures*
- Hyperactivity*
- An unpleasant musty or mousy body odor (caused by phenylacetic acid in the urine and sweat)
- Intellectual disability

How Is Phenylketonuria Diagnosed?

Almost all babies born in hospitals in the United States are screened for PKU within 48 hours of birth with a blood test that measures their levels of phenylalanine. In families with a history of PKU, the disease can usually be diagnosed in the fetus during pregnancy. A pregnant woman who has untreated PKU herself has a much greater chance of having a baby with (often severe) birth defects.

Living with Phenylketonuria

Jennifer is a happy 12-year-old with fair skin, blue eyes, and a very normal life except for her diet. Jennifer has PKU, which was diagnosed at birth through hospital screening. She cannot go out for pizza, drink diet sodas, or eat many of the common foods that most people take for granted.

Infants with PKU must begin treatment within days of being born to prevent their becoming mentally retarded. They must eat a special diet that restricts their intake of phenylalanine and provides the tyrosine that the body cannot make. Babies drink special formula* that is low in phenylalanine. People with PKU cannot have high-protein foods such as meat, poultry, fish, milk, eggs, and cheese or products containing the artificial sweetener aspartame (also known by the brand name NutraSweet). They can eat low-protein foods such as fruits, vegetables, and certain cereals.

Not adhering to the diet may cause serious problems such as a drop in IQ and problems with learning and behavior. Experts are not sure whether and at what age it is safe to stop treatment. Most recommend that people with PKU stay on the special diet for life.

Once destined to become mentally retarded, people like Jennifer can avoid mental retardation and lead independent, vibrant lives. However,

left undiagnosed and untreated, those with PKU generally develop severe mental retardation and are unable to live independent lives. PKU, therefore, is an example of an inherited (genetic) condition whose damage can be prevented by early detection and adherence to a low-protein, low phenylalanine PKU diet from birth throughout life.

Phlebitis and Venous Thrombosis

Phlebitis (fle-BY-tis) is a general term that refers to the inflammation of a vein. Phlebitis is usually treatable and not dangerous by itself. However, if the inflammation leads to or is accompanied by the formation of a blood clot, or thrombus, the condition is known as venous thrombosis, or thrombophlebitis, and is a more serious health problem. With venous thrombosis, the blood clot that has formed may block or partially block the flow of blood in the vein. If the clot or a portion of the clot breaks free of the vein, it is then called an embolus. The embolus then travels in the bloodstream away from the site where it was formed and may lodge in another part of the body, such as the pulmonary artery (leading into the lungs) or one of its branches. This is a life-threatening condition known as pulmonary embolism (PUL-mo-na-ree EM-bo-lizm).*

Terry's Tale

Terry decided to visit her doctor after she experienced slight pain in an area of her lower left leg and then discovered a streak of redness in the area. The

* **blood clot** is a thickening of the blood into a jelly-like substance that helps stop bleeding. Clotting of the blood within a blood vessel can lead to blockage of blood flow.

* **pulmonary** refers to the lungs.

* **embolism** is a blockage in a blood vessel caused by a blood clot, air bubble, fatty tissue, or other substance that traveled through the bloodstream from another part of the body.

* **hormone** is a chemical substance that is produced by a gland and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

* **menopause** (MEN-o-pawz) is the end of menstruation.

area was also swollen. The doctor examined the sore spot and then asked her if the pain was worse early in the morning when she swung her leg over the side of the bed. She said it was. He also asked if she spent much time sitting. She said that as a receptionist at a busy office, she might go hours without getting up from her desk. The doctor considered all of the information and told Terry that she had superficial phlebitis. He explained that if she followed his recommendations, she would be back to normal in a week or two. He also told her that he was glad she came into the office, because superficial phlebitis can sometimes lead to more serious health problems.

What Are Phlebitis and Venous Thrombosis?

The heart beats about 100,000 times per day, driving blood through the arteries of the body and back to the heart through the veins. Sometimes, however, the blood in veins does not flow well. It moves slowly or pools in the veins, like water forming a puddle. The pooling of blood causes the walls of the vein to stretch and become inflamed, and it sometimes causes clotting. Clots are gelled, or thickened, clumps blood that usually have a beneficial function, such as when they help to seal a wound and stop its bleeding. The inflammation of a vein is called phlebitis, and when the affected vein is close to the body's surface, it is known as superficial phlebitis. Superficial phlebitis is often painful but rarely serious. Deep vein thrombosis is the formation of a blood clot in a deep vein. It affects the large blood vessels deep in the leg. Deep vein thrombosis is potentially life-threatening. An embolus can travel in the bloodstream and enter the heart. It can then block the pulmonary* artery, the large artery that carries blood from the heart into the lungs, causing a pulmonary embolism*. This may cause death if not treated rapidly and effectively.

What Causes Phlebitis and Venous Thrombosis?

Phlebitis and venous thrombosis can occur for many reasons. A sedentary lifestyle is a risk factor. Prolonged inactivity or sitting for many hours on long car or plane rides causes pooling of blood in the legs and may cause a vein to become irritated and inflamed. An injury to the legs, a tumor, and some surgeries can inflame or otherwise damage veins and result in a slowed blood flow. People who are confined to bed, either after an operative or in general, are prone to pooling of blood in the leg veins, and some medical conditions increase the clotting potential of blood. Pregnant women are also at greater than normal risk, as are women who take estrogen (ES-trojen), a primary female sex hormone* in the form of oral contraceptives or as part of hormone replacement therapy during menopause*. Smoking is another major risk factor, along with having varicose veins.

What Are the Symptoms of Phlebitis and Venous Thrombosis?

Phlebitis usually occurs in the legs. Venous thrombosis typically affects the lower legs, the pelvis, or the thigh. However, both phlebitis and venous thrombosis can occur elsewhere in the body. The symptoms for superficial

phlebitis and for deep vein thrombosis overlap somewhat. The symptoms of superficial phlebitis include swelling, a red streak in the affected area, and pain that may become worse when walking or when first getting out of bed. Symptoms of deep vein thrombosis include swelling of the leg or arm, which may happen suddenly; leg pain that may develop suddenly or worsen when one stands up or walks; a warm feeling at the affected site that sometimes extends over larger areas; and an enlargement of superficial veins in the area, which may appear reddish-blue.

In the case of pulmonary embolism, symptoms can include heavy sweating; rapid breathing and rapid heart rate; coughing often accompanied by sharp chest pains; back pain; shortness of breath, and fainting or lightheadedness.

How Are Phlebitis and Venous Thrombosis Diagnosed?

Doctors can often diagnose phlebitis simply by asking the patient a few questions and conducting a physical examination. For venous thrombosis, doctors use tests to detect the presence of clots in the veins. One test, venography, is a way of viewing veins that entails injecting dye into a leg vein and taking an x-ray of the veins, a venogram. Doctors can also use ultrasound* to generate an image of the leg that is vaguely similar to an x-ray image. Other techniques used to diagnose venous thrombosis include magnetic resonance imaging* (MRI) and computerized tomography* (CT), which generate cross-sectional images of organs, structures, and/or blood vessels, and clots.

According to the Coalition to Prevent Deep Vein Thrombosis, deep vein thrombosis affects nearly 2 million Americans per year, and up to 600,000 of them are hospitalized annually. Of those who develop a pulmonary embolism, up to 300,000 die per year.

How Are Phlebitis and Venous Thrombosis Treated?

The danger of phlebitis is that it can lead to venous thrombosis. If clots are absent, doctors treat patients with heat packs and anti-inflammatory drugs, such as ibuprofen*, and have the person raise the affected leg to encourage better blood flow. If clots are present, doctors may prescribe blood-thinning drugs such as heparin or warfarin to dissolve the clots or to prevent the blood from clotting as easily. Such medication may prevent a clot from growing larger and may lower the likelihood that the clot will break free and cause an embolism. Clot-dissolving drugs may be injected into the affected vein. In rare cases, a doctor may recommend that a vein be opened and the clot surgically removed.

For people at high risk for developing clots, doctors often recommend preventive measures such as the use of drugs that slow or impede the clotting of blood and special compression stockings that help to keep blood from pooling in the deep veins of the legs.

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **magnetic resonance imaging** or MRI, uses magnetic waves, instead of x-rays, to scan the body and produce detailed pictures of the body's structures.

* **computerized tomography** (kom-PYOO-ter-ized toe-MAH-gruh-fee) or CT, also called computerized axial tomography (CAT), is a technique in which a machine takes many x-rays of the body to create a three-dimensional picture.

* **ibuprofen** (eye-bew-PRO-fin) is a nonsteroidal anti-inflammatory drug (NISAD) used to reduce fever and relieve pain or inflammation.

* **obesity** (o-BEE-si-tee) is an excess of body fat. People are considered obese if they weigh more than 30 percent above what is healthy for their height.

* **intestines** are the muscular tubes that food passes through during digestion after it exits the stomach.

Can Superficial Phlebitis and Thrombosis Be Prevented?

The best prevention is to stay active. Smoking and obesity* increase the risk of superficial phlebitis and thrombosis, so avoiding tobacco and maintaining a healthy weight are both good preventative measures.

Pinworm Infestation (Enterobiasis)

In cases of pinworm infestation, or enterobiasis (en-tuh-roh-BY-uh-sis), a species of small worm lives and reproduces in the human intestines. The infestation causes anal itching. Children often inadvertently spread it to schoolmates or family members.*

What Is Pinworm Infestation?

Human pinworms, *Enterobius vermicularis* (*en-tuh-ROH-be-us ver-MIH-kyoo-lar-is*), are a species of roundworm* that are usually less than one centimeter in length and resemble light-colored pieces of thread. People become infested when they swallow tiny pinworm eggs, usually after touching something that was handled by a person who is already infected. The eggs travel to the small intestine* and hatch into larvae*. Pinworm larvae then travel from the small intestine to the large intestine, where they attach to the intestinal wall. About two to six weeks after a person swallows the eggs, adult female pinworms migrate from the large intestine to the rectum, where they exit from the anus to lay numerous eggs on nearby skin. The adult pinworms then return to the large intestine, where they usually die, but the new eggs remain on the skin, where they can survive for two to three weeks.

Is Pinworm Infestation Contagious?

Pinworm infestation is highly contagious. The egg-laying causes itching, which prompts the infested person to scratch the area. By doing so, however, the person can inadvertently get some of the microscopic eggs on the fingers. If the person then touches the mouth, he or she can transfer the eggs to the lips. At that point, the individual can swallow the eggs, starting the life cycle again. In addition, the infected person may transfer the eggs to clothing, bedding, towels, toilets, and other objects in the environment. When another person picks up the clothes, makes the bed, or handles anything else that is contaminated, that person may get the eggs on his or her fingers. By touching the mouth, this person, too, can swallow the eggs to start a new infestation.

How Common Is Pinworm Infestation?

According to the Centers for Disease Control and Prevention, about 40 million people in the United States have pinworms, making it the most common worm infestation in the country. Young children have the greatest chance of becoming infested, because they often put their hands in their mouths. The parasites spread easily in preschools, schools, and childcare settings. Pinworms are also common in people living in crowded conditions. When one person in a household becomes infested, other family members often wind up with the worms as well.

What Are the Signs and Symptoms of Infestation?

Many people with pinworms have no symptoms at all. In others, symptoms are generally mild. The most common symptom is itching around the anus. The sensation becomes strongest at night, when the female worms are active on the skin. This condition may lead to restless sleep or even trouble sleeping. Children with infestations may become irritable from lack of peaceful sleep, and they occasionally lose their appetites. If a

▲ Pinworms are about one-third of an inch long and live in the human intestine. Female pinworms deposit eggs on the skin surrounding a person's anus. The eggs can then be spread to other family members through contact with sheets or clothing. *Custom Medical Stock Photo, Inc. Reproduced by permission.*

- * **roundworm** is one of several types of cylinder-shaped worms that live in people. Roundworms are also known as nematodes (NEE-muh-todes).
- * **small intestine** is the part of the intestines—the system of muscular tubes that food passes through during digestion—that directly receives the food when it passes through the stomach.
- * **larvae** (LAR-vee) are the immature forms of an insect or worm that hatches from an egg.

* **vagina** (vah-JY-nah) is the canal, or passageway, in a woman that leads from the uterus to the outside of the body.

child constantly scratches around the anus, the skin there can become raw and infected. In girls, adult worms sometimes enter the vagina* instead of returning to the anus, which may cause vaginal itching.

How Is Pinworm Infestation Diagnosed?

In some cases, a parent can see the worms at night around the anus or in the bed sheets, but usually a doctor makes the diagnosis by using the tape test. The doctor (or a parent) places adhesive tape on the skin in the anal area, usually in the morning since egg laying occurs overnight. This is done before the person takes a shower or has a bowel movement, because both activities can dislodge the eggs and worms. When the tape is removed and viewed under a microscope at a medical office, medical professionals can see eggs or worms stuck to the tape. If the doctor sees no eggs or worms but still suspects pinworms, he or she may want to repeat the test one or more times. The doctor might also examine scrapings from under the fingernails, where pinworm eggs can become stuck after the patient scratches the anal area.

What Is the Treatment?

