In patients with nephrolithiasis, stones that do not pass are often treated with ESWL, and adjunctive ureteral stents are often used to assist in urine flow and passage of stone fragments. In response to the presence of the stent, the ureter often dilates, allowing for extraluminal as well as intraluminal flow of urine and stone debris.[6] For larger stones and remaining fragments, stents may remain in for further treatment with ESWL. In nephrolithotomy or other open procedures for the removal of stones, stents are used to decrease the urinary leakage that commonly occurs.

Ureteral stents may relieve obstruction caused by primary or metastatic carcinomas, as well as other pathology (for instance, ureteral fibrosis) that leads to mechanical obstruction. Stents are also used in many surgical and percutaneous procedures involving the upper urinary tract, including nephrolithotomy and percutaneous nephrostomy tube insertion. Easily removable stents assist in maintaining a consistent lumen and outlet for urine, especially in surgical anastomoses of the ureter. Complications from a variety of surgical procedures can result in iatrogenic injury to the ureter, where stents may again be used. In fact, to offset obstruction that may be caused by any resultant ureteral edema, stents are often left indwelling for a period of 24 h after ureteroscopy.[7] Further, any other traumatic injury to the upper urinary tract may call for the use of an ureteral stent to help maintain ureteral patency and/or urinary drainage.

Ureteral stents may remain in place for weeks to months and often function without complication. However, stents can become encrusted with mineral deposits, depending on the length of time a stent has been in place, the characteristics of the stent itself, and the chemical composition of the urine. Encrustation can be minimized by keeping the urine at an acidic pH, uninfected, and dilute, with patients being instructed to maintain fluid intake of at least 2 L/day. Limited encrustation is not in itself an emergency, since dilation of the ureter often allows urine to flow around the stent, thus bypassing an obstructed lumen. Complete obstruction of urine flow is possible, although this tends to occur more often in patients with long-term stents. These patients typically require urologic consultation and in some cases may require stent replacement. In patients who received ureteral stents to treat obstruction from malignancy, 46 to 53 percent fail to drain properly, whereas those stents used as adjunctive therapy for renal stones have a much higher success rate.

Although peristaltic movements of the ureters stop with the placement of the ureteral stent, respiratory movements of the kidneys do not. These movements can result in migration of the stent, either upward toward the kidneys or downward into the bladder. Upward migration can lead to renal injury, obstruction and, in cases of infection, septicemia. Correction may entail pyelotomy, nephrostomy drainage and even, in extreme cases, nephrectomy. Changing abdominal or flank pain, or bladder discomfort, may be indicative of stent migration. X-ray examination is indicated to evaluate stent position, and urologic consultation with further studies may

eventually be necessary.

Placement of the ureteral stent itself initiates a foreign-body reaction and can predispose patients to an increased risk of urinary tract infection—up to a 7.5 percent incidence of positive urine cultures in patients with stents. Studies have shown that a higher rate of UTI exists as long as 1 month after the removal of the stent. When a UTI does occur, stent removal is not mandatory, because most infections can be managed with outpatient antibiotics. If pyelonephritis or systemic infection is evident, however, then further evaluation and emergent intervention are indicated. Plain x-ray examination and urologic consultation for evaluation of stent migration/malfunction are indicated. Antibiotic therapy should also be initiated in a timely manner.

Dysuria, urinary urgency, frequency, and abdominal and flank discomfort are common complaints in patients with ureteral stents. The use of analgesics and anticholinergics provides some relief. In some extreme cases, though, a few days of belladonna and opiate suppositories may be effective. The baseline discomfort in a functioning, well-positioned stent can range anywhere from minimal to debilitating. In some cases, the pain may be so great as to necessitate removal of the stent. However, an abrupt change in the character, location, or intensity of the pain requires further evaluation for stent malposition/malfunction. Along with these irritative symptoms, asymptomatic microscopic hematuria is often present, though clinically insignificant. Gross hematuria, with or without clots, may be the result of stent erosion through a segment of the urinary tract, stent migration, or the passage of a renal stone and requires further investigation, including urologic consultation.

COMPLICATIONS OF PERCUTANEOUS NEPHROSTOMY TUBES

While initially developed as emergent procedure for the relief of urinary obstruction, the use of percutaneous nephrostomy (PCN) has expanded beyond urinary diversion to a variety of other diagnostic procedures and therapeutic interventions. Patients with nephrostomy catheters may present to the emergency department days after placement, with complications relating either to the procedure or to the device itself. Other patients may present with complications related to the long-term use of nephrostomy catheters.

The indications for use of percutaneous nephrostomy include supravesicular obstruction or urine leak, adjunctive therapy for ESWL, or percutaneous ultrasonic lithotripsy. PCN is also used in cases of ureteral strictures, or for nephroscopy or antegrade ureteroscopy, often in conjunction with ureteral stents, as well as in cases of patients who have contraindications to surgical interventions. PCN may be indicated in cases where patients have failed ureteral stenting to relieve obstruction, especially in cases involving malignancy, or in cases of pyonephrosis, where the drainage from the kidney may be too viscous to be adequately drained by ureteral stent. Patients with urinary tract fistulas or other injuries may occasionally have PCN for postprocedure urinary diversion while the fistula closes or injury heals.

Complications in patients who have had percutaneous nephrostomy include hemorrhage, hematuria, infection (including septicemia), urinoma, obstruction, or catheter dislodgment. Complications requiring specific treatment or prolonged hospitalization occur in 4 to 8 percent of PCNs. Although patients can have other serious complications from PCN, including pneumothorax, bowel perforation, and liver or splenic injuries, these complications tend to be detected in the postoperative period and are rarely seen by emergency physicians. Hemorrhage tends to be more likely and more severe in patients with a coagulopathy. If a patient has sufficient bleeding to produce clots large enough to obstruct the nephrostomy catheter, then gentle intermittent irrigation with normal saline can be attempted to maintain the catheter's lumen until the bleeding either slows or clears. Hemorrhage—including pelvocalyceal and retroperitoneal hemorrhage—may also occur in the days following PCN. Although the large majority of patients with clinically significant hemorrhage will be recognized in the period during or shortly after PCN, patients with a history of recent percutaneous nephrostomy should trigger a higher level of suspicion. Hematuria, either transient or persistent, occurs commonly (especially after stone extraction) and is not a cause for alarm, provided that the patient is hemodynamically stable, the hematocrit is stable, and that urinary drainage is maintained. If any of the latter criteria are not met, then an arterial injury should be considered. If significant hemorrhage occurs, then aggressive blood transfusion/fluid resuscitation should be followed with urologic consultation, as the patient may require transcatheter embolization or further surgical procedures.

One to 2 percent of patients having PCN to treat pyonephrosis develop septicemia from release of bacteria or endotoxin from the renal parenchyma or collecting system into the blood. These patients can also develop perinephric abscesses. Therefore, patients with indwelling nephrostomy catheters who present to the emergency department with fever, pain, or other signs of systemic illness should have further evaluation, including urologic consultation.

Patients also may present with persistent urine leak from the nephrostomy site: up to 2 percent of patients have more than 1 week of such urinary drainage from the flank. These patients should have urologic consultation and, after treatment by ureteral catheter insertion or continued nephrostomy drainage, usually recover fully. Urinomas are a relatively infrequent complication and may be managed by ensuring that there is adequate drainage from the nephrostomy catheter. Observation and a possible second percutaneous catheter may be inserted by an urologist or a radiologist. In cases of catheter obstruction, the catheter can be intermittently irrigated with normal saline. If this does not resolve the obstruction, then an urologist should see the patient. If the catheter has become dislodged, in most cases a new puncture must be performed. If the catheter has been left indwelling for many weeks, then the renal parenchymal portion of the nephrostomy tract may be negotiated with either a guidewire or a new catheter, with varying rates of success. Any attempt at recannulation should be carried out by an urologist or a radiologist.

COMPLICATIONS OF PENILE PROSTHESES

The use of urologic implantable prostheses has increased since the modern forms became available in the early 1970s. Penile prostheses are generally of two types: semirigid penile prostheses (SRPPs) and inflatable penile prostheses (IPPs).

SRPPs provide rigidity at all times. They are paired cylindrical devices, which are implanted within the corpus cavernosa. The devices are activated by means of a hinged segment or by repositioning a flexible metal core. Two types of SRPP commonly in use are the Finney and the Small-Carrion. These types of prostheses are less expensive and more durable than the IPP type. Disadvantages of the SRPP include reduced ability to conceal the device and need for proper sizing of the device prior to implantation. Incorrect sizing can lead to sagging of the glans if the device is too small or pressure necrosis if the device is too large.

IPPs can inflate and deflate by a hydraulic mechanism. These devices are composed of paired inflatable cylinders within the corpus cavernosa, and a pump and reservoir that are commonly located within either the corpora or the scrotum. Many types of IPPs exist that use different versions of the general concept. As would be expected by the increased complexity of IPP devices, they tend to be more expensive and have a greater rate of mechanical failure. Because of the more natural appearance of this type of device, however, IPPs are still widely used despite their drawbacks.

Erosion, which is a complication of both types of prostheses, occurs through a number of mechanisms, the most prominent being the anatomic relationship of the corpus cavernosa to the urethra. The corpus cavernosa are physically in closest contact with each other in the region of the fossa navicularis. Therefore, the highest degree of pressure exerted by the prostheses to the urethra occurs in this region. Given their constantly rigid state, SRPPs have a higher rate of erosion, which is often worsened by inappropriate sizing of the device. This is particularly the case with either patients who have indwelling catheters or those who perform intermittent catheterizations. Introduction of the catheter into the lumen of the urethra adds to the local pressure and can lead to necrosis.

Because a large percentage of patients requiring penile prostheses have an underlying neurologic deficit, erosions will often present as a prosthetic device protruding from the urethral meatus. Patients with intact sensation frequently complain of pain or discomfort at the site of necrosis. In the case of SRPPs, the protruding device can usually be removed by simple extraction with forceps, followed by careful urethral catheterization and urologic follow-up.

Infection is the most devastating of complications associated with penile prostheses and nearly always results in removal of the prostheses, with long-term antibiotic coverage and wound drainage. Inability to clear the infection fully, as well as scar tissue formation, can limit the possibility of reimplantation of another device.

Penile prostheses incite a foreign body reaction within the host. An inflammatory reaction occurs shortly after implantation and results in the formation of a scar-tissue capsule. Though this capsule helps hold the device in place, it also acts as a potentiator of infection. The surface of the prosthesis provides a site for bacterial adherence, as well as a local environment that is resistant to host defenses. The periprosthetic space created between the prostheses and the capsule acts as an ideal site for the growth of bacteria and the production of an extracellular matrix. This extracellular matrix, along with the relative avascular nature of the capsule, limits the ability of immune cells and antibiotics to penetrate and eradicate infection.

The vast majority of prosthetic infections occur at the time of implantation. This being the case, it makes sense that most infections present within the postoperative period and that the most common infective agents are gram-positive cocci like *Staphylococcus epidermidis*.[8] Reduction of prosthetic infection rates is thus aimed at perioperative precautions, including the use of prophylactic antibiotics. Late infection of established prosthetic devices does occur, however. Hematogenous seeding can occur, so it is currently recommended that patients with penile prostheses be treated in accordance with the American Heart Association's bacterial endocarditis

prophylaxis guidelines during procedures likely to induce bacteremia.

COMPLICATIONS OF THE ARTIFICIAL URINARY SPHINCTER

The artificial urinary sphincter (AUS), a device used to treat urinary incontinence, has undergone five revisions since first being described in use in 1972. All types of artificial sphincters perform similar functions: to open partially when bladder pressure exceeds physiologic limits, to equalize pressures of stress, to open fully when operated, to fail in the open position, and to allow catheterization without further operations on the device. [8] The most current model, the AS-800 (American Medical Systems, Minnetonka, MN), introduced in 1982, consists of three parts: an inflatable cuff, a pressure-regulating balloon, and a pump. The cuff is typically placed around the urethra and is filled with fluid, via a pump/reservoir mechanism, providing continence through encircling compression of the urethra. For a patient to urinate, the fluid is pumped from the cuff to the reservoir. The fluid may then be pumped back into the cuff to provide continence or left in the reservoir leaving the cuff in the "open" position. All models enable catheterization without open modification of the device. The AS-800 is equipped with a deactivation button, which allows the device to be left in the "open" state. The device is reactivated by a sharp squeeze on the pump, opening a valve, which enables fluid transfer from the balloon to the cuff.

As subsequent versions of the AUS have been developed, reliability has improved. Mechanical failure rates range between 8 and 20 percent. [9] Examples of mechanical failure include fluid leaks, tube kinking, and pump failure. Fluid leaks present as the sudden onset of incontinence, with the cuff often being the source of the leaking fluid. Tube kinking is often the result of excessive tube length. These patients present in acute urinary retention, as they are unable to deflate the urethral cuff. Pump failure also manifests as a decreased ability or total inability to deflate the urethral cuff. This is usually the result of obstruction of the device's tubing by blood or other debris. Urologic consultation is necessary in these cases to further evaluate the source of the mechanical failure and treat the patient for urinary retention. These patients tend to require only replacement of the defective portion of the apparatus. Another complication, particularly seen in the use of AUS in the pediatric population, is bladder hypertonicity, which occurs after initial placement of the device. Hypertonicity may lead to renal failure, so these cases require close monitoring by nephrology and urology. [10] When the clinical presentation warrants, patients in the emergency department who have a history of AUS implantation should be evaluated for the possibility of renal failure.

Cuff erosion, which is the most common cause of total sphincter failure, tends to occur more commonly in female patients, especially when either the bladder or the vagina has been injured during the implantation procedure. The incidence ranges between 1.3 and 18 percent but has decreased in recent years. After implantation, the device is left in the deactivated state postoperatively for 8 to 12 weeks to allow perivesicular inflammation to decrease as well as to allow the urethra to restore vascularity before regular use of the AUS. Further risk factors for cuff erosion include increased cuff pressure, decreased cuff size, and urethral catheterization, all of which may lead to cuff erosion secondary to pressure necrosis. Patients with cuff erosions tend to present several months postoperatively and may present with any of the following: perineal pain, urethral discharge, gross hematuria, dysuria, urinary urgency or frequency, or recurrent incontinence. Urologic consultation is necessary, with the diagnosis being confirmed by retrograde urethrography and cystourethroscopy. Treatment includes cuff removal with possible reimplantation at a later date, antibiotics, and catheterization.

Infection is infrequent with the AUS, especially in the more recent models. Recent studies report an incidence of infection in the range of 1.2 to 2.7 percent. Like any foreign body, the AUS causes a tissue reaction, which may facilitate infection if bacteria are present. *S. epidermidis* and coliform bacteria tend to be the most common etiology for bacterial infection of the device. A patient's presentation may be subtle in cases of infection and requires a thorough history and physical examination, as well as a heightened degree of suspicion. Patients may be afebrile, lack an elevated white blood cell count, and have sterile blood and urine cultures. Others may have pain, swelling, erythema, or induration around the mechanism. In male patients, there may be thinning of the scrotal skin overlying the pumping mechanism (the most common site of infection), and induration or tenderness along the length of tubing may be palpable in the patient. Treatment of this complication includes urgent removal of the apparatus, with the possibility of reimplantation of a new device after healing.

Patients who present with recurrent urinary incontinence may have difficulties at a variety of sites in the urinary tract. Problems involving the cuff of the AUS include erosion or urethral atrophy and/or rigidity, all of which interfere in the compressibility of the urethra and lead to further incontinence. Treatments involve exchanging various parts of the AUS device itself and may be done electively. Occasionally, detrusor instability leads to increased bladder pressures that overwhelm the urethral cuff. This instability may be treated with medication. Mechanical failure of the urethral cuff may be treated with urologic follow-up and elective replacement of the defective component.

COMPLICATIONS OF PENILE RINGS

Penile strangulation can occur from pressure around the entire penile circumference by rings, hair, or other devices. Since delay in relief of strangulation can lead to vascular compromise and other serious consequences, these devices *must* be removed rapidly. Penile-strangulating objects have been placed for masturbatory purposes, as adjuncts to vacuum erection devices, to prolong erections, enhance sexual performance, and often by children during experimentation. Such devices have also been used to prevent enuresis and nocturnal emissions. In the pediatric population, the possibility of child abuse must also be considered.

Patients often delay seeking medical attention secondary to embarrassment and present to the emergency department with extreme pain. Other presenting symptoms include edema, ulceration, urinary retention, and vascular compromise with and without necrosis. As strangulation occurs, decreased venous and lymphatic drainage leads to edema and swelling of the penis distal to the site of constriction. Further swelling may lead to compromised arterial flow and gangrene of the penile tissue. Necrosis tends to involve mainly the skin and the subcutaneous tissue. However, because each corpus cavernosum has its own artery and these deeper vessels are protected by the Buck's fascia and overlying corporal tissue, gangrene of the corpora cavernosa is rare. Grades of penile strangulation have been described (Table 95-2).

Grade 1	Edema of distal penis. No evidence of skin ulceration or urethral injury.
Grade 2	Injury to skin and constriction of corpus spongiosum but no evidence of urethral injury. Distal penile edema with decreased sensation.
Grade 3	Injury to skin and urethra but no urethral fistula. Loss of distal penile sensation.
Grade 4	Complete division of corpus spongiosum leading to urethral fistula and constriction of corpus cavernosum with loss of distal penile sensation.
Grade 5	Gangrene, necrosis, or complete amputation of distal penis.

TABLE 95-2   Penile Strangulation Injuries

Evaluation of penile strangulation should include assessment of temperature, color, sensation, ability to void, and pulses (preferably by Doppler ultrasound). Some cases of penile strangulation, especially in children, the offending object, such as a hair, may be nearly invisible in the surrounding edema. Penile pain and swelling in children should trigger an increased suspicion of child abuse.

Various devices have been used to remove objects from the penis, including the standard ring cutter, wire cutters, saws, dental drills, hand-held grinding tools, and even orthopedic pneumatic drills. In the use of the latter motorized devices, continuous cool-water irrigation should be used to prevent heat injury to patients. If possible, a makeshift guard should be placed between the ring and the skin, thus isolating the action of the cutting device and preventing secondary injury to the penis. The method chosen for removal depends on the material involved, the size/thickness, and the duration that the item has been in place. Patients with grade 2 or greater injuries should have urologic consultation, and further possible evaluation for urethral injury, including a retrograde urethrogram or a Wood's lamp examination after intravenous administration of fluorescein. In extreme cases, where the constricting object cannot be removed in the emergency department, patients may require admission, with removal of the object in the operating room being followed by possible excision of devitalized tissue and skin grafting.

COMPLICATIONS OF GENITAL PIERCINGS

Body piercing—the use of needles, steel posts, rings, or other adornments—has become increasingly popular in recent years for both sexual and aesthetic reasons. An important element of history to obtain from patients is where the piercing was done (i.e., piercing parlor, doctor's office, store, by a friend, or by one's self), to assess whether aseptic technique was followed and needles were single use and sterilely packaged. If the piercing is performed by a novice, often it is too shallow, increasing injury and the chance that the body will reject the jewelry. Also, emergency physicians should attempt to ascertain the composition of the jewelry material, since contact metal-allergic dermatitis may occur with exposure to nickel or even surgical steel and gold. The resultant inflammation may in cases be so extreme as to envelop the jewelry. Lymphadenopathy and granulomatous tissue formation have occurred as a result of piercing, as has keloid formation over the long term. Genital piercing is also subject to trauma and may rupture the urethra. Trauma to the genitalia secondary to genital piercing may require urologic consultation and further evaluation if anything other than superficial injury is involved.

Infectious complications of genital piercing tend to occur at certain times:

1. When the piercing is performed, possibly with nonsterile technique and/or instruments. The instruments may include improperly sterilized spring-loaded finger-stick devices or piercing guns.
2. In the immediate postpiercing period, if the wound is not kept clean or is handled by the patient.

Embarrassment may cause patients with genital piercing to delay seeking medical attention for potential infection. *Staphylococcus aureus* is the organism most often responsible for piercing infections. However, group A b-hemolytic streptococci (GABHS) and *Pseudomonas aeruginosa* have also been isolated from infected piercing. Body piercing may be responsible for transmission of hepatitis B, hepatitis C, human papillomavirus (leading to recurrent condyloma accuminatum) and, although no cases in the literature currently exist, even HIV. Patients with relatively recent body piercing who present with unexplained hepatitis, endocarditis, or otherwise unexplained evidence of systemic infection should have a closer history of piercing obtained. Tetanus prophylaxis status should be determined for all recently pierced patients. In cases involving bacterial infection, culture specimens should obtained from the piercing site to identify the organism involved and direct appropriate antibiotic therapy. Removal of the jewelry may also be necessary in some cases. [11]

96 THE RENAL TRANSPLANT PATIENT

Richard Sinert

EPIDEMIOLOGY

Renal transplants make up the majority of solid organ transplants in the United States. For 1997, there were 19,971 solid organs transplanted, of which 12,229 were kidneys.[1] However, approximately 30,000 patients were left waiting for a kidney transplant at the end of 1997, and unfortunately, during the year approximately 1800 patients died waiting for a kidney transplant.

The knowledge that there are currently over 57,000 patients waiting for a solid organ transplant is important for emergency medicine. Since emergency physicians routinely care for victims of head trauma and other neurologic injuries, they are often in a position to identify possible donors. The potential for organ donation is often lost to the demands of caring for the severely injured. At such times, it should be remembered that 4000 patients die annually waiting for solid organ transplants.

Graft prognosis is directly related to the source of the donor kidney; recipients of cadaveric kidneys generally have more episodes of rejection and lower graft survival rates. The graft survival rate for kidneys from living donors is about 93 percent at 1 year and 77 percent at 5 years; the graft survival rate kidneys from cadaveric donors is 86 percent at 1 year and 61 percent at 5 years. The major causes of morbidity after renal transplant are hypertension (46 percent of all renal transplants), cataracts (24 percent), avascular necrosis (18 percent), malignant neoplasm (14 percent), urinary tract infection (UTI; 17 percent), chronic hepatitis (6 percent), peptic ulcer disease (4 percent), diverticulitis (3 percent), myocardial infarction (4 percent), and cerebrovascular accident (2 percent). [2]

Generally, recipients from living, related donors have lower mortality rates than recipients from cadaveric donors, probably related to fewer rejection episodes and thus lower immunosuppression requirements. Patients' survival rate after transplantation from a living donor is 98 percent at 1 year and 91 percent at 5 years, compared to survival after cadaveric donation of 94 percent at 1 year and 81 percent at 5 years. The causes of death in renal transplant patients vary among transplant centers.[3] Common causes include coronary artery disease (14 to 50 percent), sepsis (7 to 28 percent), neoplasm (9 to 28 percent), and liver failure (0 to 28 percent). During the first year, most deaths are from infectious causes. Long-term mortality rates are more closely related to the development of coronary artery disease.

This chapter discusses issues related to organ procurement, reviews the pathophysiology of graft rejection, and covers the most common medical complications seen in renal transplant patients, with special emphasis on the evaluation of the renal transplant patient with infections and acute renal failure (ARF).

ORGAN PROCUREMENT

Emergency physicians should be familiar with their departmental policies on brain death and organ procurement. Telephone and beeper numbers for the regional organ procurement organization (OPO) should be readily available.

An increasing demand for donor organs, coupled with improvements in transplant immunology, has greatly expanded the pool of patients eligible for organ donation. The donation of tissue such as skin, bones, and corneas can occur even postmortem. Recently the success of solid organ transplantation using non-heart-beating donors promises to expand the possible donor pool by 20 percent. [4] Absolute contraindications for transplant donors include HIV, sepsis, and malignancy other than primary central nervous system tumors. Advanced age is a relative contraindication; most OPOs do not harvest solid organs from individuals older than 75.

The Uniform Determination of Death Act provides guidelines outlining the neurologic criteria for the diagnosis of brain death: complete and irreversible loss of brain and brainstem function. Cerebral unresponsiveness, brainstem areflexia, and apnea are necessary to diagnose brain death. Reversible causes of brainstem depression, such as hypothermia and drug intoxication, need to be excluded. OPOs should be notified early of potential organ donors, and the OPO coordinator on call should be called even before the formal declaration of brain death.

Discussion of organ donation with the family is best done separately from discussion and acceptance of brain death. Once brain death has been declared, the OPO coordinator, who is highly trained for this delicate discussion, should broach the subject of organ donation. The emergency physician should focus on identifying possible donor candidates and giving the family a realistic prognosis for the patient. Organ donation consent rates vary widely among OPOs and from hospital to hospital. Consent rates are highest when the family initiates the discussion of organ donation. Consent rates are also higher if the discussion about organ donation is decoupled from the explanation of brain death, as described above. For multiple reasons, families may perceive a mixed message if the physicians caring for their seriously ill relative also initiates discussion of organ donation before the patients are "officially dead."

Following brain death, a number of physiologic changes occur that necessitate intervention to preserve donor organ perfusion. [5,6] Increasing cerebral edema after trauma or a cerebrovascular accident results initially in elevated catecholamine release and hypertension. With brainstem necrosis, catecholamine levels drop rapidly to 10 percent of normal values, causing hypotension, which must be corrected with fluids and vasopressors. Pituitary necrosis occurs in approximately 75 percent of organ donors, resulting in diabetes insipidus, which, if untreated, can result in significant hypovolemia. Antidiuretic hormone and free-water deficits should be rapidly replaced in these patients.

Body temperature control is often lost due to ischemia of the hypothalamus, with approximately 86 percent of donors developing hypothermia. Hypothermia has many detrimental effects on potential donor organs, including coagulopathy, shifting of the oxygen-hemoglobin dissociation curve, and hepatic and cardiac dysfunction.

PATHOPHYSIOLOGY OF TRANSPLANT REJECTION

The immune system has evolved to protect us against invasion from foreign pathogens and not renal grafts, and many of the same immune mechanisms that protect us against pathogens are also responsible for graft rejection. Enough divergence does exist between the immune response to transplants and pathogens that complete immunosuppression is not required for graft survival. Transplant research has shown that suppression of cellular, not humoral, immunity is critical for graft survival.

A newly transplanted graft is immediately identified as foreign by circulating T-lymphocytes that recognize class II human leukocyte antigen (HLA) on the surface of the donor organ. Once bound to these antigens, the T-lymphocytes differentiate, proliferate, and produce a wide array of soluble proteins called lymphokines. Lymphokines feed back to increase T-lymphocyte activation and stimulate B-cell antibody production against the graft. Specialized helper T-lymphocytes called cytotoxic T-lymphocytes are stimulated to directly attack the graft by attaching to cell-surface HLA class I antigens.

Identification of the specific components of the immune system responsible for graft rejection allows for a targeted approach to immunosuppression. Pharmacologic

protocols have been developed to selectively inhibit those components of the immune system responsible for graft rejection. [7] The doses of these immunosuppressants are then carefully adjusted to balance the risks of graft rejection with the risks of infection.

Azathioprine is a purine analogue. Metabolites of azathioprine are incorporated into DNA and RNA strands, inhibiting their synthesis and function. The immunosuppressant action of azathioprine occurs through blocking gene activation of stimulated T-lymphocytes. Azathioprine is prescribed at a dose of 2 mg/kg/day on a continuous basis as maintenance antirejection therapy. Noncompliance with azathioprine has been associated with a high rejection rate. Deleterious effects of azathioprine include leukopenia, thrombocytopenia, hepatotoxicity, and increased risk of neoplasm.

Corticosteroids have a role both in antirejection maintenance and during acute rejection episodes. Corticosteroids inhibit antigen-stimulated T-lymphocyte proliferation and inhibit lymphokine production. A major drawback of the use of steroids is their nonselectivity of immunosuppression, effecting both the cellular and humoral immunity and resulting in significantly increased risk of infection. Other deleterious effects of steroids include osteoporosis, hyperglycemia, hyperkalemia, and growth suppression in children.

Cyclosporine (CYA) and Tacrolimus (FK506) are both macrolide antibiotics produced by fungi. Although structurally unrelated, both CYA and FK506 agents block the proliferation of helper and cytotoxic T cells and inhibit lymphokine release. Unlike azathioprine and steroids, CYA and FK506 do not interfere with activation and proliferation of suppressor T lymphocytes. In fact, their major immunosuppressant effect may be directly related to their activation of suppressor cells. Both CYA and FK506 have similar toxic profiles, including, nephrotoxicity, hemolytic uremic syndrome, and hypertension. CYA has a vital role in maintenance antirejection therapy: CYA trough whole blood levels between 150 and 300 ng/mL are associated with graft survival.

INFECTIOUS COMPLICATIONS

Infection is the most common cause of early (less than 1 year) mortality and morbidity for transplant patients. Approximately 80 percent of transplant patients experience at least one infection during the first posttransplant year.

Viral Infections

Viral infections produce significant morbidity and mortality in the renal transplant recipient. The most common viral infections come from the herpes group of viruses: cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpes simplex virus (HSV), and varicella-zoster virus (VZV). Transplant patients are also more susceptible to and have a worse outcome from infections with other viruses, such as adenovirus, influenzavirus, and hepatitis virus.

CMV is responsible for more than two-thirds of febrile episodes in the first 6 months posttransplant. Transmission of CMV occurs with an organ transplant from a seropositive donor. With the primary direct CMV infection, patients often present with fever, malaise, hepatitis, pneumonitis, primary chorioretinitis, lymphadenopathy, arthralgias, and myalgias. An important indirect effect of CMV infection is augmented immunosuppression of the host, which increases the incidence of opportunistic infections such as *Pneumocystis carini*, *Listeria*, and *Aspergillus*. Diagnosis of CMV infection is established by viral culture and antibody titers. Untreated CMV has been associated with 10 to 15 percent mortality rates. Intravenous ganciclovir and foscarnet are both effective in treating CMV.

EBV infection in the renal transplant patient can present in two distinct clinical syndromes, either as the typical uncomplicated mononucleosis syndrome (characterized by fever, mild hepatitis, and leukopenia with atypical lymphocytosis) or as posttransplant lymphoproliferative disease (PTLD). [8] PTLD can range from a mild benign polyclonal disease to a rapidly progressive monoclonal form, which carries a poor prognosis. Other symptoms and signs of EBV are fever of unknown origin, weight loss, hepatotoxicity, pulmonary infiltrates, and gastrointestinal bleeding and perforation. Diagnosis of EBV is established by histologic examination of infected tissue. Primary EBV infection is treated by reducing immunosuppression and administering intravenous acyclovir. Treatment of PTLD is generally ineffective, leading to a substantial mortality rate.

VZV also presents with two distinct clinical syndromes in the renal transplant patient. The majority of transplant patients with VZV present with the typical reactivation-type infection limited to skin eruptions. A primary VZV infection occurs when tissue from a seropositive donor is transplanted to a seronegative host. This primary VZV infection produces a chickenpox syndrome that can be quite virulent, causing hemorrhagic pneumonia, encephalitis, hepatitis, and pancreatitis, with a high mortality rate. Direct immunofluorescence or viral culture is required to make the diagnosis of VZV. Acyclovir, valacyclovir, and famciclovir are all effective for both primary and reactivated VZV.

HSV infection is very common during the first transplant month. The usual presentation of reactivation disease is mucocutaneous ulcerations, which can be complicated by bacterial superinfection. Primary HSV infection can present as a disseminated disease with pneumonitis, esophagitits, or hepatitis. Diagnosis is based on direct immunofluorescence, viral culture, or serologic studies. Treatment with oral or intravenous acyclovir, ganciclovir, and foscarnet is effective.

Hepatitis viruses B and C are responsible for a 10 to 15 percent incidence of chronic liver disease in transplant patients. Disease transmission is from a seropositive donor or by contact with infected individuals. Immunosuppressive therapy directly stimulates viral replication. Both hepatitis B and C can progress to active hepatitis, cirrhosis, and hepatocellular carcinoma. In addition, infection with these viruses can suppress the host's immune defenses. Diagnosis is based on serologic and histologic studies. Therapy with interferon and lamivudine has shown limited success.

Bacterial Infections

UTIs associated with indwelling catheters are the most common bacterial infection in all transplant recipients, occurring in 30 to 40 percent. [9] The organisms responsible for UTIs in transplant patients are similar to those in nontransplant patients: *Escherichia coli*, enterococci, and *Pseudomonas aeruginosa*. UTIs in the first 6 months posttransplant have a high incidence of progressing to urosepsis and usually require longer courses of intravenous agents. UTIs during this period should all be investigated for the possibility of complicating obstruction and stone formation. Infections occurring after this period can be treated for shorter periods with less intensive courses.

The gastrointestinal tract is the next most common source of bacterial infection in the renal transplant patient. Acute bacterial gastroenteritis secondary to *Salmonella*, *Campylobacter*, and *Listeria* is common in these patients. While these bacteria usually have a benign course, occasionally *Salmonella* can spread hematogenously, resulting in endocarditis requiring a prolonged, intensive antibiotic course.

Diverticulitis, often complicated by perforation, is the other common gastrointestinal infection encountered in transplant patients. [10] Patients commonly present with findings of vague abdominal pain as the only symptom of this potentially life-threatening disease. A high index of suspicion should be maintained when evaluating transplant recipients with abdominal pain.

Listeria monocytogenes is a common opportunistic bacterial infection usually acquired by ingesting contaminated foods. Presentation is with diarrhea and abdominal cramps, which can quickly progress to pneumonia, enophthalmitis, and meningitis. Treatment consists of ampicillin and gentamicin, or trimethoprim-sulfamethoxazole (TMP-SMX).

Nocardia asteroides in renal transplant patients typically presents with fever, cough, and pulmonary infiltrates, eventually spreading to skin and central nervous system.[11] *Nocardia* can be effectively treated with TMP-SMX.

Mycobacteria tuberculosis occurs in renal transplant patients both as a primary and as a reactivation disease. [12] Risk factors for mycobacterial infection include malnutrition, history of inadequate treatment, or recent exposure to a contact with tuberculosis. There is no typical presentation for a transplant patient with tuberculosis. Instead, a highly variable presentation has been described, including cavitary pulmonary disease, miliary disease, and multiorgan involvement. Diagnosis is rarely aided by tuberculin skin testing. Definitive diagnosis is by organism identification and culture from sputum, pleural effusions, and bronchoalveolar lavage, lung, or bone marrow biopsy. Therapeutic options are complicated because of the CYA drug interactions with many antituberculosis medications.

Fungal Infections

Candida albicans infection is the result of immunosuppression (especially from steroid use) causing overgrowth of an endogenous gut flora. Mucocutaneous disease

affecting the oropharynx, esophagus, and vagina is the most common presentation. Candidal urinary tract infections, usually associated with indwelling catheters, can run a benign course with just cystitis or spread to pyelonephritis. Disseminated candidiasis often results in endocarditis, aortitis, osteomyelitis, meningitis, and brain abscess. Finding the organism in tissues, blood, or urine makes the diagnosis. Treatment of mucocutaneous candidiasis is with nystatin, clotrimazole, or oral fluconazole. Amphotericin is an effective agent for disseminated disease, but intravenous fluconazole may be preferable because of less nephrotoxicity.

Mucormycosis is caused by infections from fungi of *Rhizopus*, *Absidia*, and *Mucor* species. Risk factors include diabetes mellitus, steroid use, and deferroxamine therapy. The most feared complication is invasive rhinocerebral disease. Biopsy and histologic studies confirm the diagnosis. Amphotericin is the only available therapy, but mortality rates remain quite high.

Aspergillus fumigatus and *Aspergillus flavus* cause infections of the lungs, skin, and central nervous system in renal transplant patients.[13] Risk factors for infection include steroids, CMV infection, and neutropenia. Diagnosis is by organism identification from bronchoalveolar lavage and lung biopsy. Treatment is with amphotericin and surgical débridement of isolated lung focus if found.

Cryptococcosis occurs in 2.5 to 3.5 percent of renal transplant patients.[13] *Cryptococcus neoformans* enters through the lung and can spread to the skin and central nervous system, resulting in meningitis. Diagnosis is made by testing for cryptococcal antigen in serum and cerebrospinal fluid. Treatment consists of a combination of amphotericin and fluconazole.

Parasitic Infections

Pneumocystis carinii pneumonia (PCP) occurs in 5 to 10 percent of renal transplant patients not receiving prophylactic therapy. Risk factors include recent increases in the level of immunosuppression and concurrent CMV infections. PCP most often presents during the first 6 months posttransplant with fever, dry cough, dyspnea on exertion, and interstitial pulmonary infiltrates. Diagnosis is based on recovery of the organism on bronchoalveolar lavage or lung biopsy. Treatment is with high-dose intravenous TMP-SMX or pentamidine.

Toxoplasma gondii affects cardiac more often than renal transplant patients. Infection results in meningitis, brain abscess, pneumonia, myocarditis, endocarditis, and choriorentinitis. Diagnosis is based on histologic demonstration of trophozoites in a biopsy specimen. Treatment is with pyrimethamine with folinic acid in combination with sulfadiazine or clindamycin.

Strongyloidiasis can result in a hyperinfection syndrome of the gastrointestinal tract from *Strongyloides stercoralis*. Symptoms are usually limited to the gastrointestinal tract, with diarrhea and abdominal pain. With increased immunosuppression, strongyloidiasis can flare, producing hemorrhagic enterocolitis and pneumonia. Diagnosis is often first suspected by eosinophilia and confirmed by finding larvae in stool, body fluids, and tissue specimens. Strongyloidiasis is treated with thiabendazole.

Patient Evaluation

HISTORY   The most common reason for a transplant recipient to present to the emergency department is fever.[14] Certain important historical elements should be collected (Table 96-1). While fever is the most common symptom of infection, it may be masked by steroids, uremia, or hyperglycemia, which suppress baseline body temperature. While fever suggests infection, the absence of fever should never be used to rule out possible infection in a transplant patient.

History of recent temperature elevations

Date of transplantation surgery

Graft source: donor living related versus cadaveric

Rejection history: number of rejection episodes, date of last rejection episode, any recent changes in dosages of antirejection medications

History of chronic infections: CMV, EBV, hepatitis B and C, etc.

Recent exposure to patients with infections: chickenpox, CMV, tuberculosis, etc.

Complete list of immunosuppressant medications, compliance

Complete list of medications, even if unrelated to renal transplant, including over-the-counter medications

Baseline: blood pressure, body weight, serum creatinine level, cyclosporine level

TABLE 96-1   Key Historical Elements in Evaluation of Renal Transplant Patients

The risk of infection in a transplant patient is related to the state of immunosuppression. In general, renal grafts from living related donors have less risk of rejection, require less immunosuppression, and have less risk of infection. The degree of immunosuppression can be gauged by calculating the length of time from the transplant. Immunosuppression is at its highest level during the first 6 months posttransplant, with the greatest risk of rejection. After this period, rejection is less likely, and dosages of immunosuppressants are usually tapered down. The continued adjustment of immunosuppression over time has allowed a scheme to be developed that predicts the infectious agent by considering the age of the renal graft (Table 96-2).[15]

FIRST POSTTRANSPLANT MONTH: INFECTIONS RELATED TO SURGERY
UTIs (*Escherichia coli*)
Intravenous lines (*Staphylococcus aureus*, *Streptococcus viridans*)
Wound infections (*S. aureus*, *S. viridans*)
Pneumonia (*Streptococcus pneumoniae*)
6 POSTTRANSPLANT MONTHS: HIGHEST INCIDENCE OF OPPORTUNISTIC INFECTIONS
Viremia (CMV, EBV)
PCP
Meningitis (*Listeria monocytogenes*)
Sepsis (*Aspergillus fumigatus*)
AFTER 6 POSTTRANSPLANT MONTHS: THREE SUBGROUPS OF PATIENTS
1. Patients with good graft function on minimal immunosuppressants have the same risk of infection as the general population.
2. Patients chronically infected with latent viruses (e.g., CMV, EBV, hepatitis B and C) often have significant and ongoing end-organ damage (e.g., cirrhosis) secondary to these infections.
3. Patients with poorly functioning grafts who have sustained multiple episodes of rejection, now requiring large dosages of immunosuppressants, commonly have acute and chronic opportunistic infections (e.g., PCP, *Candida*, etc.).

TABLE 96-2   Etiology of Infection by Time from Transplant

A history of recent or repeated rejections may also suggest the presence of increased levels of immunosuppression. During a rejection episode, increased immunosuppression is commonly used, which increases the risk of infection.

Infection in a transplant recipient may be either reactivation of a chronic infection or a new infection from exposure to contagious contacts. A complete exposure history of the patient and the patient's recent contacts can provide important clues to possible infections.

PHYSICAL EXAMINATION   Renal transplant patients are immunocompromised; a high index of suspicion is required to find infections in unusual sites (Table 96-3). In addition to the common sites of infection (skin, pulmonary tract, and genitourinary tract), the head, neck, rectum, and abdomen should be closely scrutinized for infection. Infections during the first 12 weeks posttransplant are most commonly related to the surgical procedure of engraftment. Special attention should be given to the renal graft, and the examiner should look for signs of wound infection, pyelonephritis, and urine leakage with infection.

TABLE 96-3   Key Physical Examination Elements for Renal Transplant Patients

ANCILLARY TESTS   The workup for renal transplant patients with suspected infection should include routine testing (Table 96-4). Additional tests should be performed based on the patient's presenting complaint, history, and physical examination. Common sites of infection, such as the genitourinary and pulmonary tracts, should be evaluated in all patients with a urinalysis and chest radiograph. A complete blood count; determinations of electrolyte, blood urea nitrogen, and creatinine levels; and liver function tests, while rarely diagnostic, may provide clues to the infectious agent and assess function of the renal graft. A complete blood count may disclose a leukocytosis with a left shift, seen with bacterial infections, unless the immunosuppressive agents have depressed the bone marrow. In addition, leukopenia with an increase in atypical lymphocytes is commonly seen with viral infections, especially CMV. Liver function tests may show mild transaminase elevations with CMV and EBV infections. Much higher elevations of transaminase are associated with hepatitis B. Bacterial cultures of blood and urine should be obtained.

ROUTINE
Urinalysis
Chest radiograph
Complete blood count
Electrolytes, blood urea nitrogen, creatinine
Liver function tests
Blood culture
Urine culture
INDIVIDUALIZED ANCILLARY TESTS
Mycobacterial, viral, and fungal cultures of blood, urine, and infected tissue
Stool cultures and examination for ova and parasites
Sputum cultures for bacteria and mycobacteria
Serologic studies for CMV, EBV, hepatitis, toxoplasmosis, *Cryptococcus*
Renal ultrasound
Lumbar puncture

TABLE 96-4   Ancillary Tests for Evaluation of Renal Transplant Patients with Suspected Infection

If indicated, blood, urine, other body fluids, and tissue can be obtained for bacterial, mycobacterial, viral, and fungal studies. Serologic studies are especially important for the diagnosis of a wide variety of viral, fungal, and parasitic infections. Renal graft ultrasound studies should be reserved for patients suspected of having urinary obstruction, pyelonephritis, perinephric abscess, urine leak, or wound infection. A very low index of suspicion should be maintained for lumbar puncture in transplant patients because of the high incidence of *Listeria* meningitis.

ACUTE RENAL FAILURE

Failure of renal allografts is one of the most common causes of end-stage renal disease, accounting for 25 to 30 percent of all patients awaiting renal transplants. [16] Renal transplants can fail for the same reasons that native kidneys fail as well as for some unique causes (Table 96-5).

Complications of surgery
Renal artery stenosis or thrombosis
Urinary tract obstruction
Renal vein thrombosis
Rejection syndromes
Hyperacute rejection
Acute rejection
Late acute rejection
Chronic rejection
Cyclosporine and Tacrolimus nephrotoxicity
Recurrent renal disease

TABLE 96-5   Differential Diagnosis of ARF Unique to Renal Transplant Patients

ARF within the first 1 to 12 weeks posttransplantation is most likely secondary to complications of the transplant surgery itself, usually due to obstruction of a renal artery, vein, or ureter.

Rejection is related to activation of T cells, which in turn stimulate specific antibody production against the graft. Varying clinical syndromes of rejection can be correlated with the length of time after transplantation.

Hyperacute rejection occurs immediately in the operating room, when the graft becomes mottled and cyanotic. Hyperacute rejection is secondary to unrecognized ABO compatibility or a positive T-cell crossmatch.

Acute rejection appears within the first 3 months posttransplant and affects about 30 percent of cadaveric and 27 percent of living-donor transplants. [17] Approximately 15 to 20 percent of transplant patients experience recurrent rejection episodes. Patients present with decreasing urine output, elevated blood pressure, a rising creatinine level, and mild leukocytosis. Fever, graft swelling, pain, and tenderness may be seen with severe rejection episodes. Rejection is secondary to prior sensitization to donor alloantigens (occult T-cell crossmatch) or a positive B-cell crossmatch. Diagnosis depends on graft biopsy.

Late acute rejection commonly occurs 6 months after transplantation and is highly correlated with withdrawal of immunosuppressive therapy.

Chronic rejection occurs 1 year after transplantation secondary to both cellular and humoral immunologic factors. Progressive loss of renal function occurs.

Nephrotoxicity from CYA and Tracolimus (FK506) is related to hemodynamic factors. [18,19] Acute toxicity (CYA levels greater than 300 ng/mL whole blood) causes vasoconstriction and renal ischemia, which can be reversed with decreasing the drug dosage. Chronic toxicity results in fixed vascular lesions and irreversible renal

ischemia.

Patient Evaluation

HISTORY   A detailed transplant history is important for all patients presenting with ARF. Since many of the clinical rejection syndromes are correlated with the age of the graft, the date of the transplant surgery should always be obtained. The donor source is also an important risk factor for ARF because cadaveric kidneys have higher incidences of ARF and rejection. A history of recent and repeated infections also gives important clues to the patient's level of immunosuppression. In patients with infections, it is common practice to decrease immunosuppressants, which increases the risk of rejection. A complete drug history is very important because many medications affect the levels and toxicity of CYA (Table 96-6).[20]

INCREASES LEVELS OF CYA:
Calcium-channel antagonists: diltiazem, verapamil, nicardipine
Antibiotics: erythromycin, clarithromycin, doxycycline, ketoconazole
DECREASES LEVELS OF CYA:
Antibiotics: nafcillin, TMP/SMX (IV), isoniazid, rifampin
Anitconvulsants: phenytoin, phenobarbital, carbamazine
ENHANCES NEPHROTOXICITY WITHOUT ALTERING BLOOD LEVELS OF CYA:
Antibiotics: amphotericin B, acyclovir
Nonsteroidal anti-inflammatory drugs: all formulations

TABLE 96-6   Cyclosporine Drug Interactions

PHYSICAL EXAMINATION   The physical examination in transplant patients with ARF should start with an evaluation of the patient's volume status; the vital signs, the patient's weight, skin turgor, and orthostatic pulse and blood pressure changes may be helpful in identifying hypovolemia. Peripheral edema in these patients is often a misleading sign of fluid overload and can occur in hypovolemic patients due to hypoalbuminemia or venous stasis. Examination of the renal graft can often disclose swelling and tenderness associated with acute rejection, renal vein thrombosis, and obstruction.

ANCILLARY TESTS   Renal failure in transplant patients is defined as a 20 percent rise from baseline serum creatinine levels, as opposed to a 50 percent rise in other patients with ARF. As in all cases of ARF, the workup begins with a urinalysis (Table 96-7). Red blood cell casts and proteinuria are commonly seen in recurrent or de novo glomerulonephritis. The presence of white blood cells, bacteria, and nitrites is helpful in diagnosing UTIs. Routine determinations of electrolyte, blood urea nitrogen, and creatinine are rarely diagnostic of the etiology of ARF but may be helpful in determining volume status and identifying hyperkalemia, occasionally seen with CYA toxicity. CYA blood levels should be determined for all patients because of the high incidence of CYA-induced ARF. Renal ultrasound is the best test to rule out urinary obstruction. Renal biopsy is the gold standard for diagnosing rejection.

Urinalysis

Electrolytes

Blood urea nitrogen and creatinine levels

Cyclosporine level

Ultrasound study of renal graft

Renal biopsy

TABLE 96-7   Evaluation of ARF in Renal Transplant Patients

CARDIOVASCULAR DISEASE

Overall, the risk of coronary artery disease posttransplant is three- to fivefold that for age- and sex-matched control subjects. Risk factors for coronary artery disease include (1) pretransplant coronary artery disease, (2) hyperlipidemia secondary to antirejection medications, (3) hypertension, (4) steroids, (5) insulin-dependent diabetes mellitus, (6) erythrocytosis with increased blood viscosity, (7) smoking, and (8) frequent rejection episodes. [21]

Hypertension is found in approximately 50 percent of all transplant patients. Possible causes of hypertension include (1) graft rejection, (2) CYA toxicity, (3) glomerulonephritis (recurrent and de novo), (4) graft renal artery stenosis, (5) essential hypertension from native kidneys, (6) hypercalcemia, and (7) steroids. [22] Calcium channel blockers (CCB) have been shown to be particularly efficacious in treating hypertension in renal transplant patients on CYA, although CCBs interfere with CYA metabolism.

OTHER COMPLICATIONS

Chronic liver disease is an important cause of morbidity and mortality for renal transplant patients. [23] Causes of hepatic dysfunction include (1) viral hepatitis (CMV is leading cause, followed by hepatitis C and B) and (2) antirejection drugs (both azathioprine and CYA cause cholestatic jaundice).

By 15 years after transplantation, there is approximately a 50 percent incidence of malignancy. The most common sites of cancer are the skin (35 to 40 percent) and the viscera (10 to 15 percent). Lymphoproliferative malignancies, such as leukemia and lymphomas, are more prevalent among transplant patients than the general population.[24] Transplant patients are at significantly higher risk for cancers than the general population because of (1) chronic immunosuppression, (2) chronic antigenic stimulation, (3) increased susceptibility to oncogenic viral infections, and (4) direct neoplastic action of immunosuppressants.

DISPOSITION

Transplant patients are chronically immunosuppressed, attempting to balance between underimmunosuppression, with the risk of graft rejection, and overimmunosuppression, with the risk of infection. When these patients present to the emergency department with fever, increasing edema, decreased urine output, graft pain or swelling, or increasing fatigue, they should be evaluated for infection and renal graft function. These patients are complex, and it is often difficult to determine on initial assessment the presence of a serious infection or complication. It is recommended that the patient's physician or transplant coordinator be consulted to help the emergency physician in making the disposition decision.

97 RENAL IMAGING

Dan E. Wiener
Jennifer Marrast Host

The recent years have seen an explosion in the modalities available to the emergency physician to image the urinary system. This chapter reviews the different methods and discusses their role in the management of patients in the emergency department (ED).

IMAGING MODALITIES

Plain-Film Radiography

The KUB (kidneys, ureters, and bladder) is a plain full-length film of the abdomen. The kidneys can be visualized because the perinephric fat gives them a lucent outline. Renal calculi can usually be visualized, but small ureteral calculi may be hidden by bowel shadows. Calculi in the lower ureters may be confused with phleboliths and can be difficult to differentiate. The KUB by itself rarely adds to patient care in the ED and is most useful in conjunction with ultrasound or intravenous pyelography (IVP) (see below).

Ultrasound

Ultrasound is a rapid, painless method to visualize the urinary tract. The patient requires no preparation and is not exposed to the potentially harmful effects of radiation or contrast material. The limitations of this modality include poor visualization of the ureter and difficulty in imaging obese patients. The quality of the study is both operator- and equipment-dependent. Ultrasound is an anatomic study and provides no data regarding kidney function. Renal ultrasound can document the presence, location, and size of the kidneys and detect focal parenchymal lesions such as cysts and tumors. Hydronephrosis and on occasion dilated ureters and calculi can be demonstrated (Fig. 97-1). Fluid collections surrounding the kidney can also be seen. With Doppler flow capability, vascular problems in the kidney can be identified.

FIG. 97-1. Sonogram, right uterovesicular stone with hydronephrosis. (Photograph courtesy of David Frager, M.D.)

Ultrasound is performed using a 3.5-MHz transducer. With the patient in a supine position, the transducer is placed subcostally from the lateral approach. The operator sweeps the ultrasound plane to locate the kidney. Rotation of the probe permits documentation of the longitudinal and transverse renal axes. The liver is usually used as an acoustic window to visualize the right kidney and the spleen to visualize the left. Images on the right are technically superior to those on the left because the liver provides a better acoustic window than the spleen. An air-filled stomach and dilated loops of bowel can hinder visualization. The kidneys move with respiration, and having patients hold their breath after a maximal inhalation often enhances visualization.

Gerota's fascia, the renal cortex, the collecting system, the renal sinus, as well as proximal and distal calculi can be visualized. Gerota's fascia is associated with perinephric fat and is visualized as a bright area surrounding the kidney. The renal cortex is homogeneous in appearance and more reflective (brighter) than the renal medulla. The renal pelvis is centrally located and appears echogenic. Dilation of the collecting system by fluid (echo-free) is thus readily apparent. The normal ureter is not visualized, but the dilated ureter can sometimes be seen. In the longitudinal plane, the normal kidney is football-shaped and measures 9 to 12 cm. In the transverse plane, the normal kidney is C-shaped and measures 4 to 5 cm. The kidneys normally measure within 2 cm of each other in the longitudinal axis.

Intravenous Pyelography

The IVP provides both anatomic and functional information about the kidney. It is most commonly utilized in the setting of flank pain and hematuria and has long been considered the "gold standard" for visualizing renal calculi. The disadvantages of the study include the necessity of transporting the patient to x-ray, the time demand of the study, and the administration of contrast material. Concern regarding poor images in ED patients because of the lack of bowel preparation is unwarranted. [1]

Before initiation of the IVP, the patient is asked to void and the abdomen is compressed. The standard series of films taken during an IVP include the following:

1. The scout film, a plain radiograph from the level of the kidneys to the bladder prior to the administration of contrast. This allows visualization of stones that may be obscured by contrast material. The compression device is released after the scout film.
2. The nephrogram, a coned view of the kidneys 1 min after injection of contrast. This film is examined for the absence or delay in visualization, homogeneity, and duration of the nephrogram.
3. The pyelogram, two films taken 5 and 10 min after injection. Calyceal dilation or effacement, ureteral dilation, intraluminal filling defects, and the extravasation of contrast material can be seen.

4. The bladder film, taken 20 min after injection.
5. The postvoid film, used to evaluate postvoid residual bladder volume and visualize any retained contract that may have been hidden by the full bladder. Multiple views and tomograms are often used to enhance the quality of the study. When a calculus is suspected, two views are required to distinguish a peristaltic contraction from a tumor or a stricture. Delayed views are necessary in instances of obstruction or nonvisualization.

Computed Tomography

Computed tomography (CT) scanning provides both anatomic and functional information about the kidney. The renal parenchyma, collecting system, extrarenal space, ureters, and bladder can all be visualized. Renal perfusion can be assessed with the administration of contrast material. CT can identify extrarenal pathology or injury not clinically suspected. As the method of choice in assessing stable patients with suspected renal trauma, it determines the extent of the parenchymal injury, demonstrates urine extravasation or perirenal hemorrhage, and evaluates the integrity of renal vascular pedicle and status of adjacent organs. The disadvantage of CT is the time required to perform the study and the need to administer contrast if optimal results are to be obtained.

With CT, images of the kidney and urinary system are reconstructed from information collected by focused x-ray beams arranged on a plane that cuts through the patient's body in a transverse or horizontal direction. The patient lies on a movable table that passes through the CT gantry, which contains the tightly focused x-ray beams. As these beams pass through the patient, they are absorbed by a ring of detectors on the opposite side of the gantry. The intensity of the x-ray beam that reaches the detector is dependent on the absorption characteristics of the intervening tissue. The radiodensity of a small area of tissue can then be calculated from the absorption pattern of multiple beams crossing the area from different directions.

During spiral CT, the x-ray tube is in continuous rotation while the patient is moved smoothly, at a constant speed, through the scanning field. This technique improves the detection of small lesions, as scanning is performed during a single breath-hold, thus reducing the movement of intraabdominal organs and motion artifact, which occurs when imaging is performed during respiration. Data from multiple scanning planes can be used to produce three-dimensional reconstruction of lesions. In trauma, information about the extent of renal disruption, trauma to the renal pedicle, and viability of disrupted fragments can be provided. In addition, shaded surface displays allow volume surface analysis of parenchymal organs and maximal-intensity projections provide analysis of the vasculature. The selected slice thickness of a scan depends on the clinical presentation. Trauma scans are usually 8 to 10 mm thick and are obtained from the diaphragm down to the bottom of the pelvis. CT scans for renal colic utilize 5-mm slices from the top of the kidneys down to the bladder. If there is an area of subtle or equivocal findings, the radiologist may elect to make smaller cuts for clarification.

Intravenous Contrast Enhancement

The IVP and CT use intravenous contrast material containing iodinated compounds that absorb x-rays. These agents allow the vessels and organs to be more easily differentiated from adjacent nonenhancing structures. A typical imaging protocol involves the administration of 150 mL of intravenous contrast by a power injector into an intravenous catheter of adequate size, typically an 18-gauge catheter in the antecubital vein.

Intravenous contrast media are classified according to two characteristics: ionic versus nonionic and high-osmolar versus low-osmolar. Nonionic media are approximately ten times more expensive then ionic media but cause fewer lethal and adverse reactions. The relative risk of adverse reactions with ionic media is about four times greater than that seen with nonionic media.[2] High-osmolar contrast media (HOCM) are all ionic as opposed to low-osmolar contrast media (LOCM), which can be ionic or nonionic.[3] Intravenous contrast media are nephrotoxic; the least nephrotoxic is nonionic LOCM. In patients with normal renal function, there is no measurable impairment of renal function between the use of either HOCM or LOCM.[4] However, in patients with preexisting renal insufficiency and diabetes, nonionic LOCM causes less impairment to renal function than HOCM. Therefore, LOCM should be considered as the first choice of contrast media in patients with the following risk factors: age greater than 50 to 60 years, debilitation, known severe cardiovascular disease, asthma, previous allergy to contrast, renal failure, and/or diabetes.[5] For further discussion, see Chap. 294.

Oral Contrast Enhancement

Oral contrast is used with the abdominal CT scan for a patient suspected of having intraabdominal injuries. This barium- or iodine-based solution markedly increases the density of the gastrointestinal tract, differentiating bowel from other pathology. When there is a suspicion of renal injury, both oral and intravenous contrast is used. Oral contrast is a minimal threat to the kidneys and can be used in patients with depressed renal function.

Dynamic CT Scanning

In dynamic CT scanning, a series of rapid images using helical CT is obtained during peak vessel contrast enhancement. As with IVP, the kidney is visualized in the (1) vascular phase, when major vessels are visualized; (2) nephrogram phase, when contrast reaches the tubules and medullary opacification occurs; and (3) pyelogram phase, when calyceal and pelvic filling is observed. In trauma, dynamic CT is useful in demonstrating compromise of parenchymal perfusion and parenchymal fracture margins. Dynamic CT can also differentiate abscesses and hematomas.

Retrograde Urethrogram

The retrograde urethrogram is the test of choice when there is uncertainty about urethral integrity, usually due to trauma. It is an invasive procedure requiring the use of contrast material.

Using sterile procedure, the foreskin is retracted and the penis is stretched perpendicularly across the patient's thigh to prevent urethral folding. Contrast solution (Renografin 60 or Hypaque 50%, either full or half strength) is injected into the penis using the catheter tip of a 60-mL syringe or through a nonlubricated 16- or 18-Fr Foley catheter inserted just inside the urethral meatus. If a Foley is utilized, the balloon of the catheter is inserted 2 to 3 cm past the meatus and 1 to 2 mL of saline is injected into the balloon to secure the catheter in the fosa navicularis. In the direct syringe technique, slow constant pressure is used to inject 50 to 60 mL of contrast material. With the Foley technique, gravity is used to infuse the contrast medium from the filled syringe with the plunger removed and attached to the catheter, held above the patient's bed. If the medium will not flow, slow, constant pressure can be used, as with the direct syringe approach. The examination is best performed under fluoroscopic visualization. For patients with multiple injuries, fixed or portable radiographic equipment is frequently used. Radiographs are taken during the injection of approximately the last 10 mL of contrast.

In instances when a Foley catheter has already been inserted into the bladder and there is a suspected urethral injury, it is necessary to confirm that the urethra is intact and the catheter is in the bladder. The catheter should not be removed; instead, the urethrogram should be performed around it. Using a lubricated pediatric feeding tube placed alongside the existing Foley catheter, contrast material can slowly be injected to demonstrate the presence or absence of extravasation.

Cystogram

Cystography is the standard examination for bladder trauma. It is an invasive procedure requiring the use of contrast material. An anteroposterior (AP) pelvic or KUB film should be obtained as a scout film before contrast material is introduced.

Using sterile technique, a 16- or 18-Fr Foley catheter is carefully placed into the bladder. A 60-mL pistonless catheter-tip syringe is attached to the Foley and contrast material is poured into the syringe. Contrast is then allowed to enter the bladder via gravity as the syringe is placed above the level of the patient's bladder. The bladder is allowed to fill until extravasation occurs or the bladder is filled (400 mL). If bladder contraction occurs during filling, an additional 50 mL is injected by hand. In children below age 11, estimated bladder capacity is calculated based on the formula (age in years +2) × 30. Incomplete filling of the bladder can limit the quality of the study. To accurately exclude bladder rupture and extravasation, the bladder must be filled with at least 250 mL of contrast material.

Cystograms should be done using fluoroscopy or plain films in the AP oblique, and lateral projections. If there is an associated pelvic fracture, the patient should be kept in the supine position to avoid possible disruption of any retropubic hematomas. To detect posterior perforations, an AP film should always be obtained after bladder drainage.

Angiography

Angiography is the test of choice for defining vascular injuries of the kidney. It is highly invasive, requiring cannulation of the femoral artery and the use of intravascular contrast material. Indications include the absence of a functioning kidney on IVP or CT, findings of a large retroperitoneal hematoma, major renal fractures, or segmental areas of renal nonenhancement. In some instances injuries to the parenchyma and arteries can be treated using interventional angiography to stop hemorrhage.

The femoral artery is accessed by the Seldinger technique (flexible catheter advanced over a guidewire). The tip of the catheter is placed in the aorta and a midstream aortogram obtained to evaluate the number and status of the renal arteries. The catheter tip is then placed at the upper level of the proximal artery and films are obtained to capture the arterial, capillary, and venous phases.

Renal Cortical Scintigraphy (RCS)

RCS, using dimercaptosuccinic acid (DMSA), is a radionuclear study that evaluates kidney function. RCS is most commonly used in the evaluation of children with suspected pyelonephritis and, occasionally, assessment of a renal transplant.

Two hours after administration of Tc^{99m}-DMSA, scanning is performed using a gamma camera. DMSA binds to the renal tubules and accumulates in the functioning renal cortex. Intrarenal blood flow and proximal tubular cell membrane transport determine cortical uptake. Focal or diffuse areas of decreased cortical uptake of tracer without any loss of volume indicate the presence of pyelonephritis. Areas of decreased uptake with volume loss indicate old scars. Images are evaluated for the size of the kidneys, their shape and location, and differential renal function as well as the distribution of cortical uptake.

CONDITIONS

Renal Colic

The ideal imaging study in renal colic would (1) determine the size and location of the stone, (2) define the presence and degree of ureteral obstruction, and (3) identify other causes of flank pain and hematuria when renal calculi have been excluded.

Some 90 percent of renal calculi are radiopaque and theoretically visible on plain radiographs. Studies in the 1930s and more recent textbooks report visualization of stones in 85 to 90 percent of cases. These studies did not specify if the visualized "stone" was related to the patient's symptoms or confirmed by other radiographic studies. Recent comparisons between plain-film radiography and IVP (the "gold standard") found that plain radiography had a sensitivity of only 58 percent. [6] Compared with helical CT, plain radiography had a sensitivity of 45 percent and specificity of 77 percent. [7] Plain radiography alone has low utility and should not be used in the evaluation of patients with suspected renal colic; it does, however, play a role as an adjunct to IVP and ultrasound.

IVP has long been considered the "gold standard" for the evaluation of renal colic. The location of a calculus can be seen by a dye cutoff in the ureter, the size of the calculus can usually be determined, and visualization of the entire ureter secondary to a lack of peristaltic contractions is suggestive of obstruction. Identifying stones at the UV junction or the distal ureter can be difficult but is enhanced by assessment of the postvoid film. Secondary findings of stone disease include delay in the appearance of the nephrogram, distention of the renal pelvis, calyceal distortion, dye extravasation, or hydronephrosis.

Recent studies have compared the efficacy of ultrasound to IVP in the diagnosis of renal stones in ED patients presenting with renal colic [8,9,10 and 11] (Table 97-1). These studies used passage of stones, stone recovery at surgery, or repeat IVP as the gold standard and used the finding of a stone and/or evidence of hydronephrosis as a positive test result for the diagnosis of renal calculi. Both modalities are slightly better at identifying obstruction than localizing a stone. Using either stone identification or detection of obstruction, both modalities have essentially the same range of sensitivity and specificity, although ultrasound has a wider range of sensitivity, reflecting the greater dependence on operator skill and limitations of the modality. Plain-film radiographs can be used as road maps to focus the ultrasound study, with a reported 100 percent sensitivity and 95 percent specificity in identifying ureteral calculi. [12] Theoretically, ultrasound has an advantage in imaging radiolucent stones (about 10 to 20 percent of total), but if there is no dilation of the ureter, it becomes more difficult to place the visualized density correctly. Furthermore, ultrasound has particular difficulty in visualizing dilations of the upper and midureter. The distal ureter is more accessible, since the bladder acts as an acoustic window within the ureter. Ultrasound may also be limited by the delayed appearance of hydronephrosis; in a series of 216 cases of renal calculi causing obstruction, the initial sonogram was negative in 24 percent, but all these patients showed evidence of hydronephrosis when the sonogram was repeated 8 to 12 hours later. [13]

	IDENTIFICATION OF STONE AND/OR HYDRONEPHROSIS		IDENTIFICATION OF STONE		OBSTRUCTION OF HYDRONEPHROSIS	
	Sensitivity	Specificity	Sensitivity	Specificity	Sensitivity	Specificity
IVP	81–87%*	68–100%*	64%†	100%‡	80%‡	94%‡
Ultrasound	64–97%*	68–100%*	64%†	100%‡	83%‡	100%‡
Helical CT	95–98%§	96–100%§			87%§	94%§

TABLE 97-1 Imaging Modalities in Renal Colic

Published studies indicate that emergency physicians can perform bedside ultrasound examinations in patients with renal colic and detect hydronephrosis with 97 percent sensitivity as compared with an IVP. [14] The availability of ultrasound equipment for use in the ED and training of more emergency physicians has the potential to expand the use of this modality and reduce the use of IVP studies for patients with acute renal colic.

Selecting IVP or ultrasound for an individual patient requires some clinical judgment. Certainly patients with contraindications to radiation and the administration of contrast should have an ultrasound. The clinician will have to further weigh the importance of ascertaining functional information about the kidney as well as the increased likelihood of identifying the location of the stone versus the added time and radiation exposure necessary to complete an IVP. One approach would be to obtain ultrasound in all patients presenting with signs and symptoms of renal colic and only proceed to IVP if the patient is deemed to require surgical intervention or if the diagnosis remains unclear.

Helical CT without intravenous contrast has become the imaging modality of choice in many institutions for patients with acute renal colic. The helical CT takes only 5 min to perform and can identify the presence and location of calculi of all compositions, not only providing prompt and accurate diagnosis in most patients with calculi but also identifying extrarenal disorders in patients without calculi. The average dose of radiation at the skin from a helical CT is 3 to 5 cGy, comparable to 1.5 to 3 cGy (0.25 to 0.3 cGy per radiograph) from an IVP. One limitation of the helical CT is that it does not provide functional information about the degree of obstruction.

Studies demonstrate that helical CT has excellent sensitivity and specificity in the diagnosis of renal colic [15] (Table 97-1). One limitation is distinguishing phleboliths from renal calculi, but secondary signs can be used to help make this distinction. For renal colic, these signs include ureteral dilation (sensitivity 90 percent and specificity 93 percent), perinephric stranding (sensitivity 82 percent and specificity 93 percent), collecting system dilation (sensitivity 83 percent and specificity 94 percent), and renal enlargement (sensitivity 71 percent and specificity 89 percent). [16] The presence of ureteral dilation and perinephric stranding had a positive predictive value of 99 percent, and the absence of both had a negative predictive value of 95 percent (both were present or absent in 181/220 patients). Edema of the ureteral wall surrounding the calculus (rim sign) is up to 100 percent sensitive and 94 percent specific in distinguishing renal stones from phleboliths. Helical CT

should be considered positive for calculi when any of the following are seen: (1) a stone, (2) both ureteral dilation and perinephric stranding, or (3) a tissue rim sign. Urologists were able to use helical CT without further imaging in 91/105 patients who underwent lithotripsy or endoscopic stone removal. [17] The utilization of this valuable modality will depend on its institutional availability as well as its degree of acceptance among urologists.

Renal Transplant

Renal transplant failure can be secondary to graft rejection or renovascular complications. Modalities available to evaluate the transplanted kidney include angiography, ultrasound with color-flow Doppler and duplex Doppler, and renal scintigraphy. The choice of modality will depend on the clinician's index of suspicion for graft rejection or vascular compromise.

The most common vascular complication of transplant is renal artery stenosis (RAS), with an incidence of 3 to 15 percent in the first 3 years after transplant. [18] Renal artery and vein thromboses are rare, usually occur in the perioperative period, and are generally catastrophic, resulting in loss of the renal graft. In contrast, identification and treatment of RAS can result in graft salvage. Patients with RAS often present with hypertension and worsening renal function. Posttransplant patients are reported to have a 50 to 60 percent incidence of hypertension unrelated to RAS. Therefore, it is the renal transplant patient with hypertension that is progressive or difficult to control with medical therapy who should be considered at risk for RAS. The gold standard for diagnosing RAS is angiography. However, angiography is limited by its invasive nature, the use of nephrotoxic contrast agents, the risk of an adverse reaction to contrast media, and complication rates of 0.5 to 2.3 percent (hemorrhage, intimal flaps, and arteriovenous fistulas).

The conventional sonogram has limited utility but may detect some anatomic abnormalities suggesting a vascular or nonvascular diagnosis. Duplex and color-flow Doppler have been utilized to evaluate the renal artery but are technically difficult and the subject of controversy in the literature about their diagnostic accuracy. Color Doppler has the advantage of sampling long segments of vessels but cannot accurately quantitate flow disturbances. When identified, flow disturbances must be quantified by duplex Doppler. Utilizing peak flow rates, studies have attempted to define a rate of flow that can accurately predict RAS greater than 50 percent. The threshold flow-rate value that provides the best combination of sensitivity and specificity is controversial. Peak systolic velocity of 190 to 250 cm/s has a sensitivity of 90 to 100 percent for RAS greater than 50 percent. [19,20] However, specificity has varied from as low as 55 percent to as high as 95 percent. [21] The overall accuracy can be improved by using peak systolic velocity in conjunction with analysis of the waveform (rounded, smaller-amplitude waveform with stenosis) in detecting significant proximal RAS.

Renal scintigraphy is a test of vascular perfusion, parenchymal extraction, and excretion. Abnormal findings from this study include (1) impaired uptake and visualization, which is consistent with vascular obstruction or hyperacute rejection and is a poor prognostic sign; (2) normal uptake and visualization but with parenchymal retention, which is associated with poor urine flow and the retention of the secreted isotope in the tubules; and (3) decreased uptake with normal parenchymal transit time and absent or minimal cortical retention, which is consistent with chronic rejection or renovascular hypertension. Unfortunately, the effects of renal artery stenosis, graft rejection, and cyclosporine toxicity cannot be distinguished using renal scintigraphy. [22]

Captopril-augmented renal scintigrams have been utilized to distinguish physiologic from nonphysiologic RAS. Patients with normal captopril renal scintigrams are not likely to respond to angioplasty, while patients with abnormal captopril renal scintigrams will likely have a significant improvement following angioplasty. Captopril renal scintigrams can replace renal vein renin sampling in identifying patients with lesions amenable to intervention. [23]

Urinary Tract Infection (UTI)

There is considerable controversy regarding the appropriate imaging of children with UTI to identify predisposing functional and anatomic abnormalities. Sometimes, an emergency evaluation is required because of diagnostic confusion based on atypical presentations, a negative urinalysis, or treatment failure based on persistent fever and toxicity 72 h following the initiation of therapy.

Renal cortical scintigraphy (RCS) using Tc ^{99m}-DMSA is the most sensitive imaging modality for establishing the diagnosis of pyelonephritis. [24] In animal models, RCS has a sensitivity of 91 percent and specificity of 99 percent as compared with histopathology. [25] Results in humans with culture-positive UTI have shown a sensitivity of only 50 to 66 percent. [26] While its sensitivity is low, RCS is more sensitive than ultrasound, CT, or IVP. [27] Controversy exists concerning the necessity of documenting renal scarring and pyelonephritis in a child with an apparently simple UTI. [28,29] Some clinicians advocate treating all patients with a 10-day course of antibiotics, as opposed to the usual 5- to 7-day course, to avoid the need to document the presence of pyelonephritis. [30] Also, patients with vesiculoureteral reflux do not always demonstrate scarring on RCS; therefore, a normal RCS does not obviate the need to proceed with voiding cystography. RCS has more accepted utility in following renal scarring in patients with recurrent UTI and pyelonephritis, where progressive renal scarring can result in renal failure or hypertension. An advantage of RCS is that it can be used in children and neonates with poor renal function.

The voiding cystogram is used to demonstrate vesicoureteral reflux, the most common abnormality found in the urinary tract of children, which is seen in approximately 35 percent of children with UTI. Children at risk for vesicoureteral reflux include those with a family history of reflux and Caucasians. Voiding cystography can be done by radiographic or radionuclide technique. The radionuclide voiding cystogram utilizing technetium pertechnetate has the advantage of less radiation exposure but the disadvantage of poor visualization of urethral and bladder abnormalities, which are more commonly seen in boys. The radionuclide voiding cystogram is the imaging modality of choice in girls and is useful for the follow-up of patients and for screening siblings. Boys should undergo radiographic cystography. However, the relationship between vesicoureteral reflux and pyelonephritis remains controversial, with as many as 50 percent of children estimated to have another route of infection. Evaluation of patients with RCS-documented pyelonephritis found only a 37 percent incidence of vesicoureteral reflux on voiding cystograms.[31]

Ultrasound is an insensitive method for diagnosing pyelonephritis or vesicoureteral reflux but can provide anatomic information unavailable in other modalities. It can visualize renal abscesses, hydronephrosis, and obstruction at either the ureterovesical or uteropelvic junction. CT scan can accurately diagnose renal parenchymal lesions but is less sensitive than RCS is detecting pyelonephritis. CT signs of pyelonephritis include renal enlargement, poor corticomedullary definition, and patchy areas of decreased definition. Renal and perinephric abscesses are well visualized on CT. CT is not recommended in children because of the proximity of the gonads and their radiosensitivity before puberty.

Adults with pyelonephritis require only imaging studies if there is a suspicion of complications, including obstruction and perinephric abscess. CT is the imaging modality with the highest yield in demonstrating anatomic and functional renal abnormalities caused by acute pyelonephritis.

Trauma

RENAL INJURIES   Blunt trauma is the etiology in 80 to 90 percent of renal injuries. Significant renal injury is usually associated with gross hematuria or signs of shock. Although gross hematuria occurs frequently with major injuries, the absence of gross hematuria does not rule out significant injury. [32] The emergency physician should suspect renal injury in patients with flank masses, flank ecchymosis, eleventh- and twelfth-rib fractures, and fractures of the upper lumbar transverse processes. Patients with blunt trauma may have microscopic hematuria without a clinically significant urinary injury; imaging these patients would therefore not be useful. Other approaches have been advocated to reduce the incidence of normal studies in patients with microscopic hematuria after blunt trauma. In adults, imaging can be restricted to those with microscopic hematuria and signs of shock. In children, imaging can be restricted to those with associated major injuries or hematuria of more than 50 red blood cells per high-power field. [33] Penetrating trauma is different; those with stab wounds near the urinary system and gunshot wounds require radiographic evaluation for any degree of hematuria.

Decisions regarding imaging of the kidneys and urinary tract in cases of trauma are usually secondary to the management and stabilization of life-threatening injuries. In the hemodynamically stable patient with suspected intraabdominal injury, the test of choice is a CT scan of the abdomen with administration of IV and oral contrast. The CT scan is more sensitive and specific than IVP and has the advantage of imaging the entire abdomen and retroperitoneum. [34] In hemodynamically unstable patients, an intraoperative IVP is often the only imaging modality available. Ultrasound is neither sensitive nor specific for the detection of renal injuries, although it can be utilized as a screening tool for the detection of intraperitoneal fluid.

The injury pattern to kidneys includes contusions, lacerations, lacerations with extension into the collecting system, and disruptions of the renal vasculature. The renal injury scale developed by the Organ Injury Committee of the American Association for Surgery of Trauma grades these injuries on a scale of 1 to 5 [35] (Table 97-2; Fig. 97-2). Radiographic staging is used in conjunction with the clinical situation to differentiate injuries requiring surgical management from those that can be managed

nonoperatively. Grade I, II, and III renal injuries will heal spontaneously and are best managed conservatively without surgery, as opposed to grade V lesions, which should be managed surgically. There is no universal agreement on the management of grade IV lesions.

Grade I: Contusions that appear as amorphous interstitial extravasation of blood. A hematoma is a well-demarcated, hyperdense collection of blood.

Grade II: Lacerations that are superficial and limited to the renal cortex. These injuries are sometimes accompanied with a subcapsular hemorrhage (a small crescentic formation that flattens the underlying renal contour) or a perirenal hemorrhage, which infiltrates or displaces the perirenal fat.

Grade III: Lacerations greater than 1 cm depth, not involving the collecting system.

Grade IV: Lacerations extending into the medulla and communicating with the collecting system. They are almost always accompanied by a perirenal hemorrhage with extravasation of urine into the perirenal parenchyma or into the perirenal space.

Grade V: The kidneys are shattered and there may be injury to the vasculature of the renal pedicle. A shattered kidney is depicted on CT as multiple fractured planes, with separation of functioning or devitalized tissue. If renal artery occlusion has occurred, the kidney demonstrates no enhancement.

TABLE 97-2   Classification of Renal Injuries
FIG. 97-2. Classification of renal injuries. **A.** Grade I injury. Renal contusion (with subcapsular hematoma). **B.** Grade II injury. Superficial renal laceration (with subcapsular hematoma). **C.** Grade IV injury. Deep laceration extending into the collecting system. **D.** Grade V injury. Shattered kidney. **E.** Thrombotic occlusion of renal artery. There is a rupture of the intima (*a*) complicated by a subintimal hematoma (*b*). This has resulted in complete occlusion of blood flow in the artery (*c*). There is also propagation of blood clot proximally toward the aorta, as well as distally. **F.** Avulsion of UPJ.

In unstable patients, the "one-shot" IVP (a single radiograph of the abdomen taken 5 to 10 min after contrast injection) can identify major renal and urinary injuries. With early repair, this is the most effective way to preserve renal function. [36] The IVP can establish the presence or absence of bilateral kidneys, delineate the renal parenchyma, and define the collecting system and ureter. Findings of contrast extravasation or nonfunction correlate with the presence of major renal injuries. [37] There is currently no role for the standard IVP in renal trauma; a review of the literature from the pre-CT era demonstrated that IVP has a diagnostic accuracy of 50 to 90 percent for renal injuries. [38]

Angiography is used to document and treat renovascular injuries. It is indicated for patients with CT findings of large retroperitoneal hematomas, major renal fractures, and segmental areas of renal nonenhancement. Angiography can also be considered in patients with persistent or recurrent posttraumatic hematuria. [39] If a source of bleeding is identified, the patient can be treated with selective embolization.

Traumatic thrombosis, intrarenal hematomas, and vessel vasospasm are visualized by angiography as sharply demarcated defects, reflecting devitalized tissue. At the margins of the injury, homogeneous staining of the parenchyma indicates an adequate vascular supply, while heterogeneous staining indicates the presence of vessel spasm or traumatic thrombosis. Subcapsular and intrarenal hematomas are visualized as faint staining of the parenchyma and cortex in the nephrographic phase. Infarction of the kidney secondary to vessel thrombosis may be focal or global. It is recognized by the maintenance of a small rim of peripheral perfusion around the subcapsular cortex and the lack of central perfusion. Segment infarcts, depending on the distribution of the occluded vessel, may be either wedge-shaped or hemispheric. Wedge-shaped infarcts are oriented with the base toward the renal capsule and the apex toward the hilum. Arterial injuries are seen as extravasation of contrast material persisting into the venous phase. Arterial injuries should be distinguished from intrarenal urinary extravasation, which has a similar dense pattern. Injuries to the renal artery are characterized by the abrupt termination of the renal artery, just beyond its origin. Traumatic arterial aneurysms (arteriovenous fistulas) are diagnosed by opacification of the anastomosed vein after the administration of contrast into the artery.

Duplex and color Doppler ultrasound studies can detect renal infarcts, vascular pedicle injuries, and arteriovenous fistulas. Segmental or focal infarcts appear as hypoechoic wedge-shaped masses. Arteriovenous fistulas appear as increased flow velocity with arterial pulsations in the draining vein. Color Doppler demonstrates a mass of torturous vessels consisting of multiple colors indicative of the lack of organization and turbulent flow of the vessels. In renal artery occlusion, Doppler will not demonstrate flow to the kidney.

BLADDER INJURIES   The bladder is located within and protected by the pelvis. Up to 85 percent of bladder injuries are associated with a pelvic bone fracture, almost always caused by a bony spicule penetrating the bladder. Of patients with bladder rupture, 50 to 85 percent have an extraperitoneal rupture, 15 to 45 percent have an intraperitoneal rupture, and 0 to 12 percent have both. The imaging modality of choice to detect urethral and bladder injuries is a retrograde cystogram. Indications for a retrograde cystogram include (1) inability to void, (2) gross hematuria in the presence of a pelvic bone fracture, and (3) blood at the external urinary meatus. In males, a retrograde urethrogram is usually obtained first to ensure that the urethra is intact before the Foley catheter is advanced into the bladder for the cystogram study. In females, the Foley catheter can usually be placed without a urethral imaging study unless gross blood is visible at the urethral meatus. Bladder injuries are classified as types 1 to 5 (Table 97-3).

Type 1: Bladder contusion. An incomplete or unperforated tear of the bladder mucosa. This injury is associated with a pelvic hematoma and is the most common type of injury. The radiographic appearance is normal.

Type 2: Intraperitoneal bladder rupture at the junction of the mobile and stationary areas of the bladder and at the peritoneal reflection of the bladder dome. This occurs when the bladder is distended and sustains a blunt abdominal trauma, which leads to an increase in the intravesical pressure. Patients at risk for this injury include those involved in automobile crashes who are wearing lap seatbelts. This injury is characterized radiographically by contrast material running freely, surrounding loops of bowel and intraperitoneal viscera, and filling the paracolic gutters.

Type 3: Interstitial bladder injury. This type of injury is rare. It is an incomplete perforation of the serosa, leaving the mucosa intact. Retrograde cystography reveals an irregularity in the bladder wall without extravesicular leakage of contrast.

Type 4: Extraperitoneal ruptures. These are divided into simple and complex injuries. With simple injuries, extravasation of contrast material is limited to the pelvic extraperitoneal space, while complex injuries are characterized by spread of contrast material beyond the pelvic extraperitoneal space, into the retroperitoneum, scrotum, and the anterior abdominal wall.

Type 5: Combined bladder injury.

TABLE 97-3   Classification of Bladder Injuries

URETHRAL INJURIES   Injury to the female urethra is rare owing to its short length and mobility. If it is injured, the most common type is avulsion of the proximal urethra, occasionally involving the bladder neck. Urethral injury should be suspected in females who present with pelvic fractures, blood at the introitus, deep

periurethral laceration, difficulty in voiding or inability to void, unsuccessful attempts at catheterization, and the development of vulvar edema after removal of a urinary catheter. One review of 130 cases of pelvic fractures in females found that 4.6 percent had urethral injuries. [40]

The male urethra is divided into the anterior portion, which consists of the penile and bulbous urethra, and the posterior portion, consisting of the membranous and prostatic urethra. The urogenital diaphragm separates these two portions.

Injuries to the anterior urethra are associated with straddle injuries: the bulbous urethra and surrounding corpus spongiosum are crushed against the inferior aspect of the pubis resulting in a contusion and/or partial rupture of the bulbous urethra. Retrograde urethrography is the test of choice to evaluate these injuries. With partial anterior urethral rupture, the retrograde urethrogram demonstrates extravasation of contrast with maintained urethral continuity. Complete anterior disruption is rare and is identified by extravasation of the contrast medium and failure to visualize the anterior urethra completely up to the urogenital diaphragm.

In posterior urethral injuries, the prostatomembranous urethra ruptures above the urogenital diaphragm secondary to shear forces. The classic clinical findings are blood at the urethral meatus, inability to void spontaneously, a palpable bladder, and a superiorly displaced prostate on digital rectal examination. Three patterns of posterior urethral injuries have been described (Table 97-4).

Type I: The posterior urethra is stretched but intact. Hematoma collects in the prostatic fossa and the bladder is elevated high in the pelvis.

Type II: The urethra is disrupted at the membranoprostatic junction above the urogenital diaphragm. Contrast material is present in the extraperitoneal space of the pelvis.

Type III: Disruption of the membranous urethra, with extension on the injury into the proximal bulbous urethra and/or diaphragmatic rupture. Depending on the degree of the urogenital diaphragmatic injury, contrast may be visible in the perineum.

TABLE 97-4 Classification of Posterior Urethral Injuries

URETERAL INJURIES   In ureteral injuries, CT scanning with intravenous contrast or IVP usually demonstrates contrast extravasation and hydronephrosis. The most common type of injury is avulsion of the ureter at the uteropelvic junction, often occurring from falls. These injuries will show normal renal parenchyma with failure of the ureter and bladder to opacify and the accumulation of contrast material in the perirenal space.

98 VAGINAL BLEEDING AND PELVIC PAIN IN THE NONPREGNANT PATIENT

Laurie Morrison
Julie Spence

This chapter discusses the emergency department (ED) management of vaginal bleeding and pelvic pain in nonpregnant female patients. A review of the physiology of the normal menstrual cycle, the pathophysiology of abnormal vaginal bleeding, and the physiology of pelvic pain is included. Fluctuation in bleeding and pelvic pain are common in the natural history of the normal menstrual cycle. It is important, therefore, for physicians to differentiate normal variations from pathology.

EPIDEMIOLOGY

ED visits for vaginal bleeding or pelvic pain by women of reproductive-age are common. It is estimated that 5 percent of women aged 30 to 49 years will consult a physician for treatment of menorrhagia.[1] An Australian review of Pap smear requests for women aged 20 to 69 documented that 1 in 20 had abnormal bleeding.[2] Although this data may not be generalizable to the ED, it does emphasize the point that abnormal vaginal bleeding is common. Population-based data are not available for children and adolescents.

In a cross-sectional survey of reproductive-age women who presented to a primary care setting, 90 percent reported some dysmenorrhea, 38 percent experienced dyspareunia sometimes, and 39 percent reported other types of pelvic pain.[3] Overall, pelvic pain is most common in 18- to 30-year-old women. Prevalence does not vary significantly by education, parity, or race.[3] Diagnoses made on the basis of history and physical examination may overestimate the prevalence of pathology. In studies of women with pelvic pain who were referred for laparoscopy, 17 percent of adolescents and 16 percent of reproductive-age women had normal findings on examination.[4,5]

PHYSIOLOGY

Developing Children

In newborn females, the placental transfer of estradiol and gonadotropin is responsible for a mucoid or blood-tinged vaginal discharge, minor breast development, and vaginal flora similar to that in adult women. Uterine bleeding secondary to estrogen withdrawal may occur in the first 6 weeks of life in normal neonates. Bleeding after this time is always abnormal and requires investigation.

By definition, prepubertal children lack secondary sex characteristics. The labia and mons have less fatty tissue than in adults and lack protective hair. The labia minora are thin, and there is less distance between the anus and the vaginal introitus. The thin vaginal epithelium of prepubertal girls is similar to that of postmenopausal women.

Adolescents

Ten years of age tends to be the lower limit for menarche, and the mean age in North America is 12.5 years. Most children develop secondary breast changes 2 years prior to the onset of menarche. At the time of ovarian stimulation, a white or yellow vaginal discharge, which is both nonodorous and nonirritating, may appear. Early cycles are anovulatory and irregular, but unlike adult anovulatory cycles, bleeding is generally not excessive. The hypothalamic pituitary axis takes 1 to 5 years to reach full maturity, and the average time to establish ovulatory cycles is 2 years after menarche.