Once an infestation is confirmed, the doctor generally prescribes medication to get rid of the worms. The patient takes the first dose, often in the form of a chewable pill, right away and usually a second dose two weeks later. Because pinworms can be highly contagious, doctors sometimes recommend that all people who live in the same house with the infested person take the medicine as well. Reinfection is common, and a patient may have to repeat the treatment.

Are There Complications of Pinworm Infestation?

Complications of pinworm infestation are uncommon and generally minor, such as the development of a bacterial infection that results from scratching the anal area.

What Are the Preventive Measures?

Practicing good personal hygiene is the best way to avoid infestation. Individuals should wash their hands after using the bathroom and before eating and should avoid scratching the anal area and biting the nails. To limit the spread of pinworms, people with the parasites are advised to change into clean underwear every day and frequently change their night-clothes. Taking a bath or shower after waking up in the morning can help get rid of pinworm eggs, and keeping fingernails trimmed short can prevent eggs from lodging there and later being deposited somewhere else. Doctors advise that after each course of treatment for pinworms, sheets and sleeping clothes be washed, to lower the risk of reinfestation.

Plague

Plague (PLAYG) is a potentially serious bacterial infection that is spread to humans by infected rodents and their fleas.

Plague is a serious infectious disease transmitted by the bites of rat fleas. There are three major forms of plague: bubonic, pneumonic, and septicemic. Fleas carry the bacterium *Yersinia pestis* (A). When a flea bites an infected rodent (B), it becomes a vector and then passes the plague bacteria on when it bites a human (C). *Illustration by Electronic Illustrators Group. Reproduced by permission.*

Bioweapons

Plague bacteria are considered to be one of several deadly organisms that could be used in biological warfare. It is feared that the bacteria could be aerosolized (AIR-o-suh-lized), or processed into tiny particles that could be released into the air.

A plague vaccine was available to the general public but was discontinued by its manufacturers in 1999. Even if the vaccine were made available in the early 2000s, it would not be able to prevent the pneumonic form of plague, which is resistant to treatment as well.

The plague has been used as a weapon before. In 1346 the Tartar army tried to capture the port city of Caffa on the Black Sea in the Crimea. The army catapulted the bodies of plague victims over the city wall; an epidemic of plague ensued and the city surrendered.

* **lymphatic system** (lim-FAH-tik) is a system that contains lymph nodes and a network of channels that carry fluid and cells of the immune system through the body.

What Is Plague?

Plague is a disease caused by the bacterium *Yersinia pestis* (yer-SIN-e-uh PES-tis). It has been in existence for at least 2,000 years and in the 21st century is still found in Africa, Asia, South America, and North America.

There are three types of plague. Pneumonic (nu-MOH-nik) involves the lungs; bubonic (byoo-BAH-nik), the most common form, involves the body's lymphatic system*; and septicemic (sep-tih-SEE-mik) involves the bloodstream and spreads throughout the body. Septicemic plague can occur by itself or along with pneumonic or bubonic plague.

Wild rats and fleas often are associated with plague because they were the primary carriers of the disease during the most devastating outbreaks. Other types of rodents (and their fleas) can carry plague as well, such as prairie dogs, chipmunks, wood rats, and ground squirrels.

How Common Is Plague?

The World Health Organization (WHO) reports 1,000 to 3,000 cases of plague worldwide annually. In the United States, 10 to 20 cases are reported every year, usually in rural areas in the southwestern states, particularly New Mexico and Arizona. The last outbreak in the United States was in 1924 and 1925 in Los Angeles. Plague has not occurred in Europe since World War II.

How Is Plague Spread?

Plague is transmitted in several ways. The most common of these is from animal to human through the bite of infected fleas. Fleas living on infected animals ingest the animals' blood and the bacteria in it. They then spread the disease to other animals and humans through their bite, which can

THE BLACK DEATH

The first pandemic (a worldwide outbreak of disease) of plague chronicled by historians occurred between 542 and 546 C.E., during the reign of the emperor Justinian the Great (482/483–565). The plague followed trade routes to other countries, and the Roman army itself carried plague during war campaigns throughout Asia Minor, Western Europe, Italy, and Africa. Outbreaks continued for the next 300 years before the disease finally subsided.

An equally devastating second pandemic erupted nearly 800 years later, as plague once again traveled across trade routes and infected populations throughout Europe. Known as the Black Death, this fourteenth-century outbreak killed more than one-third of Europe's population.

During these two pandemics, the cause of plague (rats and, more importantly, their infected fleas) was unknown. The spread of disease went unexplained, and many people feared it was a punishment sent by God.

result in the bubonic or septicemic form of plague. Bacteria also can enter the body through an open cut or wound after direct contact with infected people or animals.

In addition, humans and animals (such as cats) with plague can spread the disease by releasing tiny drops containing the bacteria from their mouth and nose, which happens in humans when a person coughs, sneezes, or talks. As these drops enter the air, the smaller ones can float for up to one hour, whereas the larger drops settle on nearby objects. A sneeze or cough can send thousands of infected particles into the air. If inhaled, these drops can cause the pneumonic form of plague. This way of spreading the disease requires relatively close contact with an infected person or animal.

What Are the Signs and Symptoms of Plague?

Symptoms typically appear two to six days after infection. Sudden fever, chills, and headache, followed by swollen, painful, hot-to-the-touch lymph nodes*, known as buboes (BYOO-boze), are the hallmarks of bubonic plague. Lymph nodes in the groin are most commonly affected. If left untreated, the infection eventually spreads to the bloodstream, causing sepsis*, pneumonia*, or meningitis*.

In septicemic plague, the bacteria multiply in the blood, causing symptoms such as fever, chills, weakness, abdominal* pain, nausea (NAW-zee-uh), and vomiting. As the infection progresses, the blood pressure drops and the blood is unable to clot* normally. The skin looks bruised from uncontrolled bleeding, which is why historically the disease was called the Black Death.

The pneumonic form of plague takes hold rapidly, with symptoms such as fever, cough, chills, chest pain, bloody sputum*, and headache. It can progress to respiratory failure* and shock* within two to four days.

How Do Doctors Diagnose and Treat Plague?

Determining whether a person was in close contact with animals that can carry plague or has traveled to an area where the plague is known to occur can be key in making the diagnosis. Bubonic plague can be identified by the characteristic swollen lymph nodes. A blood culture* and a lymph node biopsy* may be done, as well as a culture of a sputum sample to look for *Yersinia pestis* bacteria.

Getting timely treatment for plague is critical. Without treatment, bubonic plague is fatal in 50 to 60 percent of cases. Septicemic plague and pneumonic plague are fatal in almost all cases if not treated within 24 to 48 hours.

Suspected plague patients are isolated and hospitalized, where they are treated with antibiotics, intravenous* (IV) fluids, and oxygen. Anyone who has come in close contact with someone diagnosed with plague is treated with antibiotics to prevent them from contracting the infection. All suspected cases of plague must be reported to state and local health departments. Treatment and full recovery from plague can take several

* **lymph nodes** (LIMF) are small, bean-shaped masses of tissue containing immune system cells that fight harmful microorganisms. Lymph nodes may swell during infections.

* **sepsis** is a potentially serious spreading of infection, usually bacterial, through the bloodstream and body.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

* **meningitis** (meh-nin-JY-tis) is an inflammation of the meninges, the membranes that surround the brain and the spinal cord. Meningitis is most often caused by infection with a virus or a bacterium.

* **abdominal** (ab-DAH-mih-nul) refers to the area of the body below the ribs and above the hips that contains the stomach, intestines, and other organs.

* **clot** is the process by which the body forms a thickened mass of blood cells and protein to stop bleeding.

* **sputum** (SPYOO-tum) is a substance that contains mucus and other matter coughed out from the lungs, bronchi, and trachea.

* **respiratory failure** is a condition in which breathing and oxygen delivery to the body are dangerously altered. This may result from infection, nerve or muscle damage, poisoning, or other causes.

* **shock** is a serious condition in which blood pressure is very low and not enough blood flows to the body's organs and tissues. Untreated, shock may result in death.

- * **culture** (KUL-chur) is a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.
- * **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.
- * **intravenous** (in-tra-VEE-nus) or IV, means within or through a vein. For example, medications, fluid, or other substances can be given through a needle or soft tube inserted through the skin's surface directly into a vein.
- * **inflammation** (in-fla-MAY-shun) is the body's reaction to irritation, infection, or injury that often involves swelling, pain, redness, and warmth.
- * **membrane** (MEM-brain) is a thin layer of tissue that covers a surface, lines a cavity, or divides a space or organ.

weeks or longer. Complications of plague include damage to vital organs due to lack of blood flow associated with sepsis, brain damage from lack of oxygen, lung damage, and death.

How Can People Prevent Becoming Infected?

Some people are at a higher risk for developing plague than others, such as lab technicians who handle the bacterium or blood samples taken from people who are infected, people who work in areas where plague occurs, and people who work with animals that carry the disease.

A person's risk of developing plague can be lowered by limiting contact with wild animals that might carry the disease, removing potential food sources and shelter for rodents near the home, treating pet dogs and cats weekly for fleas, and using insecticides to kill fleas around the home during outbreaks of plague in wild animals. Rat management in rural and urban areas also can minimize the potential for disease.

Antibiotics sometimes are prescribed to prevent infection if a person has been exposed to plague.

Pleurisy

Pleurisy (PLOOR-i-see) is an inflammation of the membrane* that covers the lungs and lines the chest cavity. The lining is called the pleura (PLOOR-a).*

What Is Pleurisy?

In pleurisy, the membrane covering the lungs and lining the chest cavity becomes inflamed, and excess fluids may build up in the space. When people who have pleurisy breathe in or cough, the inflammation causes pain, which is a result of friction from the inflamed pleura. The pain is a sharp, stabbing pain that begins suddenly. There are a number of different causes of pleurisy.

What Are the Symptoms of Pleurisy?

A sharp, knifelike pain when breathing in or coughing is the primary symptom of pleurisy. People who have pleurisy tend to breathe more frequently with smaller breaths to avoid pain. Ultimately, these small breaths can lead to pneumonia*.

What Causes Pleurisy?

Pleurisy may result from a number of causes. It can develop from infections, including viral, bacterial, mycobacterial, fungal, or parasitic. It also can be a result of traumatic injury from an accident or from chest surgery or radiation treatments. Sometimes, pleurisy is a complication of another disease, such as lung cancer*, sickle-cell anemia*, or connective tissue diseases such as rheumatoid arthritis*, or systemic lupus erythematosus*. Blood clots that travel to the lung (pulmonary emboli) can result in pleurisy, as can exposure to toxic substances such as asbestos. The result in all of these cases is inflammation of the pleura that causes pain when a person coughs or breathes, as well as a fluid accumulation (called a pleural effusion) between the layers of tissue that line the lung and the chest wall.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

* **cancer** is any tumorous (TOO-mor-us) condition the natural (untreated) course of which is often fatal.

* **sickle-cell anemia** also called sickle-cell disease, is a hereditary condition in which the red blood cells, which are usually round, take on an abnormal crescent shape and have a decreased ability to carry oxygen throughout the body.

* **rheumatoid arthritis** (ROO-mah-toyd ar-THRY-tis) is a chronic disease characterized by painful swelling, stiffness, and deformity of the joints.

* **systemic lupus erythematosus** (sis-TEM-ik LOO-pus eri-them-a-TO-sus), sometimes just called lupus, is a chronic inflammatory disease that can affect the skin, joints, kidneys, nervous system, membranes lining body cavities, and other organs.

BLUE ROSES

In the play *The Glass Menagerie* by Tennessee Williams (1911–1983), Laura tells her mother how a boy in her high school called her “Blue Roses.”

“Why did he call you such a name as that?” asks her mother, Amanda.

Laura explains that when she came back to school after she had an attack of “pleurosis,” the young man, Jim, asked her what had been the matter with her. She told him she had had pleurosis, and he mistook the word for “blue roses.” Thereafter, whenever Jim saw Laura, he would greet her with “Hello, Blue Roses!”

Unfortunately, it is easier to contract pleurisy than it is to find blue roses. In the play, though, Laura does recover from her pleurosis. Her problems are of a different nature. The title of the play refers to Laura’s collection of glass animals.

How Is Pleurisy Diagnosed and Treated?

Physicians may diagnose pleurisy when they hear a “friction rub” when the patient breathes deeply. Doctors can use several different laboratory tests to help diagnose the condition. Fluid from pleural effusion can be removed with a needle and sent to the laboratory for analysis. Medicines can be given to help with the pain and inflammation. However, the underlying cause of pleurisy, such as bacterial pneumonia or tuberculosis (too-ber-ku-LO-sis), must be treated. If the pleural effusion is large, the fluid may need to be drained via a needle, or a chest tube may need to be inserted in order to evacuate (remove) the abnormal accumulation of fluid and improve breathing.

Pneumoconiosis

Pneumoconiosis (noo-mo-ko-nee-O-sis) refers to a group of diseases of the lungs caused by long-term breathing of dust, especially certain mineral dusts. Forms of pneumoconiosis include black lung disease (coal worker's pneumoconiosis), silicosis, and asbestosis. The disease typically results from working in a mine for many years, but factory work and other occupations can expose people to the ill effects of breathing dusts. The term “pneumoconiosis” comes from the Greek pneumon, meaning lung, and konis, meaning dust.