Normal Menstrual Cycle

The normal menstrual cycle is 28 days and is divided into four phases: follicular, ovulation, luteal or secretory, and menses. The first 14 days are the follicular phase, during which the ovary matures an oocyte for ovulation, and the granulosa cells, lining the follicle, produce estrogen. This stimulates the endometrium to proliferate and thicken (Fig. 98-1). In response to the rising estrogen levels, the pituitary gland secretes follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which stimulate the release of the mature oocyte. The residual follicular capsule forms the corpus luteum. During the luteal phase, the corpus luteum secretes estrogen and progesterone, which maintain the endometrium and make it more receptive to implantation. If fertilization and implantation occur, the developing embryo secretes human chorionic gonadotropin (hCG) into the bloodstream, signaling the corpus luteum to continue the production of progesterone and estrogen necessary to support early pregnancy. In the absence of hCG, the corpus luteum involutes, and estrogen and progesterone levels fall. Hormonal withdrawal causes vasoconstriction in the spiral arterioles of the endometrium. This leads to the final phase, or menses, when the ischemic endometrial lining becomes necrotic and sloughs. The vaginal effluvium contains blood, endometrial tissue, and fluid. The estimated amount of menstrual blood loss ranges from 25 to 60 mL. Judging the amount of bleeding in a menstrual cycle may be difficult. The average tampon or pad absorbs 20 to 30 mL of vaginal effluent, although the number of pads or tampons used is unreliable, as personal habits vary greatly among women. In a normal cycle, fibrinolysis occurs in the uterine cavity and the cervix. In women with heavy bleeding, there may be insufficient time for fibrinolysis, and blood clots may occur. Definitions of commonly used gynecologic terminology have been included in Table 98-1.
FIG. 98-1. The hormonal, ovarian, endometrial, and basal body temperature changes and relationships throughout the normal menstrual cycle. (From Carr and Wilson,[24] with permission.)

TABLE 98-1   Definitions

Menopause

Menopause results from ovarian "burnout" and, on average, occurs at age 51.[6] During the transition phase, or perimenopausal period, there is lengthening or marked variation in the intermenstrual intervals. By age 45, only a few primordial cells remain, and the production of estrogen decreases. As a result, the pituitary continuously produces large quantities of FSH and LH. There is no midcycle rise in estrogen to trigger a further surge of pituitary hormones for ovulation. Estrogens continue to be produced in lower, subcritical levels for a short time after menopause, until the remaining follicles become atretic, and production falls to almost zero.

Pelvic Pain

The distribution of nerves in the pelvis is outlined in Table 98-2. The hypogastric nerve innervates the uterus, adnexae, and bladder dome. The second through fourth sacral nerves provide sensation for the lower segment of the uterus, cervix, bladder trigone, and rectum. Pain of either gynecologic and nongynecologic origin may be referred to the back, buttocks, perineum, or legs.

TABLE 98-2   Nerves Carrying Painful Impulses from the Pelvic Organs

The quality of pain can be characteristic of different etiologies. Visceral or splanchnic pain is colicky and caused by distention of a hollow viscus or stretching of a ligament. Examples include distention of the fallopian tube in ectopic pregnancy, uterine contractions in dysmenorrhea, and stretch of the round ligament with adhesions or in pregnancy. Peritoneal or somatic pain is sharp and localized to the region of inflamed tissue, as in salpingitis, appendicitis, and endometritis. Generalized peritonitis may be seen with larger degrees of inflammation, i.e., with spillage of blood, pus, or gastrointestinal (GI) contents into the peritoneal cavity.

The onset of pain may also provide diagnostic clues. Gradual onset may occur with a slow leak of irritants, as occurs with pelvic inflammatory disease (PID). Sudden onset of pain occurs with ischemia or cyst rupture. Cyclic pain is usually related to the menstrual cycle, and timing is helpful in establishing a diagnosis. Examples include endometriosis and dysmenorrhea (Table 98-3).

TABLE 98-3   Differential Diagnosis of Acute Pelvic Pain

PATHOPHYSIOLOGY: THE ANOVULATORY CYCLE

Anovulatory bleeding may be regular but more often is irregular due to fluctuating estrogen levels below the critical level required to maintain endometrial growth. The level of estrogen depends on the age, number, and activity of ovarian follicles. As some follicles degenerate, others resume the production of estrogen and the endometrium continues to proliferate for weeks to months, which may cause glandular hyperplasia ("Swiss cheese" hyperplasia). This estrogen steady state is insufficient to meet the growing needs of the endometrium and produces a relative estrogen insufficiency, and vaginal bleeding ensues. Alternatively, when follicle degeneration and stimulation are not balanced, absolute estrogen levels fall and withdrawal bleeding occurs. Characteristically, anovulatory cycles present as prolonged amenorrhea with periodic menorrhagia. Due to the lack of progesterone-mediated myometrial contractions and arteriolar vasospasm, anovulatory cycles are rarely associated with cramping.

PREPUBERTAL CHILDREN

History

In children, the history should focus on circumstances of bleeding, times of recurrence, and associated symptoms, including abdominal or pelvic pain. Physicians should also look for signs of precocious puberty. Children who were exposed to diethylstilbestrol (DES) in utero are at risk for adenocarcinoma of the vagina and cervix and require a formal gynecologic consultation. All presentations warrant consideration of sexual abuse.

Physical Examination

As is the case for most pediatric presentations in the ED, children should be completely undressed and thoroughly examined. This enables physicians to look for subtle signs of disease, injury, and abuse. A child's development of secondary sex characteristics should be assessed and compared with the Tanner stages of breast and pubic hair growth. Most premenarchal girls should not undergo a speculum examination or vaginoabdominal palpation except in the event of vaginal bleeding and trauma. The vast majority of examinations and procedures can be done with the parent holding the child.

Young children presenting with vaginal bleeding or trauma can be examined on the parent's lap. Children older than age 3 should be comfortable supine, lying "like a frog," for the examination of the external genitalia (Fig. 98-2A). Draping of the legs and perineum is unnecessary and usually cumbersome. Visualization of the vagina is best done by asking the child to "get up on your hands and knees like you are crawling" (Fig. 98-2B). She can rest her head on her forearms and look at her parent. The labia and buttocks are gently pressed upward and outward. If the child relaxes the abdominal and back muscles, the resulting lordosis should enable one to see the lower half of the vagina with an otoscope light. Children over age 3 may also be examined while they are supine in the knee-chest position, like a "cannonball."
FIG. 98-2. Examination positions for a prepubertal child. (From Paradise,[26] with permission.)

If cultures are indicated, they should be taken with the child in the supine position with a saline-soaked cotton-tipped swab or a soft medicine dropper. If the findings of the vaginal examination are suboptimal, or if a pelvic mass or foreign body is suspected, a rectoabdominal examination should be performed while the child is in the frog-leg position. The cervix is palpated as a midline button of tissue often described as similar in size and consistency to the eraser on a pencil. The ovaries and uterus should not be palpable. The vagina can be "milked" for blood or discharge.

The use of restraints for pelvic and vulvar examination has no role in modern practice. Conscious sedation or general anesthesia may be required to obtain an adequate examination. A speculum examination should not be performed without appropriate anesthesia.

Differential Diagnosis

The epidemiologic data and the differential diagnosis of vaginal bleeding in the prepubertal child are outlined in Table 98-4 and Table 98-5.

TABLE 98-4   Etiologies for Vaginal Bleeding in Prepubertal Children (Referral Population)

TABLE 98-5   Causes of Bleeding and Pelvic Mass by Approximate Frequency and Age Group

Investigations

Most causes of pelvic pain and bleeding in this age group can be diagnosed by taking a complete history and performing a selective physical examination. ED-based investigations are usually unnecessary. Treatment and criteria for consultation are self-evident.

Clinical Conditions in Prepubertal Children

VAGINITIS   Vaginitis is the most common cause of pelvic pain and vaginal bleeding in prepubertal children. The immature anatomy and the hypoestrogenic state predispose children to this condition. In this age group, *Staphylococcus epidermidis* and diphtheroids are the predominant vaginal flora. *Lactobacillus,* which metabolizes glycogen to lactic acid in adults, is not found in children. This contributes to the alkaline environment of the prepubertal vagina, and as a consequence, children may develop infections with organisms that are not pathogenic in adults. This topic is covered in greater depth in Chap. 104.

GENITAL TRAUMA   Trauma to the genital area must alert physicians to the possibility of sexual assault (see Chap. 289, "Child Abuse and Neglect"). Perineal trauma represents 0.2 percent of all injuries in children younger than age 15. In an American study of children (mean age, 6.2 years), unintentional injuries to the pelvis were a result of bicycle accidents, straddle injuries, and falls. The labia majora was injured most frequently, and injuries tended to be superficial. Only 3 of 56 children required surgical repair of lacerations.[7] There are case reports of vaginal injuries from water sports, including water skiing, jet-ski accidents, and riding down water chutes. The extent of the injuries range from superficial trauma to deep lacerations with life-threatening retroperitoneal bleeding and abdominal injuries.[8,9] Minor trauma, such as riding a tricycle, may induce ecchymotic bullae that may be misinterpreted as sexual abuse or a straddle injury.

Trauma to the vulva can produce ecchymoses and/or lacerations and may be associated with injury to the vagina and rectum. Straddle injuries may cause severe trauma to the mons, labia majora, buttocks, inner thigh, and periurethral areas. Injuries to the urethra may cause spasm and urinary retention, and it is important to ensure that the child is able to void prior to discharge. The hypoestrogenic skin of the prepubertal vagina tears easily with minor trauma, and there is a risk of wall perforation with a penetrating injury to both the vagina and rectum. All penetrating trauma requires a careful vaginal and rectal examination. It is prudent to refer all children with hymenal injury, or bleeding from the vagina or rectum, for prompt evaluation under anesthesia by a pediatric gynecologist.

Genital trauma management varies with the injury. Hematomas will spread liberally along tissue planes in the perineum, forming large painful masses, and cause pressure necrosis of the overlying skin. Any hematoma should be observed in the ED until it has stopped expanding in size. Small hemostatic lesions heal well with conservative management and wound care. Minor lesions that continue to bleed should respond to pressure dressings or ice packs, and in more severe cases, topical thrombin or Gelfoam (Pharmacia Upjohn, Kalamazoo, MI) absorbable gelatin sponges can be used. Older children may tolerate surgical repair of minor lacerations with local anesthesia. The use of topical anesthetics is contraindicated because of enhanced systemic toxicity. The use of delayed absorbable sutures avoids the discomfort and trauma of subsequent removal. Any crush or penetrating injury secondary to a human bite should be covered with broad-spectrum antibiotics and allowed to heal by secondary intent. There must be a low threshold for admission with subtle injuries, if there is a suspicion of danger at home, or the need for psychological and social support.

VAGINAL FOREIGN BODY   Vaginal foreign bodies classically present with intermittent bloody, foul-smelling vaginal discharge. Small wads of toilet paper are most commonly found. Foreign bodies should be suspected when the posterior wall of the lower half of the vagina cannot be visualized when the child is in the "crawling position" (see Fig. 98-2*B*) or knee-chest position (cannonball position). Toilet paper is not palpable on rectal examination, although other foreign bodies such as erasers, beads, and nuts can sometimes be appreciated. Radiographs are usually not helpful. Frequently, the object may be removed by gentle vaginal irrigation with warm water or by "milking" the vagina of any hard objects during rectal exam. Foreign bodies that cannot be removed by simple measures may require examination and removal under anesthesia.

CONGENITAL VAGINAL OBSTRUCTION   Vaginal obstruction can be secondary to a transverse vaginal septum or imperforate hymen. Imperforate hymen is found in 1 in 1000 of full-term female neonates, and a transverse vaginal septum is found in 1 in 2000 to 1 in 84,000 females. Diagnosis is made by careful examination of the perineum. Infants may go undiagnosed for weeks until they develop an abdominal mass, difficulty with urination, or a visible bulging membrane at the vagina introitus. In severe forms, children may have constipation, hydronephrosis, respiratory compromise, and edema of the lower extremities. The treatment of hydrocolpos is surgical excision of the obstruction.

PRECOCIOUS PUBERTY AND MENARCHE   Children aged 5 to 9 may develop secondary sex characteristics and experience the onset of menarche and accelerated growth indistinguishable from the normal changes of puberty. This is most frequently idiopathic in origin but can be associated with endocrine or neurologic diseases. Referral to a pediatrician is essential.

Premature menarche is cyclic vaginal bleeding in prepubertal children in the absence of pubertal development. It is a diagnosis of exclusion and beyond the purview of emergency physicians. In the ED, it is important to rule out other serious causes of vaginal bleeding prior to referral for further investigations.

URETHRAL PROLAPSE   The etiology of urethral prolapse is unknown. It frequently occurs between the ages of 2 and 10 and is more common in black children. It may present as a red or purplish, soft spongy mass approximately 1 to 2 cm in diameter, with a central dimple at the urethral meatus. Urethral prolapse may be discovered surreptitiously during a routine examination of an asymptomatic child. Vaginal bleeding is the presenting complaint in 90 percent of cases. Painless vaginal bleeding may be associated with urinary frequency or dysuria in 25 percent of cases. At times, it is difficult to discern whether the mass is urethral or vaginal in origin. Observing the child urinating on a bedpan may help to determine the etiology and precludes the use of a urinary catheter to confirm the diagnosis. Urethral prolapse is usually treated simply with sitz baths and application of topical estrogen creams. Patients presenting with red or necrotic mucosa may require surgical intervention under anesthesia.

DERMATOLOGIC LESIONS   Children with seborrhea and psoriasis may present with bleeding after minor trauma. Lichen sclerosus is seen in hypoestrogenic females. The etiology is unknown. Characteristically, lichen sclerosus appears as an hourglass-shaped depigmented area on the vulva, perianal, and adjacent skin. The skin is thin and atrophic, with tiny ivory papules that coalesce. The patches are usually dry and itchy. Mild forms of lichen sclerosus may be treated with sitz baths and 1% hydrocortisone cream for symptomatic relief. More serious cases should be referred to a dermatologist.

ADOLESCENTS AND ADULTS

History

Adolescent and adult patients presenting to the ED with pelvic pain or bleeding share many common elements of the history and physical examination. Complications related to pregnancy are always possible, and routine inquiries are both appropriate and necessary. Key points that should be routinely addressed when taking the clinical history are age of menarche, menstrual history, date of the last menstrual period (LMP), pattern of abnormal bleeding or discharge, and the presence of dysmenorrhea. Sexually active patients should be asked about contraception, current sexual activity, the use of barrier protection, HIV and hepatitis status, and a history of PID, sexually transmitted diseases (STDs), or ectopic pregnancy. Patients who present with pain should be asked about its quality, timing, location, and radiation, as well as aggravating or alleviating factors. Associated symptoms of the urinary, GI, and musculoskeletal systems, as well as the presence of fever or syncope, should be documented. A history of recent illnesses, psychological stress, weight change, or endocrine problems, including thyroid disease and pituitary tumors, should be obtained. In patients with bleeding, signs and symptoms of a coagulopathy, including nosebleeds, easy bruisability, and menorrhagia, and a family history should be noted in the examination.

Taking the history of adolescent girls is challenging. Honest responses to questioning will require assurances of confidentiality and comfort by the physician. If the patient requests a female physician, honor the request, if at all possible. Always interview the patient without the parent present. Usually this is best done if you ask the parent to leave just prior to the physical examination. Questions regarding STDs and sexual activity can be very disturbing for adolescents. It is important historical information and should be obtained in a nonjudgmental, gentle way that in itself will be educational. It is not realistic to expect an accurate history about the occurrence of periods early in menarche, as the cycle is usually irregular for the first 1 to 2 years and perhaps as long as 5 years.

Physical Examination

Vital signs should be taken in all patients. In cases of heavy bleeding, any postural changes in vital signs should be recorded. A complete examination should include a careful abdominal examination to rule out other nongynecologic causes of pain or bleeding. Femoral and inguinal nodes should be examined for size and tenderness, and the back and hips should be examined to rule out renal, musculoskeletal, or skin pathology. Signs of other illnesses, including hypothyroidism, galactorrhea, and obesity associated with hirsutism, should be documented.

Male physicians should have a chaperone during gynecologic examinations. Female physicians are equally well advised to have a chaperone. At the least, an assistant will be helpful. Prior to beginning the examination, a simple, nonthreatening explanation should be given and verbal consent obtained. Adolescents should be examined without their parents or guardians. The patient should be allowed to empty her bladder and remove any tampons prior to the examination. Positioning and draping should allow the patient to see the physician during the examination. Occasional eye contact is reassuring.

The examination of nonvirginal patients includes a speculum examination, a vaginoabdominal examination (bimanual), and a rectovaginal examination. The vulva and urethral opening should be inspected prior to inserting the warmed and lubricated speculum into the vagina. The site of abnormal bleeding should be determined through careful examination of the perineum, urethra, vulva, and perianal region. The vagina should be inspected for signs of lacerations, fissure, lesions, infection, and foreign bodies. It is imperative that the cervix is well visualized to rule out polyps, inflammation, ulcers, and evidence of cancer and STDs, including condylomata. Cultures are generally taken as part of the routine examination, especially if a mucopurulent discharge is found. The cervical os should be inspected for blood, tissue, an intrauterine device (IUD), pedunculated leiomyomata or polyps, and signs of infection.

On bimanual vaginoabdominal examination, the cervix softness, patency of the os, and pain on movement should be documented. The ovaries and uterus are palpated for size, consistency, pain, and the presence of associated masses. The adnexa and periuterine area should also be carefully examined. The rectovaginal examination is essential and should be done in every patient, especially if the patient cannot tolerate a bimanual examination. The rectovaginal examination enables evaluation of the posterior cul-de-sac for ovarian masses, the posterior wall of the uterus for size and consistency, and the uterosacral ligaments for metastatic nodules or ectopic endometriosis. Stool should be evaluated for the presence of blood.

Virginal patients with menstrual cramps, mittelschmerz, or vaginal discharge do not require a full pelvic examination, because a rectovaginal examination is generally sufficient. In the case of trauma and abnormal vaginal bleeding, a vaginal examination is necessary. It can generally be tolerated by adolescents with intact hymen if a narrow Pederson-type or Huffman speculum is used. Conscious sedation or full anesthesia may be required, depending on psychological response of the patient and the circumstances surrounding the injury or the extent of the injury or disease.

Older patients with a history of pelvic pain and bleeding should undergo a full gynecologic examination. Degenerative changes to the lumbar spine and hips may make the traditional lithotomy position difficult. Alternatively, the patient may be examined supine with knees flexed and legs dropped to the side, or lying on her side with the lower arm behind her back and thighs flexed (the Sims position). A small speculum (e.g., a 1- to 1.5-cm Pederson) should be used if the vulva and vagina appear atrophic. Physicians must remember that the vaginal walls may become adherent in individuals who are not sexually active, and a gentle digital examination may be required to ensure that a speculum examination is possible. Vaginal examination is generally well tolerated in women who are on estrogen replacement. Documentation of the size, shape, and mobility of the uterus is especially important when making a diagnosis in this population. The normal ovary should not be palpable 5 years after menopause, and any enlargement should be considered abnormal.

Differential Diagnosis and Approach to Adolescent, Reproductive-Age, and Postmenopausal Females

Causes of bleeding and pelvic mass by approximate frequency and age group are listed in Table 98-5.

VAGINAL BLEEDING   Bleeding in early puberty is usually secondary to anovulatory estrogen withdrawal for the first 2 years after menarche. The amount of blood loss is minimal. Eating disorders, excessive weight loss, stress, and exercise can cause abnormal uterine bleeding. Additionally, medications (e.g., antiseizure medications) that increase the P-450 system of the liver may increase the metabolism of endogenous hormonal glucocorticoids and may cause withdrawal bleeding. Menorrhagia secondary to anovulation is seen in 10 to 15 percent of all gynecologic patients. Nongynecologic causes of vaginal bleeding and pelvic pain must be included in the differential diagnosis, be systematically addressed during the history taking and physical examination, and be pursued with relevant investigations and consultations, if indicated. Primary coagulation disorders account for 19 percent of acute menorrhagia in adolescents. Von Willebrand disease (vWD) is the most common; however, myeloproliferative disorders and immune thrombocytopenia are also possibilities. Otherwise, the differential diagnosis for pelvic pain and/or vaginal bleeding is similar to that in adults.

The causes of vaginal bleeding in nonpregnant, reproductive-age females can be broadly grouped into three categories: nonuterine bleeding, ovulatory abnormal bleeding, and anovulatory abnormal bleeding. Ovulatory bleeding usually results in menorrhagia and intermenstrual bleeding. Nonovulatory cycles may be irregular and heavy (menometrorrhagia) or frequent and light (polymenorrhea) bleeding.

Potential sources of nonuterine bleeding include the cervix, vagina, lower urinary tract, and lower GI tract. Cervical causes include carcinoma, polyps, condylomata, eversion of squamocolumnar junction associated with oral contraceptive pill (OCP) use or pregnancy, trauma, and some infections. Vaginal sources of bleeding include carcinoma, sarcoma, adenosis, lacerations, infections, and retained foreign bodies. Lower urinary tract lesions, such as urethral caruncles and infected urethral diverticula, may mimic vaginal bleeding. Some patients may not be able to determine the source of bleeding, and lower GI causes may need to be investigated.[10]

Ovulatory bleeding is associated with regular menstrual periods that are preceded by breast tenderness, abdominal bloating, and dysmenorrhea. Abnormal bleeding may occur during ovulation, as a result of low estrogen levels. Intermenstrual bleeding may also be caused by structural and inflammatory lesions, including cervical polyps, vaginal lacerations, cervicitis, invasive cervical cancer, endometrial cancer, and fibroids. OCP use remains the most common cause of midcycle bleeding. Premenstrual spotting or delayed menses frequently results from an inadequate luteal phase or persistent corpus luteum. Other causes of abnormal or heavy ovulatory bleeding include pelvic diseases, such as endometriosis, PID, and ovarian neoplasms. Uterine causes include leiomyomas, endometrial polyps, endometrial hyperplasia or malignancy, and adenomyosis. Finally, iatrogenic factors, pregnancy and postpartum complications, and bleeding dyscrasias may result in abnormal bleeding in the woman with ovulatory cycles.[10]

Anovulatory bleeding is irregular shedding of a thickened endometrium. It is a result of chronic stimulation of the endometrium by estrogen and the absence of luteal-phase progesterone. Bleeding is heavy, with long intervals between menstrual periods. Abnormal anovulatory bleeding is seen in perimenarchal and perimenopausal women as well as in patients with endocrine disorders, polycystic ovary syndrome, exogenous hormone use, and liver or renal disease. This pattern of bleeding increases the risk of endometrial hyperplasia and adenocarcinoma.

It is important to distinguish true pathology from dysfunctional bleeding in the perimenopausal and menopausal patients (Table 98-6). Postmenopausal bleeding, i.e., any bleeding that occurs more than 6 months after cessation of menstruation, warrants prompt referral for evaluation. The amount of bleeding does not correlate with the severity of disease. Older patients may not be able to accurately describe the location of pain or bleeding in the proximity of the bladder, uterus, or rectosigmoid. It is imperative that the vagina and cervix be adequately visualized. In perimenopausal or postmenopausal women, malignancy should always be considered, since it is the most important, although not the most common, diagnosis.[11] Bleeding from a vaginal source is uncommon but may be associated with the use of pessaries and douche solutions, which can irritate the mucosa. Cervical polyps may be a source of bleeding. However, an endometrial biopsy is ultimately required to rule out other serious causes of bleeding (Table 98-7).

TABLE 98-6   Factors Frequently Used to Determine the Cause of Abnormal Bleeding in Perimenopausal Women

Factor	Approximate Percentage
Exogenous estrogens	30
Atrophic endometritis/vaginitis	30
Endometrial cancer	15
Endometrial or cervical polyps	10
Endometrial hyperplasia	5
Miscellaneous (e.g., cervical cancer, uterine sarcoma, urethral caruncle, trauma)	10

TABLE 98-7   Etiology of Postmenopausal Bleeding

Hormone replacement therapy is commonly used to relieve symptoms associated with menopause and to reduce the risk of cardiovascular disease. Most therapeutic regimens deliver sequential progestins to induce withdrawal bleeding and protect the endometrium from atypia. Other therapies use continuous administration of estrogen and progesterone to achieve an atrophic endometrium and amenorrhea.[12] In patients treated with sequential hormonal therapy, heavy or prolonged bleeding at the end of the cycle or breakthrough bleeding in two or more cycles should be investigated. Of patients on continuous therapy, 40 percent will have abnormal bleeding in the initial 4 to 6 months. There is no acceptable criteria for "abnormal bleeding" on these therapies, and investigations are warranted if bleeding continues beyond 6 months or recurs after amenorrhea is established. Although bleeding is frequently caused by an unstable or atrophic endometrium, other causes must be considered. Important conditions in the differential diagnosis include submucosal fibroids, endometrial polyps, endometrial hyperplasia, adenomyosis, and tumors. Most frequently implicated are poor compliance, poor GI absorption, drug interactions, failure to synchronize therapy with endogenous ovarian activity, and coagulation disorders. Emergency therapy should be directed at investigating and treating obvious causes of bleeding. Outpatient ultrasound and endometrial biopsy can then be arranged for stable patients.

PELVIC PAIN   The differential diagnosis of pelvic pain is broad and includes pathology of the reproductive, GI, and genitourinary tracts. Gynecologic causes of pain can be subdivided as acute, cyclic, or chronic. Causes of acute pain include inflammation from PID, rupture of ovarian cysts, adnexal torsion, symptomatic fibroid uterus, and degenerative leiomyoma. Cyclic pain may be physiologic or pathologic. Premenstrual syndrome, primary and secondary dysmenorrhea, endometriosis, and adenomyosis are examples of conditions that cause cyclic pain. Pain associated with a fever is frequently from an inflammatory or infectious etiology. Although there are many causes for chronic pelvic pain, it is rarely investigated primarily in the ED, although patients may seek relief from the pain alone. Physicians should be aware, however, that there is an association between chronic pelvic pain and somatization disorders in women with a history of sexual victimization or physical assault.[13]

Investigations

Pregnancy tests should be ordered routinely in women of childbearing age to rule out pregnancy as a cause of pain and bleeding. A complete blood count is essential in most cases of vaginal bleeding and/or pelvic pain. Coagulation studies are ordered only when indicated by the history and physical examination. In individuals with suspected endocrine disorders, determination of thyroid-stimulating hormone and prolactin levels may be helpful, but the levels are rarely available for ED evaluation.

In nonpregnant patients, ultrasound is used to determine total uterine size, presence and location of leiomyoma, and the thickness and characteristics of the endometrium. Ovarian cysts, hydrosalpinx, pelvic adhesions, tubo-ovarian abscesses (TOAs), endometriosis, and ovarian carcinoma may also be seen on pelvic ultrasound. Transvaginal ultrasound may be helpful in further delineating ovarian cysts and fluid in the cul-de-sac. Endovaginal ultrasound is also an inexpensive, noninvasive, and convenient way to visualize the endometrial cavity indirectly and may be performed in perimenopausal women with abnormal bleeding. Depending on the degree of pain and findings on physical examination, ultrasound may be deferred for outpatient evaluation. Computed tomography and magnetic resonance imaging are more expensive and less useful diagnostic modalities and are used primarily for cancer staging.

Referral for follow-up will usually lead to endometrial biopsy in women who are at risk for endometrial cancer and are not pregnant. This procedure is generally indicated for women over the age of 35 with abnormal uterine bleeding or women under the age of 35 with risk factors such as obesity and chronic anovulation.[14] Hysteroscopy is a valuable test that affords a more complete examination of the surface of the endometrium than dilation and curettage (D&C), which may miss 10 to 25 percent of lesions.[15]

Laparoscopy may be used in the evaluation of pelvic pain in nonpregnant women to establish a diagnosis if etiology is uncertain, to visualize an ambiguous adnexal mass, or to confirm the diagnosis of salpingo-oopheritis. It is relatively contraindicated in patients with pelvic masses larger than 12 cm and in patients with peritonitis, ileus, or bowel obstruction.

MANAGEMENT

General Approach

The main approach to nonpregnant patients with pelvic pain or established vaginal bleeding is to determine whether the condition requires general (e.g., resuscitation) or specific ED-based evaluation or intervention. In patients who present primarily with vaginal bleeding, the main issue is to determine whether there has been significant blood loss, and whether a condition exists (such as traumatic injury or bleeding dyscrasia) that places the patient at risk for uncontrolled or significant bleeding. If the bleeding has not led to hemodynamic compromise (and is unlikely to), then, after pregnancy has been ruled out, the only diagnoses that need to be absolutely established in the ED are trauma (including sexual abuse and assault), bleeding dyscrasia, and infection. Foreign bodies may also need to be considered in the prepubescent (particularly young child) and the elderly (e.g., retained pessary). Otherwise, patients can be referred for outpatient investigation, with the timing based on the urgency.

The approach to pelvic pain is similar. Assuming pregnancy has been excluded, acute infectious etiologies, torsion of adnexal anatomy, and nonpelvic surgical etiologies need to be considered for acute ED-based intervention and treatment. Rarely, a ruptured cyst may cause significant internal bleeding, but this is likely evident on evaluation and from the patient's level of pain. If infection is not strongly within the diagnostic possibilities, then the degree of pain may dictate further ED workup. Ultrasound and computed tomography are the most likely useful adjuncts, depending on the diagnoses remaining within consideration. Some patients with significant pain may be observed in an ED that has the capacity and capability for such activities. Reliable patients with moderate pain may be sent home on analgesics with appropriate instructions and a return visit or follow-up arranged within 12 to 24 h. Patients with mild to moderate pain of longer standing (in whom the

foregoing considerations have been excluded) may be referred for further outpatient diagnostic evaluation.

The need for inpatient management is self-evident. Significant blood loss or risk thereof, or significant pathology, will usually warrant at least an immediate consultation and likely admission or a further non-ED-based procedure. Patients with intractable pain, or in whom significant pathology cannot be excluded, should be admitted for further evaluation.

Short-Term Management

HEMODYNAMICALLY UNSTABLE   Patients who are hemodynamically unstable because of bleeding must be resuscitated according to standard protocols. Attempts should be made to localize the source of bleeding. In women with severe, persistent bleeding, immediate D&C is usually indicated. Uterine packing should be avoided, because it increases the risk of infection and may hide ongoing blood loss.

HEMODYNAMICALLY STABLE   Medical management should be considered in hemodynamically stable patients provided the diagnosis is clear. If not, the patient should be referred for further investigation and outpatient management. Short-term hormonal manipulation allows the endometrium to stabilize, which in turn will slow or stop acute bleeding.[10] If the endometrium is thin on ultrasound examination, estrogen may be used to stimulate growth of the denuded, raw surface of the endometrium. With the regimen outlined in Table 98-8, subsequent bleeding may be heavy but should not be prolonged. Oral contraceptives may be used in women who are not pregnant and have no anatomic abnormalities. The progesterone in the OCP decreases the number of available estrogen receptors and, as a result, bleeding may not stop as quickly as when estrogen is used alone. Side effects include nausea and vomiting. [10] Two treatment regimens have been developed using a fixed-dosage pill, with 35 μg ethinyl estradiol and 1 mg norethindrone (Table 98-8). In individuals with persistent light bleeding associated with anovulation, progesterone alone can be used to stabilize an immature endometrium. Bleeding occurs 3 to 10 days after discontinuation and may be heavy due to the large amount of tissue being sloughed.

Estrogen therapy
  1. Oral conjugated estrogen (e.g., Premarin) 10 mg/day (2.5 mg qid) or 25 mg IV every 2 to 4 h for 24 h. Note: the efficacy of oral and intra-venous estrogens are similar.
  2. When bleeding subsides, add medroxyprogesterone acetate (Provera) 10 mg/day.
  3. Continue both the conjugated estrogen and the medroxyprogesterone for 7 to 10 days.
  4. Stop for a synchronized withdrawal bleed.
Oral contraceptive pill
  1. Ethinyl estradiol 35 μg and norethindrone 1 mg—4 tabs for 7 days
        or
  1. Slow taper (ethinyl estradiol 35 μg and norethindrone 1 mg)
        4 tabs for 2 days
        3 tabs for 2 days
        2 tabs for 2 days
        1 tab for 3 days
Progesterone
  Medroxyprogesterone acetate (e.g., Provera) 10 mg/day is used for 10 days.

TABLE 98-8   Short-Term Medical Management of Hemodynamically Stable Uterine Bleeding

Long-Term Management

Many therapies are available for the long-term management of vaginal bleeding. Expectant management is appropriate if episodes of heavy or irregular bleeding are infrequent. The OCP is an excellent choice if contraception is required. Ovulatory menorrhagia is decreased by 50 percent, with a similar reduction in the degree of dysmenorrhea. This therapy may be effective in the treatment of patients with fibroids. [14]

Nonsteroidal anti-inflammatory drugs (NSAIDs) are helpful in the treatment of both ovulatory and anovulatory bleeding and dysmenorrhea. All of these medications have the same basic mechanism of action and inhibit cyclooxygenase in the arachidonic acid cascade. The prostaglandin inhibitors alter the ratio of prostaglandin F $_{2a}$, which causes vasoconstriction, and prostaglandin E $_2$, which causes vasodilation. NSAIDs also increase levels of thromboxane A $_2$, which causes vasoconstriction and increases platelet aggregation. These medications may reduce blood loss by 20 to 50 percent and reduce dysmenorrhea. They have a mild side-effect profile and are inexpensive. Not all women will respond, although 75 percent report a 30 percent decrease in blood loss. [16] NSAIDs are less useful in patients with fibroids. [16] Mefenamic acid (500 mg tid) and naproxen (500 mg bid) are the most well studied, and ibuprofen (400 mg q6h) has been shown to reduce menstrual bleeding in IUD users. NSAIDs should be started on the first day of the period and continued until bleeding stops and pain resolves.

Although virtually never initiated in the ED, clomiphene citrate may be used to decrease bleeding as well as induce ovulation if pregnancy is desired. If there is no risk of pregnancy and no contraindications to estrogen usage, medroxyprogesterone acetate 10 mg daily for 10 days can be used to produce scheduled bleeding. Danazol may be used to decrease bleeding significantly, although it is expensive. Patient acceptance is similar to that of patients on NSAIDs, and reduction of bleeding may be greater.[10] Side effects include musculoskeletal pain, flushing vertigo, backache, breast atrophy, and hirsutism. [16] Patients may still ovulate when using this medication. Gonadotropin-releasing hormone agonists may play a role in the induction of amenorrhea, and women on this therapy become menopausal. Other drawbacks include medication expense and bone loss when used for longer than 6 months.

Hysteroscopy is both diagnostic and therapeutic. It can be used to sample the endometrium, as well as resect polyps and myoma. Endometrial ablation may be performed in patients who do not desire fertility, have no pathologic diagnosis, and for whom medical therapy has failed. This may be performed using laser, electrocautery, or rollerball ablation. Amenorrhea is seen in about 50 percent of women treated, and decreased flow is seen in another 35 percent. [17] Improvement of symptoms of dysmenorrhea is reported in up to 80 percent of patients. Myomectomy may be useful in patients with symptomatic fibroids. Hysterectomy is reserved for selected patient populations.

Clinical Conditions in Adolescents

ABNORMAL UTERINE BLEEDING   The most common type of bleeding in adolescents is anovulatory uterine bleeding secondary to the immature hypothalamic-pituitary-ovarian axis. The amount of bleeding is usually minimal and painless. The findings on pelvic and rectovaginal examination are likely to be normal. Investigations are warranted when bleeding persists after 9 days, recurs at intervals of less than 21 days, or produces anemia. Blood loss can be considerable, with monthly losses of 100 to 200 mL resulting in iron deficiency, marrow depletion, and anemia. If bleeding at the onset of menarche is considerable or necessitates blood transfusions, a coagulopathy should be excluded. Acute menorrhagia can generally be controlled with estrogen therapy or the OCP (see Table 98-8). D&C is rarely required.

VAGINAL OBSTRUCTION   Adolescents with vaginal obstruction who escape notice as infants usually present after menarche with amenorrhea, cyclic abdominal pain, and on occasion, urinary symptoms. A lower abdominal mass and a bulging bluish membrane at the vaginal introitus are diagnostic of an imperforate vagina. A transverse vaginal septum can be diagnosed with a bimanual vaginal examination. High vaginal obstruction may be more difficult to discern on physical examination and can be confirmed with rectal ultrasound. The treatment for imperforate hymen and vaginal septum is urgent surgical intervention.

DYSMENORRHEA AND MITTELSCHMERZ   Primary dysmenorrhea is defined as painful menstruation during ovulatory periods, in the absence of pelvic disease. This significant problem, which may cause 5 to 10 percent of women to miss school or work, occurs shortly after menarche and is most severe in young, nulliparous women. The crampy lower abdominal midline pain of primary dysmenorrhea is secondary to progesterone-mediated myometrial contractions and arteriolar vasospasm. The pain precedes menstrual flow by 12 to 24 h and subsides after menses begins. In severe cases, cramps may be associated with nausea, vomiting, back pain, headache, and irritability. Dysmenorrhea can be relieved with antiprostaglandin therapy (NSAIDs). The OCP should be used as a second-line therapy. Pelvic ultrasound or laparoscopy may be helpful in the assessment of patients with uncertain diagnoses or with pain that does not respond to therapy. Secondary or acquired dysmenorrhea occurs later in life and is associated with recognizable problems with IUDs, infection, leiomyoma, or pelvic adhesions.

Mittelschmerz is defined as transient, midcycle pain at ovulation or after ovulation and is secondary to increasing ovarian capsular pressure before the follicle erupts and chemical spillage into the peritoneum with ovulation. Physical examination may reveal a slightly enlarged ovary on the affected side. The diagnosis of

mittelschmerz is clinical, and investigations are unwarranted. It is a difficult diagnosis to establish in an ED setting. However, after significant acute diagnoses have been effectively eliminated, mittelschmerz can be considered among a constellation of other pelvic pain syndromes that do not require urgent ED management. The most important treatment in both mittelschmerz and primary dysmenorrhea is sympathetic reassurance after a complete physical examination to rule out pelvic pathology. Patients should be encouraged to continue all activities, including sports. Adequate pain relief can usually be achieved with NSAID therapy.

GENITAL TRAUMA   Vaginal injuries following intercourse is one of the most common injuries. The majority of coital injuries result from vigorous voluntary sexual activity, although violent involuntary sexual activity should be considered. The most common site of injury is the posterior vaginal fornix. Misdiagnosis of coital injuries occurs frequently because either the physician fails to take an adequate history or the patient does not admit to the antecedent activity prior to the injury. Most of the coital injuries are minor, but severe injuries may lead to complications, including hemorrhagic shock.

Clinical Conditions in Reproductive-Age Females

FUNCTIONAL OVARIAN CYSTS   Normal ovarian follicles are 2 to 2.5 cm in diameter prior to ovulation, and follicular cysts may reach 8 to 10 cm. In general, these regress spontaneously in 1 to 3 months. Stretching of the capsule is the source of discomfort. Follicular cysts may rupture upon pelvic examination or with intercourse and cause immediate, sharp pain, which resolves rapidly or gradually improves over days. There may be associated peritoneal signs as a result of irritation from cystic fluid or blood.

Corpus luteum cysts are much less common and may grow to 5 to 10 cm in diameter. During the normal development of a corpus luteum, capillaries invade the granulosa cells and spontaneously bleed into the central cavity. If the degree of hemorrhage is large, the capsule is stretched, causing pain. In general, most cysts regress at the end of the menstrual cycle. Symptoms may occur from persistent corpus luteum cysts and include unilateral pelvic pain, amenorrhea, delayed menstruation, or menorrhagia. Cyst rupture is associated with sharp pain, peritoneal irritation, and bleeding. Without an hCG level determination, cyst rupture may be difficult to differentiate from an ectopic pregnancy. Hemorrhage is usually self-limited but rarely can cause marked pain, anemia, hypovolemia, and fluid in the cul-de-sac. Patients must be admitted for careful observation and to have serial hematocrits performed. Surgery is often indicated.

TORSION OF ADNEXA   Pain associated with torsion of an ovarian cyst, fallopian tube, or paratubal cyst is acute, severe, and unilateral. It is felt in the lower abdomen and pelvis and may be related to a change in position. On occasion it may be intermittent. Of patients presenting with a torsion, 90 percent will have a mass, which progressively enlarges as arterial flow continues and venous flow is compromised. Nausea and vomiting are common, and patients may have an elevated white blood cell count (WBC) or low-grade temperature. The common differential diagnosis is appendicitis. Ovarian torsion may occur with normal adnexa, but there is an increased risk with ovarian enlargement. Tumors are found in 50 to 60 percent of patients. Benign cystic teratomas (dermoids) are the most common tumors. Torsion from enlargement of other cysts, ovulation induction, or parovarian cysts may also occur. It is rarely associated with malignant tumors, which are usually fixed to the pelvis. Early surgical intervention is required.

ENDOMETRIOSIS   After dysmenorrhea, endometriosis is the second most common cause of cyclic pain in reproductive-age females. [18] A prevalence of 5 to 10 percent is widely accepted, although it has been reported in up to 60 percent of patients with infertility. There is a genetic predisposition for endometriosis, and the mean age at diagnosis is 25 to 30 years. [13] In patients with endometriosis, endometrial glands and stroma develop outside the endometrial cavity, initially causing pain with menses. As the disease progresses, pelvic adhesions develop and pain occurs throughout the cycle. If located within the ovarian capsule, endometriomas, or chocolate cysts, may result. The precise pathophysiology of endometriosis is not clear, but it is commonly believed to arise from retrograde menstruation and seeding of menstrual glands. Pain is cyclic or constant and may vary in character and intensity. It is generally worse just prior to or during menses. The number of adhesions and severity of disease correlate poorly with symptoms. [18] The hallmark of the disease is tender nodules felt along thickened uterosacral ligaments, the posterior uterus, and the cul-de-sac. Obliteration of the cul-de-sac with a fixed retroverted uterus is seen in women with extensive disease. Women with endometriomas may present with ovarian enlargement and adnexal tenderness. Alternatively, even a careful physical examination may not find an abnormality. Although the diagnosis may be suggested by history and physical examination, it can only be made upon direct visualization. Laparoscopy is the diagnostic procedure of choice. [18] Ultrasound may reveal endometriomas but is not helpful in defining focal endometriotic lesions. Therapy depends on the severity of symptoms, age, stage of the disease, and desire for future fertility. Hormonal therapy may be instituted to mimic pseudopregnancy, chronic anovulation, or pseudomenopause. [13] Endometriomas may be treated expectantly if they are less than 3 cm in diameter. Pregnancy itself leads to remission and sometimes cure.

ADENOMYOSIS   In patients with adenomyosis, dysmenorrhea occurs just prior to or at the time of menstruation. In this condition, endometrial glands grow deeply into the underlying myometrium. Menorrhagia is common and is felt to be a result of aberrant tissue impairing the normal uterine contractility. Symptoms gradually increase in the fourth and fifth decades of life. On pelvic examination, there may be a large fibroid-like mass, or adenomyoma, but more commonly it is a diffuse, infiltrative process. Therapy is symptomatic, and simple analgesics are prescribed. Some cases require surgical management. [18]

LEIOMYOMAS   Leiomyomas (fibroids) are benign tumors of muscle cell origin and are the most frequently occurring pelvic tumor. They are found in one of four white women and in one of two black women.[10] Commonly, there is more than one fibroid present. The etiology of leiomyomas is unclear, and theories include the proliferation from a single muscle cell from a small embryonic rest or a defined region of tissue with a higher level of estrogen receptors. They decrease in size during menopause, and enlargement is seen early in pregnancy and, in some cases, OCP use. Up to 30 percent of patients with leiomyomas experience pelvic pain and abnormal bleeding. Acute pain is rare, but severe pain may be experienced with torsion or degeneration. Degeneration is a result of rapid growth and loss of blood supply. This is almost exclusively seen in early pregnancy.