THE WAR AGAINST BLACK LUNG

The prevalence of black lung disease did not begin to decrease until it became clear that the cause was excessively high levels of coal dust in mines. Largely due to the efforts of coal miners' unions, occupational safety conditions improved.

In 1969 the Mine Health and Safety Act set standards in the United States for maximum allowable levels of coal dust in mines. The act also provided compensation for miners who developed black lung disease. Death rates from pneumoconiosis declined after the act was passed.

* **emphysema** (em-fuh-ZEE-mah) is a lung disease in which the tiny air sacs in the lungs become permanently damaged and are unable to maintain the normal exchange of oxygen and other respiratory gases with the blood, often causing breathing difficulty.

What Causes Pneumoconiosis?

Only microscopic-size dust particles, about 1/5,000 of an inch across or smaller, are able to reach the tiniest air sacs (the alveoli) in the lungs. Once there, they cannot be removed. They accumulate to cause a scarring and thickening of the lungs called fibrosis (fy-BRO-sis). Eventually, the lungs begin to lose their ability to supply oxygen to the body.

Black lung disease is caused by breathing coal dust, usually in mines. Silicosis results from inhaling silica dust from sand and rock, primarily in mines, quarries, and in occupations such as sandblasting. Asbestosis comes from breathing tiny asbestos fibers in mining, building construction, and other industries. Less commonly, other kinds of dust are continuously inhaled in work-related situations and cause pneumoconiosis. Inhalation of large volumes of dust also caused lung damage to rescue workers after the destruction of the World Trade Center Towers on September 11, 2001, a condition sometimes referred to as Ground Zero Lung.

What Happens When People Have Pneumoconiosis?

Symptoms Because pneumoconiosis usually takes 20 or 30 years to develop, workers often do not notice symptoms until they are over 50. The main symptoms are coughing and difficulty in breathing, which gradually increases. Complications include emphysema* (em-fe-SEE-ma) and increased risk of tuberculosis. Asbestosis patients are more likely to develop lung cancer, especially if they smoke cigarettes. Damaged lungs make the heart work harder, and heart problems can accompany severe cases of pneumoconiosis.

Diagnosis Diagnosis is made by physical examination and through a medical history that tells the doctor which dusts patients have been exposed to. The doctor may also take chest x-rays and pulmonary (lung) function tests.

* **oxygen** (OK-si-jen) is an odorless, colorless gas essential for the human body. It is taken in through the lungs and delivered to the body by the bloodstream.

Treatment There is no cure for pneumoconiosis, because the dust cannot be removed from the lungs. Even if it could, the damage done to the lungs from years of inflammatory reaction to the dust could not be undone. Except in a mild form called simple pneumoconiosis, the disease is progressively disabling. The only treatment is to avoid smoking and further exposure to dust and to treat complications.

Prevention Pneumoconiosis can be prevented by enforcing maximum allowable dust levels in mines and at other work sites and by using protective masks. Regular medical examinations, including chest x-rays for people at risk, can detect pneumoconiosis during its earlier stages, before it becomes disabling.

Pneumonia

Pneumonia (noo-MOH-nyah) is an inflammation of the lungs. It is a common illness usually caused by infection with a bacterium, virus, or fungus. It is often mild, especially in young people. Pneumonia may also cause serious illness, especially in people who are old or already have health problems, and it remains a major cause of death.

What Is Pneumonia?

When a person breathes, air enters the lungs and travels through millions of tiny sacs. In these sacs, known as alveoli (al-VEE-oh-lye), oxygen* is transferred to the blood, which carries it to all parts of the body.

Clear, healthy lungs (left); inflamed lung tissue of pneumonia (right). *Custom Medical Stock Photo, Inc. Reproduced by permission.*

When someone has pneumonia, the lung tissue becomes inflamed and the alveoli fill with mucus* and other debris, making it difficult for oxygen to be transferred. Breathing is difficult and the lungs have to work harder to take in oxygen and to exhale carbon dioxide, a dangerous waste product in the blood. Eventually, the cells of the body may not get enough oxygen, and carbon dioxide may build up in the body.

Normally, the body has ways to fight off lung infection. These include the following:

- Coughing deeply, which expels germs and keeps germ-trapping mucus from building up in the lungs
- Swallowing, causing the trachea (TRAY-kee-ah; or windpipe) to close by the vocal cords and the epiglottis (ep-i-GLOT-is). The closing of the trachea and the gag reflex prevent people from inhaling food, vomit, or stomach acid into their lungs.
- Upward waving cilia (SILL-ee-ah), small hairs that line the inside of the windpipe, filtering particles out of the air before they reach the lungs
- Good functioning of the immune system, a complex set of organs, chemicals, and white blood cells that attack germs that enter the body

These defenses usually prevent pneumonia, but sometimes a person's defenses may be weakened by illness, age, or other factors. The defenses also may be overwhelmed by a particularly heavy or virulent* dose of germs.

What Are Some Different Types of Pneumonia?

More than 75 kinds of germs can cause pneumonia. Bacteria and viruses are the most common causes. Fungi and parasites are less common causes. Chemicals, drugs, and radiation can also cause lung inflammation.

* **mucus** (MYOO-kus) is a thick, slippery substance that lines the insides of many body parts.

* **virulent** comes from the Latin word for poisonous, and describes a microbe that is especially well suited to countering the immune system.

* **respiratory tract** includes the nose, mouth, throat, and lungs. It is the pathway through which air and gases are transported down into the lungs and back out of the body.

* **intestines** are the muscular tubes that food passes through during digestion after it exits the stomach.

* **bladder** (BLAD-er) is the sac that stores urine produced by the kidneys prior to discharge from the body.

* **croup** (KROOP) is an infection involving the trachea (windpipe) and larynx (voice box) that typically occurs in childhood. It causes inflammation and narrowing of the upper airway, sometimes making it difficult to breathe. The characteristic symptom is a barking cough.

Aspiration (as-puh-RAY-shun) pneumonia occurs when someone accidentally inhales food or vomited material into the lungs.

Bacterial pneumonia Bacterial pneumonia can attack anyone, from infants to adults. The disease can be more severe in older people and those with underlying health conditions. The death rate from bacterial pneumonia is higher among the elderly than in other age groups. The most common cause of bacterial pneumonia is *Streptococcus pneumoniae* (strep-tuh-KAH-kus noo-MOH-nye), also called pneumococcus (noo-moh-KAH-kus). Sometimes a cold will be followed by streptococcal pneumonia, because the fluids produced by a cold's runny nose and sore throat make an excellent breeding ground for streptococcal bacteria. If the infection is not properly treated with antibiotics, the bacteria can multiply and cause infection not only in the lungs but also in the bloodstream, brain, and other parts of the body.

Other bacterial causes include the following:

- *Mycoplasma pneumoniae* (my-koh-PLAZ-muh noo-MOH-nye), which leads to an infection known as “walking pneumonia” because it is often mild enough to go undiagnosed for a long period of time
- *Staphylococcus* (stah-fih-loh-KAH-kus), which usually affects patients in hospitals
- *Chlamydia trachomatis* (klah-MIH-dee-uh trah-KOH-mah-tis), often seen in infants. Two other species of chlamydia also can cause pneumonia, usually in adults: *Chlamydia pneumoniae* (kla-MIH-dee-uh noo-MOH-nye) and *Chlamydia psittaci* (kla-MIH-dee-uh sih-TAH-see).
- Species of the bacteria *Klebsiella* (kleb-zee-EH-luh), *Pseudomonas* (soo-doh-MOH-nuz), and *Legionella pneumophila* (lee-juh-NEL-uh noo-MOH-fee-luh, the bacterium that causes Legionnaires', lee-juh-NAIRZ, disease)

Viral pneumonia Viral pneumonia, usually seen in children, makes up nearly half of all pneumonia cases. This type of pneumonia is usually not severe or long lasting. Causes of viral pneumonia include the following:

- Respiratory syncytial (RES-puh-ruh-tor-ee sin-SIH-shul) virus, or RSV, which typically causes more severe illness in infants and very young children
- Adenoviruses (ah-deh-no-VYE-ruh-sez), which affect the tissue lining the respiratory tract* and sometimes the eyes, intestines*, and bladder*
- Influenza (in-floo-EN-zuh) viruses, which cause flu. Pneumonia arising from influenza viruses is an important cause of serious illness among the elderly and people with other health problems.
- Parainfluenza (pair-uh-in-floo-EN-zuh) viruses, which also cause croup*

WILLIAM OSLER

Sir William Osler (1849–1919), often called the father of modern medicine, spent much of his life studying pulmonary diseases (diseases of the lungs) and is known for calling pneumonia the “old man’s friend.” He gave pneumonia this grim nickname because it swiftly ended the lives of many old men and women who had been suffering with other untreatable diseases. Ironically, Osler himself died of pneumonia after contracting influenza.

Fungal pneumonia Fungal pneumonia usually targets people with weakened immune systems. For instance, pneumonia caused by *Pneumocystis jirovecii* (noo-moh-SIS-tis yee-roh-VET-zee-eye) (formerly classified as *Pneumocystis carinii*), which was later identified as a fungus, is most common in patients with compromised immune systems, particularly those who have AIDS*. Other fungal infections that can involve the lungs are histoplasmosis (his-toh-plaz-MOH-sis), blastomycosis (blas-toh-mye-KOH-sis), coccidioidomycosis (kok-sih-dee-oyd-oh-mye-KOH-sis), and aspergillosis (as-per-jih-LOH-sis).

Who Is at Risk for Pneumonia?

Anyone can get pneumonia, but it tends to strike people whose natural defenses against infection are weak, especially the elderly and infants and young children. People with AIDS and organ transplant patients (who must take drugs to weaken the immune system) are also at higher risk, as are people living with diabetes*, chronic obstructive pulmonary disease (a lung disease), heart failure, tuberculosis*, sickle-cell anemia*, or another serious illness.

Pneumonia is a common infection among people who are hospitalized for something else, especially people recovering from surgery and those who are placed on breathing machines (ventilators). Hospital-acquired pneumonia is almost always bacterial and is often caused by strains* of bacteria that are resistant to many antibiotics. For this reason, and because it affects people who are already sick, hospital-acquired pneumonia is more frequently serious or fatal compared to cases of pneumonia acquired outside the hospital.

What Happens When People Have Pneumonia?

Symptoms Symptoms of pneumonia vary depending on the cause of the pneumonia and the health of the person with the infection. Symptoms of bacterial pneumonia may appear suddenly and include high fever, chills, rapid breathing, a deep cough that brings up greenish mucus which is sometimes mixed with blood, and severe chest pain that worsens with

The United States and the World

Pneumonia was a leading cause of death in the United States in the early decades of the twentieth century. In the early 2000s, antibiotics and good medical care usually cured pneumonia, even in the sick and elderly. Yet pneumonia occurred in so many people that, combined with influenza, it still ranked as the seventh most common cause of death in the United States. An estimated 2 million Americans got pneumonia each year, and about 60,000 died from it. In many developing countries, pneumonia remained a much greater problem, ranking first or second as a cause of death.

* **AIDS** or acquired immunodeficiency (ih-myoo-no-dih-FIH-shen-see) syndrome, is an infection that severely weakens the immune system; it is caused by the human immunodeficiency virus (HIV).

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body’s pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **tuberculosis** (too-ber-kyoo-LO-sis) is a bacterial infection that primarily attacks the lungs but can spread to other parts of the body.

- * **sickle-cell anemia** also called sickle-cell disease, is a hereditary condition in which the red blood cells, which are usually round, take on an abnormal crescent shape and have a decreased ability to carry oxygen throughout the body.
- * **strains** are various subtypes of organisms, such as viruses or bacteria.
- * **culture** (KUL-chur) is a test in which a sample of fluid or tissue from the body is placed in a dish containing material that supports the growth of certain organisms. Typically, within days the organisms will grow and can be identified.
- * **bronchoscopy** (brong-KOS-ko-pee) is a procedure used to examine the bronchi, the major air passages in the lungs, with an instrument called a bronchoscope, which is a tool for looking inside the lungs that is made up of a lighted tube with viewing lenses. A bronchoscope has channels through which samples of material can be taken from the lungs for study in the laboratory.
- * **biopsy** (BI-op-see) is a test in which a small sample of skin or other body tissue is removed and examined for signs of disease.
- * **antifungal drugs** (an-ty-FUNG-al drugs) are medications that kill fungi.
- * **dehydration** (dee-hi-DRAY-shun) is a condition in which the body is depleted of water, usually caused by excessive and unreplaced loss of body fluids, such as through sweating, vomiting, or diarrhea.
- * **acetaminophen** (uh-see-teh-MIH-noh-fen) is a medication commonly used to reduce fever and relieve pain.

breathing and coughing. Other symptoms include a bad headache, loss of appetite, tiredness, nausea, and vomiting.

People with atypical or mycoplasma pneumonia often get a persistent dry cough, sore throat, skin rash, and muscle and joint pain. Because these are not the classic symptoms of pneumonia, people may think they just have a mild case of flu.

Viral pneumonia can produce symptoms similar to those of the flu, including fever, muscle aches, breathlessness, rapid breathing, and a dry cough, which can worsen and eventually bring up a small amount of mucus.