The diagnosis of leiomyoma is made on physical examination. A mass or commonly multiple masses are palpable. In patients with acute degeneration, tenderness, rebound guarding, a fever, and elevated WBC may be seen. Pedunculated subserosal leiomyomas may undergo torsion or cause uterine cramping. Rapid growth at any age or growth after menopause is highly suspicious for malignant transformation. Treatment depends on the size of the fibroid and the severity of symptoms. Generally, fibroids are observed, and pain is managed appropriately. Medical management includes administration of NSAIDs, medroxyprogesterone acetate or depo-medroxyprogesterone acetate, and gonadotropin-releasing hormone agonists. Pedunculated intracavitary leiomyomas may be removed by hysteroscopy. Surgical removal is associated with a 25 to 30 percent rate of recurrence and significant bleeding complications. A percutaneous interventional technique involving uterine artery embolization shows promise in observational trials. Embolization appears to alleviate symptoms and cause fibroid shrinkage. [19]

BLOOD DYSCRASIAS   Bleeding disorders may become apparent with an initial presentation of abnormal menstrual bleeding. Uterine hemostasis is not well understood, and any disorder of blood vessels, platelet abnormalities, and coagulation disorders, including vWD, may result in excessive menstrual bleeding. Of historical interest, the first described case of vWD was in a 13-year-old who died as a result of uncontrollable uterine bleeding. [1] The prevalence of objectively confirmed abnormal uterine bleeding is increased in patients with vWD, carriers of hemophilia, and factor XI deficiency, at 73, 57, and 59 percent, respectively, when compared with a 9 to 11 percent rate in a population-based sample. Treatment options include use of antifibrinolytics and the OCP. The latter raises factor VIII and vWF levels and is an effective and popular form of therapy. Antifibrinolytics such as tranexamic acid reduce both plasminogen activator activity and plasmin activity to reduce the amount of bleeding. Desmopressin acetate (DDAVP,® Ferring) stimulates endogenous release of factor VIII and vWF and may be used prophylactically for minor procedures or treatment of bleeding episodes and menorrhagia. DDAVP is given intranasally, parenterally, or by subcutaneous injection. It is important that vWD patients are typed prior to instituting DDAVP, because DDAVP may induce thrombocytopenia in certain subgroups. NSAIDs are ineffective and may increase blood loss.[1]

POLYCYSTIC OVARY SYNDROME   Polycystic ovary syndrome, one of the most common endocrine disorders, is the association of hyperandrogenism and anovulation without underlying disease of the adrenal or pituitary glands. A triad of obesity, hirsutism, and oligomenorrhea is classically described, although obesity is not universally seen. When menses occurs, it is heavy and prolonged. [20] The syndrome is further characterized by acne, androgen-dependent alopecia, elevated serum concentrations of androgens, and hypersecretion of LH with a normal or low FSH level. Typical ovarian morphology, which may be seen on ultrasound, is not necessary for the diagnosis and may in fact represent a response of the ovary to chronic anovulation. The differential diagnosis includes hyperprolactinoma, acromegaly, congenital adrenal hyperplasia, and androgen-secreting tumors of the ovary or adrenal gland. Management of menorrhagia in women who do not desire fertility includes low-dose oral contraceptives or cyclic progestin administration.

OTHER CONDITIONS   Periods of physical or psychological stress, illness, malnutrition, rapid weight gain or loss, and intense physical regimens affect the hypothalamus and disrupt the normal pattern of gonadotropin release. This usually causes amenorrhea but may result in irregular, heavy bleeding. In obese women, menorrhagia may be a result of increased circulating levels of estrogen from peripheral conversion of androstenedione to estrone in fatty tissue. [14] Patients with liver and renal disease may also develop irregular bleeding.

Special Considerations

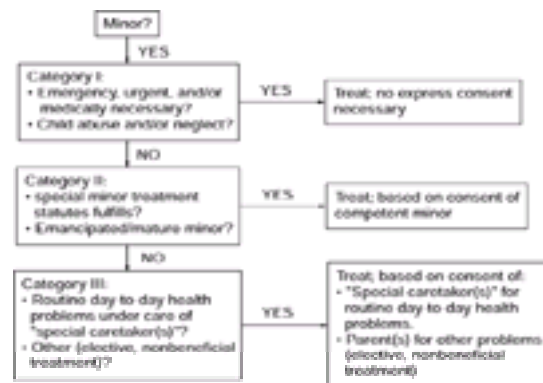
THE LEGALITIES OF TREATING ADOLESCENTS WITHOUT PARENTAL CONSENT   Consent is not required to evaluate and initiate treatment in an emergency. State consent statutes and case law vary, so emergency physicians should know and follow their state law and hospital policy with respect to consent. There should be a mechanism in place to obtain consent from the courts when necessary. The American College of Emergency Physicians policy on consent is summarized in Figure 98-3. All states allow minors to consent to diagnosis and treatment of STDs and drug abuse without parental consent. Many states have similar statutes allowing minors independent direct access to prenatal care, termination of pregnancy, and medical care for crime-related injuries. Special considerations are included in some state legislation for emancipated and mature minors. Common sense and appropriate documentation should prevail above all with respect to issues of consent. An a priori awareness of the statutes and policies and established liaisons with local child protection services and the courts should assist emergency physicians in the ongoing provision of timely emergency care.


FIG. 98-3. Initial approach to consent for treatment. (From Tsai et al,[31] with permission.)

HIV-INFECTED WOMEN   In general, there is no need to change the approach to pelvic pain and bleeding in HIV-positive women. Physicians must look for associated infections and complications of chronic illness. The rate of vaginal and pelvic infections as well as cervical dysplasia is high in this cohort of patients. In a cross-sectional survey of 386 women younger than age 50, with and without HIV, neither infection nor immunosuppression affected menstruation or the rate of abnormal vaginal bleeding.[21] This was also seen in a study of 85 seropositive women, although the power of the study was low.[22]

COMPLICATIONS OF IN VITRO FERTILIZATION   Ovarian hyperstimulation syndrome complicates 5 to 10 percent of in vitro fertilization cycles, although only few cases become severe.[23] Particular vigilance is needed with such patients presenting to the ED. The syndrome is characterized by ovarian enlargement and fluid loss from ovarian capillaries into the extravascular compartment. This leads to ascites, abdominal distention, hydrothorax, and localized or generalized tissue edema. Complications include hypovolemia, hemorrhage, and thromboembolism. The cause of the increased capillary permeability, fluid sequestration into the peritoneal cavity, and angiogenesis is not known. Presentation varies with severity. Patients with mild forms present with weight gain, increased thirst, and abdominal discomfort. More severe forms may include hypovolemia, acute respiratory distress due to the ascites and hydrothorax, pericardial effusions, hepatorenal failure, and/or thromboembolic phenomena. Factors associated with increased risk of developing ovarian hyperstimulation include age less than 35, the administration of hCG to trigger the ovulatory response, or endogenous hCG release in early pregnancy.[23]

Elevated WBC level, hemoconcentration, hyponatremia, and hypoalbuminemia may be seen in moderate and severe cases. Ultrasound examination is usually indicated and should be helpful in demonstrating the extent of ovarian enlargement, size and number of corpora luteal cysts, and degree of pelvic and abdominal fluid. Pregnancy may have occurred in patients with ovarian hyperstimulation. Investigations and treatment should be adjusted accordingly. The treatment of mild to moderate cases includes increased fluid intake, close observation, and safe analgesia. Severe cases should be followed closely with serial hematocrits. A coagulation screen, liver function tests, renal function tests, and chest x-ray should also be obtained. Management includes intravenous fluids and, in some cases, the administration of heparin. The use of diuretics should be avoided, and paracentesis, using ultrasound guidance, may be indicated for relief of respiratory distress. Pleural effusions rarely need to be tapped. Pericardial effusion should be imaged and drained under echocardiographic guidance as indicated. Although aggressive resuscitation may be required in severe cases, death remains rare.

99 NORMAL PREGNANCY

Christina E. Hantsch
Donna L. Seger

Regardless of the chief complaint, the possibility of pregnancy must be considered in every woman of reproductive age who presents to the emergency department. Pregnancy may be the cause of a patient's symptoms and signs, or pregnancy may alter the diagnosis and management of other conditions. History and physical examination alone are not adequate in excluding pregnancy, and other diagnostic information is frequently required. In one study, over 7 percent of women, who stated that there was no chance they were pregnant and reported an on-time and normal last menstrual period, were pregnant. [1] The use of oral contraceptives or contraceptive implants does not guarantee pregnancy prevention. Although the failure rate is less than 1 per 100 with compliant use of oral contraceptives, nearly 30 percent of women who rely on oral contraceptives alone to prevent pregnancy are not consistently compliant. [2] Among women with levonorgestrel implants, the annual pregnancy rate is 0.8 per 100 during the first 5 years of therapy. The failure rate of implants further increases with time. [3]

TERMINOLOGY

In obstetrics, *gravidity* denotes the total number of pregnancies regardless of duration and outcome. *Parity* denotes the number of pregnancies completed to delivery during the viable period. Parity is not increased for a pregnancy resulting in multiple births or decreased for a stillborn fetus. Notation of obstetric history typically lists the gravidity, abbreviated *G* and followed by the appropriate number, and then the parity, abbreviated *P* and followed by the appropriate number. After the gravidity and parity there may be a listing of the number of term deliveries, preterm deliveries, abortions, and living children. The latter four numbers are separated by hyphens and listed in parentheses. For example, the obstetric history of a woman during her seventh pregnancy who has had 4 term deliveries, 1 preterm delivery, and 1 abortion and has 5 living children is abbreviated G7 P5 (4-1-1-5).

The duration of pregnancy is approximately 40 weeks. By convention, gestational age (or menstrual age) is calculated from the first day of the last normal menstrual period. Pregnancy is typically divided into three trimesters of approximately equal length. The first trimester is from conception to 14 weeks; the second trimester is from 14 to 28 weeks; the third trimester is from 28 to 42 weeks. A term pregnancy requires completion of at least 37 weeks of gestation.

PHYSIOLOGY

Knowledge of the physiologic alterations that occur during pregnancy enables emergency physicians to address pregnancy-related issues as well as to differentiate the normal features of pregnancy from complications and unrelated problems. Physiologic changes depend on the stage of pregnancy.

Cardiovascular System

Maternal cardiovascular changes during pregnancy include a 40 to 45 percent increase in circulating blood volume, a 43 percent increase in cardiac output, and a 17 percent increase in resting heart rate. [4] Systemic vascular resistance is 20 percent lower. Blood pressure decreases to a nadir during the second trimester. The diastolic decrement (10 to 15 mmHg) is greater than the systolic decrement (5 to 10 mmHg). Hemodynamic measurements should be taken with the patient in the left lateral decubitus position, since body position has a significant influence on hemodynamic values. The left lateral position increases venous return by relieving the pressure of the uterus on the inferior vena cava. The increase in cardiac output is detectable from the first trimester until after delivery when readings are taken with the patient in this position. [5]

The heart is displaced up and to the left because of elevation of the diaphragm. This displacement produces a larger cardiac silhouette on chest radiograph and a slight left axis deviation on the electrocardiogram. A small, benign pericardial effusion may also contribute to the enlarged cardiac silhouette.

Respiratory System

Many women experience dyspnea during pregnancy. Although the respiratory rate is unchanged, this symptom may be the result of a hormone-induced 40 percent increase in tidal volume and the related P_{CO_2} decrease (normal value in pregnancy, 30 mmHg). Functional residual capacity is decreased because of a rise in the level of the diaphragm. [5]

Gastrointestinal System

Pregnancy-induced changes in the gastrointestinal system are due to both progressive displacement of the abdominal viscera and hormone-mediated functional alterations. Gastric reflux commonly occurs as a result of delayed gastric emptying, decreased intestinal motility, and decreased lower esophageal sphincter tone. The size and morphologic characteristics of the liver are not altered by pregnancy, but the presence of placental alkaline phosphatase may produce the increased alkaline phosphatase activity observed on analytical evaluation of maternal liver function. Bilirubin concentration and aspartate aminotransferase and alanine aminotransferase activities are unaltered. Hepatic enzyme systems are induced during pregnancy. Gallbladder emptying is delayed and less efficient, and pregnancy therefore increases the risk of cholesterol gallstones.

Urinary System

Pregnancy-related renal changes include increases in kidney size, renal blood flow, and glomerular filtration rate (GFR). By the second trimester, the GFR may be as much as 50 percent higher than it was preconception. Consequently, blood urea nitrogen and creatinine levels decrease. Dilation of ureteral and renal calyces or pelves due to ureteral compression is also frequently seen on imaging studies. These changes are often less pronounced on the left side, since the sigmoid colon cushions the left ureter from the pressure of the enlarging uterus.

Hematopoietic System

During pregnancy, circulating blood volume expands by an average of 40 to 45 percent due to an increase in both plasma volume and the number of erythrocytes. [6] Hemoglobin concentration decreases due to hypervolemia but should not fall below 11 g/dL. Maternal erythropoiesis combined with fetal erythropoiesis produce the high iron requirements of pregnancy. Reticulocyte count is also slightly increased during the second half of pregnancy, the period of marked erythropoiesis. Leukocyte counts during pregnancy range from 5,000 to 12,000 cells/mL. Dilutional effects on blood volume may also contribute to the variation in leukocyte counts. [7] Beginning in the second trimester, leukocyte function is usually depressed, and increased susceptibility to infection may occur. [8] Patients with chronic autoimmune conditions may improve clinically. Circulating coagulation factor concentrations and erythrocyte sedimentation rate increase during pregnancy. Platelet count may decrease slightly due to increased consumption. However, thrombocytopenia should prompt further evaluation for a pathologic cause.

Endocrine System

Pregnancy-related hormonal changes and feedback mechanism adjustments are incompletely understood. Characteristic changes in carbohydrate metabolism lead to hyperinsulinemia and fasting hypoglycemia. The altered response to glucose ingestion produces postprandial hyperglycemia and ensures a sustained glucose supply to the fetus. Mineral (especially iron), protein, and fat metabolism are also changed. Thyroid alterations include increased vascularity and mild hyperplasia, but clinically detectable goiter is not a normal finding in pregnancy. To assess thyroid function during pregnancy, free thyroxine and thyroid-stimulating-hormone concentrations should be measured, since they are not affected by physiologic changes of normal pregnancy.

Uterus

Uterine weight and intrauterine volume increase during pregnancy from 70 to 1100g and 10 to 5000 mL, respectively. These changes occur through marked stretching and hypertrophy of existing muscle cells rather than formation of new cells. By 12 weeks of gestational age, the uterus exceeds the capacity of the pelvis and expands into the abdominal cavity. There is a progressive increase in uterine blood flow to approximately 450 to 650 mL/min by term.

Breasts

Many women note breast tenderness and tingling from early in the first trimester. The breasts enlarge and become more nodular. Nipple size and pigmentation increase. Striations similar to those often seen on the abdominal wall may develop on the breasts.

HISTORY AND PHYSICAL EXAMINATION

Obstetric and gynecologic history, including menstrual status and contraceptive use, should be obtained on every woman of reproductive age. Cessation of menses, as well as such symptoms as nausea, vomiting, fatigue, and urinary frequency, may be suggestive of pregnancy. The date of the last normal menstrual period aids in determination of gestational age (although it may be misleading if, for example, contraceptive use was recently discontinued). Quickening, the first maternal perception of fetal movement, could also help establish gestational age. Primigravida women note fetal movement between 18 and 20 weeks' gestation. With subsequent pregnancies, quickening typically occurs about 2 weeks earlier (i.e., between 16 and 18 weeks' gestation). The patient's history of prenatal care and the course of current and past pregnancies, as well as the essential components of any medical history (past medical history, medications, allergies, social history, family history, and review of systems), should be obtained.

Physical examination of pregnant women should include routine assessment of maternal well-being as well as an evaluation of fetal status. When a fetal stethoscope is used, fetal heart tones can be heard by 16 to 19 weeks' gestation. The normal fetal heart rate ranges from 120 to 160 beats per minute. Since the fetus easily changes position, the site on the maternal abdomen where the fetal heart tones are best detected varies. Pulsation of the maternal aorta should be distinguished from the fetal heart tones.

A pelvic examination should be performed whenever pregnancy is part of the differential diagnosis. Appearance of the cervix and the presence of discharge or blood in the vaginal vault should be noted. Wet preparation and culture for Neisseria gonorrhoeae and Chlamydia trachomatis may be indicated. Bimanual examination determines size and tenderness of the uterus and adnexa.

By the end of the first trimester, the size of the uterus can also be assessed by abdominal examination. At 12 weeks' gestation, the fundus should be palpable at the level of the symphysis pubis. At 16 weeks, the fundus should be midway between the symphysis and the umbilicus; at 20 weeks, it should be at the umbilicus. From 20 to 32 weeks, the height (in centimeters) of the fundus above the symphysis approximates the gestational age. For an accurate measurement, the pregnant patient should have an empty bladder when fundal height is determined. Later in pregnancy, the presenting part of the fetus should also be determined by palpating the maternal abdomen.

DIAGNOSIS

Accurate diagnosis or exclusion of pregnancy is essential in emergency medicine. Standard analytical techniques screen blood or urine for human chorionic gonadotropin (HCG), a glycoprotein produced by the trophoblast after implantation. Since implantation occurs about 1 week after conception, these screening tests are particularly helpful in establishing or excluding early pregnancy. At 4 to 5 weeks' gestation and beyond, definitive diagnosis can be made by sonographic visualization of the embryo or fetus (see Chap. 109, "Pelvic Ultrasonagraphy"). Alternatively, in later stages detection (by fetal stethoscope or sonogram) of fetal heart activity distinct from maternal heart activity or detection of palpable fetal movement may confirm pregnancy.

Analytical Techniques

HCG is composed of a and b subunits. The HCG a subunit is indistinct from the a subunit of several other glycoproteins, including luteinizing hormone. The b subunit is unique to HCG. Qualitative enzyme-linked immunosorbent assays (ELISAs) that detect b-HCG in urine can be completed in minutes at the patient's bedside. Available commercial tests can detect b-HCG concentrations as low as 10 to 20 mIU/mL. These tests have a false-negative rate of only 1 percent in detecting pregnancy as early as 1 week after conception. However, to achieve this level of sensitivity, the analysis must be performed on a urine specimen that is not dilute. When urine is dilute, a false-negative result may be obtained for women with early pregnancy (serum HCG < 50 IU/mL). [9] Serum analysis should be performed in clinical situations when pregnancy is a concern but the urine result is questionable. Quantitative serum values are obtained by ELISA technique and can be completed in 1 to 2 h. There are several international standards for serum b-HCG, and the specific reference range should be appropriate for the standard employed.

A positive result on a pregnancy test, whether qualitative or quantitative, does not confirm a normal intrauterine pregnancy. Ectopic pregnancy, recent spontaneous or induced abortion, and HCG-secreting tumors may also produce a positive result. Single quantitative b-HCG determinations in combination with pelvic ultrasonography may differentiate intrauterine pregnancy from these conditions. [10] Serial quantitative serum b-HCG determination may be useful in some outpatient situations, since serum b-HCG levels double every 1.4 to 2.0 days following implantation in early normal pregnancy. Failure of the HCG concentration to double in this time period suggests an ectopic pregnancy or a nonviable pregnancy.

Pelvic Ultrasonography

More detailed discussions of ultrasonography and its application in emergency medicine can be found in Chap. 109. The earliest definitive sonographic finding in pregnancy is a gestational sac. Using transabdominal technique, the gestational sac can be detected at 5.5 to 6 weeks' gestation. With transvaginal technique, the gestational sac can be detected at 4 to 5 weeks' gestation. Other ultrasound markers of pregnancy and the gestational age at which they may be detected by transvaginal ultrasound include the yolk sac at 5 to 5.5 weeks' gestation, fetal pole at 5.5 to 6 weeks, and cardiac activity at 6 weeks. Correlation of these markers

SPECIFIC ISSUES IN PREGNANCY

Abdominal Discomfort

Many pregnant women experience abdominal discomfort. Round ligament tension and vascular congestion may cause lower abdominal discomfort from early in pregnancy. Braxton-Hicks contractions are irregular, palpable contractions that may occur throughout pregnancy. The differential diagnosis of abdominal pain varies with the stage of gestation and must include all the possibilities in a nonpregnant patient as well as those unique to pregnancy. Understanding of the physiologic changes of pregnancy avoids a delay in definitive diagnosis and management of pregnant patients with abdominal pain.

Medication Use

Therapeutic drug use may be necessary during normal pregnancy. Multiple factors, including gestational age and stage of development, dose and duration of exposure, and individual susceptibility, influence the potential effects of drug exposure during pregnancy. Teratogenesis is defined as the dysgenesis of fetal organs, as evidenced either structurally or functionally. Typical manifestations include restricted growth, fetal death, carcinogenesis, and malformations. [11] The fetus is most vulnerable to teratogenic effects at 4 to 12 weeks' gestation, the period of organogenesis. Exposure early in pregnancy may lead to spontaneous abortion. Exposure later in pregnancy is a less common problem but may also be teratogenic secondary to alterations in placental blood flow as well as direct potential fetal effects. Medication use during pregnancy may also have consequences in the neonate, such as central nervous system (CNS) depression, seizure, respiratory depression, kernicterus, or premature closure of the ductus arteriosus. Manifestations depend on the specific medication. Neonatal withdrawal may occur after maternal use of opiates or benzodiazepines during pregnancy. Finally, the adverse effects of fetal exposure to some medications (e.g., tetracyclines, which produce discoloration of teeth and bone, and diethylstilbestrol, which produces female genital tract abnormalities) may not be evident until later in the life of the child.

Pharmaceutical companies do not test drugs in pregnant women to determine potential fetal effects. Much of the available information on teratogenesis is based on animal studies, inadvertent human exposure during unrecognized pregnancies, and case reports or epidemiologic studies of pregnancy outcome after therapeutic drug administration. Exposure-related risk may be difficult to distinguish from spontaneous occurrence rates. Manufacturer labeling and drug reference books therefore often contain ambiguous statements concerning use of drugs in pregnancy. The US Food and Drug Administration (FDA) currently employs a system that classifies drugs in five risk categories based on available information (Table 99-1). Because of ambiguity and potential inaccuracy within this system, alternative ways of outlining estimated fetal risk for both physicians and the general population are being investigated. [11]

Drug Category	Risk during Pregnancy
A	Controlled studies have failed to demonstrate a fetal risk in the first trimester (and there is no evidence of risk in later trimesters), and the possibility of fetal harm is remote.
B	Either animal studies have not demonstrated a fetal risk but there are no controlled human studies, or animal studies have demonstrated an adverse effect that was not confirmed in controlled human studies in women in the first trimester (and there is no evidence of risk in later trimesters).
C	Either animal studies have revealed adverse effects on the fetus (teratogenic or embryocidal) and there are no controlled studies in humans, or no human or animal studies are available. Drugs should only be used if the potential benefit justifies the potential fetal risk.
D	Evidence of human fetal risk exists, but the benefits of use in pregnant women may be acceptable despite the risk.
X	Studies in animals or humans have demonstrated fetal risk, or there is evidence of fetal risk based on human experience. The risk of use in pregnancy clearly outweighs any possible benefit. Drugs are contraindicated for use in women who are or may become pregnant.

TABLE 99-1   Food and Drug Administration Categorization of Drug Risk in Pregnancy

ANTIMICROBIAL AGENTS   Antimicrobial medications are frequently used during pregnancy. All of these agents enter the fetal circulation to some extent. The potential teratogenic effects are unknown for some antimicrobials. Information on the safety of newer extended-spectrum or late-generation agents is limited. [12] Table 99-2 lists known pregnancy-related contraindications to some frequently used antibiotics.

Antimicrobial Agent	Known Maternal or Fetal Concern
Erythromycin estolate	Maternal hepatotoxicity
Fluoroquinolones	Fetal cartilage abnormalities
Kanamycin	Fetal cranial nerve VIII damage
Metronidazole	Fetal midline facial defects (first trimester)
Streptomycin	Fetal cranial nerve VIII damage
Sulfonamides	Fetal hemolysis, neonatal kernicterus (near term)
Tetracyclines	Fetal bone and teeth abnormalities
Trimethoprim	Folate antagonism (first trimester)

Source: From American College of Obstetricians and Gynecologists.[13]

TABLE 99-2   Pregnancy-Related Contraindications of Some Frequently Used Antibiotics

Penicillin and cephalosporins are generally regarded as safe for use in any trimester. Neither group has been associated with teratogenesis in either animals or humans. Erythromycin does not cause known adverse fetal effects, but the estolate formulation is contraindicated in pregnancy, since it may cause maternal cholestatic hepatitis. Sulfonamides (including the sulfamethoxazole component of trimethoprim-sulfamethoxazole) are not known human teratogens. Maternal use close to term, however, may cause complications in the neonate. Sulfonamides compete with bilirubin for albumin binding. The fetus clears free bilirubin via the placenta, but in the neonate free bilirubin accumulates and may cause kernicterus. Trimethoprim, the other component of this combination antibiotic, should be avoided in the first trimester, since it is a folate antagonist and may cause neural tube abnormalities. If trimethoprim-sulfamethoxazole offers a clear advantage over other antibiotics, it is reasonable to use; however, the period of gestation should be considered in making such a decision. Tetracyclines are contraindicated in pregnancy, since they chelate calcium and cause abnormalities in fetal bone development and teeth discoloration. Maternal hepatic and renal toxicity have also been caused by tetracyclines. Fluoroquinolones have led to fetal cartilage abnormalities in animals and as of this writing remain contraindicated throughout pregnancy. [12]

ANALGESIC AGENTS   Acetaminophen is the agent of choice for analgesia or antipyresis in pregnancy. Aspirin should be avoided during pregnancy. Although evidence is conflicting, aspirin use in the first trimester has been associated with congenital defects. Use later in pregnancy may cause coagulation abnormalities with hemorrhagic complications in both the neonate and mother. Premature ductus arteriosus closure and cardiovascular complications in the neonate may also be a result of maternal aspirin use late in pregnancy. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) may prolong gestation and labor through inhibition of cyclooxygenase. Unfortunately, nonaspirin NSAIDs cannot be employed as tocolytic agents, since they, like aspirin, cause premature ductus closure and subsequent pulmonary hypertension.[11] Use of NSAIDs (especially indomethacin) has also been associated with oligohydramnios, intestinal perforation, hydrops fetalis, and renal failure.

GASTROINTESTINAL AGENTS   Many pregnant women, particularly those in the first trimester, suffer nausea and vomiting. Conservative measures, such as reduced meal size and avoidance of specific foods, frequently ease symptoms. Intravenous fluids and electrolyte replacement may alleviate symptoms, but in some cases medications may be necessary. As with most medications, the safety of antiemetics has not been studied in prospective human trials, but the benefit of improved metabolic conditions and maternal well-being should be considered in the management decision. [13] Phenothiazines, such as promethazine and

prochlorperazine, may be considered. Several other antiemetics, including metoclopramide and ondansetron, are presumed safe based on data from animal studies.

Physiologic changes in pregnancy often lead to dyspepsia during the third trimester. Most over-the-counter antacid preparations are regarded as acceptable. [11] The histamine antagonists cimetidine and ranitidine have no known teratogenic effect in animals. Although they have not been evaluated in humans, their use in general is considered safe.

ANTIHISTAMINES   Sufficient data on fetal outcome after diphenhydramine exposure are lacking. An association with cleft palate has been reported, but in subsequent studies the frequency was not increased above background rates. Use of diphenhydramine is probably safe after the first trimester and until the last 2 weeks of pregnancy. Antihistamines in general should not be used during the last 2 weeks of pregnancy, since fetal exposure during that time has been associated with an increased risk of retrolental fibroplasia. Risks of the newer nonsedating antihistamines are not known.

COLD PREPARATIONS   Over-the-counter cold preparations are frequently combination medications containing sympathomimetic agents. All sympathomimetic drugs have vasoconstrictive properties and may lead to vascular-mediated congenital defects. Data on specific agents and their teratogenic potential are inconclusive. Conservative measures for control of symptoms during upper respiratory infections are preferred. When medication is necessary, each component of a combination preparation should be considered before a choice is made. First-trimester exposure to dextromethorphan or guaifenesin has not been associated with adverse fetal effects.

ANESTHETICS   Proper use of most agents for local or regional anesthesia, including subcutaneous infiltration of lidocaine, has not been associated with detrimental fetal effects. Combination preparations such as TAC (tetracaine, adrenaline-epinephrine, and cocaine) and LAT (lidocaine, adrenaline, and tetracaine) should not be used due to the potential risks of absorbed cocaine and adrenaline-epinephrine.

CONTRACEPTIVES   Pregnancy may occur in women taking oral contraceptive agents either due to a failure of therapy or to noncompliance. While there is no demonstrated risk of fetal malformation due to contraceptive use in early pregnancy, they should be discontinued as soon as pregnancy is recognized. [3,11]

Radiation Exposure

Teratogenic potential depends on the total radiation dose as well as the gestational age at exposure. The absorbed dose of radiation is measured in grays (Gy), the SI unit, or rads (1 Gy is equivalent to 100 rad). A dose of more than 50 to 100 mGy (5 to 10 rad) and/or exposure at a gestational age of 8 to 15 weeks is of the most concern. Cumulative doses may also be hazardous to the developing embryo or fetus. Table 99-3 lists the radiation doses of some common emergency department radiographic tests.[14] For procedures in which radioactive material is administered, the dose absorbed by the fetus is variable. Fetal exposure may be minimized by adequate hydration to minimize bladder concentrations, maintain brisk urine output, and enhance clearance of the material. Exposure from a lung ventilation-perfusion scan using xenon 133 and technetium 99m is typically less than 5 mGy. Ultrasound and magnetic resonance are the only radiation-free imaging techniques. The short-term electromagnetic field exposure with magnetic resonance imaging has not been shown to have teratogenic effects. [15]

Procedure	Absorbed Dose, mGy*
Chest radiograph (two views)	<0.01
Pelvic radiograph	1.7
Single abdominal radiograph (KUB)	2.9
Lumbar spine series (three views)	3.5
Intravenous pyelogram	3.6
Chest CT scan	0.06
Pelvic CT scan	26
Abdominal CT scan	8.0

Abbreviations: CT, computed tomography; KUB, kidney, ureter, and bladder.
*1 mGy is equivalent to 0.1 rad.

TABLE 99-3   Radiation Exposure to the Uterus and Fetus

Immunizations

Indications for tetanus toxoid (alone or with diptheria toxoid) are unchanged in pregnant women, since there is no evidence of teratogenicity. [16] Live-virus vaccines, including measles, mumps, rubella, poliomyelitis, and varicella, should be avoided in all trimesters of pregnancy as well as for 3 months preconception. [17] The influenza vaccine is an inactivated (killed-virus) vaccine that can be administered during pregnancy. The Advisory Committee on Immunization Practices, the Center for Disease Control and Prevention, recommends vaccination against influenza for women who will be in the second or third trimester during the influenza season, since women at those stages of pregnancy are at increased risk of influenza-related complications. [18] Immunoglobulins, including tetanus, hepatitis, rabies, and varicella immunoglobulin, can be administered when indicated regardless of the stage of gestation. [16]

PREVENTIVE MEDICINE AND COUNSELING

Nutrition and Nutritional Supplementation

Maternal nutrition is important to pregnancy outcome. Total weight gain as well as the pattern of weight gain affect newborn birth weight. Maternal weight gain begins in the first trimester and is most significant during the first half of pregnancy. Average total gain is 12.5 kg (28 lb). A balanced diet with sufficient caloric intake for appropriate weight gain supplies necessary vitamins. Routine supplementation with a multivitamin, therefore, is not necessary. [19] Vitamin supplementation may be necessary for women with special nutritional needs or those who follow a restricted diet (e.g., vegetarian). Since folic acid supplementation prepregnancy and during early pregnancy may prevent neural tube defects, the Centers for Disease Control recommends a regular daily folic acid intake of 400 µg for all fertile women. [20] As soon as pregnancy is established, this supplementation of 1 mg/day should be started. For women with a previous pregnancy affected by neural tube defect, the supplementation should be further increased to 4 mg/day. [20] Appropriate use of vitamin preparations is not harmful (and often folic acid supplementation is provided by a multivitamin preparation) in any trimester of pregnancy, but excess intake of some vitamins (e.g., A, D, C, and B$_6$) may lead to congenital defects. [19]

With the exception of iron, minerals do not need to be supplemented during normal pregnancy if dietary intake is appropriate. Since most women of childbearing age have poor iron stores and normal dietary intake cannot meet the increased demand during pregnancy, iron supplementation is recommended. Gastrointestinal side effects can be reduced, while still providing iron during the period of greatest demand, by initiation of iron supplementation after the first trimester. Zinc deficiency may be associated with neural tube defects. Daily intake of zinc during pregnancy should be 15 mg. [20,21]

Caffeine

Results of human studies on the effects of caffeine use during pregnancy are conflicting, particularly regarding the potential association between caffeine intake and early fetal loss.

Aspartame

Aspartame (Nutrasweet™) is metabolized to phenylalanine. Phenylalanine crosses into fetal circulation and at very high concentrations can lead to mental retardation. Except in cases of excessive maternal dietary intake or maternal heterozygous carriers of phenylketonuria, fetal toxicity is unlikely.

Substance Abuse

Substance abuse is one of the greatest threats to normal pregnancy.[22] Illicit substances as well as alcohol and tobacco may affect pregnancy outcome through their effects on both the mother and the fetus. Frequently, multiple substances are involved, since substance abusers rarely use a single substance.

ILLICIT SUBSTANCES   Use of cocaine, opiates, or amphetamines is associated with multiple complications of pregnancy and congenital abnormalities. Data on other substances, such as hallucinogens and "designer drugs," is inconclusive. Effects of abused substances as well as the general health and well-being of the mother are of concern when treating a pregnant substance abuser.[22] A multidisciplinary approach is important.

NICOTINE   Cigarette smoking, a habit to which 25 to 30 percent of reproductive-age women admit, increases the risk of many pregnancy complications. Only 20 percent of smokers quit by the time of the first prenatal evaluation.[23] Although the mechanism by which nicotine produces some of these adverse outcomes is incompletely understood, exposure to nicotine is associated with higher rates of spontaneous abortion, abruption, preterm labor, and low birth weight. Smoking cessation by 16 weeks' gestation may ameliorate adverse effects.[22] Attempts at cessation should first be made without pharmacologic intervention. Recommendations for the use of nicotine gum (pregnancy category C) and nicotine patches (pregnancy category D) should be individualized. Prior cessation attempts and total number of cigarettes per day should be considered in assessing the potential risks and benefits of such interventions.[23]

ALCOHOL   Ethanol readily crosses the placenta and enters the CNS of the developing fetus. Fetal exposure to ethanol produces a characteristic clinical condition known as fetal alcohol syndrome, which includes CNS dysfunction, growth retardation, and facial abnormalities. CNS abnormalities including microcephaly, mental retardation, and behavioral disorders are typically the most severe. This syndrome may result from ethanol use during any period of gestation; however, the greatest risk is with first-trimester exposure. Furthermore, although evidence supports a dose-related response to ethanol exposure, there is no established safe quantity of alcohol that may be consumed.[22]

Travel

In general, a normal pregnancy does not prevent women from traveling to reasonable destinations. The possibility of travel-related diseases or the development of complications while in remote areas is an issue that should be addressed before travel is begun. High-altitude stays of a few days' duration have not been associated with risk to the fetus, but exposure for longer duration increases the chance of fetal growth retardation, maternal high blood pressure, and premature delivery. Travel in pressurized aircraft has not been associated with adverse outcome in an otherwise uncomplicated pregnancy. Some commercial airlines, however, enforce restrictions limiting travel during the third trimester. Frequent ambulation is important during travel of long duration regardless of the period of gestation. Protective restraint devices should be used at all times in automobiles and airplanes. Lap belts should have a snug, comfortable fit under the abdomen and across the upper thighs.[24]

Exercise

Although exercise for both fitness and recreation has become a routine activity for many women, the effects of physical exertion on pregnancy outcome are not known, since there has not been a prospective, randomized trial studying this issue. Decreased rate of weight gain and subcutaneous fat deposition in the third trimester has been demonstrated in one (nonrandomized) study, although overall weight gain remained within the normal range.[25] In general, uncomplicated pregnancy should not limit the ability to engage in moderate physical exercise. The American College of Obstetricians and Gynecologists recommends some modifications in exercise routines in view of the physiologic and morphologic changes of gestation.[5] Non-weight-bearing activity and activities that minimize the chance of even mild abdominal trauma are preferable. Exercise in the supine position should be avoided completely after the first trimester due to potential for decreased cardiac output. Although there does not appear to be a need to alter goal intensity as judged by heart rate, exercise should be stopped at the onset of fatigue rather than continuing to exhaustion. Extra attention should be given to augmentation of heat dissipation, hydration, and appropriate clothing during activities. Adequate dietary intake should be ensured. As for all individuals, regular activity is preferable to sporadic exertion. Subjective benefits of exercise both preconception and during early pregnancy have been reported.[26] Specific recommendations for exercise during pregnancy need to be individualized and made with the knowledge that there is no conclusive evidence on which to base recommendations.

DISPOSITION

Whenever pregnancy is diagnosed in the emergency department, timely access to prenatal care should be arranged. Recommendations for prenatal care for a normal pregnancy include an initial obstetric evaluation no later than 6 to 8 weeks' gestation. Management plans need to be made in view of the condition. Discharge instructions should include recommendations about symptoms and signs for which the patient should be urgently reevaluated (Table 99-4). Recommendations on activities, lifestyle, and appropriate use of prescription and over-the-counter medications should be given.

Change in fetal movement pattern
Fever, chills
Refractory emesis
Visual disturbance
Abdominal pain
Significant headache
Anasarca
Dysuria
Vaginal bleeding and fluid loss
Abnormal vaginal discharge

TABLE 99-4   Symptoms and Signs in Pregnancy that Mandate Prompt Evaluation

Obstetric consultation should be obtained whenever there is uncertainty regarding issues, such as specific travel, immunization, medication, or management options. Gestational age, fetal heart tones (if gestational age >16 to 19 weeks), analytical values, parity, and general maternal information should be provided to the consultant.

Ectopic pregnancy (EP) occurs when a conceptus is abnormally implanted outside of the uterine cavity. It is a leading cause of pregnancy-related maternal death. Today, earlier diagnosis and hence decreased morbidity and mortality have been made possible by transvaginal sonography and improved sensitivity of serum pregnancy markers. As a result more patients may be eligible for conservative medical and surgical therapies.

PATHOPHYSIOLOGY AND EPIDEMIOLOGY

Fertilization of the oocyte usually occurs in the ampullary segment of the fallopian tube. In normal pregnancy, the zygote passes along the fallopian tube and implants into the endometrium of the uterus, with subsequent development of the placenta. An EP occurs when the zygote is implanted in any location other than the uterus; 95 percent of ectopic pregnancies occur in the fallopian tube. Extratubal sites include the abdominal cavity, cervix, and ovary. Abdominal ectopic pregnancies most commonly derive from early rupture or abortion of a tubal pregnancy, with subsequent reimplantation in the peritoneal cavity.

The fallopian tube is 10 to 12 cm long and is divided into four anatomic segments (proximal to distal): interstitial (cornual), isthmic, ampullary, and fimbrial. The ampullary segment is the longest. The most common site for EP is the ampullary segment, and the second most common site the isthmic segment. Interstitial (cornual) EP is uncommon (>3 percent) and fimbrial EP is rare. Operative description of tubal rupture reveals that it is more common with isthmic than with ampullary implantations. Ectopic pregnancies that have identifiable embryos or fetuses are more frequently associated with rupture. Rupture during the first few weeks of pregnancy is usually located in the isthmic segment of the tube, whereas interstitial rupture is seen later in pregnancy, typically at 9 to 16 weeks of gestation.

Tubal gestations that reach stages of fetal viability are rare (<5 percent of cases), and live-born offspring are extreme rarities. A normal placenta is found in only about 10 percent of ectopic pregnancies, possibly accounting for the much higher incidence of a blighted ovum in extrauterine pregnancies. Tubal abortion occurs when the vascular supply to the placenta is disrupted with bleeding into the fallopian tube and hematoma formation. Intermittent distention of the fallopian tube with blood can occur with leakage of blood from the fimbriated end of the fallopian tube into the peritoneal cavity. The aborting EP and associated hematoma can be completely or partially extruded out of the end of the fallopian tube or through a rupture site in the tubal wall. Tubal rupture is thought to be spontaneous; however, precipitating factors may include trauma associated with coitus or a bimanual examination.

EP represents about 2 percent of pregnancies. The postulated etiology of EP can be divided into two main categories: (1) mechanical or anatomic alterations in the tubal transport mechanism and (2) functional/hormonal factors that alter the fertilized ovum. Possible causes of mechanical or anatomic alterations in tubal transport include pelvic inflammatory disease (PID), previous surgical procedures on the fallopian tube, previous EP, intrauterine contraceptive devices (IUDs), previous induced abortions, peritubal adhesions (secondary to postabortal or puerperal infection, appendicitis, or endometriosis), and diethylstilbestrol (DES) exposure (possibly resulting in tubular diverticula or hypoplasia). PID results in damage to the mucosa of the fallopian tube. The most common cause of PID is infection resulting from sexually transmitted diseases. PID has been reported to increase the risk of EP six- to sevenfold. Each episode of PID increases the probability of EP. PID represents the most common and clear-cut risk factor in the development of EP.[1]

Tubal ligation is also a risk factor for EP. The more tissue-destructive the ligation procedure, the higher the EP rate. Extrauterine pregnancy rates as high as 51 percent of pregnancies have been reported with laparoscopic tubal electrocautery, as compared with rates of 12 percent using nonlaparoscopic methods. Infertility surgery on the fallopian tube has a reported 2 to 7 percent incidence of subsequent EP. Any patient who requires surgery for treatment of an EP is also at a higher risk of developing a subsequent EP. In general, future pregnancies following any prior tubal surgery should be suspected of being ectopic. It is not clear whether this higher incidence of EP is secondary to the underlying disease state or a result of the surgical procedure. IUDs have also been implicated in EP, with 3 to 4 percent of pregnancies occurring with an IUD in place estimated to be ectopic. Increased risk of EP is independent of the type of device. Following discontinuation of the IUD, the risk of EP is no longer significantly increased. Functional and hormonal mechanisms associated with an increased incidence of EP include assisted reproduction with chemical ovulation induction (clomiphene citrate, follicle-stimulating hormone, luteinizing hormone), gamete intrafallopian transfer (GIFT) and in vitro fertilization, altered tubal motility from the effects of estrogen and progesterone, and inherent defects in the fertilized ovum.

The incidence of EP has increased over the last two decades from 4.5 per 1000 reported pregnancies (0.45 percent) in 1970 to 19.7 per 1000 reported pregnancies (nearly 2 percent) in 1992. Reported pregnancies included live births, legally induced abortions, and ectopic pregnancies. An overestimation of the incidence of EP is possible, since the denominator, reported pregnancies, could be biased by lack of reporting of illegally terminated pregnancies or undetected spontaneous abortions. Some possible reasons postulated for the increased incidence of EP include the increased incidence of sexually transmitted tubal infections, unsuccessful tubal sterilizations, assisted reproductive techniques, previous pelvic surgery, and more sensitive and earlier diagnostic techniques. Overall, EP is more common in nonwhite than white women and in women above 35 years of age.[1]

The case-fatality rate per 10,000 ectopic pregnancies decreased from 35.5 in 1970 to 8.8 in 1980 to 3.8 in 1989. This trend was observed in both white and nonwhite women. However, nonwhite women overall had a 3.4 times greater risk of death than white women. Teenagers were the age group with the highest mortality rate. The observed decreased mortality is attributed largely to improved diagnostics and also a heightened awareness among medical personnel. However, EP remains the leading cause of maternal death in the first trimester of pregnancy and is the second leading cause of maternal mortality overall.[1]

CLINICAL FEATURES

The classic triad of symptoms in EP is abdominal pain with vaginal bleeding or spotting in a woman with amenorrhea. While frequently seen in cases of EP, the positive predictive value of this presentation is low, as it is more commonly seen in threatened or spontaneous abortion than in EP and may occur in nonpregnant women due to other causes. Many other presentations occur and range from sudden abdominal pain with life-threatening hypovolemic shock to an absence of symptoms with an EP discovered incidentally on ultrasound exam. To achieve the goal of early diagnosis in as many cases as possible, EP should be considered in all women of childbearing potential who present with abdominal or pelvic complaints or with unexplained signs or symptoms of hypovolemia.

History

Elements of the history that increase the risk for EP are absent in nearly 50 percent of cases and are therefore useful only in increasing clinical suspicion in equivocal cases. The menstrual history is often abnormal, with amenorrhea of between 4 and 12 weeks reported in approximately 70 percent of cases. No missed menses are reported in approximately 15 percent of cases; thus neither a normal menstrual history nor prolonged amenorrhea has a sufficient negative predictive value to rule out

an EP.[2]

Abdominal pain is expected in EP with tubal rupture but may be absent without rupture. Overall, up to 10 percent of ED patients with EP may not report pain. The classic pain of rupture is lateralized, sudden, sharp, and severe. However, many atypical pain patterns occur. A ruptured EP may present with shoulder pain from referred diaphragmatic irritation. This was reported in up to 20 percent of patients in one study. Pain may be absent even with rupture, as 4 percent of women in one study with hemoperitoneum from ruptured EP did not report pain. When nonruptured EP is painful, the pain is presumably from tubal distention. With the goal of early diagnosis, the absence of pain is not sufficient to exclude EP from consideration in a patient with other signs or symptoms of the disorder. [2]

Vaginal bleeding is noted in up to 80 percent of cases of EP. Bleeding is usually scanty, but other patterns may occur. Classically, light bleeding occurs at or about the time of expected menses and may be mistaken for a normal period. Bleeding usually precedes pain. The duration of bleeding ranges from 1 day to several months before diagnosis. Heavy bleeding should increase suspicion for threatened abortion or another complication of an intrauterine pregnancy but does not rule out an EP. Typical early pregnancy symptoms may occur and may not differ from symptoms of previous normal intrauterine pregnancies. [2]

Physical Examination

The physical examination in EP is highly variable. In cases of ruptured EP, patients may present in shock, with an adnexal mass and tenderness. Peritoneal signs will usually be present due to peritoneal irritation from blood and is seen in about 90 percent of patients. Relative bradycardia may occur, as in other causes of intraabdominal hemorrhage, as a consequence of vagal stimulation. In cases of rupture without hemodynamically significant bleeding, less prominent peritonitis without significant alteration of vital signs would be expected. Fever is rare, occurring in less than 2 percent of cases. In the more common situation of an unruptured EP, the vital signs are likely to be normal. An adnexal mass or fullness with tenderness is seen in approximately two-thirds of patients. Interestingly, at surgery, the EP may be on the opposite side from the mass. This has been noted in up to 20 percent of patients and is most often secondary to a corpus luteum cyst. Cervical motion tenderness is often seen and blood is often present in the vaginal vault. The cervix may have a blue coloration, as in a normal pregnancy. An enlarged uterus may also be detected, misleading the examiner into believing that the pregnancy is intrauterine. Pelvic examination may be completely normal in cases of ectopic pregnancy. Fetal heart tones are very seldom audible in cases of EP. [2,3]

DIAGNOSIS

The differential diagnosis for women of childbearing potential who present with abdominal or pelvic symptoms or abnormal vaginal bleeding is broad (Table 100-1). In these patients, no combination of signs or symptoms has sufficient negative predictive value to rule our ectopic pregnancy. Pregnancy testing is therefore mandatory. If pregnancy is detected, EP should remain part of the differential diagnosis unless another diagnosis can be made with a high level of certainty. When another diagnosis is not made or when EP is considered along with another diagnosis, EP must be ruled out with a combination of laboratory and imaging studies.