People who are elderly or who have immune system problems often have milder symptoms in the beginning, even though their illness may be more dangerous. They might, for instance, have just a low-grade fever, tiredness, or confusion, and a sense of being ill.

Diagnosis To identify the infection, the doctor first asks questions about the patient's symptoms and then listens to a patient's chest with a stethoscope. Fluid in the lungs often produces a crackling sound when a person breathes, which can point to pneumonia. Sometimes the doctor will not be able to hear any air moving through the affected part of the lung. Chest x-rays may also be taken, and a cloudy, dense-appearing area may be seen in one or both lungs, particularly in a person who has bacterial pneumonia.

Next, the doctor may take samples of blood and sputum (SPYOO-tum, coughed-up mucus) to try to find out what is causing the pneumonia. These samples can be examined under a microscope and sent to the lab for culture* and identification of the organism causing the infection. In severe cases, a bronchoscopy* or a lung biopsy* may be performed.

Treatment If a specific type of bacteria has been identified as the cause of the pneumonia, the doctor can prescribe antibiotic drugs that target those bacteria. If the germ is not identified but bacteria are suspected, the doctor may give antibiotics that are active against the most likely bacteria, which is called empirical treatment. If the cause is a virus or fungus, antibiotics will not help. Instead, antiviral and antifungal drugs* may be prescribed, although not all viruses have treatments.

When the pneumonia is severe, people are often hospitalized, particularly if they are in danger of dehydration*, need more oxygen, or cannot breathe well enough on their own.

Two medical organizations, the Infectious Diseases Society of America and the American Thoracic Society, jointly developed guidelines for physicians on the best methods for diagnosing and treating pneumonia. The guidelines are revised every few years to reflect current medical research.

People with pneumonia get relief from symptoms and aid their recovery by:

- Taking an over-the-counter, non-aspirin pain reliever such as acetaminophen* to ease fever and muscle aches

DOCTORS AND BEST PRACTICES

Various physician organizations have developed recommendations for the diagnosis and treatment of many diseases, including pneumonia. The pneumonia guideline of the Infectious Diseases Society of America, for example, describes the specific laboratory, x-ray, and other tests that should be performed to diagnose pneumonia; lists the specific drugs that should be used to treat different types of pneumonia; and gives specific benchmarks for when it is safe for a patient recovering from severe pneumonia to leave the hospital. Guidelines such as these are developed by groups of medical experts who carefully review the latest medical research. By following this type of best-practice guideline, doctors can be confident they are giving their patients up-to-date and effective medical care.

- Resting and drinking liquids to combat dehydration
- Using a humidifier to keep air cool and moist, to ease breathing
- Staying away from cigarette smoke, which irritates the lungs

With treatment, bacterial pneumonia symptoms usually improve within a day or two and are gone in one to two weeks, but symptoms of viral pneumonia and mycoplasma pneumonia can last longer.

How Is Pneumonia Prevented?

The pneumococcal (nu-moh-KAH-kal) vaccine* works well against pneumococcal bacteria that cause pneumonia and is recommended for people over age 65 and children under two years of age, those with certain other illnesses, or those with weakened immune systems. The vaccine typically needs to be given only once in a lifetime. Yearly flu vaccines can help prevent pneumonia caused by influenza viruses. Because pneumonia often is caused by contagious respiratory infections, people can protect themselves further by avoiding being near people who are sick; by hand washing; not touching used tissues; and never sharing food, drinks, or eating utensils.

Poliomyelitis

Poliomyelitis (po-lee-o-my-uh-LYE-tis), or polio, is a condition caused by the polio virus and involves damage of nerve cells. It may lead to weakness and deterioration of the muscles and sometimes paralysis. Thanks to an extremely successful vaccination program, this disease has disappeared from the United States and much of the world, although it still exists in some countries.*

What Is Poliomyelitis?

Poliovirus, part of the enterovirus* group, makes its home in the alimentary canal, which includes the mouth, esophagus, stomach, intestines, colon, and rectum, but when the viral infection spreads it can destroy nerve cells that make muscles work. These damaged nerve cells, called

ENDING POLIO: A TIMELINE

1955: Jonas Salk's vaccine containing dead, or inactive, poliovirus (IPV) is licensed, and mass numbers of school children are vaccinated, leading to an enormous decrease in the number of polio cases over the next few years and a 60–70 percent prevention rate.

1963: Albert Sabin's oral polio vaccine (OPV), containing a live but weakened virus, becomes the new recommended vaccination in the United States. It offers lifelong protection, can be swallowed, and is easy to administer. In very rare cases, however, it actually causes paralytic polio.

1979: The last cases of wild polio (polio that is not vaccine-related) are reported in the United States.

2000: IPV becomes the exclusive polio vaccine used in the United States. Experts believe that because polio has virtually disappeared in the United States, the benefits of using OPV are no longer worth the very small risk of contracting the disease from OPV.

motor neurons, cannot rebuild themselves. As a result, the body's muscles no longer function correctly.

Types of paralytic polio include spinal, bulbar (BUL-bar), and bulbospinal (bul-boh-SPY-nul). The spinal type is most common, affecting the muscles of the legs, trunk, and neck. The bulbar form involves nerves of the brain stem* and can cause problems with breathing, talking, and swallowing. Bulbospinal polio is a combination of the first two types.

How Common Is Poliomyelitis?

Polio essentially has been wiped out in the United States and many other developed countries following the introduction of a polio vaccine in 1955. Before that, polio occurred in epidemic* form, with more than 21,000 paralytic cases (mostly children) in the United States in 1952 alone. The last cases of naturally occurring polio infection (known as “wild polio”) acquired in the United States were reported in 1979. In the following two decades, only 152 cases of polio were reported, most of them vaccine-associated paralytic polio (VAPP), a rare complication of the oral (by mouth) polio vaccine (OPV). Children in the United States in the early 2000s receive a vaccine containing an inactivated form of the virus that cannot cause polio. Although wild polio has not been found in the United States for more than two decades, it is still present in parts of Africa and Asia.

Is Poliomyelitis Contagious?

Poliovirus is extremely contagious and can pass easily from person to person. The virus typically is found in feces* and can spread when people touch contaminated objects and then touch the mouth or nose, or handle food without washing their hands first. The virus can live in feces for weeks, making the spread of infection difficult to control. It can also spread through contact with tiny drops of fluid from a sick person's mouth or nose or by drinking contaminated water. After entering the mouth or nose, the virus multiplies in the throat or gastrointestinal tract and eventually can invade the bloodstream where it can move to other parts of the body. In a very small number of people, about 1 to 2 percent, the virus invades the central nervous system*, that is, the brain and spinal cord, where it can cause paralysis.

The infection is most contagious seven to 10 days before symptoms begin and for the same period after they appear. The virus spreads more readily in areas with poor sanitation.

What Are the Signs and Symptoms of Poliomyelitis?

Poliovirus infections come in four types: asymptomatic (a-simp-toh-MA-tik), abortive, nonparalytic (non-pair-uh-LIH-tik), and paralytic (pair-uh-LIH-tik). In more than 90 percent of cases, people do not know that they have caught the poliovirus because they experience no symptoms (asymptomatic) or only minor symptoms (abortive), such as sore throat, vomiting, or other symptoms resembling those of the flu. Nonparalytic

▲ Dr. Albert Bruce Sabin developed the oral polio vaccine. *The Library of Congress.*

Polio in History

Polio has caused paralysis and death for most of human history. Reference to paralytic poliomyelitis can be found in Egyptian stone engravings more than 3,000 years old. At the start of the 20th century, however, few people had ever heard of the disease until epidemics of polio began to occur with regularity in developed countries. In the summer of 1916, polio became a more familiar condition in the United States when a devastating epidemic struck New York. The outbreak left 27,000 people paralyzed and 9,000 dead. Almost 40 years later, on April 12, 1955, the announcement came that Dr. Jonas Salk had developed the first effective vaccine against paralytic poliomyelitis. With the development of this and other later vaccines, polio was eradicated throughout most of the industrialized world.

- * **brain stem** is the part of the brain that connects to the spinal cord. The brain stem controls the basic functions of life, such as breathing and blood pressure.
- * **epidemic** (eh-pih-DEH-mik) is an outbreak of disease, especially infectious disease, in which the number of cases suddenly becomes far greater than usual. Usually epidemics are outbreaks of diseases in specific regions, whereas widespread epidemics are called pandemics.
- * **feces** (FEE-seez) is the excreted waste from the gastrointestinal tract.
- * **central nervous system** (SEN-trul NER-vus SIS-tem) is the part of the nervous system that includes the brain and spinal cord.
- * **cerebrospinal fluid** (seh-ree-bro-SPY-nuhl) is the fluid that surrounds the brain and spinal cord.
- * **ventilator** (VEN-tuh-lay-ter) is a machine used to support or control a person's breathing.

polio has more severe symptoms, including stiff neck due to meningitis and muscle stiffness in the back and legs. Paralytic polio, the rarest but most severe form of the disease, attacks the central nervous system (the part of the nervous system that includes the brain and spinal cord) and can cause muscle weakness, spasms, and paralysis. About one-third of patients who develop paralysis recover much of the use of their muscles weeks to months after infection. The remainder have long-lasting effects from the disease.

How Is Poliomyelitis Diagnosed?

A doctor may suspect polio in an ill patient with paralysis, particularly if the person has not been immunized against polio. The doctor may follow up with questions about recent travel, because while the polio vaccine has wiped out the disease in the United States, polio still occurs in some other countries. During a physical examination, a doctor looks at the extent of the muscle paralysis and may take samples of blood, bowel movements, fluid from the throat, or cerebrospinal fluid*, and have them tested for the virus.

What Is the Treatment for Poliomyelitis?

No cure for polio exists. Doctors instead focus on easing a patient's symptoms, which includes controlling pain and muscle spasms and matching supportive care to the patient's muscle weakness. For abortive cases and many nonparalytic cases of polio, a doctor typically recommends rest, fluids, and pain medication, as well as moist heat on muscles to ease stiffness. The doctor may also prescribe antibiotics to treat urinary tract and other bacterial infections that can occur in patients with polio.

Patients with severe cases of polio, particularly the paralytic form, often require hospitalization. In the 1940s and 1950s, medical professionals placed patients inside metal tanks called iron lungs, which assisted their breathing. Although medical technology has progressed since then, many people who have polio still need machines called ventilators* to help them breathe as they recover, as well as additional supportive care. Patients with paralytic polio may need physical therapy, crutches, leg braces, or surgery to help them regain their strength and movement.

What Should People with Poliomyelitis Expect?

If the disease does not damage the spinal cord and brain, patients typically make a full recovery. Symptoms in cases of abortive polio generally last less than a week. In nonparalytic cases, symptoms can continue for one to two weeks. If the polio infection causes paralysis, several months may pass before the muscles begin to regain their strength and mobility. Permanent paralysis, described as paralysis that lingers after 12 months, usually occurs in the legs, but sometimes affects other muscles, too. People who become paralyzed by the poliovirus receive physical therapy to keep their muscles from deteriorating, and they may need leg braces to walk or

FDR AND POLIO

Franklin Delano Roosevelt (FDR, 1882–1945) contracted polio at the age of 39 while vacationing on Campobello Island in New Brunswick, Canada. After a day of swimming and playing with his children, he went to bed tired and aching and awoke unable to move his legs. Two weeks later, doctors identified his illness as polio. Roosevelt never walked unassisted again.

When he contracted polio in 1921, Roosevelt had already begun a life in politics, and he did not let the disease stop him. In 1932 he ran for president of the United States and won. Although FDR did not try to hide his bout with polio, he went to great pains to disguise the extent of his disability. The public never saw him in his wheelchair. In 1938 FDR established the March of Dimes, which funded the research and immunization effort that eliminated polio from the Americas.

In 1998 a sculpture of Roosevelt in his wheelchair was added to the FDR memorial in Washington. Depicting him this way was controversial. Some people felt that he would not have liked being shown in his wheelchair in the sculpture. Others argued that he would be glad to have his image encourage people with disabilities to accomplish great work.

* **pneumonia** (nu-MO-nyah) is inflammation of the lungs.

* **kidney stones** are hard structures that form in the urinary tract. These structures are composed of crystallized chemicals that have separated from the urine. They can obstruct the flow of urine and cause tissue damage and pain as the body attempts to pass the stones through the urinary tract and out of the body.

a wheelchair to get around. Others may require help breathing for the rest of their lives. Additional complications include the following:

- Pneumonia* due to swallowing difficulties
- Fluid in the lungs
- Kidney stones*
- High blood pressure
- Post-polio syndrome, which affects 25–50 percent of people previously infected and develops many years, sometimes decades, after the initial infection. It causes symptoms of muscle pain, new or increased weakness, and paralysis.

Although a diagnosis of paralytic polio is a frightening one, most survivors go on to lead fulfilling lives. The violinist Itzhak Perlman, who caught the virus at four years of age and wears leg braces, is one example. Franklin D. Roosevelt, who got polio at the age of 39, went on to become president of the United States.

How Can Poliomyelitis Be Prevented?