All Patients	Pregnant Patients
Appendicitis	Normal (intrauterine) pregnancy
Inflammatory bowel disease	Threatened abortion
Ovarian pathology	Inevitable abortion
Cyst	Molar pregnancy
Torsion	Heterotopic pregnancy
Pelvic inflammatory disease	
Endometriosis	
Sexual assault/trauma	
Urinary tract infection	
Ureteral colic	

TABLE 100-1 Differential Diagnosis of Ectopic Pregnancy

Pregnancy Testing

The diagnosis of pregnancy is central to the diagnostic workup of possible EP. When a patient is not pregnant, there is no ectopic pregnancy. Pregnancy tests currently in use rely on the detection of the b subunit of human chorionic gonadotropin (bhCG) in the urine or serum. Human chorionic gonadotropin (hCG) is a hormone produced by the trophoblast and is normally undetectable in the serum. Intact hCG consists of the a and b subunits. Tests based on detection of the intact molecule or the a subunit cross-react on immunologic assays with hormones found in the nonpregnant individual and are thus less specific then tests for the bhCG subunit.

Human chorionic gonadotropin preparations are currently standardized in relation to the International Reference Preparation (IRP). Other standard preparations are not equivalent. A preparation often referred to in earlier literature is the Second International Standard (2nd IS). The IRP is roughly equal to 1.7 times the 2nd IS. To avoid confusion when interpreting the literature, attention must be paid to the standard used. In this chapter, hCG and bhCG concentrations are in reference to the IRP unless otherwise noted.[3]

Very early in either an intrauterine pregnancy (IUP) or an EP, detectable amounts of bhCG are released into the serum and filtered into the urine. The concentration of bhCG is fairly closely correlated in the urine and serum, with urinary concentration also depending upon urine specific gravity. Qualitative urine and serum tests for pregnancy usually use the enzyme-linked immunosorbent assay (ELISA) methodology. In the laboratory setting, ELISA tests can detect bhCG at concentrations below 1 mIU/mL. Qualitative tests in clinical use are typically reported as "positive" when the bhCG concentration is ³20 mIU/mL in urine and ³10 mIU/mL in serum. A "positive" qualitative test therefore implies that bhCG is present in at least this concentration. At this level of detection, the false-negative rate for detection of pregnancy will not be more than 1 percent for urine and 0.5 percent for serum and may be less. In clinical use, the performance of urine qualitative testing has been found to be from 95 to 100 percent sensitive and specific as compared with serum tests. One study showed that in 100 percent of 95 patients with EP, pregnancy was correctly diagnosed with a sensitive qualitative urine test (Hybritech Tandem ICON II). [4] Urine tests can be performed rapidly at the bedside, and kits from some manufacturers may be used for either urine and serum. A bedside test for urine is therefore the best first test for pregnancy when EP is suspected. Dilute urine may cause a false-negative urine pregnancy test.[5] This is most likely to occur early in pregnancy when bhCG levels are low (<50 mIU/mL). If urine is not available, use of a bedside serum test may be considered. When a bedside urine test is negative and EP is still being considered, a quantitative serum test should be performed. The sensitivity of quantitative serum testing for the diagnosis of pregnancy is virtually 100 percent when an assay capable of detecting ³5 mIU/mL of bhCG is used. [4,5]

Laboratory Tests and Ectopic Pregnancy

The final diagnosis of EP is made either by ultrasound (US) or direct visualization via the laparoscope or at surgery. Laboratory tests are used as part of an overall diagnostic and management scheme to either raise or lower the level of suspicion for EP. All laboratory tests must be interpreted in light of the clinical picture and findings from US. No single diagnostic test or combination of laboratory tests is currently considered to have sufficient negative predictive value to completely rule out EP or abnormal IUP or positive predictive value to definitively diagnose them.

Much is known about the dynamics of bhCG production in normal and pathologic pregnancy. Early in pregnancy, bhCG levels rise rapidly. bhCG levels decline in nonviable pregnancies and in successfully treated EP. Absolute levels of bhCG tend to be lower in pathologic pregnancies than in IUP, but there is much overlap. Owing to the variability in absolute levels and the overlap between normal and pathologic pregnancies, no single bhCG level can reliably distinguish between a normal and a pathologic pregnancy. *Doubling time* refers to the time needed for bhCG concentration in the serum to double. In normal pregnancy, serum levels of bhCG increase by at least 66 percent every 48 h in 85 percent of patients. Absolute levels of bhCG are lower and doubling times longer in EP and other abnormal pregnancies. This and many other observations has lead to the widely used rule of thumb stating that the serum concentration of bhCG approximately doubles every 2 days early in a normal pregnancy and that longer doubling times indicate pathologic pregnancy. Varying degrees of sensitivity and specificity are obtained using different criteria for evaluating bhCG levels. Sensitivities for the diagnosis of EP between 36 and 75 percent with specificities of 63 to 93 percent have been reported.

Even in EP, approximately 13 percent of patients will have an increase in serum bhCG of at least 66 percent in 2 days. A serum bhCG which fails double in 48 h is thus suggestive but not diagnostic of an EP or an abnormal IUP. Serial measurements of bhCG are therefore used to either heighten or lower the suspicion for EP but are not diagnostic.[6]

Progesterone (P) is a steroid hormone secreted by the ovary, adrenal glands, and placenta during pregnancy. During the first 8 to 10 weeks of pregnancy, ovarian production of P predominates and serum levels remain relatively constant. After the tenth week of pregnancy, placental production increases and serum levels rise. Absolute levels of P are lower in pathologic pregnancies and fall when a pregnancy fails. This observation has led multiple authors to propose various P levels as a diagnostic aid in differentiating an early normal from a pathologic pregnancy. As with other diagnostic tests, the sensitivity of P testing increases and the specificity decreases as a lower threshold value is selected. Most pathologic pregnancies have P levels £10 ng/mL. For P £ 5 ng/mL, nearly 100 percent of pregnancies will be pathologic; there are no normal pregnancies reported with P £ 2.5 ng/mL. Progesterone levels >25 ng/mL have a 97 percent sensitivity for viable IUP. An intermediate value of P £ 15 ng/mL is 70 percent sensitive and 73 percent specific for EP. A recent metanalysis revealed that 91.7 percent of pregnancies had P £ 17.5 ng/mL. For patients with P > 17.5 ng/mL, the authors concluded that clinical follow-up and no further diagnostic workup was needed. [7] As can be appreciated from the above, there is considerable overlap between P levels in normal and pathologic pregnancy. Very low values for serum P thus should increase the clinical suspicion for EP or abnormal IUP, but no value is diagnostic or can completely exclude the diagnosis. Certain authors strongly advocate protocols using serum P levels instead of or as an adjunct to quantitative bhCG levels. However, P levels may not be routinely available on an urgent basis and, as noted, many patients have intermediate values, thus limiting the usefulness of the test. Consequently, the role of serum progesterone assays is currently unclear and it is undergoing further evolution and evaluation.

Numerous other serum markers for the diagnosis of EP have been investigated. These include secretory endometrial protein, estradiol, the pregnancy-associated proteins A to D, and others as well as routine laboratory tests such as amylase, creatine kinase, sedimentation rate, and others. None have been accepted as superior to bhCG measurements at this time.

Sonography and Ectopic Pregnancy

Sonography plays an essential role in the diagnosis of EP. The primary goal of sonography in suspected EP is to determine if an IUP is present. Sonographic findings may also be useful in planning therapy when an EP is discovered. Noninvasive therapies are often reserved for EPs in which no cardiac activity is seen or those in which the mass is less than a specified size, though this area is undergoing rapid change. In addition, sonography provides information regarding fetal age and viability when an IUP is present. It has previously been assumed that if an IUP exists, the diagnosis of EP has been excluded. This assumption is based on the historical incidence of heterotopic pregnancy (combined IUP and EP), reported to occur once per 30,000 pregnancies. This is no longer a completely safe assumption, with heterotopic pregnancy now occurring in up to 1 in 3000 pregnancies in the general population. In vitro fertilization and other efforts to enhance fertility with the use of ovulation-inducing drugs has resulted in a higher incidence of heterotopic pregnancy. Studies have reported up to a 1:95 incidence in the in vitro fertilization population. In this group heterotopic pregnancy should be considered even when sonography demonstrates an IUP. For other patients, demonstrating an IUP still provides a high degree of confidence in ruling out EP. This confidence should be somewhat tempered when a patient has risk factors for EP.[8]

Advances in sonographic imaging include improved portability, decreased cost, and improved image quality of newer machines. Use of transvaginal scanning allows earlier detection of an IUP or an EP. These advances have contributed to increasing use of real-time, bedside sonography in the emergency department (ED) performed by emergency physicians. ED sonography has the further advantage of allowing a potentially unstable patient to remain under continuous observation in the ED. ED sonography in the first trimester of pregnancy has been shown to be accurate and to contribute to earlier diagnosis and treatment of EP. It has been endorsed by the American College of Emergency Physicians (ACEP) and the Society for Academic Emergency Medicine (SAEM). However sonography is a highly operator-dependent procedure. Widespread validation in the community setting of the positive results obtained in academic teaching hospitals does not yet exist. Sonography is a valuable adjunct to the physical examination and laboratory data in the diagnosis of EP when used by emergency physicians, but the limitations of the procedure, equipment, and operator must be kept in mind. [9,10 and 11]

Identification of an IUP with sonography is dependent upon operator and technical factors and gestational age as reflected in bhCG levels. Technical factors include the approach [transabdominal (TA) versus transvaginal (TV)], body habitus (possible interference from abdominal wall fat), patient preparation (full bladder needed for TA scanning) and equipment characteristics. Higher-quality equipment produces better images, which are easier to interpret. The quality of the image and the accuracy of the interpretation also depend on the skill of the person who obtains and interprets the images. All of these must be considered when making clinical decisions based upon sonographic results. [11,12 and 13]

The sequencing of TA versus TV sonography is situation- and operator-dependent. Usually, TA scanning is performed first. Among other differences, TA scanning is less invasive and offers a wider field of view and easier orientation to the pelvic organs. A full bladder is required for an appropriate acoustic window. TA scanning is often diagnostic. When TA sonography is not diagnostic, TV scanning should be performed. With TV scanning, the shallower depth of field and higher frequencies made possible by the lack of interposed abdominal fat allows better visualization of small structures such as early pregnancies. Orientation to the pelvic organs is more difficult with TV scanning than with TA. A full bladder is not required. There are reports of negative TV but positive TA sonography in cases of EP, so both studies should be performed if the study performed first is not diagnostic. [12,14]

When sonography reveals an unequivocal IUP and no other abnormalities, EP is effectively excluded unless heterotopic pregnancy is a consideration. A living IUP may be definitely diagnosed when cardiac activity is seen within the uterine cavity (cardiac activity usually can be seen by 6 weeks in TV and 7 weeks in TA). It may still be necessary to consider another diagnosis to explain the chief complaint when an IUP is found. If an embryo without cardiac activity is visualized, the diagnosis of fetal demise can be made provided that the crown-rump length is at least 5 mm. Again, there may be other coexisting diagnoses. Diagnosis of an IUP when cardiac activity is not seen is less certain. A gestational sac found early is seen as a small, sonolucent structure surrounded by an echogenic ring (see Fig. 109-8 in Chap. 109). This is normally seen by 5 weeks since the last normal menses. At approximately 6 weeks, the yolk sac becomes visible. The yolk sac is a bright (echogenic) ring within the gestational sac. By 7 weeks, cardiac activity is usually visible within the embryo, with both the embryo and yolk sac visible (see Fig 109-9 in Chap. 109). An intrauterine pregnancy with cardiac activity is referred to as a viable IUP. Generally, the gestational sac, yolk sac, and fetal pole can be visualized by TV at 4.5, 5.5, and 6 weeks respectively. Visualization by TA is approximately one week later.

No further diagnostic testing is needed when sonographic findings confirm or are highly suggestive of EP. An empty uterus with embryonic cardiac activity visualized outside the uterus is diagnostic of EP. This is seen in less than 10 percent of EP using TA scanning but in up to 25 percent of cases when the TV approach is used. When a pelvic mass or free pelvic fluid are seen in conjunction with an empty uterus, EP is considered highly likely. One study suggests that the combination of an echogenic adnexal mass with free fluid in the setting of an empty uterus confers a 100 percent risk of EP, while a large amount of free fluid alone has a 95 percent and a mass alone a 71 percent risk (Table 100-2).[15] A metanalysis of studies published regarding TV sonography for EP suggests that in addition to a living extrauterine pregnancy, an extrauterine gestational sac is highly predictive of EP. The analysis also suggested that any adnexal mass (other than a simple cyst) has a 99 percent specificity and a 96 percent positive predictive value with 84 percent sensitivity for the diagnosis of EP. [16] It has also been suggested that the thickness of the endometrial stripe is predictive of EP when no diagnostic findings are noted on sonography. A large retrospective study found that the average thickness of the endometrial stripe was 6 mm in cases later proved to be EP, while in cases of IUP the stripe measured about 13 mm on average.[17]

Ancillary Findings	Risk of Ectopic Pregnancy
Small amount of free pelvic fluid	52%
Echogenic adnexal mass	70%
Moderate/Large amount of free pelvic fluid	86%
Any mass plus echogenic fluid	97%

TABLE 100-2   Ancillary Ultrasound Findings Suggestive of Ectopic Pregnancy in High-Risk Patients

If sonography fails to reveal a definite IUP or fails to show findings strongly suggestive or diagnostic of an EP, the test should be considered indeterminate and interpreted in light of quantitative serum bhCG levels. The concept of the "discriminatory zone" was developed by Kadar and colleagues to relate bhCG levels and sonography findings in a clinically useful way.[18] The discriminatory zone is the level of bhCG at which findings of an IUP are expected on sonography. If the bhCG level is higher than the discriminatory zone and the uterus is empty, this is interpreted as suggestive of an EP. An empty uterus with a bhCG level below the discriminatory zone is an indeterminate finding representing an early IUP, an EP or other pathologic pregnancy. The actual level of bhCG representing the discriminatory zone is operator- and technique-dependent. With TV scanning, a conservative discriminatory zone is 1800 to 2000 mIU/mL. For TA scanning, an IUP should be detectable when the bhCG level reaches about 6000 mIU/mL. [14,16] Clinicians should understand this concept and collaborate closely with imaging specialists in equivocal cases to avoid confusion. When EP is suspected, sonography should be performed even in patients with low bhCG levels. Dart and colleagues found that approximately one-third of patients presenting to an ED with the eventual diagnosis of EP and bhCG >1000 mIU/mL were identified by TV sonography. They were also able to identify patients with IUP and low bhCG levels. [19]

Diagnostic algorithms using the concept of the discriminatory zone have been proposed and tested. A study of 1263 consecutive ED patients with clinically suspected EP by Barnhart et al. found 205 cases of EP, of whom 81.5 percent were hemodynamically stable.[21] In stable patients, they correctly diagnosed 49.1 percent of EP and 96 percent of IUP on the initial visit with a combination of bhCG levels and TV sonography. They used a level of 1500 mIU/mL as their discriminatory zone. If the bhCG level was >1500 mIU/mL and the uterus was empty, dilation and curettage (D&C) or laparoscopy was used to diagnose EP. [A D&C was performed on patients not wishing to continue the pregnancy. If chorionic villi were present, IUP was considered confirmed]. When the bhCG level was <1500 mIU/mL and the uterus empty, they performed serial bhCG measurements every 2 days. If bhCG failed to increase by at least 66 percent in a 2-day period, an operative procedure was used to diagnose possible EP. TV sonography was repeated if the bhCG level was >1500 mIU/mL. With use of this protocol, 100 percent of EP were identified without any complications (sensitivity = 100 percent). The specificity of the protocol was 99.9 percent. [20] In another prospective study, Braffman and colleagues studied 1427 ED patients with suspected EP. Patients with bhCG >1500 mIU/mL had sonography which was diagnostic in 1158 (81 percent). [21] The study was indeterminate in 269 (19 percent). Sixty-five (24 percent) of the patients with indeterminate scans were later found to have an EP. [21] The lack of definitive findings on sonography thus should not be regarded as a benign finding if a patient is suspected of having an EP.

Invasive Diagnostic Techniques

Culdocentesis has been largely supplanted by tests for bhCG in combination with sonography, but it may have use in some circumstances, primarily when sonography is unavailable. Laparoscopy may be both diagnostic and therapeutic. D&C may provide a definitive diagnosis of IUP, thus excluding EP except in cases of heterotopic pregnancy.

Culdocentesis

Culdocentesis is the technique of needle aspiration of the rectovaginal cul-de-sac through the posterior fornix of the vagina. Possible results include a dry aspiration, which has no diagnostic value. If clear, nonbloody peritoneal fluid is aspirated, the tap is considered negative. Aspiration of nonclotting blood constitutes a positive tap, considered indicative of an EP. However, there is no consensus regarding the criteria for a positive test. Volumes between 0.3 mL and 10 mL with hematocrit from 3 to 15 percent have been proposed by various authors. The pathophysiologic basis for culdocentesis is that a ruptured EP will bleed into the pelvic peritoneal cavity. Some 85 to more than 90 percent of patients with a ruptured EP will have a positive culdocentesis. Surprisingly, up to 70 percent of patients with an unruptured EP will also have a positive result. A basic limitation of the technique is thus that it is less sensitive in the diagnosis of nonruptured than ruptured EP. Another cause of a false-negative results is that in cases of rapid bleeding, intraperitoneal blood may clot due to lack of sufficient dwell time to produce defibrination. False-positive results occur because of technical errors (entering a vein or other vascular structure with the needle) or a ruptured corpus luteum cyst. Aspiration of purulent material may indicate another diagnosis, such as PID.

A study by Vermesh and colleagues evaluated 252 consecutive patients, most of whom had culdocentesis followed by surgery for suspected EP. [22] A total of 210 patients (83 percent) had a positive culdocentesis defined by fluid with a hematocrit ³15 percent. Of these, 191 patients (91 percent) had an EP verified at surgery. Twenty-seven of the patients who were discharged after a negative culdocentesis were later found to have an EP, illustrating the poor sensitivity of this procedure for detection of EP. The authors concluded that culdocentesis has less value than noninvasive tests in the management of suspected EP. [22]

Krol and Abbott have reviewed and discussed culdocentesis in the diagnosis of suspected EP in the ED setting. [23] Their conclusion was that in spite of the limitations of the procedure, it has two remaining indications: in unstable patients suspected of a ruptured EP, culdocentesis may be valuable when bedside sonography is not available, and in stable patients, culdocentesis should be considered when sonography is not available. Their logic is that a positive test would facilitate an appropriate, rapid surgical intervention. [23] These conclusions seem reasonable except that few emergency physicians today have regular experience with culdocentesis. As with any invasive procedure, complications as well as false-negative and false-positive results are expected to increase with operator unfamiliarity.

Laparoscopy

Laparoscopy is primarily useful in patients with suspected EP and a nondiagnostic sonogram. It may provide an earlier diagnosis and a possible route for definitive treatment when compared with serial bhCG measurements and sonography. Laparoscopy has a high sensitivity for the diagnosis of EP with low false-negative rates, reported to occur in 3 to 4 percent of cases. False-negative tests are presumably more common early in the course of EP. False-positive rates are somewhat greater, with rates of 1.6 to 6.2 percent; reported. As with other invasive techniques, results will vary with the skill of the operator and the quality of the available equipment. If a laparoscopist is available who is skilled in the diagnosis and laparoscopic treatment of EP, laparoscopy is a viable alternative, which may be accomplished rapidly and with low morbidity.

Dilatation and Curettage

Uterine curettage provides a method for the definitive diagnosis of an IUP when chorionic villi are obtained from the uterine cavity. EP is thus excluded unless a heterotopic (combined) pregnancy is present. The procedure can be performed in a outpatient setting with intravenous sedation. The procedure terminates an IUP if present and is thus applicable only when termination of pregnancy is desired or when a nonviable pregnancy has been documented. A progesterone level of £5 ng/mL or stable or falling bhCG levels provide good though not certain evidence of nonviability. The specimen obtained at D&C is examined for the presence of chorionic villi. This may be done at the bedside by suspending the specimen in saline. Villi are observed to float, and absence of material that floats is presumptive evidence of absent villi and thus suggestive of an EP. One study reported a 6.6 percent; false-negative rate (i.e., villi were reported as present in cases later proved to be EP) with this method and there are false-positive tests as well. The results should thus be interpreted cautiously and formal histologic exam of the specimen is needed in addition to bedside suspension of the specimen.

TREATMENT

The traditional treatment of EP has been laparotomy and salpingectomy. Over the last two decades, more conservative surgical and medical approaches have been developed that allow fallopian tube preservation, outpatient treatment, or shorter hospital admissions, and decreased medical expenditures. The treatment of EP can be divided into surgical and medical approaches. Most authors would agree that if laparoscopy is needed for diagnosis, a surgical approach is most appropriate. For unruptured EP, the most frequently used surgical approach is laparoscopic salpingostomy; the most frequently used medical approach is methotrexate treatment. For ruptured EP, laparotomy is the treatment of choice in hemodynamically unstable patients, although laparoscopic approaches have been utilized when the bleeding can be readily controlled. [24]

Surgical Approach

Overall, laparoscopy as compared with laparotomy has emerged as the preferred surgical approach in the treatment of EP in a hemodynamically stable patient. Laparoscopy has been shown to be associated with less blood loss, reduced postoperative adhesion formation, reduced analgesic requirements, reduced hospital stay and convalescence period, and reduced medical expenditures as compared with laparotomy. In a review of studies examining salpingostomy via a laparoscopic or laparotomy approach, the rates of persistent EP for the laparoscopic approach (3 to 20 percent) versus laparotomy (zero to 11 percent) were reported to be comparable. Reproductive outcomes for patients attempting to conceive after the procedure [intrauterine pregnancy (61 percent) and recurrent EP (15 percent)] also

were reported to be similar. Laparotomy is reserved for cases that are too difficult for laparoscopic surgery, for hemodynamically unstable patients, and where the operator is inexperienced with operative laparoscopy. Surgical methods for the treatment of tubal EP include salpingectomy, salpingostomy, salpingotomy, segmental tubal resection and anastomosis, and fimbrial evacuation. Fimbrial evacuation of distal ectopic pregnancies is not recommended because of the higher recurrence rate of EP and high incidence of persistent trophoblastic tissue. Which of the other approaches is used depends on hemodynamic stability, the portion of the fallopian tube involved, and the patient's desire for future pregnancy. Segmental tubal resection and anastomosis is recommended for an unruptured pregnancy in the isthmic portion of the fallopian tube because of associated scarring and narrowing of the tube using other methods (e.g., salpingostomy or salpingotomy). [24]

In cases where future fertility is of no concern or the patient is hemodynamically unstable, salpingectomy is the definitive surgical method. Laparoscopic salpingostomy is recognized as the preferred surgical method for the treatment of unruptured EP in patients where future fertility is desired. This more conservative approach has been reported to result in a higher rate of subsequent intrauterine pregnancies (61 versus 38 percent). However, salpingostomy compared to salpingectomy is associated with an increased risk of persistent EP (3 to 20 percent) and recurrent EP (15 versus 10 percent, respectively). Salpingostomy is performed via laparoscopy by making a linear incision (by electrocautery, scissors, or laser) over the antimesenteric side of the fallopian tube overlying the EP. The products of conception are removed (by forceps or suction) and the incision is left open to heal by secondary intention. The tubal incision can also be sutured (salpingotomy).[24]

Specific indications for laparoscopic salpingostomy include hemodynamic stability, ectopic size £5 cm, unruptured or ruptured fallopian tube with minimal tubal destruction, appropriate location of the conceptus (ampullary, infundibular, isthmic), surgical accessibility of the fallopian tube, and the patient's with to preserve reproductive potential. Laparotomy can also be used to perform a linear salpingostomy and should be utilized for patients who are hemodynamically unstable or for whom the laparoscopic approach is difficult (e.g., secondary to adhesions).

To assess for a persistent EP following laparoscopic salpingostomy, a weekly hCG level is obtained. By the second postoperative week, the hCG level should be undetectable or less than 20 mIU/mL. If hCG values are above 20 mIU/mL 2 weeks postoperatively, then a repeat sample shoud be obtained 2 weeks later to establish absence of hCG concentrations. Persistent trophoblastic tissue can be found in the fallopian tube or peritoneum; it is most commonly found in the proximal portion of the fallopian tube. Persistent ectopic pregnancies have been successfully treated by surgical reoperation, methotrexate treatment, or expectant management.[24,25]

Medical Treatment

Methotrexate administration is the most common medical treatment for EP. Other compounds have been used for local injection, including prostaglandins, hyperosmolar glucose, potassium chloride, and mifepristone (RU486). Expectant management with serial hCG levels and ultrasound is also a medical option.

Methotrexate is a potent folate antagonist that inhibits the enzyme dihydrofolate reductase, blocking DNA synthesis prior to cell division. Methotrexate effectively inhibits cell division in rapidly dividing cells such as trophoblastic tissue. Many different methotrexate regimens have been used, including both systemic and direct injection into the ectopic gestational sac under ultrasound guidance or laparoscopy. Somewhat higher success rates have been reported for single-dose intramuscular administration of methotrexate (92 percent) versus local injection under ultrasound (81 percent) or laparoscopy (79 percent). Systemic and local administration of methotrexate produced similar peak plasma concentrations and areas under the curve. [24,25]

Systemic treatment has evolved as the most commonly used methotrexate treatment in selected patients, avoiding possible additional cost and/or morbidity from laparoscopic or US guidance techniques for local injection. Both single-dose (methotrexate 50 mg/m^2) and multiple-dose (1 mg/kg IM every other day for 4 days or 48 h) regimens have been used. Possible side effects associated with methotrexate treatment include bone marrow suppression, acute and chronic hepatotoxicity, stomatitis, pulmonary fibrosis, alopecia, and photosensitivity. Leucovorin has been commonly coadministered to diminish the possible side effects; however, some clinicians report that it is not needed. Precautions are taken following methotrexate treatment to minimize the danger of tubal rupture, including only one pelvic exam by one examiner (similar to placenta previa). [26,27]

Abdominal pain (lasting 4 to 12 h) is common (33 to 59 percent) 3 to 7 days after initiation of methotrexate treatment and is thought to be secondary to methotrexate-induced tubal abortion. This can represent a clinical dilemma in that it is difficult to differentiate expected pain from therapeutic tubal abortion and pain from rupturing persistent EP. Patients presenting with abdominal pain in this time frame following methotrexate administration should have a complete blood count and US to rule out significant free fluid in the cul-de-sac and should be evaluated for other causes of abdominal pain. Such patients may need admission to the hospital for observation. Hemodynamic instability and/or falling hematocrit would require surgical intervention. [26,27]

Single-dose intramuscular administration of methotrexate for the treatment of EP in selected patients represents an outpatient approach that can be initiated in the ED. A treatment protocol should be developed jointly with the emergency and ob/gyn departments. Patients should be instructed that (1) treatment failure occurs in at least 5 to 10 percent of cases, (2) failure is more likely in pregnancies past 6 weeks gestation and tubal mass greater than 3.5 cm in diameter; (3) elective surgery may be necessary if medical therapy fails and emergent surgery may be necessary if tubal rupture occurs (approximately a 5 percent chance); (4) vaginal bleeding, abdominal and/or pleuritic pain, weakness, dizziness, or syncope (possible signs of tubal rupture) should be reported immediately; (5) no sexual intercourse (which can possibly increase the risk of tubal rupture) until hCG concentrations are absent (usually 14 to 21 days following methotrexate); (6) no alcohol or multivitamins with folic acid should be consumed. [26,27]

Stovall et al. reported the largest (120 women) prospective series of patients receiving a single-dose of intramuscular methotrexate. [26] In that favorable series, a nonlaparoscopic diagnostic algorithm was used. Inclusion criteria for single-dose intramuscular methotrexate treatment included hemodynamic stability, TV ultrasound demonstrating an unruptured EP (if identified) £3.5 cm in the greatest diameter, hCG titers increasing after curettage (if performed), and patient's desire for future fertility. The protocol consists of:

Day 0: Lab tests (CBC, quantitative hCG, Rh, serum creatinine), intramuscular methotrexate (50 mg/m^2); if Rh negative, give Rhogam 300 µg.

Day 4: Quantitative hCG.

Day 7: Quantitative hCG, CBC, transaminases; if <15 percent decline or rise in hCG between days 4 to 7, repeat methotrexate (50 mg/m^2).

Weekly hCG titers should be obtained until negative. If hCG titer has diminished less than 50 percent over a 2-week period, then a repeat dose of methotrexate should be given.[26]

In a recent review of the treatment of EP by Yao, more stringent guidelines were recommended, including only treatment in women with hCG <2000 mIU/mL, tubal diameter <2 cm, and absence of fetal cardiac activity. [24] Certain prognostic factors have been identified that are associated with a higher failure rate of methotrexate treatment, including larger tubal diameter, higher hCG concentrations, severe abdominal pain, and presence of fetal cardiac activity. However, no clear consensus has been established for exact tubal diameter or hCG concentration thresholds. Methotrexate is contraindicated in patients with hepatic dysfunction (transaminases greater than twice normal), renal disease, WBC <2000, or platelet count <100,000. [27] Following methotrexate administration, it is not uncommon to observe a transient rise in hCG concentrations between days 1 and 4. Serial ultrasound exams have revealed that the tubal EP may actually increase in size and vascularity before its resolution, and that hCG resolution does not correlate with sonographic resolution. [24]

One randomized trial to date has compared systemic methotrexate (intramuscular; four-dose treatment over 1 week) to laparoscopic salpingostomy in the treatment of tubal pregnancy in 100 patients with laparoscopically confirmed unruptured EP. Primary treatment with either methotrexate or laparoscopic salpingostomy revealed similar success rates (82 versus 72 percent of patients, respectively); homolateral fallopian tube patency rates (3 months after treatment) were also comparable (55 versus 59 percent of patients, respectively). Long-term fertility outcome from this study has not yet been reported. [28]

CLINICAL APPROACH AND DISPOSITION

With the goal of early diagnosis, when a patient with signs or symptoms suggestive of EP is found to be pregnant, further testing to determine if the pregnancy is intrauterine should be undertaken. The nature and timing of additional diagnostic measures depends upon the clinical condition of the patient. Unstable patients

suspected of ectopic pregnancy should receive resuscitation, urgent consultation, and operative intervention. Surgery may be both diagnostic and therapeutic if an EP is found or may reveal another cause for the patients condition. When bedside ED sonography is available, it may be valuable even in unstable patients if it does not interfere with resuscitation, consultation, and rapid transfer to the operating room.

Ideally, all pregnant patients with suspected EP should receive immediate sonography. However, issues of availability during off hours may make this impractical. Stable patients who are judged to be at low risk for EP can be considered for discharge and outpatient follow-up. At a minimum, such patients should have a quantitative bhCG level obtained to facilitate subsequent management. Culdocentesis remains an option where sonography is unavailable but at this time is used infrequently.

There are a number of options for stable patients with a bhCG level outside the discriminatory zone and negative sonography. These include consultation or discharge for follow-up in 2 days for reexamination and repeat bhCG levels. Culdocentesis, D&C, and laparoscopy are also options in this circumstance. The flowchart illustrates a suggested diagnostic approach (Fig. 100-1).

101 EMERGENCIES DURING PREGNANCY AND THE POSTPARTUM PERIOD

Gloria J. Kuhn

Pregnant women are susceptible to all of the diseases seen in nonpregnant women as well as diseases present only in the gravid and postpartum periods. In 1994, 8 percent of American women aged 14 to 44 were pregnant and delivered approximately 3.9 million live births. While the majority of pregnancies result in the delivery of a healthy infant from a healthy mother, there are conditions that can complicate the natural course of pregnancy. This chapter discusses diseases that have the potential of complicating pregnancy and increasing morbidity and mortality rates for either the mother or the fetus.

MORTALITY AND MORBIDITY RATES

The lethal triad in pregnancy has been hemorrhage, infection, and preeclampsia. In the United States, maternal mortality and morbidity rates have been significantly reduced, but these three diseases remain the most common complications of pregnancy.

Direct maternal death includes the death of the mother due to obstetrical complications of pregnancy, labor, or the puerperium. Indirect maternal death includes death not directly due to obstetrical causes but resulting from previously existing disease or a disease that developed during the gravid period or was exacerbated by the pregnancy.[1]

The maternal mortality ratio (number of maternal deaths per 100,000 live births) decreased from 582 per 100,000 live births in 1935 to 8.5 per 100,000 live births in 1994 for white women. Unfortunately, the ratio for African-American women is about three times as high. This difference appears to result from socioeconomic factors that result in lack of prenatal care and dietary deficiencies. In 1990, 40 percent of black mothers did not receive prenatal care, compared to 20 percent of white mothers.[2] The black-white mortality rate differential is greatest for diseases seen in the first trimester: ectopic pregnancy, spontaneous abortion, induced abortion, and gestational trophoblastic disease (GTD).

Maternal mortality rates greatly increase with increasing age in all races. The leading causes of maternal death are pulmonary embolus (mostly thromboembolic), ectopic pregnancy, pregnancy-induced hypertension (leading to cerebrovascular accident), hemorrhage (mainly postpartum), and infection.

The disorders most commonly associated with stillbirths are hemorrhage (mainly abruptio placentae), pregnancy-induced hypertension, and pulmonary embolism (primarily amniotic fluid embolism). The gravest threats to the neonate are preterm birth and low birth weight. Low birth weight varies on a racial basis. For white women it is 60 per 1000 live births, while for blacks it is 120 per 1000 births, which accounts for the differences in infant mortality rates between the two groups. Low birth weight also contributes to morbidity rates as a result of respiratory distress, intraventricular hemorrhage, septicemia, necrotizing enterocolitis, bronchopulmonary dysplasia, and retinopathy of prematurity.

Preterm infants who weigh at least 500 g and are born at 24 weeks gestation are considered to be at the lower limit of viability but have much higher rates of mental retardation and severe visual impairment than do full-term, normal-birth-weight infants.

EMERGENCIES DURING THE FIRST HALF OF PREGNANCY

While pregnancy is usually considered in terms of trimesters, when discussing patterns of emergencies, dividing pregnancy into halves is advantageous. Emergencies during the first half include ectopic pregnancy, vaginal bleeding, GTD, urinary tract infection (UTI), and hyperemesis gravadarum.

Vaginal Bleeding

The differential diagnosis of vaginal bleeding during the first trimester should include abortion (most common cause), ectopic pregnancy, and GTD. Other causes include implantation bleeding (physiologic) seen around or just after the time of expected menses due to the burrowing of the embryo into the highly vascular decidual tissue, cervical ectropion, and cervicitis due to infection from gonorrhea, *Chlamydia,* or bacterial vaginosis.

Any woman of childbearing age who presents with a chief complaint of abdominal pain or vaginal bleeding and has not had a hysterectomy should be tested for pregnancy. If a serum or urine pregnancy test result is positive, further evaluation for ectopic pregnancy or spontaneous abortion is indicated. Risk factors for ectopic pregnancy include prior ectopic pregnancy, tubal surgery, history of salpingitis, or assisted fertility. Likewise, women of childbearing age with syncope, hypotension, or mental status changes should have pregnancy testing and evaluation for ectopic pregnancy (see Chap. 100).

SPONTANEOUS ABORTION   Estimates of pregnancies that abort spontaneously range from 20 to 40 percent. About 75 percent of spontaneous abortions occur before 8 weeks of gestation. The World Health Organization defines spontaneous abortion as loss of pregnancy before 20 weeks or loss of a fetus weighing less than 500 g. Inevitable abortion will occur in the face of vaginal bleeding and dilatation of the cervix. Incomplete abortion is defined as passage of only parts of the products of conception and is more likely to occur between 6 and 14 weeks of pregnancy. Complete abortion is passage of all fetal tissue, including trophoblast and all products of conception, before 20 weeks of conception. Missed abortion is a fetal death at less than 20 weeks without passage of any fetal tissue for 4 weeks after fetal death. Septic abortion is evidence of infection during any stage of abortion.

The most common cause of fetal wastage is chromosomal abnormalities, accounting for 50 to 60 percent of all losses. Other risk factors include advanced maternal age, prior poor obstetric history, concurrent medical disorders, previous abortion, certain infections, including syphilis and HIV, and some anatomic abnormalities of the upper genital tract. Exposure to some agents, such as certain anesthetic agents, certain heavy metals, and tobacco, is also thought to contribute to the incidence of abortion.

A pelvic examination is mandatory as part of the history and physical examination in order to determine the amount and site of bleeding, whether the cervix has dilated, and whether any tissue has been passed. The amount of bleeding as pads used per hour, last menstrual period, and past medical and obstetric history should be part of the history obtained.

If hemodynamic instability is present, fluid resuscitation should be immediately started. A complete blood count (CBC), blood type, Rh factor and antibody screen, urinalysis (UTI has been associated with increased fetal wastage), and quantitative b serum human chorionic gonadotropin (bhCG) level should be obtained. Vaginal ultrasound studies should be performed to rule out ectopic pregnancy, as a prognostic tool for fetal viability, and to diagnose retained products of conception.

If the patient is bleeding heavily, a Yankower tip is useful to suction blood from the vaginal vault. All material in the vaginal vault should be examined to determine whether it is blood clot or products of conception. Products of conception should be sent for pathologic examination. If tissue is protruding from the cervical os, its careful removal with ring forceps may allow the os to close and decrease bleeding. However, care must be taken to ensure that the tissue is not the rare cervical

ectopic pregnancy. If profuse bleeding continues in the face of inevitable abortion, 20 U of oxytocin can be added to a liter of normal saline solution and infused at 150 to 200 mL/h to obtain hemostasis until dilatation and curettage can be performed.

The quantitative bhCG analysis may be very helpful. The b subunit of bhCG is first detectable as early as 9 to 11 days following ovulation (usually 24 days after the last menstrual period) and reaches 200 IU/mL at the expected time of menses.[3] An abnormally high bhCG level suggests advanced pregnancy, multiple gestation, GTD, or, rarely, an ovarian tumor.

Ultrasound studies combined with determinations of bhCG levels can be both diagnostic and prognostic. If the bhCG level is greater than 2000 IU/mL, an intrauterine gestation should be visible. A yolk sac is seen at 36 days, and a heatbeat is noted 41 to 47 days after the last menstrual period. Gestational sacs with a mean diameter greater than 25 mm without an embryo or greater than 20 mm without a yolk sac are definitely abnormal, and loss of pregnancy will result.[3]

Patients with a diagnosis of threatened abortion can be safely discharged if close follow-up is ensured. While low level of activity and even bed rest are sometimes advised, there is no proven effectiveness of this practice. Generally speaking, a miscarriage cannot be avoided. Intercourse and tampons are to be avoided to minimize likelihood of infection. The patient with an incomplete abortion should have the uterus evacuated. The patient with a complete abortion, as shown by ultrasound and/or complete passage of products of conception, can be safely discharged after follow-up is ensured to ascertain that the bleeding has stopped. The patient with a nonviable fetus can either be admitted or discharged to be followed up within a week by her physician, depending on the comfort level of the patient and physician with this decision. Warnings should be given to return immediately if there is heavy bleeding (more than one pad per hour for 6 h), pain, or fever.

All pregnant patients with vaginal bleeding who are Rh negative should be treated with Rh immunoglobulin (Rhogam) if unsensitized. A dose of 300 µg is recommended. Ideally, Rhogam should be administered prior to discharge, but it can also be administered within 72 h by the primary care physician or obstetrician when the woman presents several days or weeks after vaginal bleeding has begun.[4]

GESTATIONAL TROPHOBLASTIC DISEASE GTD is a neoplasm that arises in the trophoblastic cells of the placenta. It complicates 1 in 1700 pregnancies in North America and is more common in Asian women. The noninvasive form of the disease is the hydatidiform mole, which is either complete or partial. Complete moles are more common, and in this form there is no actual fetus, while in the partial mole a deformed, nonviable fetus is present. Both moles and invasive forms of GTD are composed of trophoblasts that produce bhCG.

Symptoms include vaginal bleeding in the first or second trimester (75 to 95 percent of cases) and hyperemesis (26 percent). GTDs, or molar pregnancies, that persist into the second trimester are associated with preeclampsia. When pregnancy-induced hypertension is seen prior to 24 weeks of gestation, the possibility of a molar pregnancy should be considered. The uterus is excessive in size for gestational age and shows a placenta with many lucent areas interspersed with brighter areas on ultrasound study. If GTD is suspected because of abnormally high bhCG levels, a uterine size either larger or smaller than expected, and ultrasound findings suggestive of the diagnosis, obstetric consultation should be obtained. Treatment is by suction curettage in the hospital setting because of risk of hemorrhage. After evacuation, bhCG levels should be monitored, and failure to fall is evidence of persistent or invasive disease necessitating chemotherapy.[5] Metastasis to lung, liver, and brain may occur. Trophoblastic embolization, although extremely rare, may occur, with resulting rapid onset of respiratory distress resembling amniotic fluid embolus.

Urinary Tract Infection

Infections of the urinary tract are the most common bacterial infections during pregnancy. The highest incidence of bacteriuria has been reported in African-American multiparas with sickle-cell trait, while the lowest incidence is seen in affluent white women of low parity.

Pregnant women with UTI are at increased risk for pyelonephritis, and pyelonephritis is a risk factor for preterm labor and low birth weight. The increased risk of pyelonephritis is the result of hydroureter, dilatation of the renal pelvis, and consequent urinary stasis. Pregnant patients with asymptomatic bacteriuria identified on microscopic analysis should have a urine culture performed and be treated if the culture is positive. Untreated, 25 percent will develop symptomatic infection, while treatment will decrease the incidence of symptomatic UTI by 80 to 90 percent.[6]

Symptomatic UTI requires a urine culture and antibiotic therapy. There are various regimens, although only 7-day regimens are recommended during pregnancy. The recurrence rate during pregnancy for all regimens is about 30 percent.

Treatment choices include nitrofurantoin (one tablet bid), ampicillin; or cephalexin. Trimethoprim-sulfamethoxazole is relatively contraindicated in the first trimester because of antifolate properties of trimethoprim, and sulfonamides are contraindicated in the third trimester due to risk of fetal hyperbilirubinemia.

Reliable patients with asymptomatic bacteriuria can be discharged after urine culture, with treatment withheld pending results of culture. If there is any question as to compliance with follow-up, such patients should be treated with the same antibiotic regimen prescribed for pregnant patients with UTI. Patients with pyelonephritis should generally be hospitalized.

Nausea, Vomiting, and Hyperemesis Gravidarum

Nausea and vomiting of pregnancy are generally seen in the first 12 weeks. Both are extremely common, with nausea seen in 70 percent of patients and vomiting in 50 percent, and symptoms are mild in most. Hyperemesis gravidarum is intractable vomiting with weight loss and laboratory values that show hypokalemia or ketonemia. The cause is not known. Women who lose more than 5 percent of prepregnancy body weight have an increased risk of intrauterine growth restriction and low-birth-weight infants. Patients with GTD may also present with intractable vomiting.

The presence of abdominal pain in nausea and vomiting of pregnancy or hyperemesis gravidarum is highly unusual and should suggest another diagnosis. Occasionally, women with ruptured ectopic pregnancies present with nausea and vomiting as well as diarrhea and abdominal pain. After the first trimester, the volume of the gallbladder increases during fasting and postcontraction after a meal. Also, biliary sludge seems to increase in pregnancy in 30 percent, predisposing to stone formation.[7] Cholelithiasis and cholecystitis are more common in pregnant women than in women of comparable age and health status who are not pregnant. Differential diagnosis of vomiting or vomiting with abdominal pain should include cholecystitis, cholelithiasis, gastroenteritis, pancreatitis, hepatitis, peptic ulcer, pyelonephritis, ectopic pregnancy, and fatty liver of pregnancy.

Findings upon physical examination are usually normal except for signs of volume depletion. Rectal examination should be performed to rule out fecal impaction and occult blood. A pelvic examination should be performed if there is pelvic pain, vaginal bleeding, or discharge.

If the examination reveals only loss of volume, laboratory tests to consider include CBC, serum electrolyte determinations, blood urea nitrogen (BUN) and creatinine determinations, and urinalysis. The finding of ketonuria is important, since it is an early sign of starvation. Serial measurement of urinary ketones can be used to determine success of therapy.

Treatment consists of intravenous fluids containing 5% glucose in either lactated Ringer's or normal saline solution to reverse dehydration and ketonuria. A number of antiemetic drugs can be used (Table 101-1) for patients who remain nauseated or continue to vomit after fluid hydration. Initially, the patient should be given nothing by mouth. Oral fluids should be started after the nausea and vomiting are controlled and prior to discharge.

TABLE 101-1   Antiemetics

The patient may be discharged after reversal of ketonuria, correction of electrolyte imbalance, and a successful trial of oral fluids. Discharge with antiemetic medication is usually necessary. Admission guidelines include uncertain diagnosis, intractable vomiting, persistent ketone or electrolyte abnormalities after volume repletion, and weight loss over 10 percent of prepregnancy weight.

EMERGENCIES DURING THE SECOND HALF OF PREGNANCY

Hypertension, Preeclampsia, Eclampsia, and the HELLP Syndrome

Hypertension complicating pregnancy accounts for 18 percent of maternal deaths. It is also implicated in abruptio placentae and in the birth of preterm and low-birth-weight infants. Hypertension is defined as a blood pressure 140/90 mmHg or greater, a 20-mmHg rise in the systolic, or 10-mmHg rise in the diastolic blood pressure. Thus, a normal-appearing blood pressure may in fact be in the preeclampsia range for a given patient. Pregnancy-induced hypertension (PIH) is elevated blood pressure that develops as a result of pregnancy and regresses postpartum. It cannot be distinguished from transient hypertension during pregnancy except retrospectively. Accordingly, the American College of Obstetricians and Gynecologists no longer use the term PIH, preferring the following, more useful classification: (1) chronic hypertension, (2) preeclampsia superimposed on chronic hypertension, (3) transient hypertension, and (4) preeclampsia or eclampsia. [8] Transient hypertension develops after the midtrimester, is mild, does not compromise the pregnancy, and regresses postpartum but may return in subsequent gestations. Preeclampsia is the combination of hypertension, pathologic edema, and proteinuria. [9] The cause of preeclampsia is not known, but recent research suggests that, in women who will develop preeclampsia, there are fewer placental cytotrophoblasts. These do not invade as deeply, remaining in an early stage and failing to take on the characteristics of blood vessel cells. [10]

Eclampsia is the superimposition of seizures on preeclampsia or aggravated hypertension. Seizures are defined as eclamptic if they occur from the twentieth week of gestation to 7 days after delivery but have been reported as late as 26 days after delivery. All chronic hypertensive disorders, regardless of their cause, predispose to development of preeclampsia or eclampsia (Table 101-2). Blood pressure alone is not always a dependable indicator of severity of disease and must be evaluated in the context of other signs and symptoms[11] (Table 101-3).

TABLE 101-2   Risk Factors for Development of Hypertension during Pregnancy

TABLE 101-3   Criteria for Hypertension, Preeclampsia, and Eclampsia

Presenting complaints of preeclampsia include headache, visual disturbances, edema, or abdominal pain. It always occurs after 20 weeks of gestation unless GTD is present.

The HELLP syndrome (an acronym for *he*molysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) is an important clinical variant of preeclampsia that has a predilection for the multigravid patient, in contrast to the primigravida, in whom preeclampsia is more common. In the HELLP syndrome, the blood pressure is variable and may not be elevated initially. This fact, combined with the usual complaint of epigastric or right upper quadrant pain, makes it easy to mistake the HELLP syndrome for other causes of abdominal pain, such as gastroenteritis, hepatitis, pancreatitis, or pyelonephritis. The HELLP syndrome should be considered in any pregnant or postpartum patient who presents to the emergency department with a chief complaint of abdominal pain. The diagnosis can be made based on clinical findings coupled with laboratory results (Table 101-4).

Test	Findings in HELLP Syndrome
CBC and peripheral smear	Schistocytes
Platelet count	<100,000 but suspicious if <150,000
Liver function tests (AST, ALT)	Elevated but below levels in viral hepatitis (<500 IU/L)
Renal function tests	Normal or elevated BUN and creatinine levels
Coagulation profile	Abnormal

Abbreviation: AST, serum aspartate aminotransferase; ALT, serum alanine aminotransferase.

TABLE 101-4   Laboratory Evaluation for Suspected Preeclampsia or HELLP Syndrome

All patients with a sustained blood pressure of 140/90 or greater and any symptoms that may be secondary to hypertension should be hospitalized. Patients with severe hypertension whose blood pressure is greater than 140/90, and who have epigastric or liver tenderness, visual disturbance, or severe headache are managed in the same way as patients with eclampsia, with administration of magnesium sulfate,[12] antihypertensives as needed, and delivery of the fetus. The dose of intravenous magnesium sulfate is 4 to 6 g over 15 min followed by intravenous infusion of 1 to 2 g/h. Reflexes and serum magnesium levels should be followed to avoid neuromuscular depression. Angiotensin-converting enzyme (ACE) inhibitors should never be used because of fetal side effects. Table 101-5 lists pharmacologic agents for the treatment of hypertension in preeclampsia and eclampsia.

Generic Name	Trade Name	Mechanism of Action	Dosage	Comment
Magnesium sulfate		Smooth muscle relaxation	4–6 g IV over 15 min, then 1–2 g/h	Neuromuscular depression
Hydralazine hydrochloride	Apresoline	Arterial vasodilator	2.5 mg IV, then 5–10 mg IV for 20 min up to 40 mg total dose; 5–10 mg IM q 20–30 min, titrated	Must wait 20 min for response between IV doses; possible maternal hypotension
Labetalol	Normodyne Trandate	Selective α and nonselective β antagonist	20 mg IV, then 40–80 mg IV for 10 min to 300 mg total dose; IV infusion 1–2 mg/min titrated	Less reflex tachycardia and hypotension than with hydralazine
Nitroglycerin	Nitrostat IV Tridil Nitro-Bid IV	Relaxation of venous (and arterial) vascular smooth muscle	5 µg/min infusion, double q5min	Requires arterial line for continuous blood pressure monitoring; potential methemoglobinemia
Sodium nitroprusside	Nipride Nitropress	Vasodilator	0.25 µg/kg/min infusion, increase 0.25 µg/kg/min q 5min	Potential cyanide toxicity

TABLE 101-5   Pharmacologic Agents for Antihypertensive Therapy in Preeclampsia and Eclampsia

Complications of severe preeclampsia, HELLP syndrome, and eclampsia include spontaneous hepatic and splenic hemorrhage, end-organ failure, abruptio placentae, intracranial bleeding, and death of the fetus. Emergency obstetrical consultation should be obtained, or transfer to a tertiary care hospital should be arranged as soon as the patient is stabilized.

Methyldopa is the drug most often used to treat pregnant patients with chronic hypertension as use of this drug does not adversely affect the fetus. [11] Dosage can be started at 250 mg every 6 h and titrated for control of blood pressure. sedation may occur during initiation of therapy or when dosage is increased but is usually transient. Close follow-up should be assured for patients placed on methyldopa therapy.

Vaginal Bleeding during the Second Half of Pregnancy

The differential diagnosis of vaginal bleeding during the second half of pregnancy includes abruptio placentae, placenta previa, preterm labor, and bleeding from various lesions of the cervix and lower genital tract. One-third of fetuses die when vaginal bleeding occurs after 20 weeks of gestation. [13]

ABRUPTIO PLACENTAE   Abruptio placentae, the premature separation of the normally implanted placenta from the uterine wall, accounts for 30 percent of bleeding in the second half of pregnancy. This complication can occur either spontaneously or as the result of trauma to the abdomen. The spontaneous form is far more common, with hypertension the most common risk factor. Other risk factors include hypertension, increased maternal age, multiparity, smoking, cocaine use, and previous abruptions. Abruption can be complete, partial, or concealed. In concealed abruption, there is little or no vaginal bleeding. However, shock may ensue as the actual blood loss is not evident, and establishing the diagnosis may be delayed. The diagnosis of abruption may be difficult, since clinical signs and symptoms depend on the size of the abruption and the amount of blood loss.

Signs and symptoms include vaginal bleeding (unless concealed), abdominal pain, back pain, uterine tenderness, and uterine irritability. Fetal distress, hypotension, and disseminated intravascular coagulation can develop. Abruptio placentae is frequently misdiagnosed as preterm labor. Complications include fetal death, maternal death from hemorrhage or disseminated intravascular coagulation, fetomaternal transfusion, and amniotic fluid embolism. Laboratory tests that should be ordered include CBC, type and crossmatch, coagulation profile, and renal function studies. Crystalloids should be given to maintain maternal volume status. Emergency obstetrical consultation is necessary whenever abruption is suspected. Cardiotocodynamometry and ultrasound studies are used to monitor fetal well-being, and emergency delivery may be necessary. Some centers may elect to treat small abruptions expectantly. Tocolytics should not be given by the emergency physician in the presence of suspected abruption.

PLACENTA PREVIA   Placenta previa, the implantation of the placenta over the cervical os, accounts for 20 percent of bleeding episodes in the second half of pregnancy. Incidence is increased with multiparity and prior cesarean section. The patient presents with painless bright-red bleeding. This complication should be distinguished from the "bloody show," which is passage of a very small amount of bright-red blood mixed with mucus at the onset of labor. Since disruption of the placenta by digital or speculum examination can lead to catastrophic bleeding, digital and speculum examination should be avoided. [14] The safest course is to perform emergency ultrasound studies first.

PREMATURE LABOR AND PREMATURE RUPTURE OF MEMBRANES   Preterm (premature) labor is defined as labor prior to 37 weeks' gestation,[15] while premature rupture of membranes (PROM) is rupture of membranes prior to onset of labor. Preterm labor, occuring in 10 percent of deliveries, is the leading cause of perinatal death and disease, accounting for approximately 85 percent of neonatal deaths not due to lethal genetic or congenital abnormalities. Three major factors contribute to spontaneous or induced delivery before 34 weeks: (1) PROM, (2) spontaneous preterm labor without PROM, and (3) complications that jeopardize fetal or maternal health, mandating early delivery.

Many known factors are associated with preterm labor. More common ones include: PROM, abruptio placentae, drug abuse (particularly of cocaine and amphetamines), multiple gestations, polyhydramnios, cervical incompetence, and infection. Sexually transmitted diseases, including syphilis, gonorrhea, *Chlamydia,* and bacterial vaginosis are two to three times more likely to be associated with preterm labor. The presence of low-grade infection is felt to be one of the most important causes of PROM because bacterial colonization can reduce the tensile strength of membranes. [16] Of importance is the association of digital pelvic examinations and increased frequency of PROM. As a result of this finding, cervical examinations should not be performed from 37 weeks gestation unless the results of the examination will clearly influence clinical management. Of course, all digital examinations during pregnancy should be done using sterile gloves.

Labor is defined as regular uterine contractions resulting in progressive cervical effacement and dilatation. When a woman presents to the emergency department with the suspected onset of labor, the date of the last menstrual period should be ascertained and the estimated date of delivery calculated. The gestational age is the number of weeks from the first day of the last menstrual period. If that date is not known, gestational age can be estimated clinically (see Chapter 99). The patient should be asked about the frequency and duration of contractions, about passage of blood-stained mucus ("bloody show"), and whether there has been rupture of

membranes, usually signaled by a gush of fluid or constant leakage of fluid.

In addition to the routine physical examination, the fundal height should be measured, fetal heart tones auscultated, and a sterile speculum examination performed. A pooling of fluid in the vaginal vault or leakage of clear fluid from the cervix is evidence of PROM. If there is no fluid, the woman should be asked to press on the fundus or perform a Valsalva maneuver to determine whether there is leakage of fluid. Any fluid should be tested with nitrazine paper (pH > 6.5 indicates amniotic fluid) and swabbed on a glass slide to be examined for ferning, indicating amniotic fluid. The presence of blood or semen may interfere with both of these tests. On visual examination, if the cervix is posterior in the vagina, thick, and closed, it is not yet ripe for labor. If, in contrast, it is midposition to anterior within the vagina, moderately effaced, and approximately 2 cm dilated, the uterus is undergoing changes preparatory to expulsion of the fetus. Tests for *Chlamydia,* gonorrhea, and group B streptococcus should be performed and secretions examined for bacterial vaginosis. If PROM is suspected or confirmed, digital examination should be deferred if possible or, if performed, should be done using sterile gloves.

A number of critical questions must be considered. Has PROM occurred? Is the woman in premature labor? What is the best estimate of gestational age? Is there fetal distress? Is the woman a candidate for tocolytic therapy? All women suspected of premature labor or PROM require obstetric consultation.

Viability of the fetus is possible at 23 weeks of gestation, but mortality and morbidity rates are extremely high. A number of drugs have been used to inhibit labor, but none is completely effective, and there is potential for serious side effects (Table 101-6). Tocolysis was the third most common cause of adult respiratory distress syndrome and death in pregnant women in Jackson, Mississippi, over a 14-year period. [17] Since tocolytic drugs can delay delivery by only a few days, the purpose of tocolytic therapy is to allow time for administration of glucocorticoids to speed fetal lung maturity [18] and transport of the mother to a center equipped to provide intensive care for the fetus. If a patient presents to an emergency department in preterm labor and the fetus is not mature enough to do well (prior to 34 weeks' gestation), the patient should be transported to a tertiary care facility that has a high-risk ICU for mother and child. Tocolytic therapy should be started prior to transport rather than attempting to deliver the infant at the initial emergency room. [19]

TABLE 101-6   Potential Complications of Tocolytic Agents

Candidates for tocolysis are women in preterm labor between 24 and 34 to 36 weeks of gestation. Prior to 23 weeks, chances of survival of the fetus are remote and the probability of permanent disability high. At about 25 weeks, even a 2-day increase in length of gestation can add 10 percent to the likelihood of neonatal survival. Beyond 34 to 36 weeks, the infant should be mature enough to do well without specific treatment, and the possible side effects of tocolysis are to be avoided.

The decision to institute tocolysis should be made only after consultation with the obstetrician who will be caring for the patient and who can explain the risks and benefits (see Table 101-6). Tocolytics should not be given if abruption is suspected.

Protocols for tocolysis are shown in Table 101-7. b-adrenergic agents have been shown to have serious side effects. However, terbutaline (Brethine), 0.25 mg given subcutaneously and repeated hourly as needed until contractions stop, is commonly used. Common side effects include tachycardia, hypotension, palpitations, headaches, and tremor. Terbutaline should be withheld if the maternal pulse exceeds 140 beats per minute. The combination of magnesium sulfate and nifedipine is potentially dangerous, since nifedipine can enhance the toxicity of magnesium and result in neuromuscular blockade, interfering with both pulmonary and cardiac function. Careful monitoring of the mother and fetus with use of any of these agents, alone or in combination, is mandatory.

TABLE 101-7   Tocolytic Therapy Protocols

The use of prostaglandin synthase inhibitors, particularly indomethacin, has been found to be effective in delaying delivery by 48 h, but there have been increased rates of neonatal morbidity, with complications including closure of the ductus arteriosus, necrotizing enterocolitis, and intracranial hemorrhage. Recommendations for routine use of this agent for tocolysis must await further investigations.

Since preterm infants are at increased risk of developing group B streptococcus infection and there is reason to suspect that the infection may cause preterm labor, 5 million units of penicillin G is given intravenously unless the patient is allergic to it. [16]

EMERGENCIES DURING THE POSTPARTUM PERIOD

Postpartum hemorrhage and infection continue to be the most common emergencies seen during the postpartum period, but amniotic fluid embolism, while rare, is important because of its high morbidity and mortality rates for both mother and fetus. Eclampsia may occasionally present during this period. Peripartum cardiomyopathy (PPC) is seen during the last month of pregnancy or within 5 months of delivery.

Puerperal Hemorrhage

Postpartum hemorrhage is implicated in approximately 28 percent of pregnancy-related deaths. Since most postpartum hemorrhages occur in the first 24 h postdelivery, unless the delivery takes place at home or in a freestanding birthing center, such patients are unlikely to present to the emergency department. However, delayed hemorrhage may be seen days to weeks postpartum.

The differential diagnosis of hemorrhage in the period immediately following delivery includes uterine atony, uterine rupture, laceration of the lower genital tract, retained placental tissue, uterine inversion, and coagulopathy. After 24 h, retained products may cause bleeding. Other causes include uterine polyps or a

coagulopathy, most commonly von Willebrand disease.

A history as to length and amount of bleeding should be obtained because physiologic bleeding takes place in the postpartum period and may be of variable duration, not uncommonly extending for periods of up to 5 weeks after delivery. The patient should be questioned about difficulty delivering the placenta. Manual delivery of the placenta increases risk of postpartum hemorrhage.

A careful history and physical examination should elicit the diagnosis in the majority of cases (Table 101-8). The commonest cause of bleeding within the first 24 h is uterine atony. Normally, after delivery the uterus is firm, globular in shape, and palpable at or below the umbilicus. When uterine atony occurs, the uterine fundus is "doughy" in consistency and possibly palpable above the umbilicus. The best way to diagnose this is by abdominal palpation and bimanual examination. If the tone of the uterus is good but blood is seen to be coming from the cervical os, the possibility of retained products of conception or uterine rupture must be considered. Uterine rupture is more common after prior cesarean section as a result of separation of the scar. Prior uterine surgery and multiparity can also predispose to this complication. Very rarely, rupture occurs in the face of no prior risk factors. Another cause of bleeding is inversion of the uterus, which occurs most commonly after strong traction is placed on the umbilical cord in an effort to deliver the placenta. Replacement of the fundus is emergent and may require anesthesia. Diagnosis of the cause will allow proper treatment (Fig. 101-1).

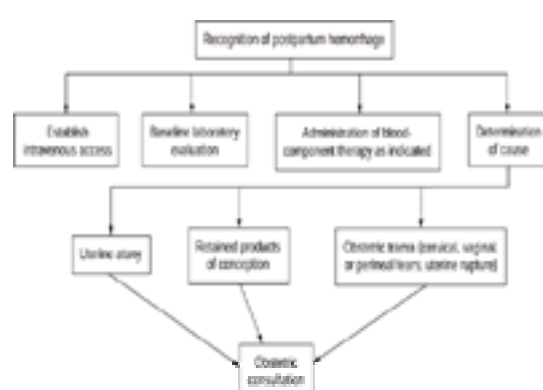
TABLE 101-8   Physical Findings, Cause, and Treatment of Postpartum Hemorrhage


FIG. 101-1. Management plan for postpartum hemorrhage. (From American College of Obstetricians and Gynecologists: *Postpartum Hemorrhage.* Washington, 1998, with permission.)

The management of postpartum hemorrhage is dependent on stabilization of the patient and diagnosis of the cause of bleeding (see Table 101-8). If bleeding is massive, two large-bore intravenous lines should be started, CBC and clotting studies performed, and the patient typed and crossmatched for blood. A red-top tube should be kept by the bedside, and if a clot has not formed by 7 min, a coagulopathy, either causing the bleeding or resulting from the blood loss, may be present.

Good lighting and suction should be maintained. A speculum examination should be performed to inspect for trauma to the vaginal, vulvar, or cervical tissues. Any lacerations should be repaired after local anesthesia is provided. If a laceration is extensive, the patient should be taken immediately to the operating room.

If a mass is seen in the vaginal vault and the uterus cannot be palpated on the abdominal examination, the possibility of uterine inversion is strong. Emergency obstetric consultation is required.

If blood is seen to be coming from the cervix, the possibility of atony or retained products of conception is high. If atony is present and the uterus is large and doughy, the patient should be treated with oxytocin. It is administered by diluting 20 to 30 U in 1 L of normal saline or lactated Ringer's solution and infusing the fluid at 200 mL/h. Methylergonovine maleate, an alternative agent, can be given at a dose of 0.2 mg intramuscularly, has an onset of action of 7 min, and lasts for 2 h. This agent should not be used if hypertension or preeclampsia is present. Once bleeding is controlled, the patient can be discharged on an oral maintenance dose of 0.2 mg q6h.

If the uterus has good tone, the possibility of retained products of conception is high. An ultrasound study confirms the diagnosis.

Postpartum Infections

Pelvic infection is the most common serious complication of the puerperium. Any persistent fever over 38.0°C (100.4°F) should be considered to be caused by genital tract infection until proven otherwise. Extragenital causes of fever include respiratory tract infection (more common after cesarean section), pyelonephritis, mastitis, and thrombophlebitis.

The route of delivery is the single most significant risk factor for uterine infection, with the vast majority of endometritis occurring secondary to cesarean section. Other risk factors include lower socioeconomic level, multiple gestations, younger maternal age, longer duration of labor and membrane rupture, and internal fetal monitoring. Women with all of these risk factors who were not given antibiotics prophylactically have been found to have a 90 percent rate of pelvic infection. Digital examination after 37 weeks' gestation is thought to predispose to infection.

The most common pathogens are those that normally reside in the bowel and also colonize the perineum, vagina, and cervix. Both gram-positive and gram-negative aerobes, anaerobes, *Mycoplasma hominis,* and *Chlamydia trachomatis* are seen. *Gardnerella vaginalis* is isolated more often in younger women. Many infections are polymicrobial.

Signs and symptoms of postpartum endometritis are foul-smelling, profuse, and bloody discharge and abdominal pain. Only scant discharge may be present, especially in patients with group A b-hemolytic streptococci. Shaking chills suggest bacteremia. Uterine and adnexal tenderness is found upon bimanual examination.

Infection may be localized to the decidua and adjacent myometrium and, if this is the case, responds readily to antibiotic therapy. Complications include parametrial phlegmons; surgical, incisional, and pelvic abscesses; infected hematomas; septic pelvic thrombophlebitis; necrotizing fasciitis; and peritonitis. Necrotizing fasciitis is a feared complication with high mortality and morbidity rates. Risk factors for this complication are obesity, diabetes mellitus, and hypertension.

The mainstay of treatment is antibiotic therapy, drainage of any collections of purulent material, and debridement of necrotic tissue. Routine vaginal cultures are of

little clinical utility because of contamination with local flora. Blood culture results are positive in the minority of patients.

Oral antibiotics can be used on an outpatient basis for mild illness when disease is confined to the decidua and myometrium. Any patient who appears toxic or moderately ill, has had a cesarean section, or has underlying comorbid conditions should be hospitalized for parenteral therapy. There are many regimens of therapy. The combination of ampicillin and gentamicin is sufficient for 90 percent of patients. The b-lactam antimicrobials have the advantages of being safe and requiring administration of only one drug, thus being cost-effective. Cephalosporins that can be used include cefoxitin, cefotetan, and cefotaxime. Other regimens include clindamycin and gentamicin or metronidazole plus ampicillin and an aminoglycoside.

AMNIOTIC FLUID EMBOLUS   Mortality rates between 60 and 80 percent have been reported for amniotic fluid embolism. Neurologic morbidity rates are even higher, and few patients are without sequelae.[19] In a national registry of patients with amniotic fluid embolus, if the amniotic fluid had meconium staining, no mother survived without neurologic deficit. If the infant is still in utero at the time of the embolus, both mortality and neurologic morbidity rates are high. The factors that cause this catastrophe are not known. The only significant relationship found thus far is fetal male sex.

Onset is sudden, with the mother displaying cardiovascular collapse. Seizure or seizure-like activity at the time of collapse is common. Patients display profound cardiovascular instability, severe hypoxemia, and, if survival is long enough, disseminated intravascular coagulation. Death is rapid, with many patients dying within 1 h of onset of symptoms. It has been suggested that the syndrome resembles that seen with anaphylactic or septic shock. Histologic findings at autopsy usually show material of fetal origin, such as squamous cells, hair, fat droplets, trophoblasts, and other nonspecific cellular debris as well as proteinaceous material, in the maternal circulation. The cause is unknown.

Care is supportive, with use of high concentrations of oxygen and treatment of disseminated intravascular coagulation if the patient survives long enough. Delivery of the infant should be immediate, but infant mortality and morbidity rates remain high even with immediate delivery. [20]

PERIPARTUM CARDIOMYOPATHY   PPC is the development of heart failure during or shortly after labor with no apparent cause. Most women have an underlying cause found during workup for PPC.[20] Causes include chronic hypertension, mitral stenosis, obesity, viral myocarditis, and preeclampsia. Terbutaline for tocolysis has been found in many patients who have congestive heart failure but no underlying heart disease. Still, there is a small group of women for whom no cause can be found. PPC appears to be similar to the idiopathic cardiomyopathy seen in young, nonpregnant women. Biopsy shows evidence of myocarditis in up to 30 percent.

Patients present with signs and symptoms of congestive heart failure. Dyspnea, orthopnea, cough, palpitations, and chest and abdominal pain are common complaints. Massive cardiomegaly is seen on chest radiograph and echocardiograph. Treatment is with diuretics and fluid restriction. Digitalis should be used with caution, since 60 percent of patients have complex ventricular arrhythmias. Afterload reduction has been used, but ACE inhibitors should be avoided if the patient is undelivered. Because of the high association of pulmonary embolus with PPC, anticoagulation with heparin is often recommended. If no underlying cause can be found, the prognosis is very poor, with mortality of almost 50 percent at 1 year. Many survivors demonstrate diminished contractile reserve when studied with dobutamine challenge in periods remote from pregnancy. [21]

102 COMORBID DISEASES IN PREGNANCY

Jessica L. Bienstock
Harold E. Fox

This chapter provides an overview of the management of chronic medical conditions in pregnant women, outlining the differences in management strategies that may be considered in view of the physiologic changes of pregnancy and the presence of a second "patient," the fetus.

DIABETES

Diabetes mellitus complicates approximately 2 to 3 percent of all pregnancies. Diabetes in pregnancy is falls into two categories: approximately 90 percent of pregnant diabetic patients have gestational diabetes and 10 percent have diabetes that predates the pregnancy. Those with gestational diabetes are subdivided into classes A_1 and A_2, the former being controlled by diet alone and the latter requiring insulin therapy. Patients with preexisting diabetes, even if they were previously managed with oral hypoglycemic agents, are all treated with insulin therapy during pregnancy. Oral hypoglycemic agents are not used during pregnancy as they do not provide an adequate level of glucose control. In addition, some of these agents have been associated with an increased risk of congenital anomalies, hyperbilirubinemia, and irreversible b-cell hyperplasia in exposed infants. Pregnant diabetic patients are at increased risk for fetal death *in utero,* particularly patients with preexisting vascular disease and preeclampsia as well as those with poor glycemic control.

The goals of glucose control for all patients with gestational diabetes is a fasting plasma glucose level of <90 mg/dL and one hour postprandial blood glucose levels of <140 mg/dL. Those patients with gestational diabetes who are managed by diet alone rarely develop acute glycemic complications because their glucose values rarely reach levels consistent with diabetic ketoacidosis.

Among patients with insulin-dependent diabetes, the need for insulin tends to increase throughout the course of pregnancy. In general, during the first trimester, the initial insulin requirement is 0.7 U/kg per day. By late pregnancy, patients generally require 1 U/kg per day. Generally two-thirds of the total insulin dose is given in the morning and one-third in the evening. Usually, two-thirds of the morning dose consists of NPH and one-third of regular insulin. The evening dose consists of half NPH and half regular insulin. Occasionally, this regimen may result in nocturnal hypoglycemia between 1 and 3 A.M. Administering the predinner NPH at bedtime has been suggested as a way of remedying the problem.

Pregnant diabetics are at increased risk for several pregnancy complications, including hypertensive diseases, preterm labor, spontaneous abortion, and pyelonephritis in addition to hypoglycemia and diabetic ketoacidos (DKA).

About 10 percent of insulin-dependent diabetics will develop ketoacidosis at some point during pregnancy. [1] Ketoacidosis has been reported to occur more rapidly and at lower glucose levels in pregnant patients as compared with nonpregnant patients. While classically the diagnosis of ketoacidosis requires a plasma glucose of >300 mg/dL, DKA may develop in pregnancy at lower glucose value. Beta sympathomimetic agents used for tocolysis, such as ritodrene and terbutaline, have been associated with an increased risk of diabetic ketoacidosis. Pregnant women in DKA are treated with a constant low-dose insulin infusion. General management guidelines are the same as for nonpregnant patients (see Chap. 203).

With contemporary medical management, fetal loss is less frequent, although the literature reports a fetal mortality rate in patients treated for DKA 50 to 90 percent. It is not uncommon to find pathologic patterns of fetal heart rate during DKA; these tend, however, to improve as maternal status improves. Steps should be taken to improve uterine blood flow, such as administration of oxygen, and left lateral uterine displacement.

Up to 45 percent of insulin-dependent diabetics will require evaluation for severe hypoglycemia at some time during the course of their pregnancy. [2] Hypoglycemia generally presents as sweating, tremors, blurred or double vision, weakness, hunger, confusion, paraesthesias, anxiety, palpitations, nausea, headache, or stupor. Hypoglycemic episodes are generally well tolerated by the fetus. Mild hypoglycemia—that is, a glucose <70 mg/dL—in a patient who is able to follow commands can be treated by administration of one cup of low-fat milk together with bread or crackers every 15 min. This regimen is preferred over more highly concentrated glucose solutions because it avoids "overshoot" and subsequent hyperglycemia. In patients who are unable to cooperate with oral therapy owing to severe hypoglycemia, parenteral therapy may be begun using one ampule (50 mL) of a 50 percent dextrose solution given via intravenous push. Alternatively, the patient may be treated using glucagon 1 to 2 mg IM or SC. In addition, intravenous therapy should be instituted with D_5W at a rate of 50 to 100 mL/h. Consideration should be given to the avoidance of subsequent hyperglycemia from glycogen mobilization with acute glucose administration. The goal is normoglycemic control without wide swings.

HYPERTHYROIDISM

Hyperthyroidism in pregnancy is associated with an increased risk of preeclampsia and for neonatal morbidity, including low birth weight and possibly congenital malformations. Symptoms of hyperthyroidism closely mimic symptoms of normal pregnancy and may consist of nervousness, palpations, heat intolerance, and inability to gain weight despite a good appetite. Thyrotoxicosis in pregnancy may also present as hyperemesis gravidarum.

Hyperthyroidism in pregnancy is treated with propylthiouracil (PTU). The time to onset of action of PTU is generally 4 to 6 weeks to achieve maximum effect. PTU is started at a dose of 100 to 150 mg three times a day and increased as needed to a maximum dose of up to 200 mg three times a day. The goal of therapy is to maintain a free T4 level at the upper range of normal. Approximately 2 percent of patients taking PTU will experience a mild purpuric skin rash within the first 4 weeks of therapy. If this occurs, the PTU should be stopped and replaced with methimazole. Agranulocytosis occurs in about 0.3 percent of patients treated with PTU. If agranulocytosis develops, the PTU should be stopped and methimazole should not be started.

THYROID STORM

Patients with thyroid storm present with fever, volume depletion, cardiac decompensation. Thyroid storm has been associated with a mortality rate of up to 25 percent. Patients are treated with intravenous fluids, oxygen, antipyretic agents, as well as PTU 400 mg PO q8 h and sodium iodide 1 gm IV in 500 mL of intravenous fluid each day. Long-term use (>10 days) of sodium iodide results in a high incidence of fetal goiter and hypothyroidism. Propranolol 40 mg PO q6 h is administered unless evidence of cardiac failure is present. Acetaminophen is used for treatment of hyperthermia; a cooling blanket may also be used. Steps should be taken to improve uterine blood flow, such as administration of oxygen as well as maintenance of adequate maternal hydration and left lateral uterine displacement. Radioactive iodine therapy is not used, as the fetus will concentrate iodine 131 after the tenth to twelfth week of gestation, and congenital hypothyroidism results.

HYPERTENSION

Hypertension in pregnancy can be divided into chronic hypertension and preeclampsia. In addition, patients with chronic hypertension not uncommonly develop superimposed preeclampsia. This section discusses only the management of chronic hypertension. Preeclampsia is discussed elsewhere (see Chap. 101).

Chronic hypertension complicates 4 to 5 percent of all pregnancies. It is diagnosed by sustained elevation of arterial blood pressure >140/90 mmHg before the twentieth week of gestation. Pharmacotherapy for pregnant hypertensive patients is generally started when the systolic blood pressure exceeds 160 mmHg or the diastolic blood pressure exceeds 100 mmHg. Commonly used agents for the treatment of chronic hypertension in pregnancy include alpha methyldopa (Aldomet), labetalol, and nifedipine. Antihypertensive agents that are generally not used in pregnancy include diuretics, because of their association with a reduction of uteral placental blood flow, and angiotensin-converting enzyme (ACE) inhibitors, owing to their teratogenic effects as well as fetal/neonatal hypotension and anuria. Maternal mortality associated with chronic hypertension is usually the result of severe hypertension and associated congestive heart failure or cerebrovascular accident. Fetal perinatal outcome is most closely associated with the development of superimposed preeclampsia or placental abruption. However, antihypertensive therapy has not been shown to alter the incidence of fetal complications.

Management of an acute hypertensive crisis in pregnancy is most commonly accomplished with intravenous labetalol (10 mg every 5 to 10 min up to a total dose of 300 mg). Hydralazine (5 to 10 mg every 15 min) given as intravenous bolus injections is an alternative still used by many obstetricians. The aim of antihypertensive therapy in pregnancy is to maintain the blood pressure between 140 and 150 mg systolic and 90 to 100 mg diastolic. Persistent blood pressure levels below this range may jeopardize placental perfusion. Acute intervention for blood pressure control should include fetal monitoring as well as careful assessment of fetal well-being. In all chronic hypertensives, the possibility of superimposed preeclampsia must always be considered (see Chap. 101).

DYSRHYTHMIAS

Significant cardiac dysrhythmias are rare in pregnancy. However, medications such as lidocaine, digoxin, and procainamide may be used for the usual indications and in the usual therapeutic doses and have not been shown to be harmful to the fetus. Use of b blockers for acute tachydysrhythmias has not been associated with adverse neonatal outcomes,[3] but maintenance b blockers are a group C drug and should be prescribed in consultation with a cardiologist and obstetrician. Verapamil has been shown to be effective in the conversion of supraventricular tachycardia to sinus rhythm without adverse fetal effects. Anticoagulation using unfractionated or low-molecular-weight heparin for the treatment of atrial fibrillation in pregnancy appears safe and may be used if the patient meets the criteria for anticoagulin described for nonpregnant patients. Cardioversion also appears safe for the fetus.[4] The presence of an artificial pacemaker has not been shown to affect the course of pregnancy.[5]

THROMBOEMBOLISM

The incidence of deep venous thrombosis in pregnancy ranges between 0.5 and 0.7 percent. Factors associated with an increased risk of venous thromboembolism in pregnancy include advanced maternal age, increasing parity, multiple gestation, operative delivery, bed rest, obesity, history of previous thromboembolism, antithrombin III deficiency, protein S or protein C deficiency, and the lupus anticoagulant syndrome. Postpartum deep venous thrombosis is reported to occur 3 to 5 more times more often than antepartum deep venous thrombosis and 13 to 16 times more frequently after cesarean section as opposed to vaginal delivery.

The clinical diagnosis of deep venous thrombosis (DVT) is similar in pregnant patients to that in nonpregnant patients. Pregnant patients commonly complain of swelling and leg discomfort; duplex Doppler studies should be done to confirm the diagnosis. Impedance plethysmography may also be safely used in pregnancy. Iodine-125 fibrinogen scanning should not be used because unbound iodine crosses the placental barrier and enters the fetal circulation, where it may concentrate in the fetal thyroid. Radionuclide venography using particles of technetium 99m is of no risk to the fetus and can be used to obtain studies of the lower extremity as well as to perform perfusion lung scans.

Diagnosis of pulmonary embolism in pregnancy is similar to that in the nonpregnant patient. Ventilation perfusion ($\dot{V}/\dot{Q}$) scans may safely be performed in pregnancy. No adverse fetal effects of xenon-133 or technetium-99m lung scanning have been reported. Pulmonary arteriography may also be performed in pregnant women if $\dot{V}/\dot{Q}$ scanning is indeterminant. The diagnostic efficiency of spiral CT scanning has not been studied in pregnancy. Treatment for both DVT and pulmonary embolism in pregnancy is with intravenous heparin, with the goal of maintaining the PTT at $1\frac{1}{2}$ to 2 times control. Low-molecular-weight heparin may also be used for both the prophylaxis and treatment of thromboembolic disease at a dose of 1 mg/kg enoxaparin subcutaneously twice a day. Warfarin is not used in pregnancy, as it crosses the placenta and is associated with embryopathy in the first trimester; in the second and third trimester it may lead to a variety of central nervous system and opthamalogic abnormalities. Protamine sulfate may be safely used in pregnancy for patients who require rapid reversal of their heparin anticoagulation. Although there is minimal experience with the use thrombolytic therapy in pregnancy, its use may be entertained in life-threatening situations.

ASTHMA

Asthma complicates between 0.4 and 1.3 percent of all pregnancies. In general, however, there are no differences in the outcome of pregnancies in well-controlled asthmatics versus the general population. Severe asthmatics with poorly controlled disease, however, do have a slight increase in the risk of preterm birth, stillbirth, and low-birthweight babies. Approximately one-third of patients with asthma worsen in pregnancy, approximately one-third remain stable, and one-third improve.[6]

The presentation of asthma in pregnancy is similar to that of the nonpregnant state, with the usual triad of cough, wheezing, and dyspnea. Unfortunately, pulmonary embolism (PE) can also present with similar symptom, and—as noted because of the hypercoagulable state of pregnancy, pregnant women, are at increased risk for PE. Therapeutic agents that are safely used in pregnancy include inhaled glucocorticoids, such as beclomethasone, and cromolyn sodium by inhaler. These agents are used as preventive therapy. For acute therapy of asthma exacerbations b_2 agonists such as salbutamol, metaproterenol, albuterol, and isoproterenol may be given via nebulizer. Intravenous methylprednisolone and oral prednisone can be used in pregnancy, as they do not cross the placenta. Any time glucocorticoids are used, maternal hyperglycemia should be considered in acute management (see discussion of diabetes, above). Epinephrine 0.3 mL (1:1000 dilution) can be given subcutaneously. Oxygen should be administered and titrated to maintain an arterial P_{O_2} ³ 65 mmHg. Fetal monitoring should be done after 20 weeks of gestation.

Clinical management of a pregnant asthmatic patient is best guided by the use of the peak expiratory flow rate to assess the severity of the obstruction and monitor the response to therapy. Peak expiratory flow rate is not altered by pregnancy, with mean peak expiratory flow rates in normal pregnant women ranging between 380 and 550 L/min. Peak expiratory flow rates do not change significantly as pregnancy progresses.[7] Peak expiratory flow rates of less than 100 L/min or that demonstrate <10 percent improvement with treatment are a sign of a potentially poor prognosis. Aggressive management is warranted.

The interpretation of arterial blood gases in a pregnant asthmatic must take into account the results in light of the normal values for pregnancy. The normal maternal P_{O_2} ranges between 101 and 108 mmHg early in pregnancy and falls to 90 to 100 mmHg near term. The normal Pa_{CO_2} in pregnancy ranges from 27 to 32 mmHg and the normal pH ranges from 7.40 to 7.45. The patient should be placed in a near sitting position with a leftward tilt, as up to 25 percent of normal pregnant women in third trimester will develop moderate hypoxia in the supine position. There should be a low threshold for obtaining arterial blood gas assessment as part of the evaluation of pregnant women with asthma, particularly patients who present with obvious hypoventilation and cyanosis whose asthma does not improve after initial therapy or who have peak flow of <200 L/min.[10] Goals of therapy include maintenance of a P_{O_2} >65 mmHg or an oxygen saturation of >95 percent on an F_{O_2} of 35 to 60 percent.

Indications for intubation of the pregnant asthmatic with status asthmaticus include (1) inability to maintain the Pa_{O_2} >65 mmHg (90 percent hemoglobin saturation) despite supplemental oxygen; (2) inability to maintain a Pa_{CO_2} < 40 mmHg; (3) evidence of maternal exhaustion; (4) significant acidosis (pH < 7.20 to 7.25) refractory to initial management with bronchodilator therapy; and (5) altered mental status.[8] Standard agents for rapid-sequence intubation can be used.

Medications for asthma that may have adverse fetal effects include iodides, which may be associated with neonatal hypothyroidism and goiter, as well as sodium bicarbonate, which, without adequate ventilation, can diminish the transfer of carbon dioxide from the fetus to the mother. Glucocorticoids may also cause alterations in carbohydrate metabolism, although this is a secondary concern in the acute setting. Essentially, acute management should be guided by consideration for the

mother. The best outcome for the developing fetus is based on optimal treatment of the mother.

CHRONIC RENAL DISEASE

Maternal risks associated with renal disease are linked to the degree of renal compromise. As renal function diminishes, fertility decreases. Pregnancy rarely occurs in women who have a preconception serum creatine of >3 mg/dL. Preterm delivery and superimposed preeclampsia frequently complicate pregnancies of patients with underlying renal disease. Patients with chronic pyelonephritis may have an increased number of recurrences due to bacteriuria, increased glucosuria, and mechanical compression of the ureter in the third trimester pregnancy. Those with a history of reflux nephropathy are at increased risk of sudden escalating hypertension and worsening renal function. Urolithiasis is associated with more frequent urinary tract infections. Patients with lupus nephropathy are at greatly increased risk for exacerbations of the disease and superimposed preeclampsia, particularly if their disease was not in remission for at least 6 months prior to conception.

CYSTITIS AND PYELONEPHRITIS

The increased urinary stasis associated with pregnancy makes the urinary tract the most common infection during pregnancy. After midpregnancy, mild right-sided hydronephrosis can be found in 75 percent of patients and mild left-sided hydronephrosis is seen in 33 percent of patients. Asymptomatic bacteriuria is present in between 2 to 10 percent of pregnant women. Acute cystitis occurs in about 1 percent of pregnant women, whereas acute pyelonephritis occurs in approximately 2 percent of all pregnancies. The presentation of both cystitis and pyelonephritis is similar in pregnant and nonpregnant women. Causative organisms are similar to those in the general population, with *Escherichia coli* being the etiology in approximately 75 percent. It is not uncommon for acute pyelonephritis to precipitate preterm labor. Therefore prompt therapy is imperative. In addition, pregnant women are at increased risk for the development of bacteremia and septic shock as compared with the nonpregnant population.

Patients with simple cystitis may be treated with a 10-day course of oral nitrofurantoin, ampicillin, or a cephalosporin. Trimethoprin, a folate antagonist, is used by many obstetricians after the first trimester. Single-dose antibiotic therapy is not used for the treatment of cystitis in pregnant patients owing to the high rate of treatment failure. Treatment of pregnant patients with pyelonephritis is much more intense than that of nonpregnant patients. Patients are generally hospitalized, aggressively hydrated, and treated with intravenous antibiotics. The intravenous antibiotics of choice are generally a cephalosporin, such as cefazolin, or ampicillin plus gentamicin. Intravenous antibiotics are continued until the patient is afebrile for at least 48 h and costovertebral angle tenderness has resolved. Patients are then discharged home on oral antibiotics to complete a 10-day course of therapy. Many providers choose to continue women with a history of pyelonephritis during the course of their pregnancy on antibiotic suppression for the remainder of their pregnancy. This is generally accomplished using nitrofurantoin at a dose of 50 to 100 mg/day.

INFLAMMATORY BOWEL DISEASE

Pregnant patients with inflammatory bowel disease are at increased risk for nutritional and metabolic abnormalities that may put the fetus at increased risk for intrauterine growth restriction. Pregnancy itself, however, seems to have little effect on inflammatory bowel disease. When an exacerbation does occur during pregnancy it most frequently happens in either the first trimester or the postpartum period. It is hypothesized that this is due to a correlation with levels of circulating corticosteroids during pregnancy.