The polio vaccine is the best way to prevent the disease, and its use has eliminated polio from the United States and much of the world. Its success is similar to that of another virus-caused illness: smallpox. Whereas polio still exists in some countries, smallpox has disappeared completely due to a worldwide smallpox-vaccination effort that in about 10 years

* **mucous membranes** are the thin layers of tissue found inside the nose, ears, cervix (SER-viks) and uterus, stomach, colon and rectum, on the vocal cords, and in other parts of the body.

eradicated the smallpox virus worldwide by 1980. A similar program for polio vaccination was underway in the early 2000s, but the disease persisted in such places as Afghanistan, India, Pakistan, and numerous countries in Africa. In many of these countries, poor sanitation and crowded conditions contribute to the spread of the disease just as health officials are trying to get everyone immunized.

In the early 21st century, IPV is the only polio vaccine used in the United States, and it does not cause VAPP. Children might have a sore spot where they receive the shot, but side effects from the vaccine are very rare. Children receive IPV routinely as part of the childhood immunization schedule. Most adults who were vaccinated as children do not need to receive the vaccine again. People traveling to places where polio is still found (such as Africa and Asia), lab workers who handle poliovirus, and medical professionals who care for patients with polio may need a repeat vaccination. If polio is wiped out worldwide, then immunization against polio will no longer be needed.

Polyps

Polyps (POL-ips) are growths of tissue that project from the mucous membranes. These growths normally are benign (be-NINE), which means they are not a threat to someone's health, but in some cases they can develop into cancerous tumors. Medical professionals do not completely understand the cause of polyps.*

What Are Polyps?

Three of the most common types are colorectal, cervical, and nasal polyps.

Colorectal polyps Colorectal polyps grow in the colon* or rectum*, which are both parts of the large intestine. The early discovery of polyps is important because between 75 and 90 percent of colorectal cancers develop from polyps. People who have colorectal polyps may notice unusual cramping, stomach pain, or bleeding when they have a bowel movement, or they may not experience any symptoms at all. Doctors usually check for polyps in people who have these symptoms. Doctors may also check for polyps in people whose relatives have been diagnosed with colorectal polyps, because polyps sometimes run in families. Most colorectal polyps develop in people who are more than 50 years old.

Polyps may start off benign, but over a period of years, they can transform into invasive cancer. Medical professionals can find and remove polyps before they become cancerous and thus prevent most colorectal cancer. For this reason, medical professionals recommend that people of a certain age or with a certain family history of colorectal cancer be screened for polyps. The most common procedure for diagnosing colorectal polyps is colonoscopy (ko-lon-OS-ko-pee), an examination of the rectum and the entire colon. The doctor inserts a flexible lighted instrument into the colon that transmits images of the inside of the colon to a monitor. If this procedure reveals any polyps, a doctor orders their removal to prevent the development of cancer. In the past, doctors sometimes ordered another procedure, called sigmoidoscopy (sig-moyd-OS-ko-pee), instead of colonoscopy. The sigmoidoscope, however, only examines the rectum and lower colon and does not reach the upper part of the colon where many cancerous polyps may occur.

Medical professionals generally recommend that individuals have their first colonoscopy at least by the age of 50 and then that they continue to have screenings every few years. The age of the first screening colonoscopy—and the frequency of subsequent ones—depends on the number of risk factors each person has. Risk factors include a diagnosis of irritable bowel syndrome or a family history of colorectal cancer. The higher the risk, the earlier screening colonoscopies should begin, and the more frequently they should be repeated.

Cervical polyps Cervical polyps develop in the cervix, which is the lower part of the uterus*. The discovery of cervical polyps are important because, while most are benign, some may be cancerous and a sign of cervical cancer.

The most common symptom of cervical polyps is abnormal bleeding from the vagina*. Cervical polyps are relatively common and are usually found during a woman's annual pelvic examination, when the doctor checks the uterus, cervix, and vagina for any abnormalities. Most cervical

* **colon** (KO-lin), also called the large intestine, is a muscular tube through which food passes as it is digested, just before it moves into the rectum and out of the body through the anus.

* **rectum** is the final portion of the large intestine, connecting the colon to the outside opening of the anus.

* **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.

* **vagina** (vah-JY-nah) is the canal, or passageway, in a woman that leads from the uterus to the outside of the body.

King George III of England (1738–1820), who reigned from 1760 to 1820, is thought to have had porphyria (from a painting by Benjamin West). *National Archives & Records Administration.*

- * **benign** (be-NINE) refers to a condition that is not cancerous or serious and will probably improve, go away, or not get worse.
- * **asthma** (AZ-mah) is a condition in which the airways of the lungs repeatedly become narrowed and inflamed, causing breathing difficulty.
- * **ataxia** disorder involving an unsteady gait.
- * **cystic fibrosis** (SIS-tik fy-BRO-sis) is a disease that causes the body to produce thick mucus that clogs passages in many of the body's organs, including the lungs.
- * **genes** (JEENS) are chemical structures composed of deoxyribonucleic acid (DNA) that help determine a person's body structure and physical characteristics. Inherited from a person's parents, genes are contained in the chromosomes found in the body's cells.

polyps are benign*, and medical professionals can remove them easily. Only rarely do cervical polyps develop into cancer.

Nasal polyps Nasal polyps develop in the sinuses, the cavities in the skull that are located near the top of the nose and under the eyes. People who develop nasal polyps usually have a history of allergies, hay fever, sinus infections, asthma* ataxia* (motor dysfunction), or cystic fibrosis*. Nasal polyps can cause problems with breathing, so medical professionals will either remove them or treat them with medications that the person inhales. Nasal polyps rarely become cancerous.

Porphyria

Porphyria (por-FEER-ee-a) refers to a group of acquired or inherited disorders that result when problems occur in the pathway the body uses to convert chemicals called porphyrins into heme, a compound primarily found in red blood cells. Common symptoms of porphyria are sensitivity to light, skin rashes, abdominal (ab-DOM-i-nal) pain, discoloration of the urine, and changes in mental status or personality.

What Is Porphyria?

When individuals inherit a defective gene* from one or both parents, they may develop a form of porphyria. Sometimes, however, individuals who do not inherit the disorder may still develop it. The term “porphyria” derives from the Greek word “porphura,” which means “purple pigment.”

In many patients experiencing an acute attack of this disorder, body fluids, such as the urine, turn purple in color.

Porphyria is divided into eight different types. All eight types are a result of a problem in the chemical process by which the body produces heme, a compound that carries oxygen and makes blood red. The production of heme requires eight different enzymes*. If any one of these enzymes fails, compounds that should be turned into heme build up in the body instead, especially in the liver* and in the bone marrow*, and cause problems. Some of these compounds are called porphyrins (POR-fi-rinz), from which the disease takes its name. It is the failure of various enzymes that cause the different forms of porphyria.

Some of the eight types of porphyria are rare. While exact numbers are not available, an estimated one person in 10,000 to 50,000 may be affected with some form of porphyria.

Acute intermittent porphyria This form of porphyria only occurs when it is triggered by certain drugs, starvation or crash dieting, infection, and some hormones* in women. This form of porphyria is more common in women than in men. It usually occurs first during the early adult years. Symptoms include stomach pain, leg cramps, and muscle weakness. As its name indicates, it tends to occur from intermittently (periodically). In its most acute* forms, it can cause seizures*, paralysis*, depression*, and even hallucinations* or coma*.

Porphyria cutanea tarda Porphyria cutanea tarda (ku-TAY-ne-a TAR-da) (PCT) is the most common form of porphyria and causes blisters on the parts of the body that are exposed to sunlight. Some people with this form also develop liver disease, and up to 50 percent of patients with PCT also have hepatitis* C. Substances that can cause an attack of PCT include alcohol, heavy intake of iron (iron overload), or the use of birth control pills. Porphyria cutanea tarda usually does not affect younger women. However, the increased use of substances that can trigger an attack, such as alcohol or birth control pills, has resulted in increased numbers of younger women developing the disease. This type of porphyria is not inherited. Only about 20 percent of cases have a family history of the disease.

Protoporphyrin Protoporphyrin (pro-to-por-FEER-ee-a) usually starts in childhood. The skin is extremely sensitive to sunlight, and painful rashes, redness, and itching may develop.

How Is Porphyria Diagnosed and Treated?

Diagnosis Medical professionals diagnose porphyria when they find an excess of porphyrins (compounds involved in making heme) in the urine. More laboratory tests help pinpoint specific forms of porphyria. Individuals who have received a diagnosis of porphyria should consult their doctor about all medicines, other drugs, or hormones they are taking or thinking about taking, as some are dangerous to individuals with this disorder.

* **enzymes** (EN-zimes) are proteins that help speed up a chemical reaction in a cell or organism.

* **liver** is a large organ located beneath the ribs on the right side of the body. The liver performs numerous digestive and chemical functions essential for health.

* **bone marrow** is the soft tissue inside bones where blood cells are made.

* **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.

* **acute** describes an infection or other illness that comes on suddenly and usually does not last very long.

* **seizures** (SEE-zhurs) are sudden bursts of disorganized electrical activity that interrupt the normal functioning of the brain, often leading to uncontrolled movements in the body and sometimes a temporary change in consciousness.

* **paralysis** (pah-RAH-luh-sis) is the loss or impairment of the ability to move some part of the body.

* **depression** (de-PRESH-un) is a mental state characterized by feelings of sadness, despair, and discouragement.

* **hallucinations** (ha-LOO-sin-AY-shuns) occur when a person sees or hears things that are not really there. Hallucinations can result from nervous system abnormalities, mental disorders, or the use of certain drugs.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

* **hepatitis** (heh-puh-TIE-tis) is an inflammation of the liver. Hepatitis can be caused by viruses, bacteria, and a number of other noninfectious medical conditions.

Treatment Treatments vary depending on the patient's specific needs:

- To treat acute intermittent porphyria, a patient receives heme in a drug called hematin.
- Drug treatment for some other forms of porphyria is also available.
- Doctors may recommend a type of sugar called glucose to help treat acute attacks.
- For porphyria cutanea tarda, in which the patient's body has an excess of iron, patients often benefit from systematic draining of the blood, in which medical professionals remove a pint of blood from the patient's body once or twice a week for several weeks, until iron levels drop to normal.
- In those patients with both PCT and hepatitis C, doctors treat both illnesses, because the treatment of hepatitis C is essential to the control of PCT.
- Avoiding light and other substances that can trigger an attack is important for people who are susceptible to any form of porphyria. Most sunscreens are not helpful for preventing skin eruptions.
- Sometimes a patient may take beta-carotene (bay-ta-KAR-o-teen) to help with light sensitivity. Beta-carotene, a compound found in certain foods such as dark-green and deep-yellow fruits and vegetables, is one of the building blocks of vitamin A.
- To prevent attacks, doctors also recommend that patients avoid those substances that trigger symptoms.

Post-Traumatic Stress Disorder

Post-traumatic stress disorder, or PTSD, is a condition in which a person has long-lasting psychological symptoms after experiencing an extremely stressful event. In PTSD, people who have survived a terrifying event relive their terror in nightmares, memories, and feelings of fear. It can

be severe enough to interfere with everyday living and can occur after a natural disaster, military combat, rape, mugging, or other violent event. More than one-third of PTSD victims never fully recover.

Sara's Story

Sara felt herself trying to scream, but no sound came from her throat. Hands seemed to be gripping her. A face appeared, and Sara reached up and swung her arms wildly. She tried to fight off her attacker, but she felt defenseless. Suddenly Sara heard her mother's voice trying to wake her, to pull her out of the nightmare. She cried as her mother hugged her tightly in the dark. Sara had experienced the same nightmare many times over the past several weeks. The details sometimes changed, but the dream always ended the same way: with someone trying to hurt her. In reality, Sara had been attacked the previous month on her way home from school. Now she was showing signs of PTSD.

What Is Post-Traumatic Stress Disorder?

PTSD is a condition that occurs among people who have lived through or seen a traumatic, or very stressful, event, such as war, natural disasters, serious accidents, child abuse, rape, or other threatening acts of violence. Psychological trauma refers to an emotional shock that leads to lasting psychological damage. The traumatic event may be any event that involves the threat of serious injury or death and to which the person responds with fear and helplessness. For some individuals with PTSD, the traumatic event involves a direct attack on them. For others, simply being a witness to a violent incident, such as a murder, can lead to PTSD. The condition is a problem particularly for people who engage in military combat or whose countries are the site of such combat. People with this disorder often relive the terrifying events through nightmares and disturbing memories. They may have trouble sleeping and may feel emotionally numb or cut off from other people. The symptoms can be severe enough and last long enough to interfere with everyday activities. PTSD is considered acute if the symptoms last less than three months after the traumatic event and chronic if the symptoms last more than three months. Delayed onset PTSD occurs when the symptoms do not begin until six or more months after the traumatic experience.

Who Is Affected by Post-Traumatic Stress Disorder?

It is estimated that about 10 percent of women and 5 percent of men in the United States have PTSD at some point in their lives, but this is a small fraction of all those who have experienced a highly stressful event. In women, the events most often linked to PTSD are rape, sexual abuse, physical attack, being threatened with a weapon, and childhood abuse. In men, the most common events are rape, combat, and childhood neglect and abuse.