In general, the treatment of the pregnant patient with inflammatory bowel disease is the same as that of the nonpregnant patient. Antidiarrheal drugs including codeine, opium, paregoric, and Lomotil may also be used safely in pregnancy. While sulfasalazine and corticosteroids may be safely used in pregnancy, the possibility of the development of gestational diabetes must be considered in all patients on steroid therapy. Sulfa drugs are theoretically contraindicated in the third trimester due to concerns about neonatal hyperbilirubinemia, but they are used fairly commonly by obstetricians without adverse effect. It is important to supplement women who are taking sulfasalazine with folic acid, as sulfasalazine is known to inhibit the absorption and metabolism of folate. The use of suppressive therapy with azathioprine or 6-mercaptopurine has been reported to be safe during pregnancy, but experience with these agents is very limited. Total parental nutrition is a potentially useful adjunct to therapy in some patients who have severe nutritional deficiencies, and it may be safely used in pregnancy. Metronidazole for the treatment of perianal fistulas in patients with Crohn disease is generally not recommended until after completion of the first trimester.

SICKLE CELL DISEASE

Women with sickle cell disease are at increased risk for miscarriage, preterm labor, and other complications due to impaired oxygen supply and sickling infarcts in the placental circulation. Pregnant women are at increased risk for vascular occlusive events, particularly during the third trimester and the postpartum period. Painful crises present similarly in the pregnant and the nonpregnant state. Treatment of painful crises in pregnancy is similar to that for nonpregnant patients. Cornerstones of management include aggressive hydration and analgesic therapy. Both oral and intravenous narcotics can be used. Caution should be exercised when using nonsteroidal antiinflammatory agents, particularly after 32 weeks of gestation, because of oligohydramnios and a significant risk of premature closure of the fetal ductus arteriosus. Hydroxyurea should not be used in pregnancy because of its teratogenic effects. Sickle cell crisis that does not respond to conservative management is commonly managed using partial exchange transfusion via automated erythrocytapheresis. Simple transfusion alone can be helpful when the hemoglobin level is <6g/dL.[9] The incidence of fetal death in utero can be minimized during sickle cell crisis by using information from continuous electronic fetal monitoring in a woman with a potentially viable fetus. While fetal heart rate patterns are frequently nonreassuring during the acute episode of vasoocclusive crisis, fetal heart rate patterns tend to normalize as the crises improve. In utero resuscitation (oxygen, intravenous hydration, left lateral uterine displacement, fetal scalp manipulation) should be initiated prior to consideration of emergency delivery.

While the majority of sickle cell crises in pregnancy are vasoocclusive crises, aplastic crises present a unique problem as they are usually caused by parvovirus B19 infection, which has been associated with hydrops fetalis. This disease thus presents a risk to both the pregnant woman and her fetus. Careful sonographic fetal assessment should be performed to evaluate the fetus for evidence of parvovirus infection. Once patients with sickle cell disease has been exposed to parvovirus B19, they are unlikely to acquire the infection a second time due to acquired immunity.[10] Then the pregnant patient with a past history of aplastic crisis is unlikely to experience it again.

MIGRAINE

Pregnancy usually improves classic migraines. However, when migraines do occur, they are difficult to treat, because ergot alkaloid should not be used and there has been little experience with the use of sumatriptan in pregnancy. Treatment therefore rests upon the use of analgesics and antiemetic agents. Acetominophen, codeine, and meperidine have all been shown to be safe for use in pregnancy.

Prophylactic therapy using b blockers, such as propanol (40 to 160 mg/day) or atenolol (50 to 100 mg/day), have also been shown to be effective.

SEIZURE DISORDERS

Seizure disorders occur in 0.15 to 1.0 percent of all women of childbearing age. Seizure frequency tends to increase slightly in pregnancy because of the increased volume of distribution, an increase in plasma clearance, and poor medication compliance. Management of a pregnant patient with a known seizure does not differ from that of a nonpregnant woman. Consideration of potential adverse effects of antiseizure medication mandates the use of single-drug therapy when possible. Approximately 45 percent of patients will experience an increase in seizure frequency during pregnancy. Medication doses may need to be increased in pregnancy; however, the serum therapeutic levels do not change. The use of valproic acid is generally avoided in pregnancy because of its association with 1 to 3 percent risk of neural tube defects.

A single maternal grand mal seizure may be followed by fetal bradycardia lasting for up to 20 mins. While transient maternal hypoxia and acidosis are potential threats to the fetus, there is usually no apparent harm caused by isolated seizures. Steps should be taken to optimize the intrauterine environment, including administration of oxygen and left lateral uterine displacement. In contrast, status epilepticus poses a real threat to both mother and fetus with 50 percent of fetuses and 33 percent of mothers not surviving the event. Aggressive management with intubation and ventilation should be considered early in the management of pregnant women with status epilepticus.

HUMAN IMMUNODEFICIENCY VIRUS (HIV)

All pregnant HIV-infected patients beyond 14 weeks gestation should be on zidovudine therapy in an effort to decrease the risk of vertical transmission. Randomized clinical trials of zidovudine have documented a reduction in the vertical transmission rate from 25 to 8 percent. [11] Pregnancy does not appear to alter the natural course of HIV disease, nor do uninfected babies born to HIV-positive women appear to be at increased risk for neonatal complications when compared with appropriate control patients. Patients with CD4+ counts of <200 should be maintained on prophylaxis for *Pneumocystis carinii* pneumonia using trimethoprim/sulfamethoxazole (TMP/SMX; Bactrim DS). Alternatively, aerosolized pentamidine may also be used in pregnant patients. Treatment of overt opportunistic infections in HIV-infected pregnant women should be addressed just as in those who are not pregnant. Patients may present with respiratory insufficiency. The prompt initiation of artificial ventilation in such patients may improve the intrauterine environment and therefore the outcome for the fetus.

SUBSTANCE ABUSE

All pregnant women identified in the ED as substance abusers should be referred to a high-risk obstetrics clinic and be offered substance-abuse counseling. The incidence of a positive urine toxicology test for cocaine ranges from 6 to 27 percent in urban and suburban hospitals. Cocaine use has been associated with an increased risk of placental abruption and fetal death in utero as well as an increased risk of intrauterine growth restriction, preterm labor, premature rupture of membranes, spontaneous abortion, and cerebral infarcts in the fetus. Maternal complications of cocaine use include myocardial infarction, hypertension (which can result in aortic dissection), pulmonary edema, and cardiac dysrhythmias. Subarachnoid hemorrhage, ruptured aneurysms, and strokes have all been reported in cocaine users and are most likely related to transient hypertension. Treatment of acute cocaine intoxication is handled in the usual manner.

Pregnant women in opiate withdrawal are currently treated with methadone or clonidine. There is currently insufficient evidence regarding the use of buprenorphine in pregnancy. Pregnant women should not have methadone discontinued during pregnancy, as it may increase the risk of fetal death in utero and tends to decrease compliance with prenatal care. Patients in withdrawal may be treated with clonidine 0.1 to 0.2 mg sublingually every hour up to 0.8 mg until signs of withdrawal resolve. The maintenance dose is then 0.8 to 1.2 mg/day in divided doses for the first 7 days and tapering for the following 3 days. Treatment for acute opiate overdose is discussed in Chap. 287.

The incidence of alcohol abuse during pregnancy is difficult to determine as most studies have been limited to single hospitals or urban settings, but it probably ranges between 1 and 2 percent. In the largest study, almost 7 percent of women had detectable alcohol in urine samples taken at the time of delivery. [12] It is felt that two or more drinks a day may contribute to increased rates of spontaneous abortion, low-birthweight infants, preterm deliveries, and perinatal mortality. Alcohol use in pregnancy can result in fetal alcohol syndrome, the incidence of which is 0.1 to 0.3 percent of live births. Patients who present in coma due to acute alcohol intoxication or in alcohol withdrawal are managed similarly to nonpregnant patients. Short-acting barbiturates such as pentobarbital can be used for withdrawal, although benzodiazepines should be avoided in early pregnancy if at all possible because of possible teratogenicity. Disulfiram (Antabuse) is a potential teratogen and should be avoided in pregnancy.

Domestic Violence

Between 14 and 17 percent of pregnant women experience domestic violence during the course of their pregnancy. [13] It is a particularly vulnerable time during which "intimate violence" may escalate. Late entry into prenatal care, unintended pregnancy, drug and alcohol use, depression, and housing problems have all been associate with an increased risk of domestic violence. Pregnant women who are the victims of domestic violence are at an increased risk for placental abruption, fetal fractures, uterine rupture, and preterm labor. It is imperative to keep a high index of suspicion and be prepared to initiate appropriate referrals to social service and law enforcement agencies. In addition, for Rh-negative women who have experienced blunt abdominal trauma, consideration should be given to the administration of Rhogam to prevent isoimmunization. (see Chap. 101 for a detailed discussion.)

Effect of Pregnancy and Laceration on Medication Considerations for Concurrent Illness

The classic teratogenic period is from day 31 after the last menstrual period (LMP) in a 28-day cycle to 71 days from the LMP. During this critical time, organs are forming, and teratogens may cause overt malformation. Administration of drugs early in the period of organogenesis will affect the organs developing then, such as the heart or neural tube. Closer to the end of the classic teratogenic period, the ear and palate are forming and may be affected by a teratogen.

Before day 31, exposure to a teratogen produces an all-or-none effect. With exposure around conception, the conceptus usually either does not survive or survives without anomalies. If the organism remains viable, organ-specific anomalies do not develop because repair or replacement permits normal development. A similar insult at a later stage may produce organ-specific defects; after the first trimester, chronic exposure may produce growth restriction.

The Food and Drug Administration (FDA) lists five categories of labeling for drug use in pregnancy:

Category A: Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester, and the possibility of fetal harm appears remote.

Category B: Animal studies do not indicate a risk to the fetus, there are no controlled human studies, or animal studies do show an adverse effect on the fetus, but well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus.

Category C: Studies have shown the drug to have animal teratogenic or embryocidal effects, but no controlled studies in women are available or no studies are available in either animals or women.

Category D: Positive evidence of human fetal risk exists, but benefits in certain situations (e.g., life-threatening situations or serious diseases for which safer drugs cannot be used or are ineffective) may make the use of the drug acceptable despite its risks.

Category X: Studies in animals or humans have demonstrated fetal abnormalities, or evidence demonstrates fetal risk based on human experience, or both, and the risk clearly outweighs any possible benefit.

Table 102-1, Table 102-2, Table 102-3 and Table 102-4 list medications to be avoided in pregnancy. Table 102-5 lists categories of drugs generally considered safe during breast-feeding.

Drug	Effect
ACE inhibitors	Renal failure, oligohydramnios
Aminoglycosides	Ototoxicity
Androgenic steroids	Masculinize female fetus
Anticonvulsants	Dysmorphic syndrome, anomalies
Antithyroid agents	Fetal goiter
Aspirin	Bleeding, antepartum and postpartum
Cytotoxic agents, i.e., methotrexate	Multiple anomalies
Isotretinoin	Hydrocephalus, deafness, anomalies
Lithium	Congenital heart disease (Ebstein anomaly)
Methotrexate	Anomalies
Nonsteroidal anti-inflammatory drugs (prolonged use after 32 weeks)	Oligohydramnios, constriction of fetal ductus arteriosus
Tetracycline (after first trimester)	Discoloration of deciduous teeth, inhibits bone growth
Thalidomide	Phocomelia
Warfarin	Embryopathy—nasal hypoplasia, optic atrophy

Complicating Effects of Radiation

The major factor determining the degree of risk to the fetus in an imaging technique is the amount of ionizing radiation involved in the test. Exposure to ionizing radiation occurs with plain x-ray films, angiography, fluoroscopy, nuclear medicine, and computed tomography (CT). Nonionizing studies include magnetic resonance imaging (MRI) and ultrasound.

The risks of radiation exposure vary with gestational age.

The predominant deterministic effect due to exposure during the first 2 weeks of pregnancy is resorption of the embryo.

The second to eighth week postconception is the period of organogenesis. Significant x-ray exposure during this period may result in teratogenesis (birth defects). Examples include gross malformation and growth retardation, the latter of which can occur both at term and later at adulthood. Neuropathology and small head size may also occur as a result of significant exposures during weeks 2 to 8.

The embryo has developed into a fetus at about the seventh to eighth week, and neurologic development occurs during the next 7 weeks. Significant x-ray exposure at this time (between weeks 8 and 15) may result in mental retardation, small head size, and decreased IQ. Other possible but less likely effects due to significant exposure during this period include growth retardation as an adult and sterility. Even less likely but still possible are cataracts, neuropathology, and growth retardation at term.

Most of the deterministic effects mentioned above are either not observed or observed much less frequently when the fetus receives significant radiation dose beyond 15 weeks postconception. Mental retardation has been observed as a result of significant exposure during the eighth to twenty-fifth weeks but not beyond. Other effects that have been observed because of exposure after week 15 include sterility and growth retardation as an adult. Less likely effects that have been demonstrated are cataracts, neuropathology, and growth retardation at term.

The most recent evidence suggests that 10 rad is a threshold for human teratogenesis, and the fetus appears to be most vulnerable at 8 to 15 weeks' gestation. The American College of Radiology's position states that there is no single diagnostic test that results in radiation doses that threaten the well-being of the developing

embryo or fetus. However, cumulative doses from multiple procedures may enter the harmful range.

The radiation doses involved in commonly used diagnostic tests are given in Table 102-6.

Dosage, rad	Procedure
0.00003	Chest radiography (two views) with shielding of the maternal abdomen.
0.686–1.398	Intravenous pyelogram full series; in the case of a suspected stone a one-shot pyelogram should be used when a renal ultrasound is inconclusive or unavailable
.1	Kidney, ureter, bladder—single abdominal film
0.51–0.126	Lumbar spine series (three films)
0.168–0.359	Lumbosacral spine series (three films)
0.007–0.02	Mammography—diagnostic for suspected breast cancers
0.01	Cerebral angiography
0.056	Upper gastrointestinal series
1.9–3.9	Barium enema
<0.1	Head computed tomography (CT)
<0.3	Chest CT
5.0	Abdominal CT
7.0	Lumbar spine CT
0.50	Pelvimetry CT

TABLE 102-6   Radiation Exposure to the Uterus/Fetus

A common nuclear medicine imaging study used by the emergency department physician is the ventilation/perfusion scan. Total fetal exposure to xenon 133 and technetium 99m is about 0.5 rad, and they can be used safely in pregnancy. Fetal exposure from other studies using technetium 99 range from 0.03 to 0.06 rad/mCi and are safe in pregnancy. Because the excretion of these radionuclide particles is often via the maternal bladder, which is close to the fetus, hydration and frequent voiding need to be encouraged.

The two nonionizing imaging studies used frequently are ultrasound and MRI. Ultrasound has been studied extensively over the past 25 years and has no known teratogenic effect. There is much less experience with MRI, but thus far there are no known harmful effects.

103 EMERGENCY DELIVERY

Michael J. VanRooyen
Julia B. VanRooyen

The anxiety experienced by the emergency physician caring for a woman in active labor is not simply due to infrequent experience with normal deliveries in routine practice but also to awareness of the potential for serious and rarely fatal complications of labor. In addition, the initial management of such third-trimester emergencies as preeclampsia, eclampsia, and hemorrhage has major consequences for maternal and child survival. It is therefore important for emergency physicians to be prepared for actively laboring patients or for patients presenting during late pregnancy.

Despite advances in prenatal care and nearly ubiquitous availability of obstetric units in the United States, precipitous deliveries do occur with some frequency in emergency departments (ED). Out-of-hospital delivery may occur because patients are poorly educated, have had no prenatal care, lack transportation, residence in a remote location, or experience premature labor or delivery. A relatively recent and controversial practice is intentional precipitous labor, in which a woman desiring to avoid hospital charges delays care until the final stages of labor.

PREHOSPITAL MANAGEMENT

Regardless of the reason for precipitous delivery, this and other third-trimester emergencies require preparedness by both hospital and prehospital providers. Emergency medical system (EMS) personnel must be trained to recognize active labor and manage the precipitous delivery appropriately. Pregnancy-related complications that may occur in the prehospital setting include preeclampsia, eclampsia, maternal hemorrhage, and complications of labor such as cord prolapse and fetal distress. Prehospital personnel need to be aware of available obstetric and neonatal units in the system's catchment area. The development of specialty centers has led to a significant decline in neonatal mortality, particularly among infants weighing less than 1500 g at birth. High-risk maternal units have proliferated as well. As a consequence, transport of pregnant patients for reasons of maternal bleeding, eclampsia or preeclampsia, fetal distress, multiple gestations, fetal anomalies, and other maternal health problems including traumatic injuries has increased markedly. The most common reason for the transport of patients to tertiary care centers is simple premature rupture of membranes.

Prehospital units transporting patient in active labor should be prepared by carrying sterile delivery packs and medical supplies and medications for maternal and neonatal emergencies. The transport team should be trained to assist in the precipitous delivery of an infant and educated in the use of basic obstetric supplies. Prehospital protocols should be reviewed often so that EMS personnel remain prepared for the rare but potentially catastrophic pregnancy-related event.

EMERGENCY DEPARTMENT PREPAREDNESS

Every ED should be prepared for emergency delivery by preparing a basic delivery kit (Table 103-1) and having an infant warmer/isolette and supplies for neonatal resuscitation (see Chap. 9, on neonatal resuscitation). Medications for emergency delivery are listed in Table 103-2. Because of the relative infrequency of ED delivery, extra care must be taken to educate physicians and nursing staff through periodic didactic and equipment orientation sessions.

Surgical scissors
Placenta basin
Rubber bulb syringe
Neonatal airways
Towels
Hemostats
Cord clamps
Sterile gloves
Gauze sponge (4 × 4)
Syringes (10-mL)
Needles (23-gauge)

TABLE 103-1   Equipment and Supplies for Emergency Delivery*

Medication	Dose	Indication
Oxytocin 10 μg/mL	Infuse 2 L of 20 U/L R/L normal saline solution	Give routinely for uterine contraction and to reassess immediately postpartum
Methyl ergonovine (methergine)	0.2 mg IM	Control of postpartum hemorrhage
Hydralazine 20 mg/mL	1–10 mg IV push q 20–30 min to treat diastolic BP > 100 mmHg	Control of hypertensive crisis (to diastolic BP 90–100 mmHg)
Labetalol HCL	20–50 mg IV push, followed by 50 mg increments up to a total dose of 1 mg/kg	Alternative to Hydralazine
Magnesium sulfate (50% solution) 1 g/10 mL	Infuse 4–6 g IV over 20 minutes	First-line control of eclamptic seizures
Calcium gluconate 10%	1 ampule (10 mL) IV push	Magnesium toxicity (antagonist administration)
Phenytoin	10 mg/kg loading, followed by second loading dose of 5 mg/kg 2 h later	Second-line drug for eclamptic seizures
Terbutaline sulfate 1 mg/mL	0.25 mg SC q3 h	Tocolysis
Fentanyl 50 μg/mL	50 μg IV or IM	Short-acting narcotic analgesic
Lidocaine (Xylocaine) 1%	1–10 mL locally	Local anesthetic
Prochlorperazine (Compazine) 10 mg/mL	5–10 mg IV	Nausea and vomiting
Naloxone (Narcan) 0.4 mg/mL	0.4 mg–2 mg IV	Narcotic overdose

TABLE 103-2   Medications for Emergency Delivery and Indications for Use

EVALUATING THE PREGNANT PATIENT

Any pregnant woman beyond 20 weeks gestation who arrives in the ED with signs of active labor should be carefully evaluated to determine the condition of both

mother and fetus. An important component of this is the medical and obstetric history of the patient, including parity and estimated date of delivery (EDD). If the last menstrual period (LMP) is known and a pregnancy wheel is not available, the EDD can be calculated by adding 9 months and 7 days to the LMP. Although useful for providing a rough estimate, ultrasound examination late in the third trimester is not an accurate predictor of gestational age, as estimates of EDD can vary up to 3 weeks. Fundal height also provides a rapid estimate of gestational age in the patient who does not recall her LMP or EDD. Fundal height is measured in centimeters (centimeters = weeks of gestation ± 2 weeks) from the pubic symphysis to the top of the fundus as palpated by the examiner. This measurement can lead to overestimation in obese patients. One must obtain pertinent medical information on such matters as allergies, medications, drug and alcohol use, and prenatal care as well as to elicit any past history of complications with prior deliveries or precipitous labor.

Every patient presenting with signs of active labor should receive immediate monitoring of maternal vital signs and fetal heart rate. Maternal blood pressure should be monitored, and Doppler heart tones are helpful to confirm normal fetal heart rate (120 to 160 beats per minute). A persistently slow fetal heart rate (less than 100 beats per minute) is an indicator of fetal distress, and emergent obstetric consultation is necessary.

DISTINGUISHING TRUE FROM FALSE LABOR

The confirmation of true labor as opposed to false labor is an important initial step in the management of the term or near-term pregnant patient. False labor is defined as uterine contractions that do not lead to cervical changes. False labor is characterized by irregular, brief contractions usually confined to the lower abdomen. These contractions, commonly called Braxton-Hicks contractions, are irregular in both intensity and duration. False labor may persist for several days. It is most commonly treated in the outpatient setting by hydration and rest. Uncommonly, admission may be required for supportive care.

True labor is characterized by painful, regular contractions of steadily increasing intensity and duration leading to progressive cervical dilatation. True labor typically begins in the fundal region and upper abdomen and radiates into the pelvis and lower back. True labor also leads to progressive descent of the fetus into the pelvis in preparation for delivery and to cervical dilatation and effacement.

PHYSICAL EXAMINATION

Patients without vaginal bleeding should be examined both bimanually and with a sterile speculum. Patients presenting with vaginal bleeding should initially be evaluated with ultrasound prior to any speculum or bimanual examination to rule out placenta previa (see below).[1] If ultrasound is not available for an actively bleeding patient in labor, careful examination with sterile speculum may be performed to estimate the degree of cervical dilatation. However, no digital exam should be performed, and emergent obstetric consultation should be obtained. If spontaneous rupture of membranes (SROM) is suspected, examination with a sterile speculum should be performed and digital exam avoided, as studies have shown an increased risk of infection after a single digital examination.[2] It is particularly important to avoid digital examinations in the preterm patient where prolongation of gestation is desired. Sterile speculum examination allows confirmation of SROM, visualization of the cervix as well as estimation of dilatation and collection of cervical cultures, particularly group B streptococcus, *Neisseria gonorrhoeae* and *Chlamydia*. For pelvic examination, the lithotomy position is typically used. Stirrups are not necessary, although they are helpful. Alternatively, a bedpan may be employed to elevate the patients buttocks enough to allow speculum examination. Lubricant should be avoided unless rupture of membranes has been confirmed, as lubricant may produce a false-positive nitrazine test.

The abdomen should be inspected and palpated to determine fundal height. The cervix is then examined to determine effacement, dilatation, and station. Effacement of the cervix is the process of thinning that occurs during labor. Effacement has conventionally been described in terms of a percentage of normal cervical length. This method is confusing and has poor interrater reliability. More recently, the preferred method is to describe the degree of effacement in terms of actual length of remaining cervix in centimeters. Cervical dilatation describes the diameter of the cervical os and is an indicator of the progression of labor. The index and middle finger of the examining hand are used to determine the diameter, expressed in centimeters (fingertip to 10 cm); 10 cm indicates full dilatation. The station indicates the level that the fetus occupies in the pelvis, with the reference point being the maternal ischial spines, palpable on either side of the vaginal canal at about 4 and 8 o'clock. If the fetus remains above the ischial spines, the station is described as negative. Once the fetal head has reached the level of the ischial spines, the station is zero, with further descent into the pelvis described as +1 or +2. A +3 station corresponds to visible scalp at the introitus, indicating a fetal position consistent with impending delivery.

Both digital exam and Leopold maneuvers provide information about the presentation of the child and can indicate a potential breech presentation or cord prolapse. Leopold maneuvers involve the palpation of the fetus through the maternal abdomen to determine fetal position and presentation. Such maneuvers are relatively unreliable in inexperienced hands. A pregnant woman should not be kept flat on her back for a prolonged period of time, since compression of venous return by the gravid uterus can lead to maternal hypotension and fetal hypoperfusion. After examination, the patient should be placed in the left lateral position.

Rupture of Membranes

Determining whether membranes have ruptured is an important predictor of the likelihood of imminent labor as well as the potential for complications such as infection or cord prolapse.[3] SROM occurs during the course of active labor in most patients, although it may occur prior to the onset of labor in 10 percent of third- trimester patients. SROM typically occurs with a gush of clear or blood-tinged fluid. It can be confirmed by using nitrazine paper to test residual fluid in the fornix or vaginal vault while a sterile speculum examination is performed. Amniotic fluid has a pH of 7.0 to 7.4 and will turn nitrazine paper dark blue. Vaginal fluid typically has a pH of 4.5 to 5.5 and will make the nitrazine strip remain yellow. False-positive tests may occur with blood, lubricant, or other contaminants. Another test used to confirm rupture of membranes (ROM) is ferning, or observing sodium chloride crystals on a slide as amniotic fluid dries.

If membranes are intact, an amniotomy should not be performed in the ED, as this may lead to precipitous labor and increase the potential for cord prolapse. Note whether meconium appears after the ROM, indicated by the presence of thick, greenish-brown fluid. ROM occurring prior to the onset of labor is called premature ROM. Prolonged ROM occurs if delivery does not take place within 18 h of ROM. ROM that occurs before 37 weeks is called preterm ROM.

Third-Trimester Bleeding

Patients who present with third-trimester bleeding require urgent and very careful evaluation. It is important to distinguish serious causes of third-trimester bleeding from the "bloody show" that can accompany normal labor, although this can be difficult (Table 103-3). The most helpful characteristic is the amount of bleeding. With bloody show, there is typically a small amount of blood on the perineum or undergarments, while previa and abruption can cause active bleeding of significant amounts.

Examination	Placenta Previa	Placental Abruption	Bloody Show
Vaginal discharge	Moderate to large amount of bright red blood	Varying amounts of dark, clotted blood	Small amounts of blood or pink blood-tinged fluid
Abdominal exam	Nontender	Marked tenderness, constant, excruciating uterine pain	Nontender, intermittent pain
Bimanual exam	Contraindicated	Contraindicated	Sterile exam
Laboratory tests	Possible decreased hematocrit	Coagulopathy, disseminated intravascular coagulation possible	Normal
Confirmatory test	Ultrasound	No accurate confirmatory test (ultrasound <50% sensitive)	None
Fetal status	Usually normal	Fetal distress (HR < 100)	Normal

TABLE 103-3   Differentiating Etiology of Third-Trimester Vaginal Bleeding in the Actively Laboring Patient

Placenta Previa

Placenta previa occurs when the placenta partially or completely overlies the internal cervical os. Because of the rich vasculature of the placenta, disruption of the placenta by minor manipulation, even a bimanual examination or early cervical dilatation, may induce catastrophic maternal hemorrhage. The presence of placenta previa should be suspected in any third-trimester patient presenting with painless vaginal bleeding, particularly bright red blood per vagina. The primary risk factor for placenta previa is a history of prior cesarean section(s). If previa is suspected, an emergent ultrasound prior to speculum or bimanual examination is required. [4] (Also see Chap. 108, "Complications of Gynecologic Procedures.") If previa is present on ultrasound and the patient is actively laboring, no further examination should be performed and arrangements should be made for immediate transport to labor and delivery for cesarean section. Patients who are not in labor and bleeding only minimally can sometimes be managed conservatively by observation.

Placental Abruption

Abruptio placenta (or placental abruption) is the separation of the placenta from its implantation site prior to delivery. This may lead to massive blood loss, although bleeding may be concealed within the uterus up to 20 percent of the time. Placental abruption is classically characterized by the vaginal bleeding, a "rock-hard" painful uterus, and fetal distress (decrease in fetal heart rate to <100 beats per minute). [5] Maternal coagulopathy may also be present in abruption (Table 103-3). Risk factors for abruption include maternal hypertension, smoking, cocaine use, and trauma.

Fetal Distress

Fetal distress may occur during active labor, and care must be taken to evaluate the fetal status as often as possible. Indicators of fetal distress include decelerations in fetal heart rate. This is defined as a persistent drop in fetal heart rate during contractions persisting more than 30 s after a contraction. While many EDs do not have fetal monitoring devices, Doppler heart tones should be measured after each contraction to detect the presence of decelerations. Episodic bradycardia persisting for more than 5 min is an indication for immediate cesarean section.

EMERGENCY DELIVERY

The initial step in the management of a woman in active labor is to obtain vital signs and initiate supportive therapy, including obtaining venous access and monitoring the mother and fetus if fetal monitoring is available. A sample for "type and screen" should be sent to the blood bank to determine maternal Rh status and ABO blood type. If the pelvic examination reveals no remaining cervix and fetal presentation at the introitus, delivery is imminent. Labor can progress very rapidly in multiparous patients. The stage of labor and the parity of the patient should be taken into account when transport of a laboring patient to another facility is being considered.

As the cervix becomes fully dilated and effacement becomes complete, the fetus continues to descend and the patient experiences the urge to push. Patients delivering in the emergency setting may have difficulty controlling these expulsive efforts, and they are in even greater need of assistance, reassurance, and instruction. Preoccupation with the delivery should not exclude the needs of the mother or minimize the importance of maternal cooperation to accomplish a controlled delivery.

Determination of fetal position is best accomplished in the emergency setting by evaluation of the presenting portion of the infant. Pelvic examination should reveal evidence of the infant's position, including palpable skull sutures and fontanelles (Fig. 103-1) or, in the case of breech delivery, the infant's buttock or extremity. Confirmation may be accomplished by personnel familiar with Leopold maneuvers.
FIG. 103-1. Movements of normal delivery. Mechanism of labor and delivery for vertex presentations. **A.** Engagement, flexion, and descent. **B.** Internal rotation. **C.** Extension and delivery of the head using the modified Ritgen maneuver. After delivery of the head the infant's nose and mouth should be suctioned and the neck checked for encirclement of the umbilical cord. **D.** External rotation bringing the thorax into the anteroposterior diameter of the pelvis. **E.** Delivery of the anterior shoulder. **F.** Delivery of the posterior shoulder. Note that after delivery, the head is supported and used to gently guide delivery of the shoulder. Traction should be minimized.

The typical delivery position is the dorsal lithotomy position, which allows maximum visualization and control of the delivery. As time allows, the perineum may then be prepared by washing with mild soap and water and swabbing with povidone-iodine. Drapes should be placed over the patient, and gowns, masks, and sterile gloves donned by medical personnel attending the patient. Pediatric and obstetric services should be notified as appropriate for the institution.

The process of fetal descent during labor and delivery is described by six cardinal movements: (1) engagement, (2) flexion, (3) descent, (4) internal rotation, (5) extension, and (6) external rotation (Fig. 103-1). As the fetus descends through the birth canal and reaches the introitus, the perineum bulges to accommodate the fetal head. Delivery can be aided by gentle digital stretching of the inferior portion of the perineum. The perineum will undergo gradual thinning and stretching to enable the passage of the fetus. The use of routine episiotomy for a normal spontaneous vaginal delivery has been discouraged in recent years and increases the incidence of third- and fourth-degree lacerations at the time of delivery. [6,7]

If an episiotomy is necessary, it may be performed as follows. A solution of 5 to 10 mL of 1% lidocaine is injected with a small-gauge needle into the posterior fourchette and perineum. While protecting the infant's head, a 2- to 3-cm cut is made with scissors to extend the vaginal opening. The incision must be supported with manual pressure from below, taking care not to allow the incision to extend into the rectum.

Control of the delivery of the neonate is the major challenge. As the infant's head emerges from the introitus, the physician should support the perineum with a sterile towel placed along the inferior portion of the perineum with one hand while supporting the fetal head with the other. Mild counterpressure is exerted to prevent the rapid expulsion of the fetal head which may lead to third- or fourth-degree perineal tears.

As the infant's head presents, the left hand may be used to control the fetal chin while the right remains on the crown of the head, supporting the delivery. This controlled extension of the fetal head will aid in the atraumatic delivery. The mother is then asked to breathe through contractions rather than bearing down and attempting to push the baby out rapidly. Immediately following delivery of the infant's head, the infant's nose and mouth should be suctioned. This is particularly important in infants presenting with meconium in order to prevent aspiration. A simple bulb will assist in the routine clearing of the infant's nose and mouth. After suctioning, the neck should be palpated for the presence of a nuchal cord. This is a common condition, found in 25 percent of all cephalad-presenting deliveries. If the cord is loose, it should be reduced over the infant's head; the delivery may then proceed as usual. If the cord is tightly wound, it may have to be clamped in the most accessible area by two clamps in close proximity and cut to allow delivery of the infant.

After the airway is cleared, delivery of the body is allowed to progress. After delivery of the head, the head will restitute, or turn to one side or the other. As the head rotates, the physician's hands are placed on either side of it, providing gentle downward traction to deliver the anterior shoulder. Care should be taken to provide only gentle traction, as jerky or forceful movements may cause a brachial plexus injury. The physician's hand then gently guides the fetus upward, delivering the posterior

shoulder and allowing the remainder of the infant to be delivered. At this point, it is very important to control delivery of the body to prevent perineal lacerations.

A point of practical concern is the need to maintain control of the newly born infant. The combination of amniotic fluid, blood, and white, cheesy desquamation called vernix makes the infant very slippery. It is useful to prepare for the delivery by placing the posterior (left) hand underneath the infant's axilla prior to delivering the rest of the body. The anterior hand may then be used to grasp the infant's ankles and ensure a firm grip. In obstetric training, the student is often instructed to hold the infant close to his or her chest "like a football."

The infant is then loosely wrapped in a towel and stimulated as it is dried. In the setting of an uncomplicated delivery, the mother may immediately hold the child while the cord is being cut provided that the child has responded well to initial stimulation and has a clear airway and good respiratory effort. The umbilical cord is double clamped and cut with sterile scissors; the infant is then further dried and warmed in an incubator, where postnatal care may be provided and Apgar scores calculated at 1 and 5 min after delivery. Scoring includes general color, tone, heart rate, respiratory effort, and reflexes.

In the case of suspected meconium aspiration, the infant is delivered, the cord is double clamped and cut immediately, and the infant is placed in an incubator for airway assessment and possible intubation prior to being stimulated to breathe spontaneously. Intubation allows for the trachea to be suctioned adequately prior to spontaneous breathing, thus reducing the risk of meconium aspiration. If a cyanotic or apneic child is delivered and does not immediately respond to stimulation, neonatal resuscitation is instituted (see Chap. 9, "Neonatal Resuscitation and Emergencies").

COMPLICATIONS OF DELIVERY

Cord Prolapse

In the event that the bimanual examination reveals a palpable, pulsating cord, the examiner's hand should not be removed, but rather should be used to elevate the presenting fetal part to reduce compression of the cord.[8] Immediate obstetric assistance is then necessary, as a cesarean section is indicated. The examiner's hand should remain in the vagina while the patient is transported and prepped for surgery in order to prevent further compression of the cord by the fetal head. [9] No attempt should ever be made to replace a prolapsed cord.

Shoulder Dystocia

Shoulder dystocia is the impaction of fetal shoulders at the pelvic outlet after delivery of the head. Typically, the anterior shoulder is trapped behind the pubic symphysis, leading to delay of delivery of the rest of the infant. It usually occurs in the delivery of larger infants with disproportionately large shoulders compared with the fetal head. Although rare, shoulder dystocia is a serious concern because of the risk of fetal morbidity and mortality if it is not managed promptly and appropriately. Complications of shoulder dystocia include brachial plexus injury from overaggressive traction and fetal hypoxia from impaired respirations and compression of the umbilical cord, leading to compromised fetal circulation.

Shoulder dystocia is first recognized after the delivery of the fetal head, when routine downward traction is insufficient to deliver the anterior shoulder. After delivery of the infant's head, the head retracts tightly against the perineum (the "turtle sign").[10] Upon recognizing shoulder dystocia, the physician should suction the infant's nose and mouth and call for assistance to position the mother in the extreme lithotomy position, with legs sharply flexed up to the abdomen (the McRoberts maneuver) with the legs held by the mother or an assistant. The bladder should be drained if this has not already been done. A generous episiotomy may also facilitate delivery. Next, an assistant should apply suprapubic pressure to disimpact the anterior shoulder from the pubic symphysis. It is important to remember never to apply fundal pressure, as this will further force the shoulder against the pelvic rim. [11]

To deliver the impacted anterior shoulder, a corkscrew maneuver (Wood's maneuver) is the first manipulation attempted. The physician grasps the posterior scapula of the infant with two fingers and rotates the shoulder girdle 180° in the pelvic outlet in an attempt to rotate the posterior shoulder into the anterior position and in the process deliver the shoulder. Gentle traction may then be applied as the patient pushes, and the infant is delivered through an oblique pelvic diameter. If the corkscrew maneuver fails to reduce the dystocia, the physician may then attempt to deliver the posterior shoulder. The physician's hand is passed posteriorly into the vagina until the infant's posterior arm is felt. The elbow is grasped and flexed, and the arm is delivered with the posterior shoulder. The anterior shoulder usually follows.

Breech Presentation

Breech presentations occur in 3 to 4 percent of term pregnancies and are associated with a morbidity rate three to four times greater than that of cephalad presentations. Breech presentations most frequently occur in premature infants, since final rotation in the pelvis may not have occurred. The major concern in breech deliveries is head entrapment. In a normal cephalic delivery, the larger head dilates the cervical canal, thus ensuring that the rest of the infant follows. With breech deliveries, however, the head emerges last and then may become trapped by an incompletely dilated cervix (Fig. 103-2).
FIG. 103-2. Management of the vaginal breech delivery. **A.** The Pinard maneuver. The operator's hand is placed behind the fetal thigh, putting gentle pressure at the knee and allowing delivery of the leg. **B.** A similar maneuver of the opposite leg. **C.** The feet are grasped with the thumb and third finger over the lateral malleolus and the second finger is placed between the two ankles. **D.** With maternal expulsive efforts, the breech is delivered to the level of the umbilicus. The sacrum should be kept anterior. **E.** Again, with maternal expulsive efforts, the infant is delivered to the level of the clavicles, keeping the sacrum anterior. Excessive outward traction by the operator will frequently result in the nuchal arms. **F.** The fetus is rotated 90° allowing visualization of the now anterior right arm. **G.** The arm is well visualized and a single digit is used to deliver it. Delivery of the opposite arm is accomplished by rotating the fetus 180° in a clockwise direction and repeating the maneuver. **H.** Delivery of the fetal vertex is accomplished by placing the operator's fingers over the maxillary processes of the fetus, keeping the body parallel to the floor. The body should never be lifted above parallel to prevent hyperextension of the neck. An assistant applies suprapubic pressure, aiding flexion of the fetal head and accomplishing delivery.

Breech presentation is associated with a greater incidence of fetal distress and umbilical cord prolapse. Breech presentations may be classified as frank, complete, incomplete, or footling. The frank breech and the complete breech presentation serve as a dilating wedge nearly as well as the fetal head, and delivery may proceed in an uncomplicated fashion. Footling and incomplete breech positions are not safe for vaginal delivery. The main point in a frank or complete breech presentation is to allow the delivery to progress spontaneously. This lets the presenting portion of the fetus dilate the cervix maximally prior to the presentation of the fetal head. It is recommended that the examiner refrain from touching the fetus until the scapulae are visualized. Then the infant may be gently supported by wrapping a towel around its lower half. The infant is then gently rotated until one arm emerges and then rotated the opposite way to allow delivery of the other arm. Do not pull on the fetus, as this may put pressure on the head within the pelvis or entrap the extended fetal arm.

Footling and incomplete breech positions are not considered safe for vaginal delivery because of the possibility of cord prolapse or incomplete dilatation of the cervix.

In any breech delivery, immediate obstetric consultation should be requested.

Preterm Delivery

Preterm delivery is a major cause of precipitous childbirth and is often the cause of emergency delivery. Preterm infants also more often present in the breech position, which is associated with a greater incidence of infant morbidity and mortality. Carefully control the delivery to reduce the likelihood of trauma to the fragile preterm infant. Deliver the infant slowly and immediately dry and warm it while performing the initial assessment, as the premature infant is much more likely to require resuscitation. The decision to initiate resuscitative efforts in the ED is often difficult, as patients may deliver extremely premature fetuses of unknown gestational age. One sign of extreme prematurity is eyelids that are still fused. In general, even very premature deliveries (18 to 22 weeks) should receive initial resuscitative efforts until determination of viability is made.

POSTPARTUM CARE

Immediately after the delivery of the infant, the umbilical cord is clamped. The placenta should be allowed to separate spontaneously, assisted with gentle traction. This process can take several minutes, and often the mother and baby have already been moved from the ED to the labor and delivery suite before the placenta delivers. Aggressive traction on the cord risks uterine inversion, tearing of the cord, or disruption of the placenta, which can result in severe vaginal bleeding. [12]

After the removal of the placenta, the uterus should be gently massaged to promote contraction. Oxytocin (20 U in 1 L of 0.9 normal saline) is infused at a moderate rate to maintain uterine contraction (Table 103-2). Uterine atony may follow a precipitous delivery and may lead to excessive vaginal bleeding. Additional oxytocin may be administered, as well as methyl ergonovine (Methergine) 0.2 mg [intramuscularly (IM) only] or prostaglandin F-2 alpha (Hemabate) 0.25 mg IM. With significant postpartum hemorrhage, vigorous bimanual massage should be continued while contractile agents are administered. Episiotomy or laceration repair may be delayed until an experienced obstetrician is able to close the laceration and inspect the patient for fourth-degree (rectovaginal) tears. [13]

104 VULVOVAGINITIS

Gloria J. Kuhn

Vulvovaginitis is inflammation of the vulva and vaginal tissues. It is usually characterized by a vaginal discharge and/or vulvar itching and irritation. A vaginal odor may be present. It accounts for 10 million visits to physicians per year in the United States, and is the most common gynecologic complaint in prepubertal girls. [1]

The most common causes of acute vulvovaginitis include (1) infections, (2) irritant or allergic contact vulvovaginitis, (3) local response to a vaginal foreign body, and (4) atrophic vaginitis.

The three most frequent infectious causes are trichomoniasis (caused by *Trichomonas vaginalis*), bacterial vaginosis (BV; caused by replacement of normal flora by overgrowth of anaerobes and *Gardnerella vaginalis*), and candidiasis (usually caused by *Candida albicans*).[2] BV is the most common cause of vaginal discharge or malodor. Polymicrobial infection in women with vaginitis is not uncommon. Vulvovaginal candidiasis, contact vaginitis, and atrophic vaginitis may occur in virgins and after menopause, but other forms of infectious vulvovaginitis are generally found only in sexually active women. [2]

A detailed gynecologic history should be obtained and a pelvic examination performed. Microscopic evaluation of fresh vaginal secretions using both normal saline solution (demonstrating clue cells for BV and motile *T. vaginalis* for trichomoniasis) and 10% potassium hydroxide (KOH) slide preparation (demonstrating yeast or pseudohyphae for candidiasis) and fishy odor in BV (whiff test) will, in most instances, provide a diagnosis (Table 104-1). Culture for *T. vaginalis* is more sensitive than microscopic examination. One of the most helpful diagnostic tools is measurement of the pH of the vaginal secretions. Secretions should be tested for pH using nitrazine paper. A pH greater than 4.5 is typical of BV or trichomoniasis, while a pH below 4.5 represents physiologic discharge or a fungal infection. [3]

Test	Finding	Diagnosis
pH	>4.5	Bacterial vaginosis
pH	>4.5	Trichomoniasis
Normal saline solution	Clue cells	Bacterial vaginosis
Normal saline solution	Motile trichomonads	Trichomoniasis
KOH preparation	Pseudohyphae and/or buds	Candidiasis
KOH preparation	Fishy odor (whiff test)	Bacterial vaginosis

TABLE 104-1   Diagnosis of Vaginitis Based on Vaginal Secretions

Signs of vulval inflammation and minimal discharge in the absence of vaginal pathogens suggest the possibility of mechanical, chemical, allergic, or other noninfectious causes of vulvovaginitis.

All treatment recommendations are taken from the 1998 guidelines for the treatment of sexually transmitted diseases from the Centers for Disease Control and Prevention (CDC).[3]

NORMAL VULVOVAGINAL ENVIRONMENT

In females of childbearing age, estrogen causes the development of a thick vaginal epithelium with a large number of superficial cells serving a protective function and containing large stores of glycogen. Glycogen is used by the normal flora, consisting of lactobacilli and acidogenic cornynebacteria, to form lactic and acetic acids. The resulting acidic environment favors the normal flora and discourages the growth of pathogenic bacteria. Lack of estrogen or a dominence of progesterone results in an atrophic condition, with loss of the protective superficial cells and their contained glycogen. This is turn results in loss of the acidic environment. Normal vaginal secretions may vary in consistency from a thin, watery material to one that is thick, white, and opaque. The quantity may also vary from scant to a rather copious amount. This material is odorless and produces no symptoms. The normal vaginal pH varies between 3.5 and 4.1. Alkaline secretions from the cervix before and during menstruation and semen, which is alkaline, reduce acidity, predisposing to infection. Before menarche and after menopause, the vaginal pH varies between 6 and 7. Because of scant nerve endings in the vagina, the patient usually does not have symptoms until both the vagina and vulva are involved in an inflammatory or irritant process.