Shell-shocked Veterans

About 30 percent of men and women who have spent time in combat zones experience what is called Post-traumatic stress disorder. In years past, a number of names were given to the emotional problems some soldiers had after returning from war, including the following:

Civil War: soldier's heart

World War I: shell shock

World War II: combat fatigue

- * **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.
- * **cortisol** (KOR-ti-sol) is a hormone that helps control blood pressure and metabolism, the process of converting food into energy and waste products. It plays a part in the stress response.
- * **epinephrine** (eh-pih-NEH-frin) is a chemical substance produced by the body that can also be given as a medication to constrict, or narrow, small blood vessels, stimulate the heart, and cause other effects, such as helping to open narrowed airways in conditions like asthma and croup.
- * **norepinephrine** (NOR-e-pi-ne-frin) is a body chemical that can increase the arousal response, heart rate, and blood pressure.
- * **opiates** (O-pea-atz) are painkilling chemicals that can cause sleepiness and loss of sensation.

Children and teenagers can show signs of PTSD. Researchers have found that the disorder is extremely common in young people who experience such violence as seeing a parent murdered or raped, witnessing a school shooting, or being the victim of sexual abuse. It is also common in young people who are exposed to a lot of violence in their community. While it is unclear why PTSD develops in some people but not in others, at least one factor, a high degree of family support, lowers the risk of PTSD in young people.

Victims of PTSD are at higher risk for alcohol or other substance abuse and suicide attempts. PTSD increases risk for other disorders such as clinical depression, panic disorders, and social phobias. Victims of PTSD are also more likely to engage in impulsive behaviors. Females have a higher risk for developing PTSD than males. Females are also more likely to develop PTSD as a result of a violent crime such as rape. Individuals with a prior history of trauma, preexisting anxiety disorders, or preexisting depression are at an increased risk for developing PTSD.

What Causes Post-Traumatic Stress Disorder?

Traumatic events occur frequently. The National Center for Post-Traumatic Stress Disorder estimates that just over 60 percent of men and 50 percent of women experience at least one traumatic incident at some point. Not all develop PTSD, but studies show that up to 14 percent of them do. The cause of PTSD can be any event that threatened serious physical harm. Such events include violent personal attacks, such as rape, sexual molestation, or mugging; natural disasters, such as hurricanes, tornadoes, or earthquakes; accidents, such as fires or car crashes; terrorist attacks, such as the the 2001 World Trade Center bombing in New York City and at the Pentagon in Washington, D.C.; wartime suffering; or military combat. The common element in these events is that people lived through a period when they faced great harm and felt fearful and defenseless. Their situations were life-threatening and overwhelming.

In the early 2000s, doctors did not understand why some people respond to such experiences by developing PTSD, while others do not. However, researchers have reported finding physical changes in some people who have survived traumatic events. Researchers investigated factors that may set apart people who experience PTSD after a very stressful event from those who do not. They have found that people with PTSD tend to have abnormal levels of key hormones* involved in the body's response to stress. In particular, levels of cortisol* are lower than normal, while levels of epinephrine* and norepinephrine* are higher. In addition, when people are in danger, they produce high levels of natural opiates*, body chemicals that temporarily block pain. Scientists have found that people with PTSD keep making higher levels of these substances even after the danger has passed, which may account in part for the emotional numbness often experienced in the disorder.

What Are the Symptoms of Post-Traumatic Stress Disorder?

The symptoms of PTSD may be mild or severe. One person may become slightly cranky, for instance, while another may have violent outbursts. In general, the symptoms seem to be worse if another person caused the event that triggered PTSD. People may have more trouble with their feelings after a rape, for example, than after a flood. Common symptoms of PTSD include:

- Reliving the event in nightmares or disturbing memories
- Being very distressed by reminders of the event
- Avoiding places or situations that bring back the unwanted memories
- Trying to avoid thinking or talking about the event
- Being unable to recall an important part of the event
- Losing interest in activities that were once enjoyed
- Feeling distant from other people or emotionally numb
- Having sleep problems
- Being irritable or angry
- Having trouble concentrating
- Being easily startled

Most people who have been through a very frightening event will have a noticeable reaction in the days and weeks just afterward. The diagnosis of PTSD is considered only if the symptoms last more than a month. The course of the disorder varies. Some people with PTSD recover within months, whereas others have symptoms that last much longer. Occasionally, the onset of symptoms may not show up until years after the stressful event.

In severe PTSD, people can become overwhelmed by the feeling that nothing really matters. Because they almost lost their lives in an unexpected event, they may fear they are still at risk. This fear causes them to withdraw and become depressed. Depression, in turn, makes it hard for them to concentrate, learn, or perform a job. Students may experience falling grades. People with PTSD may also have difficulty sleeping, because they are trying to avoid nightmares. They may be overly protective of themselves and loved ones and avoid situations in which most people would say there is no danger. They may be easy to anger, or they may experience chest pains, rapid breathing, or dizziness for no apparent reason.

What Are Flashbacks?

Among the most disturbing symptoms of PTSD are flashbacks, vivid waking memories in which people relive a terrifying event. Ordinary objects and activities serve as reminders of the event and act as the triggers. Triggers may be prompted by sights, smells, or sounds, such as when a combat veteran has a flashback of his experience after hearing the crack

School Violence and PTSD

If violence occurs in a school, psychologists and social workers provide counseling for students who witness or experience it. Such students are at risk for PTSD. Common symptoms in children include the following:

- Having flashbacks and disturbing memories
- Having recurring nightmares and dreams of death
- Believing in omens and predictions of future disasters
- Expecting an early death
- Avoiding any reminders of traumatic experiences
- Fearing another trauma
- Repeatedly engaged in play that reenacts the trauma
- Feeling emotional numbness or anger
- Being disinterested in activities
- Having frequent stomachaches or headaches
- Being nervous much of the time

of fireworks that sound like gunfire. During flashbacks, people may lose touch with reality and reenact the event for minutes or hours. While having a flashback, people may actually believe they see, hear, or smell aspects of the original experience. For the duration of the flashback, they may believe that the awful event is happening all over again. Because of the overwhelming nature of flashbacks, people with PTSD may consciously avoid known triggers.

How Are Children Affected?

Young children with PTSD may experience less specific fears, such as being afraid of strangers. They may also avoid situations and become preoccupied with words or objects that may or may not be linked to the stressful event. They may have sleep problems, and they may lose previously learned skills, such as toilet training. In addition, they may act out parts of the distressing event in their play.

Older children may also reenact part of the event in play or drawings. They may remember details that happened during the event in the wrong order. In addition, they may believe that there were warning signs that predicted the event. As a result, they may think that they can avoid future problems by always staying alert for such signs. Teenagers show symptoms similar to those of adults, but they are more likely to become aggressive or to make poorly thought-out decisions they later regret.

How Is Post-Traumatic Stress Disorder Treated?

Some studies show that counseling people soon after a disaster may prevent or relieve the symptoms of PTSD. For example, a study of 12,000 children who lived through a hurricane in Hawaii found that those who got counseling early were doing much better two years later than those who did not get counseling.

Cognitive behavioral therapy Cognitive behavioral (COG-ni-tiv bee-HAV-yor-al) therapy helps people change specific, unwanted types of behavior and faulty thinking patterns. In one form of the therapy, people describe and mentally relive a stressful event under safe, controlled conditions. This lets them face and gain control of the fear that was overwhelming during the actual event. In most approaches, gradual exposure to the traumatic event is paired with relaxation in a supportive environment. With systematic desensitization, people start out with less upsetting events and work up to the most disturbing event, or they confront the stressful event one piece at a time.

Group therapy In group therapy, several people with similar problems meet as a group with a therapist. This setting is often ideal for people with PTSD, because it lets them get support and help from others who understand what they are going through. Group therapy may help people feel more confident and able to trust again. In addition, as people share their stories and tips for coping with the fear, rage, grief, and shame

caused by their experiences, they may start to shift their focus from the past to the present.

Play therapy Play therapy may help young children who are not able to talk about their feelings directly. The therapist uses play, games, and art to help children remember and describe the stressful event safely and express their feelings about it.

Medications Medications may help reduce certain symptoms, such as sleep aids for those with PTSD who have trouble sleeping and anti-anxiety drugs for those who are easily startled. Antidepressants may improve conditions that often occur with PTSD, such as depression and panic disorder, in which repeated attacks of overwhelming fear strike often and without warning. Anticonvulsants* have also been used to control impulsive behavior and sudden emotional changes.

Help for Post-Traumatic Stress Disorder

Counselors for treating PTSD include the following:

- **Crisis counselor:** a professional who provides emotional support, practical help, and information to individuals or groups who recently have survived large-scale violence or disasters.
- **Clinical psychologist:** a mental health professional who has earned a non-medical doctoral degree. Clinical psychologists can do psychological testing and provide mental health counseling.
- **Psychiatrist:** a medical doctor who has completed specialized training in the diagnosis and treatment of mental illness. Psychiatrists can prescribe medications, diagnose mental illnesses, and provide mental health counseling.
- **Victim's advocate:** a professional who provides emotional support, practical help, and information to victims of a crime such as sexual assault.

* **anticonvulsants** (an-tie-kon-VUL-sents) are medications that affect the electrical activity in the brain and are given to prevent or stop seizures.

Postpartum Depression

Postpartum depression (PPD) is a serious depression occurring within the first year after giving birth and lasting more than a few weeks.*

What Is Postpartum Depression?

Many new mothers experience the “baby blues,” also called maternal or postpartum blues. This is hardly surprising considering that the female hormones* estrogen* and progesterone*, which are maintained at very high levels during pregnancy, drop precipitously during the first 24 hours after giving birth. Giving birth is also a life-changing experience for all mothers, and having a new baby is both stressful and exhausting. However, women who suffer from postpartum depression have feelings of anxiety*, sadness, or emptiness that interfere with their daily routines and possibly with their ability to care for the baby. Women who are predisposed to stress and depression may have a particularly hard time coping with a fussy baby and the fatigue that accompanies caring for a newborn.

Characteristics associated with PPD may include the following:

- Feeling insecure or inadequate as a mother
- Loss of one's sense of personal identity
- Feeling overwhelmed by responsibilities
- Feeling abandoned by a partner, family, and/or friends
- Being overcome by worry regarding the baby's safety and health
- Having problems with breastfeeding

How Common Is Postpartum Depression?

An estimated 10 to 15 percent of new mothers experience PPD. However, some experts believe that it is under-diagnosed and that PPD is the most common problem confronting new mothers. Clinical depression occurs in about 15 to 25 percent of the population and is more common in

WHO IS AT RISK FOR PPD?

Factors that can increase a woman's susceptibility* to PPD include the following:

- Previous depression or another mental illness such as bipolar disorder*
- A family history of depression or other mental illness
- An unplanned or unwanted pregnancy
- Being a young mother
- Depression during pregnancy
- Complications during pregnancy
- Vulnerability to stress
- Lack of emotional support from partner, family, or friends
- Stressful situations, including marital or financial difficulties, job loss, poverty, abuse, illness, or death of a loved one
- Substance abuse*

women than in men. Furthermore, women are most likely to experience depression during their primary reproductive years, ages 25 to 45, so it is not surprising that they may be prone to PPD. Women who have experienced PPD previously have a 50 percent risk of recurrence following subsequent pregnancies.

What Causes Postpartum Depression?

Although the precise cause of PPD is unknown, physical, emotional, and lifestyle factors can all contribute. Women suffering from PPD are thought to have an increased genetic* susceptibility to depression resulting from hormonal changes, including those that occur during their monthly menstrual cycle*.

However, an abrupt drop in female hormones is only one of the physiological changes that accompanies giving birth. During pregnancy the endocrine* system's stress response is damped down. In most cases the stress response returns to its normal pre-pregnancy level following delivery. In women with PPD, however, the endocrine system can overreact to stress, producing too much of the stress hormone cortisol*. A woman's inability to filter out irrelevant or stressful stimuli* also has been associated with PPD.

The levels of thyroid gland* hormones may drop sharply after giving birth, leading to low energy, fatigue, and depression. Postpartum levels of neurotransmitters* that support feelings of well-being, such as serotonin*, can also be low. Postpartum changes in blood volume, blood pressure,

* **susceptibility** (su-sep-ti-BIL-i-tee) means having less resistance to and higher risk for infection or disease.

* **bipolar disorder** a group of mood disorders that are characterized by alternating episodes of depression and mania.

* **substance abuse** is the misuse of alcohol, tobacco, illegal drugs, prescription drugs, and other substances such as paint thinners or aerosol gases that change how the mind and body work.

* **genetic** (juh-NEH-tik) refers to heredity and the ways in which genes control the development and maintenance of organisms.

* **menstrual cycle** (MEN-stroo-al SYkul) culminates in menstruation (men-stroo-AY-shun), the discharging through the vagina of blood, secretions, and tissue debris from the uterus that recurs at approximately monthly intervals in females of reproductive age.

* **endocrine** (EN-do-krin) refers to a group of glands, such as the thyroid, adrenal, and pituitary glands, and the hormones they produce. The endocrine glands secrete their hormones into the bloodstream, and the hormones travel to the various organs in the body that they affect. Certain hormones have effects on mood and sometimes are involved in symptoms such as irritability, emotional swings, fatigue, insomnia, depression, suspiciousness, and apathy.

* **cortisol** (KOR-ti-sol) is a hormone that helps control blood pressure and metabolism, the process of converting food into energy and waste products. It plays a part in the stress response.

* **stimuli** (STIM-yoo-lie) are things in the environment that excite a person to function, become active, or respond. The singular form is stimulus.

* **thyroid gland** (THY-roid GLAND) is located in the lower part of the front of the neck. The thyroid produces hormones that regulate the body's metabolism (me-TAB-o-LIZ-um), the processes the body uses to produce energy, to grow, and to maintain body tissues.

* **neurotransmitters** (nur-o-trans-MIH-terz) are chemical substances that transmit nerve impulses, or messages, throughout the brain and nervous system and are involved in the control of thought, movement, and other body functions.

* **serotonin** (ser-o-TO-nin) is a neurotransmitter, a substance that helps transmit information from one nerve cell to another.

* **immune system** (im-YOON SIS-tem) is the system of the body composed of specialized cells and the substances they produce that helps protect the body against disease-causing germs.

* **hyperactivity** (hy-per-ak-TI-vi-tee) is overly active behavior, which makes it hard for a person to sit still.

* **chronic** (KRAH-nik) lasting a long time or recurring frequently.

* **paranoia** (pair-a-NOY-a) refers to either an unreasonable fear of harm by others (delusions of persecution) or an unrealistic sense of self-importance (delusions of grandeur).

and the immune system* can further contribute to fatigue and mood swings.

Other factors that can contribute to PPD include the following:

- Disrupted work and home routines
- Sleep loss
- Insecurities about being a good mother
- Unrealistic expectations of being a perfect mother
- Feeling unattractive
- Lack of free time
- A demanding baby or older children

How Do Women Know They Have Postpartum Depression?

Symptoms of PPD can vary greatly, but they include all symptoms of clinical depression lasting more than two weeks:

- Restlessness, hyperactivity*, and anxiety
- Lack of energy or motivation
- Severe mood swings
- Overreaction to minor problems
- Intense irritability or anger
- Feelings of being overwhelmed or hopeless
- Feelings of worthlessness, shame, or guilt
- Overwhelming sadness and excessive crying
- Loss of interest or pleasure in enjoyable activities
- Withdrawal from family and friends
- Loss of interest in sex
- Problems with concentration, decision-making, or memory
- Severe fatigue or exhaustion
- Insomnia or sleeping too much
- Over- or under-eating, excessive weight gain or loss
- Chronic* headaches, aches or pains, or stomach problems

Women with PPD may be overprotective of their babies or behave in a hyper-vigilant manner. They may also have difficulty bonding with their babies.

Symptoms of severe PPD include the following:

- Not eating
- Frantic behavior
- Paranoia*
- Disinterest in the baby
- Thoughts or fears of harming one's self or the baby

How Do Doctors Diagnose and Treat Postpartum Depression?

Diagnosis Many women with PPD attempt to hide it, seeing their depression as a personal weakness rather than an illness. They may feel embarrassed, ashamed, or guilty about their feelings. Physicians sometimes administer a questionnaire to distinguish between PPD and the postpartum blues. A 2008 study found that just three questions were enough to identify women with PPD. These questions detected the following:

- Blaming oneself when things go wrong
- Feeling anxious or worried without good cause
- Feeling scared or panicky without justification

A simple blood test can determine whether thyroid hormone levels are low.

Treatment PPD usually can be treated effectively with antidepressant medications*. There are antidepressants available that are unlikely to cause side effects* in breastfeeding infants. Medication is often combined with other treatments, especially supportive talk therapy with a psychologist*, psychiatrist*, therapist, or social worker. Talk therapy can help women work through problems and learn to change the ways that depression causes them to think, feel, and act. Sometimes psychotherapy* alone is used to treat PPD. Support groups or marriage or family counseling can also help. Exercise and good nutrition can improve mood and aid in recovery. Caffeine should be avoided since it can trigger anxiety and mood swings.

Hormone replacement therapy is sometimes used to treat PPD. Estrogen replacement therapy can restore estrogen levels and may ease PPD symptoms. Thyroid medicine is effective against depression stemming from low levels of thyroid hormones.

Alternative therapies that may help relieve PPD include the following:

- Omega-3 fatty acids in seafood or as a nutritional supplement
- Massage therapy
- Acupuncture for relaxation
- Creative outlets such as art, music, or drama

Complications With treatment PPD usually eases within a few months. Halting treatment early can lead to relapse. Even with treatment women with PPD are more likely to have subsequent major depressive episodes.

Women with untreated PPD may have difficulty caring for their babies and accomplishing other tasks. This situation, in turn, can intensify feelings of low self-esteem*, guilt, and depression. Untreated PPD may last for a year or longer and progress into a chronic depressive disorder.

* **antidepressant medications** are used for the treatment and prevention of depression.

* **side effects** are unwanted symptoms that may be caused by vaccines or medications.

* **psychologist** (sy-KOL-uh-jist) is a mental health professional who can do psychological testing and provide mental health counseling.

* **psychiatrist** (sy-KY-uh-trist) is a medical doctor who has completed specialized training in the diagnosis and treatment of mental illness. Psychiatrists can diagnose mental illnesses, provide mental health counseling, and prescribe medications.

* **psychotherapy** (sy-ko-THER-a-pea) is the treatment of mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth.

* **self-esteem** is the value that people put on the mental image that they have of themselves.

IS IT THE “BABY BLUES” OR PPD?

Up to 80 percent of new mothers experience mood swings—feeling elated one moment and sad the next. These postpartum blues usually surface three to five days after delivery and subside within a few weeks as hormone levels stabilize. PPD lasts much longer and is usually much more severe and interferes with daily life. Sometimes the depression builds slowly, not peaking until as much as a year after delivery. PPD can develop after the birth of any child, not just the first.

Researchers believe that untreated PPD can adversely affect babies, possibly resulting in the following:

- Problems with mother-child bonding
- Increased crying
- Sleeping and eating difficulties
- Behavior problems, including temper tantrums and hyperactivity
- Developmental delays, including delays in language

Can Postpartum Depression Be Prevented?

Women with a history of depression should be monitored for a recurrence as soon as they become pregnant. Early recognition of PPD can lead to early treatment, minimizing its impact. Women with a history of PPD are sometimes started on antidepressants as soon as they give birth.

Some scientists believe that breastfeeding can help prevent PPD in some women. Lactating women have diminished neuroendocrine and behavioral responses to at least some types of stressors, other than those that present a threat to the infant.

Techniques for preventing or managing PPD include the following:

- Resting as much as possible and sleeping when the baby sleeps
- Getting good nutrition, exercise, and avoiding alcohol
- Having realistic expectations and asking for help when needed
- Taking time for oneself and one's partner and friends
- Sharing experiences with other mothers
- Joining a support group
- If possible, avoiding additional major life changes

Pregnancy

Pregnancy is the period of time between conception (kun-SEP-shun) and birth. A full-term pregnancy lasts nine months and usually does not involve major health problems. Sometimes, however, complications develop that jeopardize the health of mother and/or baby.

What Is Pregnancy?

Pregnancy is the interval beginning when an egg and sperm unite and ending when a baby is born. A full-term pregnancy lasts nine months (38–40 weeks). Physicians calculate the start of pregnancy from the first day of the last menstrual period, with a full term pregnancy running 40 weeks. This pregnancy measurement is referred to as the menstrual age and is approximately two weeks ahead of when ovulation and fertilization actually happens. The stages of pregnancy are referred to as trimesters and are

Anatomy of human ovum and human sperm. *Illustration by Frank Forney. Reproduced by permission of Gale, a part of Cengage Learning.*

- * **hormones** are chemical substances that are produced by various glands and sent into the bloodstream carrying messages that have certain effects on other parts of the body.
- * **uterus** (YOO-teh-rus) is the muscular, pear-shaped internal organ in a woman where a baby develops until birth.
- * **sperm** are the tiny, tadpole-like cells males produce in their testicles. Sperm can unite with a female's egg to result eventually in conception.
- * **chromosome** (KRO-mo-zom) is a unit or strand of DNA, the chemical substance that contains the genetic code to build and maintain a living being. Humans have 23 pairs of chromosomes, for a total of 46.
- * **embryo** (EM-bree-o), in humans, is the developing organism from the end of the second week after fertilization to the end of the eighth week.
- * **cervix** (SIR-viks) is the lower, narrow end of the uterus that opens into the vagina.

each three months in duration. Each trimester is associated with distinct developmental stages.

Fertilization and Implantation Eggs are formed in the ovaries, a part of the female reproductive tract. Each month, one of the two ovaries forms egg follicles, fluid-filled cysts that have the potential to grow into mature eggs. Only one follicle actually creates and releases a mature egg each month. In releasing the egg, the follicle ruptures. The cells that made up the follicle then begin to secrete hormones* that are needed to maintain a pregnancy. The egg released from the ovary travels down the fallopian tube toward the uterus*. On this journey, if sperm* meets and fertilizes the egg in time to implant in the uterus, pregnancy has the potential to occur. Sperm and egg actually meet in the fallopian tube where a sperm fertilizes the egg. One sperm cell is all that is required to fertilize an egg.

Normal fertilization takes place over approximately 24 hours. During this time the outside of the egg changes to ensure that other sperm cells will not penetrate. Once the egg is fertilized, all of the genetic material necessary for a new life is present, and the gender is determined. The female can only contribute an X chromosome* (females are XX). Males may contribute an X or Y chromosome (males are XY). If the sperm that fertilizes the egg is carrying an X chromosome, the result will be female. If the sperm carries a Y chromosome, the result will be male. The fertilized egg is referred to as an embryo* as it undergoes multiple cell divisions. Three to four days later, the embryo leaves the fallopian tube and implants in the uterus, where the cells continue to divide and grow as the pregnancy progresses. Some women experience episodes of spotting, or slight bleeding, around the time of implantation. Once implantation occurs, a mucous plug is formed that seals the cervix* to prevent the entry of more sperm.

Human chorionic gonadotropin (hCG) is a hormone produced by the placental tissue growing near the embryo used in pregnancy tests. This hormone is present in the maternal blood about one week after conception, but not present in the urine for a home pregnancy test until three to four weeks into the pregnancy. Throughout pregnancy, distinct and intricately synchronized hormonal changes are necessary for a fetus to make it

to full term. Progesterone is the hormone necessary for a successful pregnancy to occur, and it also prevents menstrual cycles* during pregnancy.

First Trimester The first trimester lasts about 12 weeks. Week three to week eight are referred to as the embryonic stage of pregnancy. In this period, the internal organs such as the heart are forming, and the embryo is especially vulnerable to damaging outside factors such as alcohol, bacterial infections, viruses, and toxins that would not significantly harm an adult body. The nervous system, including the brain, forms around the third week of pregnancy. Proper formation of the nervous system requires an adequate amount of vitamins, including folic acid, one of the B vitamins. Without proper nutrition, an embryo may malformed or lost. Around the fifth week of pregnancy the heart begins to beat. After the eighth week, the embryo is referred to as a fetus*.

Second Trimester The second trimester lasts from week 13 to week 27. During this stage the fetus rapidly increases in size and length. Organs continue to grow and move into their final physical locations. Skin is formed, blood creation begins, movement occurs, and the fetus begins to hear sounds. The lungs are beginning to produce a substance known as surfactant, which allows the air sacs in the lungs to inflate properly and not collapse when they deflate. Without the surfactant, a baby cannot breathe outside of the body of the mother. This is one of the reasons why a baby born too early may not survive.

Third Trimester The third trimester lasts from about week 28 to the time of birth, usually around week 40. Week 40 is used to calculate the due date, but a full term pregnancy may be anywhere between 38 and 42 weeks. During the third trimester the fetus gains significant weight and the eyes open. The fetus can detect light and begins making antibodies as part of the immune system. After 38 to 40 weeks, the baby is delivered through the vagina* or by cesarean section*.

What Are the Normal Discomforts of Pregnancy?

As a woman gains weight and her body changes to accommodate a growing fetus, she may experience some of the following signs or symptoms:

- Anemia*
- Backache
- Breast tenderness
- Constipation
- Edema (water retention)
- Fatigue
- Food aversions and cravings
- Frequent urination
- Heartburn
- Hemorrhoids*

▲
Ultrasounds (also called sonograms) can be used to monitor the development of the fetus during pregnancy. *Photo Researchers, Inc.*

* **menstrual cycle** (MEN-stroo-al SYkul) culminates in menstruation (men-stroo-AY-shun), the discharging through the vagina of blood, secretions, and tissue debris from the uterus that recurs at approximately monthly intervals in females of reproductive age.

* **fetus** (FEE-tus) is the term for an unborn human after it is an embryo, from 9 weeks after fertilization until childbirth.

* **vagina** (vah-JY-nah) is the canal, or passageway, in a woman that leads from the uterus to the outside of the body.

* **cesarean section** (si-ZAR-ee-an SEK-shun) is the surgical incision of the walls of the abdomen and uterus to deliver offspring in cases where the mother cannot deliver through the vagina.

General weight-gain recommendations for women who are expecting only one baby. *Illustration by GGS Information Services, Inc. Reproduced by permission of Gale, a part of Cengage Learning.*

* **anemia** (uh-NEE-me-uh) is a blood condition in which there is a decreased hemoglobin in the blood and, usually, fewer than normal numbers of red blood cells.

* **hemorrhoids** (HEM-o-roidz) are a mass of dilated veins in swollen tissue at the margin of the anus or nearby within the rectum.

* **stretch marks** are stripes or lines on the skin (such as on the hips, abdomen, and breasts) from excessive stretching and rupture of elastic fibers, especially due to pregnancy or obesity.

* **varicose veins** (VAR-i-kose VAYNZ) are abnormally swollen or dilated veins.

Recommended weight gain for pregnant women

<u>If you are:</u>	<u>You should gain:</u>
Underweight	About 27 to 40 pounds
Normal weight	About 25 to 35 pounds
Overweight	About 15 to 25 pounds
Obese	About 15 pounds or less

SOURCE: National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, U.S. Department of Health and Human Services

- Nausea and vomiting
- Stretch marks*
- Varicose veins*

Symptoms vary from woman to woman, and even between pregnancies for an individual woman.

What Are the Common Complications of Pregnancy?

Most women get through pregnancy and give birth without any major health problems. However, a few experience complications, and some of these threaten the health of both mother and/or baby. In the worst cases, these problems can be very frightening, and they are very difficult to handle when they result in the loss of a baby.

Hyperemesis gravidarum (morning sickness) Hyperemesis gravidarum (morning sickness) is the name for the nausea and vomiting some women experience during pregnancy. But it is misnamed in some cases. Some women have it in the morning, others at noon, and still others at night. Some women feel queasy only occasionally, whereas others feel sick all day long. Overall, about half of all pregnant women experience some degree of morning sickness, but it usually subsides on its own after about the third month of pregnancy. Only rarely does it require medical attention. The cause of morning sickness is unclear, but probably it is related to the hormonal and other chemical shifts that occur in early pregnancy.

Miscarriage Miscarriage (MISS-care-ij) is also called spontaneous abortion; it occurs when a pregnancy suddenly ends on its own. Bleeding, cramping, and abdominal pain often signal a miscarriage. Most miscarriages occur before the fourteenth week of pregnancy, which is why many women wait to tell their family and friends about a pregnancy until they have passed the three-month mark. Occasionally, a woman will have a “late” miscarriage, which means that it occurs during the second trimester. After

the twentieth week, the unexpected end of a pregnancy is called stillbirth if the baby is born dead and premature birth if the baby is alive but born before the thirty-seventh week.

As many as 40 percent of pregnancies end in miscarriage, although most of these occur so early that a woman may not even realize that she is pregnant. Early miscarriages often occur when the body naturally rejects an embryo that is not developing properly. Later miscarriages are much less common. Reasons for late miscarriages include a placenta* that is improperly attached to the uterus, the placenta separating from the wall of the uterus for some reason, and other causes.

Gestational diabetes Gestational* diabetes* is a type of diabetes that occurs when a woman does not produce enough insulin to handle the increased blood sugar that accompanies pregnancy. Any woman can develop this common problem, but women who are older, are overweight, and who have relatives with diabetes are at higher risk. A special diet often can control the problem without medication. Untreated diabetes during pregnancy increases the risk of certain birth defects. Such infants often have abnormally high birth weights and are prone to developing low blood sugar in the hours after birth. Most cases of gestational diabetes are temporary and disappear after the baby is born.

Ectopic pregnancy An ectopic (ek-TOP-ik), or tubal, pregnancy is one in which the fertilized egg begins to develop outside the uterus, usually in a fallopian tube*. Cramps, nausea, dizziness, tenderness in the lower abdomen*, and light vaginal bleeding often accompany ectopic pregnancies. Early detection and treatment of an ectopic pregnancy are essential. If left untreated, the condition can lead to rupture of the fallopian tube and then to massive internal bleeding and shock, thus becoming life-threatening to the mother.

* **placenta** (pluh-SEN-ta) is an organ that provides nutrients and oxygen to a developing baby; it is located within the womb during pregnancy.

* **gestational** (jes-TAY-shun-al) means relating to pregnancy.

* **diabetes** (dye-uh-BEE-teez) is a condition in which the body's pancreas does not produce enough insulin or the body cannot use the insulin it makes effectively, resulting in increased levels of sugar in the blood. This can lead to increased urination, dehydration, weight loss, weakness, and a number of other symptoms and complications related to chemical imbalances within the body.

* **fallopian tubes** (fa-LO-pee-an tubes) are the two slender tubes that connect the ovaries and the uterus in females. They carry the ova, or eggs, from the ovaries to the uterus.

* **abdomen** (AB-do-men), commonly called the belly, is the portion of the body between the thorax (THOR-aks) and the pelvis.

CESAREAN LAW

A cesarean section is the method of delivering a child by surgically opening the abdomen and uterus. It is performed when delivery through the vagina presents risk to the mother or child.

The name of the procedure comes from the traditional story that the Roman ruler Julius Caesar (100–44 B.C.E.) was delivered by such surgical means. More likely is the explanation that Cesarean law forbade the burial of a deceased mother before the baby was delivered.

Written accounts of the rescuing of an infant from its dead mother were recorded as early as 500 B.C.E. Cesarean sections were known to have been practiced by the ancient Romans, Indians, and Jews in the Roman era.

How Common Are the Common Pregnancy Complications?

The approximate percentages of pregnant women affected by the common complications of pregnancy are as follows:

- Ectopic pregnancy: 2 percent
- Gestational diabetes: 1 to 10 percent
- Miscarriage: as many as 40 percent of pregnancies end in miscarriage, often before a woman even knows she is pregnant. Of confirmed pregnancies, about 10 percent end in miscarriage.
- Morning sickness: 50 percent. Severe nausea and vomiting that require medical care occur in less than 0.5 percent of pregnancies.
- Placenta previa: 1 percent
- Premature birth: 7 to 12 percent of deliveries. About one-third of these are caused by preterm labor.
- Preeclampsia/Toxemia: 5 to 10 percent

* **ultrasound** also called a sonogram, is a diagnostic test in which sound waves passing through the body create images on a computer screen.

* **cervix** (SIR-viks) is the lower, narrow end of the uterus that opens into the vagina.

* **convulsions** (kon-VUL-shuns), also called seizures, are involuntary muscle contractions caused by electrical discharges within the brain and are usually accompanied by changes in consciousness.

* **coma** (KO-ma) is an unconscious state, like a very deep sleep. A person in a coma cannot be awakened, and cannot move, see, speak, or hear.

An ultrasound* can be used to examine the abdomen and confirm the diagnosis of an ectopic pregnancy. An ultrasound sends sound waves into the body that bounce off internal structures. A computer converts the returning sound waves into an image of the internal structures. Ectopic pregnancies usually are removed surgically.

Incompetent cervix An incompetent cervix* is the cause of about 25 percent of late miscarriages. The cervix is the muscular opening of the uterus into the vagina (va-JY-na). An incompetent cervix opens too early due to the pressure exerted by the growing fetus. An incompetent cervix can be caused by many factors, including a genetic tendency for it, stretching or tearing of the cervix during previous deliveries, and carrying multiple fetuses. An incompetent cervix can be treated by stitching the cervix closed during the second trimester or by bed rest for the last several months of pregnancy.

Preeclampsia/eclampsia and toxemia The terms “preeclampsia/eclampsia” and “toxemia” are used interchangeably to mean pregnancy-caused hypertension (high blood pressure). The exact cause of preeclampsia/eclampsia is unknown and likely has multiple factors. Eclampsia is defined as preeclampsia plus convulsions. The only known treatment for advanced preeclampsia (in which blood pressure cannot be controlled with medications) or eclampsia is abortion or delivery by cesarean section or induction of labor. Most cases of toxemia are characterized by swelling of the face, hands, and ankles; too-rapid weight gain; headaches; and protein in the urine. When left untreated, toxemia can cause nausea, vomiting, blurred vision, convulsions*, and coma*.

Toxemia most often affects young women during the last months of their first pregnancy, and the cause is unknown. Often, treatment involves hospitalization until the blood pressure returns to normal, followed by limited activity and sometimes bed rest at home.

Placenta previa Placenta previa (PREE-vee-a) is a condition in which the placenta is lying low in the uterus. It can be dangerous if the placenta actually covers the cervix during labor and delivery. During birth the baby still requires the blood, oxygen, and nutrients provided by the placenta, and so the placenta should remain attached to the uterus until after the baby is born, and then it is expelled. Placenta previa can lead to premature labor, and women with this problem sometimes must limit their activity or stay in bed until the baby is born. Doctors can monitor the position of the placenta using ultrasound. When it is time for the baby to be born, doctors perform a cesarean section if the placenta is still covering or very close to the cervix.

Preterm labor and premature birth More babies are born past their expected due date than before it, but in the United States, one in eight babies is born prematurely. A premature birth means delivery

before the thirty-seventh week of pregnancy. About one-third of premature babies are born early because the mother goes into labor too soon (the other cases occur because the amniotic sac* ruptures prematurely or because a health problem with the mother or baby requires early delivery).

Among the many risk factors for preterm labor are smoking, alcohol use, drug abuse, vitamin deficiencies, a job that requires standing for long periods, infections such as German measles, placenta previa or other physical causes, and poor nutrition.

Preterm labor that results in a premature birth poses serious health problems for the baby who has not finished developing inside the uterus.

What Are the Risk Factors for Pregnancy Complications?

Older women (over 35 years) have a higher probability than younger women of experiencing high blood pressure, diabetes, and cardiovascular disease while pregnant, but these conditions are controllable with good medical care. Older women also are more prone to miscarriage, preterm labor, and postpartum (after birth) bleeding, and they have an increased risk of having a child with birth defects.

By contrast, teen mothers are twice as likely to have premature babies and babies with low birth weight as are older mothers. Teenagers are also prone to premature labor, prolonged labor, toxemia, and anemia. About one-third of pregnant teens do not receive adequate medical care during pregnancy (as compared to about one-fourth of older women). Finally, while the chance of dying from pregnancy-related complications is very low overall, the rate is much higher in women younger than 15 than in women older than 15.

Can Pregnancy Complications Be Prevented?

Many complications of pregnancy develop in healthy mothers for unknown reasons. However, if a woman is in poor health before becoming pregnant, the likelihood of her having complications is higher than usual. Regular prenatal* care, or medical care during pregnancy, is very important, because it allows doctors to detect and treat problems with mother or baby as early as possible.

Preventing Pregnancy

Birth control is the process of preventing a pregnancy. It may be attempted via barrier methods such as diaphragms and condoms, hormone supplements, or through behavioral methods such as timing when sexual intercourse occurs. Behavioral methods rely on attempting to determine a period of physical infertility based on knowledge of the woman's menstrual cycle. During these supposed periods of infertility the sexual

* **amniotic sac** (am-nee-AH-tik SAK) is the sac formed by the amnion, the thin but tough membrane that lines the outside of the embryo in the uterus and is filled with fluid to cushion and protect the embryo as it grows.

* **prenatal** (pre-NAY-tal) means existing or occurring before birth, with reference to the fetus.

* **contraception** (kon-tra-SEP-shun) is the deliberate prevention of conception or impregnation.

partners assume it is safe to have sexual intercourse without the risk of pregnancy. These methods are not completely reliable. Abstinence is the only way to eliminate the possibility of pregnancy.

Contraception devices The diaphragm and the condom are two commonly used contraception* devices. The diaphragm is molded rubber cup with a wire embedded around its edge. A woman is measured for this form of contraception by a medical professional, who also explains how to insert and position the diaphragm across the cervix. The diaphragm provides a mechanical barrier so that sperm cannot enter the uterus through the cervix. Used with spermicidal jelly, the diaphragm is an effective method of birth control with no side effects. The condom is a thin rubber sheath worn over the erect penis that collects the sperm, preventing it from entering the woman's vagina. Another kind of condom is inserted into the vagina before intercourse and serves the same barrier function. Diaphragms are washed and reused; condoms are used only once.

Behavioral birth control The rhythm method, also known as the fertility awareness method, involves avoiding sexual intercourse during the most fertile time in the menstrual cycle. The fertile time in a menstrual cycle is during the ovulation stage. Counting from the first day of the last menstrual cycle, ovulation generally occurs approximately eleven days later. The signs indicating the ovulation stage include increased cervical mucous and increased basal body temperature. The basal body temperature is the temperature of the body early in the morning while at rest. Basal body temperature increases slightly approximately one to two days after ovulation.

Birth control may be attempted by abstaining from sexual intercourse from day 11 and the appearance of cervical mucous until three days after the increase in basal body temperature. However, this method is often less successful because ovulation varies from person to person. Because a sperm may live in the female reproductive tract for up to seven days and the egg remains fertile for about 24 hours, a pregnancy may occur anywhere from seven days before ovulation to three days afterward. In addition, ovulation does not always occur on day 11 from the last menstrual cycle, does not always involve noticeable cervical mucous, and may have an irregular basal body temperature. Ovulation may take place anywhere from day 11 to day 21 of the cycle and at different times during each cycle. These variables cause the rhythm method of birth control to less dependable than other methods.