BACTERIAL VAGINOSIS

BV is a clinical syndrome that occurs when the normal H_2O_2-producing *Lactobacillus* species in the vagina are replaced by high concentrations of anaerobic bacteria, *G. vaginalis,* and *Mycoplasma hominis.* BV is the most common cause of a malodorous discharge, but over half of the women who meet the clinical criteria for diagnosis are asymptomatic. The cause of this microbial alteration in the normal vaginal flora is not understood. While BV is rarely seen in women who have never been sexually active, it is not clear whether the disease is the result of a sexually transmitted pathogen.

Bacterial vaginosis can be diagnosed by the use of clinical and microscopic criteria. The CDC states that for the disease to be diagnosed, three of the following signs or symptoms must be present: (1) a homogeneous, white, noninflammatory discharge that smoothly coats the vaginal walls; (2) presence of clue cells on microscopic examination (epithelial cells coated by bacteria); (3) pH greater than 4.5; and (4) a fishy odor to the discharge after addition of KOH (whiff test). [3] Gram staining, which demonstrates a concentration of bacterial morphotypes characteristic of BV, is an acceptable laboratory method of diagnosing BV. Culture of *G. vaginalis* is not recommended.[3]

Research has demonstrated an association between BV and adverse pregnancy outcomes due to preterm labor and premature rupture of membranes (PROM), leading to recommendations that high-risk patients (i.e., those who previously delivered a premature infant) be screened for BV during the second trimester of pregnancy.[4] BV has also been associated with pelvic inflammatory disease, endometritis, and vaginal cuff cellulitis after surgical procedures.

Recommendations for treatment are controversial for asymptomatic patients. Several drug regimens are available (Table 104-2).[3] All symptomatic patients, unless allergic to the drug, should be treated with metronidazole regardless of pregnancy status. [3] Because of the association of BV with postsurgical infection, strong consideration should be given to prophylactic treatment of infected women prior to surgical abortion.

Treatment of BV in infected pregnant women who are at high risk for premature labor has decreased the incidence of this complication. Currently, according to the US Food and Drug Administration (FDA), oral metronidazole is contraindicated in the first trimester of pregnancy but can be used in the second trimester. However, intravaginal metronidazole (0.75%) gel is designated a category B drug by the FDA, allowing its use throughout pregnancy. [3,4,5 and 6] However, this and other alternative pharmacotherapies are less effective (Table 104-2). A large randomized clinical trial is currently under way to determine whether all asymptomic pregnant women should be treated for BV.

Overall cure rates 4 weeks after treatment did not differ significantly between a 7-day regimen of either oral metronidazole, metronidazole vaginal gel, or clindamycin vaginal cream. Metronidazole vaginal gel has the benefit of fewer side effects (i.e., gastrointestinal disturbance and unpleasant taste). [4] All patients on oral metronidazole should avoid alcohol during and for 24 h, and in some cases longer, after treatment because of the disulfiram-like reaction that can occur. Based on frequency of cure rates, alternative treatments are not as efficacious.

CANDIDA VAGINITIS

Candida species are a common cause of vaginitis. While there are no reliable figures as to prevalence of vulvovaginal candidiasis (VVC) because the disease is not reportable, it is estimated that 75 percent of women will experience at least one infection during their childbearing years (with the highest attack rate during the third trimester of pregnancy), making it the second commonest vaginal infection. [2] A small subpopulation of women, less than 5 percent, have repeated episodes of disease with no apparent factors being responsible for recurrent infection.

The organism can be isolated from up to 20 percent of asymptomatic, healthy women of childbearing age, some of whom are celibate. Therefore, this infection is not considered a sexually transmitted disease (STD), although it can be transmitted that way. Factors that favor increased rates of asymptomatic vaginal colonization include pregnancy, oral contraceptives, uncontrolled diabetes mellitus, and frequent visits to STD clinics (perhaps as a result of antimicrobial therapy). It is rare in premenarchial girls[4] and has a decreased incidence after menopause unless replacement estrogen is being used, emphasizing the hormonal dependence of VVC. Immunity to *Candida* infections is primarily cell mediated.

Candida albicans strains account for 85 to 90 percent of those isolated from the vagina, while *Candida glabrata* and *Candida tropicalis* are the commonest non-albicans strains and are often more resistant to conventional therapy. Candidal organisms gain access to the vaginal lumen and secretions predominantly from the adjacent perianal area. Candidal organisms must first adhere to the vaginal epithelial cells for colonization to take place, and *C. albicans* adheres in greater numbers than do other strains.

Factors that enhance the germination of *Candida* (e.g., pregnancy and estrogen therapy) tend to precipitate symptomatic vaginitis, while conditions that inhibit germination (normal flora and local mucosal cell-mediated immunity) prevent acute vaginitis in carriers of yeast. The growth of *Candida* is held in check by the normal vaginal flora, and symptoms of vaginitis usually occur only when the normal balance is upset. Conditions that inhibit growth of normal vaginal flora, particularly *Lactobacillus* species (e.g., systemic antibiotics, especially broad-spectrum agents), diminish the glycogen stores in vaginal epithelial cells (e.g., diabetes mellitus, pregnancy, oral contraceptives, and hormonal replacement therapy), or increase the pH of vaginal secretions (e.g., menstrual blood or semen) may cause increased colonization by *Candida,* which is an opportunistic organism, and subsequent symptomatic infection. Tight-fitting, particularly synthetic, undergarments may also contribute to the problem because of increased temperature, moisture, and local irritation.

Clinical symptoms include leukorrhea, severe vaginal pruritus (commonest symptom), external dysuria, and dyspareunia. Symptoms vary in severity, but exacerbation is frequently seen in the week prior to menses or with coitus. Odor is unusual.

Gynecologic examination may reveal vulvar erythema and edema, vaginal erythema, and, occasionally, thick "cottage-cheese" discharge, seen most often in pregnant patients. The discharge may vary from none to watery to homogeneously thick.

The diagnosis of *Candida* vaginitis is made by microscopically examining a wet mount or normal saline sample of vaginal secretions for yeast buds and pseudohyphae (Fig. 104-1; sensitivity 40 to 60 percent). Two drops of 10% KOH added to the vaginal scretions dissolves the vaginal epithelial cells, leaving yeast buds and pseudohyphae intact, increasing the sensitivity (80 percent) of microscopic examination and yielding almost 100 percent specificity. Culture should only be done in a symptomatic patient with negative findings on microscopic examination. [3]
FIG. 104-1. Hyphal elements of *C. albicans* seen on high-power magnification during saline microscopy. The patient had florid candidal vaginitis.

Most treatment regimens (Table 104-3) are effective in relieving symptoms, but recurrence of infection is common.[3] The topically applied azole drugs are more effective than nystatin, with relief of symptoms in 80 to 90 percent of patients who complete treatment. Creams, lotions, sprays, vaginal tablets, suppositories, and coated tampons are all equally efficacious, and the choice of vehicle should depend on the patient's preference. The azole drugs are all available over the counter (OTC) with durations of 1, 3, or 7 days. One-day treatment with oral fluconazole is as effective as use of topical preparations. [7,8] Partners should not be treated unless the woman has frequent recurrences.

Agent	Formulation	Dosage Regimen
UNCOMPLICATED VVC		
Butoconazole	2% cream	5 g/d for 3 d
Clotrimazole	100-mg vaginal tablet	2 tablets/d for 3 d
Miconazole	200-mg vaginal suppository	1 suppository/d for 3 d
Nystatin	100,000-U vaginal tablet	1 tablet/d for 14 d
Tioconazole	6.5% ointment	5 g intravaginally in a single dose
Fluconazole	150-mg tablet PO	1 tablet as a single dose
COMPLICATED VVC		
Fluconazole	100-mg tablet PO	1 tablet weekly
Ketoconazole	200-mg tablet PO	1 tab/d for 1–2 weeks
Clotrimazole	500-mg vaginal suppository or tablet	1 suppository or tablet weekly

Note: Not all possible regimens are listed.

TABLE 104-3   Treatment Regimens for Vulvovaginal Candidiasis

Self-medication should only be advised in women with previously diagnosed VVC and recurrence of similar symptoms. If symptoms persist or recur within 2 months, the patient should be seen so that vaginal and microscopic examinations can be performed. Cultures should be considered for patients with frequent recurrences. All possible precipitating factors, such as high blood glucose levels, should be controlled. However, the majority of women with recurrences do not have obvious precipitating causes.

Uncomplicated VVC (i.e., mild-to-moderate symptoms, sporadic, nonrecurrent disease in a normal host with normally susceptible *C. albicans*) responds to all azoles, including single-dose therapy. Complicated VVC (i.e., severe symptoms, recurrent disease, abnormal host, or resistant organism, such as *C. glabrata*) requires therapy lasting from 10 to 14 days with topical or oral azoles. [3]

Management of women with frequent recurrences is aimed at control, rather than cure, with a long-term suppressive prophylactic regimen. Diagnosis should be certain, oral contraceptives stopped, and blood glucose level checked in diabetics.

Other than initial burning and irritation, side effects of local agents are unusual. Oral agents occasionally cause nausea, abdominal pain, and headaches. Ketoconazole can cause liver toxicity as well as adverse drug interactions with a variety of other medications.

TRICHOMONAS VAGINALIS

Trichomoniasis is caused by the protozoan *T. vaginalis.* Trichomonads are frequently found in the urethra and Skene glands and may be recovered from urine. It is estimated that 2 to 3 million American women contract the disease annually. Trichomonas is almost always a STD, and its prevalence correlates with the overall level of sexual activity of the population studied. [2,9] Recent epidemiologic surveys indicate a possible decline in prevalence. Vaginal trichomoniasis may be associated with adverse pregnancy outcomes, particularly PROM and preterm delivery. [10,11] Trichomoniasis is also reported to facilitate the transmission of HIV.

Seventy percent of men having intercourse with infected women demonstrated the organism within 48 h, while 85 percent of women whose male partners were infected developed trichomonas infection. There is a high prevalence of gonorrhea in women with trichomoniasis. Oral contraceptives, spermicidal agents, and barrier contraceptives are all thought to reduce transmission.

Infection ranges from asymptomatic carrier state to severe, acute inflammatory disease. A vaginal discharge is reported by 50 to 75 percent of patients. It may vary in character from the classic picture of a yellow-green frothy discharge, seen in 20 to 30 percent of patients, to a gray discharge to scant or no discharge. Other symptoms include vulvovaginal soreness and irritation (25 to 50 percent); pruritis, which may be severe (25 to 50 percent); dysuria (25 percent); and malodorous discharge (25 percent). A sense of vulvovaginal fullness may be intense or mild. As many as half of symptomatic women complain of some degree of dyspareunia. Symptoms may be more severe before, during, or after menstruation when the vaginal pH is more alkaline. Lower abdominal pain is rare and should alert the physician to the possibility of other diseases.

Just as symptoms vary in severity, so do the findings on examination. Gynecologic examination reveals the classic "strawberry cervix" secondary to diffuse punctate hemorrhages in only 2 percent of patients. Diffuse erythema is seen in 10 to 33 percent of patients.

The diagnosis of trichomoniasis vaginitis is made through use of the "hanging-drop" slide test, which has a sensitivity of 80 to 90 percent in symptomatic patients. A cotton swab is used to obtain a specimen of secretions from the vaginal vault (not the endocervix) and is placed within a drop of normal saline solution on a glass slide. Microscopic examination reveals many polymorphonuclear leukocytes (PMNs) and motile, pear-shaped, flagellated trichomonads, which are slightly larger than the leukocytes. As a screening test in asymptomatic individuals, the microscopic test may only be 40 percent sensitive, but has virtually 100 percent specificity. Cultures are about 95 percent sensitive and should be considered in symptomatic patients with elevated pH, PMN excess, and absence of motile trichomonads and clue cells.

The causative organism is a flagellated protozoan that may live quiescently in the paraurethral glands and from this nidus of infestation cause overt infection in the susceptible vagina. *Trichomonas vaginalis* may survive up to 24 h in tap water, in hot tubs, in urine, on toilet seats, and in swimming pools, but the usual sequence of events begins with a large deposit of inoculum of organisms contained in the alkaline semen at time of intercourse. Because up to 25 percent of women and 90 percent of men harboring the organisms are asymptomatic, it is difficult to control spread of disease. The cornerstone of therapy remains metronidazole (Table 104-4).[3,12] Recurrence of disease is frequent and may necessitate more than one course of treatment. There is a 90 percent cure rate with either the single- or multiple-dose regimen. The single-dose treatment is preferable because of lower cost, fewer side effects, and greater patient compliance.

Agent	Dose
RECOMMENDED REGIMEN	
Metronidazole	2 g PO in a single dose
ALTERNATIVE REGIMEN	
Metronidazole	500 mg PO bid for 7 d

Note: Avoid alcohol during and for at least 24 h after treatment. Metronidazole can be used in pregnant women but not approved by the US Food and Drug Administration until the second trimester.

TABLE 104-4   Treatment Regimens for Trichomoniasis

GENITAL HERPES

Genital herpes is a sexually transmitted infection caused by a DNA-containing virus specific to human beings. Sexual transmission can occur during asymptomatic periods. Usually, genital herpes is the most frequently encountered of the diseases causing genital ulcers and is thought to be associated with an increased risk for HIV infection.[3] There are two antigenic groups: herpes simplex virus 1 (HSV-1) and herpes simplex virus 2 (HSV-2). Initially, HSV-1 caused oral lesions and HSV-2 genital lesions, but this is no longer the case. Overall, 85 to 90 percent of genital herpes infections are caused by HSV-2, but some studies have found up to 30 percent are caused by HSV-1. Symptomatic genital herpes is the most frequent cause of painful lesions of the lower genital tract in American women. Neonatal

infection with high mortality and morbidity rates after passage through an infected birth canal has been seen. Although the actual prevalence is not known, it may be one of the most frequent sexually transmitted diseases. It remains a recurrent disease with no cure at this time.

Initial presentation occurs 1 to 45 days (mean 5.8 days) after exposure. Usually, initial infection is more severe and lasts longer than do subsequent recurrences. There may be both local and systemic manifestations. The lesions begin as painful, fluid-filled vesicles or papules, which progress to well-circumscribed, occasionally coalescent, shallow-based ulcers. They then heal by reepithelialization of mucous membranes or by crusting by the epidermal surface. Symptoms peak in 8 to 10 days and decrease over the next week. Ulcers last 4 to 15 days, with total healing in 21 days. Lymphadenopathy is usually present, and when the deep inguinal nodes are involved, severe pelvic pain may result. Urethritis is usually present, causing severe dysuria, which may cause urethral spasm and urinary retention. Initial disease involves the cervix in over 80 percent of cases. Pharyngitis and secondary spread of lesions to other body sites, usually below the waist, have been reported in up to two-thirds of patients. Systemic symptoms, such as fever, malaise, headache, and myalgias, are common. Hepatitis, aseptic meningitis, and autonomic nervous system dysfunction can occur. Aseptic meningitis has been seen more frequently with HSV-2 than with HSV-1 infection and has been reported in about 30 percent of patients. Sacral autonomic nervous dysfunction is rare but can result in decreased cutaneous sensation and bladder and bowel dysfunction. After the attack is over, the inactive virus resides in the sacral dorsal root ganglia. Under various stimuli, both exogenous and endogenous, the virus travels down the sensory nerve root to the lower genital area, where it replicates and becomes symptomatic.

Recurrent episodes are usually milder than the initial disease, and the patient usually does not have systemic symptoms. A recurrence may be heralded by genital tingling. Recurrent genital lesions are fewer, smaller, and more often unilateral. Lesions may be ulcerative or resemble a fissure or excoriations. Recurrences tend to occur in the same location and have the same appearance from episode to episode. Symptoms last 4 to 8 days, and the lesions have usually disappeared by 10 days. Frequency of attacks and intervals between attacks are highly variable. The average number of symptomatic recurrences is 5 to 8 per year. Asymptomatic infections, defined as culture-positive viral shedding in the absence of symptoms or lesions, have been documented.

Approximately 25 percent of initial presentations occur in women with preexisting antibody to herpes simplex virus. The initial episodes tend to be less severe and resemble recurrent infections. They may in fact represent recurrent infections in patients who had previous asymptomatic infections. Clinically, it is impossible to distinguish between HSV-1 and HSV-2 infections, but HSV-1 usually causes milder initial disease, results in recurrence less frequently, and results in milder recurrent episodes.

Diagnosis is suspected by clinical presentation and confirmed by either culture or polymerase chain reaction, which is extremely sensitive in detecting low concentrations of viral DNA but not yet widely available. The virus can be isolated from vesicle fluid and the base of a wet ulcer. Intact vesicles, if present, should be unroofed and the fluid cultured directly. Scrapings of an ulcer may be taken for a Pap smear or Tzanck preparation. A Tzanck smear stained with either Wright or Giemsa stain is positive if multinucleated giant cells are present, which may be seen in up to 50 percent of cases. Serologic analysis is useful in classifying the initial herpetic episode as primary or nonprimary but is usually not indicated.

Treatment is not curative. Multiple antiviral agents and regimens are available (Table 104-5). Systemic antiviral agents provide partial control of the signs and symptoms and accelerate healing of the lesions, but do not affect the frequency or severity of recurrences. Topical therapy is not effective. [3] Patients with severe disease may need hospitalization and intravenous therapy. In recurrent episodes, treatment should be started during the prodrome or within 1 day of onset of lesions if treatment is to be beneficial. For patients with frequent recurrences (six or more episodes per year) daily suppressive therapy can be used but should be discontinued after 1 year to allow assessment of the patient's recurrent episodes. Daily suppressive therapy reduces the frequency of recurrences by at least 75 percent. Suppressive therapy does not lessen the rate of viral shedding, and therefore patients should be advised of their continued risk of infecting sexual partners.

Agent (Oral Tablets or Caplets)	Dose
INITIAL EPISODE	
Acyclovir	400 mg tid for 7–10 d
Famciclovir	250 mg tid for 7–10 d
Valacyclovir	1 g bid for 7–10 d
EPISODIC RECURRENT INFECTION	
Acyclovir	400 mg tid for 5 d
Famciclovir	125 mg bid for 5 d
Valacyclovir	500 mg bid for 5 d
DAILY SUPPRESSIVE THERAPY	
Acyclovir	400 mg bid
Famciclovir	250 mg bid
Valacyclovir	1 g daily
INTRAVENOUS THERAPY FOR SEVERE INITIAL PRESENTATION	
Acyclovir	5–10 mg/kg qid for 5–7 d

Note: All agents categorized class B may be used for pregnant patients.

TABLE 104-5 Treatment of Genital Herpes

The safety of acyclovir and valacyclovir during pregnancy has not been established. In pregnant patients with life-threatening disease, such as encephalitis, pneumonitis, or hepatitis, intravenous acyclovir should be used. It should not be used for recurrent episodes or as suppressive therapy. Pregnant women treated with the drug should be reported to the Glaxo-Wellcome registry, which is kept in cooperation with the CDC (1-800-722-9292, extension 38465). Current registry findings do not indicate an increased risk for major birth defects after acyclovir treatment. [2,3,12]

Systemic analgesics may be needed. Some patients have severe dysuria when the urine comes in contact with vaginal and vulvar tissues. Pouring warm water over these tissues during urination may provide symptomatic relief. [12,13]

CONTACT VULVOVAGINITIS

Contact dermatitis results from the exposure of vulvar epithelium and vaginal mucosa to a primary chemical irritant or an allergen. In either case, characteristic local erythema and edema occur. Severe reactions may progress to ulceration and secondary infection. Common irritants and/or allergens include chemically scented douches; soaps; bubble baths; deodorants; perfumes, dyes, and scents in toilet paper, tampons, and pads; feminine hygiene products; topical vaginal antibiotics; and tight slacks, pantyhose, and synthetic underwear.

Clinically, patients report local swelling and itching or a burning sensation. The gynecologic examination reveals an erythematous and edematous vulvovaginal area. Local vesiculation and ulceration are seen more commonly with allergens or when primary irritants are used in strong concentrations. Vaginal pH changes may promote colonization and infection with *C. albicans,* thus obscuring the primary cause.

Diagnosis of contact vulvovaginitis is made by ruling out an infectious cause and by identifying the offending agent. Most cases of mild vulvovaginal contact dermatitis resolve spontaneously when the causative agent is withdrawn. For patients with severe, painful reactions, cool sitz baths and wet compresses of dilute boric acid or Burow's solution may afford relief. Topical corticosteroids, such as hydrocortisone acetate, fluocinolone acetonide, or triamcinolone acetonide, relieve symptoms and promote healing. Oral histamines may be helpful if a true allergic reaction is present. If superinfection with *C. albicans* has complicated the case, it needs to be treated.

VAGINAL FOREIGN BODIES

Children and adolescents may insert objects intravaginally during periods of genital exploration or sexual stimulation. In young girls, the most commonly inserted foreign bodies are rolled-up pieces of toilet paper, toys, and small household objects. [1] In adolescents and adult women, it is often a forgotten tampon or sponge contraceptive. Foreign objects left in place for more than 48 h can cause severe localized infections due to *Escherichia coli,* anaerobes, or overgrowth of other vaginal flora. Patients present with a foul-smelling and/or bloody vaginal discharge. The only treatment necessary for vaginitis secondary to the presence of a foreign body is removal of the object.[1] In most cases, the vaginal discharge and odor will disappear without further therapy within several days.

PINWORMS

Pinworms (*Enterobius vermicularis*) may migrate from the anus to the vagina in children and cause intense pruritus that is often most intense during the night, when gravid female worms pass out from the intestinal tract to lay eggs on the perineal skin. Cellophane tape can be used to obtain material for a slide, which can be examined microscopically for the presence of ova, which are large and double walled in appearance. The child and all family members need treatment with an antiparasitic agent, either mebendazole [Vermox (Janssen Pharmaceutica, Inc.)], a single oral dose of 100 mg chewed well, or pyrantel pamoate [Antiminth (Pfizer, Inc.)], a single oral dose of 11 mg/kg (maximum 1 g). Repeat treatment 2 weeks later should be administered, since mature worms seem more vulnerable to treatment than do young worms.[14]

ATROPHIC VAGINITIS

During menarche, pregnancy, and lactation and after menopause, the vaginal epithelium lacks the stimulation of estrogen. The maturation of the vaginal and urethra mucosa depends on the presence of estrogen and can be altered by the absence of estrogen or the presence of antiestrogenic factors, such as hormones, drugs, or diseases. Menopause results in a vaginal mucosa that is attenuated, pale, and almost transparent as a result of decreased vascularity. The vagina loses its normal rugae. The squamous epithelium atrophies, the glycogen content of the cells decreases, and the vaginal pH ranges from 5.5 to 7.0. The mucosa is only three or four cells thick and is less resistant to minor trauma and infection. Marked atrophic changes can cause atrophic vaginitis. It is important to distinguish between symptomatic atrophic vaginitis, which is rare, and an atrophic vagina that is a result of physiologic changes of menopause. When symptomatic vaginitis occurs, the vaginal epithelium is thin, inflamed, and even ulcerated. Symptoms include vaginal soreness, dyspareunia, and occasional spotting or discharge, which may be a thin, scant, yellowish or pink material. The cervix atrophies and retracts and may become flush with the apex of the vault. The upper one-third of the vagina constricts, and the entire vagina becomes shorter in length and loses its elasticity. The increased vaginal pH may permit the growth of nonacidophilic coliform organisms, bacteria not normally found in the vagina, and the disappearance of *Lactobacillus* species. This can lead to the development of a clinical vaginal infection with copious purulent discharge. Unless estrogenic replacement therapy is used, *Candida* and *Trichomonas* infections are rare. The changes seen vary widely from one patient to another. A Pap smear of the cervix and vagina is mandatory in the face of bleeding to rule out carcinoma. A wet preparation will show erythrocytes and increased PMNs associated with small, round epithelial cells, which are immature squamous cells that have not been exposed to sufficient estrogen. The treatment of atrophic vaginitis consists primarily of topical vaginal estrogen. Nightly use of half or all of the contents of an applicator for 1 to 2 weeks should be sufficient to alleviate symptoms. [3] An alternative regimen is use of oral estrogen (0.625 mg conjugated estrogen). Estrogen should not be prescribed for any patient with a past history of cancer of any of the reproductive organs. Atrophic vaginitis is usually not seen in patients who are already on systemic estrogen replacement therapy. Patients should be referred for follow-up to monitor therapy and for the results of the Pap smear.

105 PELVIC INFLAMMATORY DISEASE

Amy J. Behrman
Suzanne Moore Shepherd

INTRODUCTION

Pelvic inflammatory disease (PID) comprises a spectrum of infections of the female upper reproductive tract. It is a common and serious sexually transmitted disease, generally initiated by ascending infection from the cervix and vagina. The inflammatory processes falling within the rubric of PID may include salpingitis, endometritis, and tubo-ovarian abscess, and extend to produce pelvic peritonitis, and perihepatitis. The annual rate of PID in industrialized countries has been reported to be as high as 10–20 per 1000 women of reproductive age, with over one million cases estimated to occur per year in the United States. [1] These numbers clearly underestimate the true incidence because of both atypical and wide variability of symptoms and the relatively poor reliability of the clinical diagnosis. Long term sequellae, including tubal factor infertility (TFI), ectopic pregnancy, and chronic pain, may occur in as many as 25 percent of patients. The annual direct and indirect costs of the acute disease and its sequella are projected to rise to $10 billion/year by 2000.

Patients with PID frequently present to emergency departments with non-specific complaints and findings. Early diagnosis and aggressive treatment may provide rapid clinical and microbiologic improvement, identify co-existent disease, decrease transmission, and minimize the likelihood of serious sequelae.

ETIOLOGY

Neisseria gonorrhoeae and *Chlamydia trachomatis* can be isolated in many, if not most, cases of PID, and therapy has traditionally been directed primarily against these organisms. However, newer, more sensitive and specific evaluative tools have become available which have significantly improved our understanding of PID. Polymicrobial infection, including anaerobic and aerobic vaginal flora, has clearly been demonstrated in studies relying on cultural material from the upper reproductive tract. [2] Earlier culdocentesis studies suggested that 80 percent of PID was polymicrobial, but there is evidence that this may represent a degree of contamination of the cul-de-sac by the procedure. Laparoscopy cultures more conservatively point to mixed infection in 30 to 40 percent of cases. Pathogenic organisms may include anaerobes, *Gardnerella vaginalis,* enteric gram-negative rods, *Hemophilus influenzae, Streptococcus agalactine, Mycoplasma hominis,* and *Urea urealyticum. N. gonorrheae* and *C. trachomatis* may often be instrumental in the initial infection of the upper genital tract, while anaerobes, facultative anaerobes, and other bacteria are increasingly isolated as inflammation increases and abscesses form. *Gardnerella vaginalis* may also play a role in the initiation of ascending infection. [3] The microbiology of PID also reflects the predominant sexually transmitted diseases present within a given population.

Pathology and Risk Factors

Most cases of PID are presumed to originate with sexually transmitted disease (STD) of the lower genital tract followed by ascending infection of the upper tract. The original STD may not be symptomatic. It is estimated that 10 to 20 percent of untreated gonococcal or chlamydial cervicitis may progress to PID. The precise mechanisms by which infection in the upper genital tract is initiated and propagated remain unclear. The female genital tract is an open system; therefore a vehicle to transport potential pathogens is unnecessary. Although the cervical mucus serves as a functional barrier to ascending infection much of the time, its efficacy may be decreased by hormonal changes during ovulation and by retrograde menstruation. Bacteria may also be carried by or along with sperm into the uterus and tubes. Uterine infection is usually limited to the endometrium but may be more invasive in a gravid or post-partum uterus. Initial gonorrheal adherence is to non-ciliated cells, but it is felt that surface components of the organism affect neighboring ciliated cells. Tubal infection initially affects only the mucosa, but acute, complement-mediated transmural inflammation may develop rapidly. Inflammation may extend to uninfected parametrial structures including the bowel. If purulent material from the tubes spills into the abdomen, frank pelvic peritonitis may result. Infection may extend via direct or lymphatic spread beyond the pelvis to involve the hepatic capsule with acute perihepatitis and focal peritonitis (Fitzhugh-Curtis syndrome).

Risk factors for PID within a sexually active population include multiple sexual partners, history of other STDs, substance abuse, and frequent vaginal douching. Younger age is associated with increased risk, possibly because of a larger zone of cervical ectopy in young women, increased cervical mucosal permeability, lower prevalence of protective chlamydial antibodies, risk-taking behavior, or a combination of these factors. [4] Barrier contraception is associated with lower risk of PID. IUD use is associated with a 2 to 9 fold increased risk for PID, with the highest risk in the first four months after insertion. [5,6] Oral contraceptive pills (OCPs) increase the risk of endocervical infection, probably by increasing the zone of cervical ectopy. However, OCPs decrease the risk of symptomatic PID, possibly by increasing the viscosity of cervical mucus, decreasing menstrual blood flow (and hence decreasing retrograde menstruation), or modifying local immune responses. [7] Bilateral tubal ligation (BTL) does not provide protection from PID, but patients with BTL may have a clinically milder form of the disease. [8] Bacterial vaginosis (BV) is associated with an increased risk of PID, and BV organisms are frequently cultured from upper genital tract specimens in PID. Pregnancy decreases the risk of PID as the cervical os is protected by a mucous "plug." However, PID can occur during the first trimester and may cause fetal loss.

Complications

PID is associated with a number of serious clinical sequelae. Tubo-ovarian abscess is reported in up to one-third of women hospitalized for PID. [9,10] Infection and inflammation can lead to scarring and adhesions within tubal lumens. The rate of potentially fatal ectopic pregnancy is 12 to 15 percent higher in women who have had PID. TFI is increased 12 to 50 percent in women with a past diagnosis of PID, and the incidence of TFI increases with the number and severity of past PID episodes. Asymptomatic or "silent" PID appears to be associated with TFI, as well: 50 percent of women with TFI have no history of PID but do have scarring of the fallopian tubes and exhibit antibodies to *N. gonorrhoeae* and/or *C. trachomatis.*[11] Chronic pelvic pain and/or dyspareunia has been reported in 18 percent of women with past histories of PID.[12]

DIAGNOSIS

Clinical Findings

Lower abdominal pain is the most frequent presenting complaint in PID. Other symptoms may include abnormal vaginal discharge, vaginal bleeding, post-coital bleeding, dyspareunia, irritative voiding symptoms, fever, malaise, nausea, and vomiting. PID may be minimally symptomatic or asymptomatic. [9]

The physical examination is usually notable for lower abdominal tenderness, mucopurulent cervicitis, cervical motion tenderness, and bilateral adnexal tenderness. However, women with PID often present with mild pelvic pain, which can be overlooked by the clinician. Disproportionate unilateral adnexal tenderness and/or adnexal mass or fullness may indicate an ovarian abscess. Abdominal guarding and rebound tenderness will develop with peritonitis. Right upper quadrant tenderness, particularly with jaundice, may indicate Fitzhugh-Curtis syndrome. Signs of other STDs should be noted and evaluated.

Laboratory evaluation in the ED should always include a pregnancy test. The possibility of ectopic pregnancy or septic abortion must be considered, and concurrent pregnancy will affect the treatment for PID. Saline-treated and potassium hydroxide-treated wet preparations of vaginal secretions should be examined for leukorrhea (more than 1 pmn/epithelial cell), trichomoniasis, and clue cells. The absence of leukorrhea has been suggested to be a good negative predictor for PID. [13] Endocervical swabs should be sent for culture and can be gram stained for gonococci. DNA probes for gonorrhea and chlamydia are useful, if available. Elevated white blood cell counts, sedimentation rates, and/or C-reactive protein support the diagnosis of PID. The syphilis test for rapid plasma reagin should be performed. Patients should be counseled on testing for hepatitis and HIV. HIV-infected women with PID may present with more severe symptoms and more frequent coinfection with Candida and human papillomavirus. [14]

Due to the need for early treatment to minimize serious sequelae in vulnerable populations, the diagnosis of PID is usually based on clinical criteria with or without laboratory evidence. The wide range of clinical findings may lead to under or over diagnosis. Table 105-1 details the current Centers for Disease Control and Prevention (CDC) diagnostic criteria for PID. [14]

All major criteria below must be present
    Lower abdominal pain
    Tenderness on lower abdominal examination
    Cervical motion tenderness
    Adnexal tenderness
In addition, one or more of the following criteria, will enhance the specific-
    ity of the diagnosis
    Temperature >101°F (38.3°C)
    Abnormal cervical or vaginal discharge
    Laboratory evidence of *Chlamydia trachomatis* or *Neisseria gonorrhoeae*
    Elevated erythrocyte sedimentation rate or C-reactive protein

The following definitive criteria are warranted in selective cases
    Positive transvaginal ultrasound, or other imaging technique, showing
        thickened, fluid filled tubes with or without tuboovarian abscess or free
        pelvic fluid, or
    Positive endometrial biopsy, or
    Positive laparoscopy

TABLE 105-1   Diagnostic Criteria for Pelvic Inflammatory Disease

Procedures

If greater accuracy for the diagnosis of PID is desirable, a number of procedures can be performed. These procedures are not necessary, nor are they indicated, in every case of presumptive PID. In fact, transvaginal pelvic ultrasound is the only procedure that may be considered part of routine evaluation whenever PID is considered within the differential diagnosis.

Transvaginal pelvic ultrasound may demonstrate thickened, fluid-filled fallopian tubes or free pelvic fluid in acute, severe PID. [15] These findings alone are not specific enough to make a definitive diagnosis. However, pelvic abscesses may be seen as complex adnexal masses with multiple internal echoes. Pelvic ultrasound will also be useful in evaluating the possibility of ectopic pregnancy in those patients where the differential includes both entities.

Endometrial biopsy can also be used for the definitive histopathologic diagnosis of endometritis. Endometritis is uniformly associated with salpingitis. Specimens for culture may also be obtained but will frequently be contaminated with vaginal flora. The procedure is performed with an endometrial suction pipelle curette and is well tolerated. Endometrial biopsy is approximately 90 percent specific with similar sensitivity. Although this procedure is not difficult, few emergency practitioners are currently trained to do it. Thus, it is best deferred to a gynecologist. Further, its diagnostic utility in the ED setting is limited as results are not immediately available.

Culdocentesis can also be performed rapidly in the ED. However, its utility is also limited. The potential positive findings of leukocytes and bacteria are non-specific and may be a product of other inflammatory processes, such as appendicitis or diverticulitis, or due to contamination with vaginal contents.

Laparoscopy is the current gold standard for the diagnosis of PID [16]. It is significantly more sensitive and specific than clinical criteria alone. The minimum criteria to diagnose PID laparoscopically include visible hyperemia of the tubal surface, tubal wall edema, and the presence of exudate on the tubal surface and fimbriae. Pelvic masses consistent with tubo-ovarian abscess or ectopic pregnancy can also be directly visualized. Hepatic capsule exudate and/or adhesions may be demonstrated. Material may be obtained for definitive culture without the risk of vaginal contamination. However, the procedure is invasive and expensive, requiring an operating room and anesthesia. Findings on laparoscopy do not necessarily correlate with the severity of illness, because the laparoscopist can see only the surface of structures. Laparoscopy may fail to define up to 20 percent of cases.

Differential Diagnosis

The differential diagnosis for PID may include any of the following processes, depending on the specific constellation of signs and symptoms present: cervicitis, ectopic pregnancy, endometriosis, ovarian cyst, ovarian torsion, spontaneous abortion, septic abortion, cholecystitis, gastroenteritis, appendicitis, diverticulitis, pyelonephritis, or renal colic.

THERAPY

Treatment

Treatment of PID is aimed at relieving acute symptoms, eradicating current infection, and minimizing the risk of long-term sequelae. There is no clear role for anti-inflammatory drugs per se at this time, but effective analgesia should be administered. [10,17] Therapy initiated in the emergency department must include intravenous hydration and empiric, broad-spectrum antibiotics to cover the full range of likely organisms. All regimens should be effective against anaerobes, gram-negative facultative organisms, and streptococci, as well as *N. gonorrheae* and *C. trachomatis*. A variety of inpatient regimes with broad spectrum coverage have been shown to be effective in eliminating acute symptoms and to effect microbiologic cure (84 to 98 percent cure rates). It is less clear that these regimens can reduce long-term sequelae. However, evidence suggests that long-term outcomes are improved if antibiotics are begun within 48 h of symptom onset. Current CDC recommendations are shown in Table 105-2 and Table 105-3. Few investigators have assessed and compared parenteral and oral antibiotic regimens, or inpatient versus outpatient regimens, with regard to documented elimination of endometrial and tubal infection. [18,19] Several new regimens, including azithromycin, appear promising in terms of adequacy of coverage and potential patient compliance but are not currently recommended by the CDC because of lack of data. However, many ED practitioners have already included this in their armamentarium.

Ceftriaxone 250 mg IM, *or*

Cefoxitin 2 g IM plus probenecid 1 g PO, *or*

Other parenteral third-generation cephalosporin

   plus

Doxycycline 100 mg PO bid × 14 days

   or alternative regimen:

Ofloxacin 400 mg PO bid × 14 days

   plus

Metronidazole 500 mg PO bid × 14 days

Cefoxitin 2 g IV q6h
plus
Doxycycline 100 mg IV/PO q12h
or alternative regimen:
Clindamycin 900 mg IV q8h
plus
Gentamycin loading dose IV/IM (2 mg/kg) and then maintenance 1.5 mg/kg q8h

Source: Adapted from Centers for Disease Control and Prevention.[14]

TABLE 105-3   Inpatient Antibiotic Management of Pelvic Inflammatory Disease

If an IUD is present, it should be removed after antibiotics have been started. Parenteral antibiotics may be switched to oral antibiotics 24 h after evidence of clinical improvement. All patients should be re-evaluated in 72 hours for evidence of substantial clinical improvement (defervescence, decreased abdominal tenderness, decreased uterine, adnexal, and cervical motion tenderness) and compliance with their regimen. [20,21 and 22] Patients who do not improve within this time frame should be re-evaluated for possible laparoscopic or surgical intervention, i.e., drainage of pus loculations or tubo-ovarian abscess, or to reconsider other possible diagnoses.

Surgical Intervention

The majority of tubo-ovarian abscesses (60 to 80 percent) will resolve with antibiotic administration alone. If patients do not respond clinically to antibiotics, laparoscopy may be useful to identify pus loculations requiring drainage or alternative pathologies. An enlarging pelvic mass may indicate bleeding secondary to vessel erosion or a rupturing abscess. Unresolved abscesses may be drained percutaneously, laparoscopically, or surgically. [10,15]

Disposition

As the incidence of PID has risen, the rate of hospitalization has fallen. With the increasing availability of outpatient parenteral therapy, hospitalization rates may fall further. There is little data to demonstrate whether outpatient treatment is as effective as inpatient treatment in optimizing long-term clinical outcomes. Admission decisions in the ED are based on severity of illness, likelihood of compliance with outpatient medications, likelihood of major anaerobic infection (IUD, suspected pelvic or tubo-ovarian abscess, or history of recent uterine instrumentation), certainty of diagnosis, coexistent illness and immunosuppression, pregnancy, patient age, and other major fertility issues. Admission is warranted in a number of circumstances (see Table 105-4).

Pregnancy
Surgical emergencies, such as appendicitis, which cannot be ruled out
Immunosuppression (including HIV infection with low CD4)
Pelvic abscess demonstrated or suspected
Intrauterine device in place
High fever, or severe nausea and vomiting
Compliance with an outpatient regimen unlikely
Failed outpatient therapy
Adolescence
Significant fertility issues present

Source: Adapted from Centers for Disease Control and Prevention.[14]

TABLE 105-4   Admission Criteria for Pelvic Inflammatory Disease

PREVENTION

Uncomplicated endocervical infections with *N. gonorrheae* and *C. trachomatis* are under-diagnosed and undertreated in emergency departments.[23] Improving education, diagnosis, and empiric treatment rates for these infections, as well as for minimally symptomatic PID, should result in lower incidence and prevalence of PID and should decrease the incidence of major long-term sequelae, such as infertility and ectopic pregnancy.

Patients discharged with PID are frequently noncompliant with medications, frequently do not understand their diagnoses, and frequently do not obtain partner treatment.[24,25] Patients should be educated about these issues, as well as the advisability of testing and treatment for other STDs, including syphilis and HIV. Patients should understand the use of barrier contraceptives and other "safe sex" techniques to lessen their risk of re-infection.

Partners of PID patients should be empirically treated for *N. gonorrheae* and *C. trachomatis* if they have had sexual contact with the patient in the 60 days preceding the onset of her symptoms. Sexual contact should be avoided until one full course of treatment is completed.

106 BREAST DISORDERS

Carol A. Terregino
Rachelle A. Greenman

Few if any breast disorders could be considered imminently life-threatening. However, the psychological and personal issues associated with this part of the anatomy classify such disorders as emergent for the patient. This chapter begins with a functional anatomic and physiologic review appropriate to emergency medicine, reviews the physical examination of the breast and common abnormalities detected by inspection and palpation, and then focuses on infectious, inflammatory, and neoplastic entities that emergency physicians may encounter in their practices. Few evidence-based recommendations exist concerning the management of breast disorders beyond the management of breast carcinoma.

ANATOMY

The human breast is formed from the milk stream, an ectodermally derived tissue, which eventually atrophies, leaving behind the nipple bud. The glandular part of the organ develops subcutaneously. Breast ducts extend down from the nipple into the glandular portion of the breast. The mature breast lies between the deep and the superficial layers of the superficial pectoral fascia. Within the axillary space lie multiple groups of nodes, which are of great interest to the surgeon. Knowledge of the lymphatic drainage of the breast allows prediction of sites of metastatic spread.

Three tissue types make up the mature breast: epithelium, fibrous stroma, and fat. The fat composition of the breast increases with age, allowing improved radiographic detection of abnormalities by mammography. Cooper's ligaments are strands of dense connective tissue that extend from the skin through the fat to the underlying deep fascia. Any contraction or impingement on these ligaments, as commonly occurs with cancer, causes a dimpling pattern of the skin. The glandular portion of the breast is composed of ducts that extend downward from the nipple areolar complex and branch radially, terminating in spaces called ductal glandular units, the milk-producing glands of the lactating breast. At the surface of the nipple are 15 to 30 orifices lined with low columnar or cuboidal epithelium that meets with squamous epithelium at the surface.

In prepubescence, the breast tissue is composed of dense fibrous stroma and scattered ducts. Increase in adipose tissue and glandular development are under hormonal influence. The development of breast buds in a prepubescent female unaccompanied by other changes of puberty is called prepubertal gynecomastia, and this entity should not be confused with puberty. During phases of the menstrual cycle, the breast undergoes cyclic changes, including hypertrophy of the stroma and the epithelium and intralobular fluid accumulation corresponding to perimenstrual breast engorgement. During pregnancy there is an increase in lobular units; this is termed adenosis of pregnancy. In lactating females, prolactin stimulates milk production. Milk expulsion is under the control of oxytocin stimulation of myoepithelial cells.

EXAMINATION OF THE BREAST

A systematic approach to the breast examination is essential. The breasts must be inspected for size and symmetry, although some degree of asymmetry is not uncommon and is usually normal. The contour of the breast must be inspected, with special attention to dimpling, masses, or flattening. In order to accentuate potential dimpling, have the patient raise her hands above her head. The color, venous pattern, and any edematous changes should be noted. Nipple inversion of long standing is common and usually normal. Areolar or nipple rashes or ulcerations should be noted. For palpation of the breast, the patient must be in a supine position. Placement of a pillow under the patient's shoulder on the examination side and her arm above her head helps to spread the breast tissue over the chest and make palpation of nodules easier. A patterned approach should be used to ensure that all breast tissue is palpated. The pads of the three middle fingers should be used with a rotatory motion. The consistency of the breast changes with age and the hormonal milieu. Nodules should be described according to their quadrant (upper and lower, outer and inner), shape, size, relationship to surrounding tissue, and tenderness. The nipple should be palpated and compressed for discharge.

ABNORMAL LACTATION

Lactation is the response to normal hormonal stimulation associated with pregnancy and the postpartum period. Prolactin secretion is under a negative control; its levels are determined by neurohormonal transmitters affecting its inhibitory factors, the most important one being dopamine. High levels of estrogen and progesterone during pregnancy inhibit the release of prolactin inhibitory factor. The rising estrogen levels also increase the growth of pituitary lactotrophs. While the prolactin secreted during pregnancy prepares the breast for lactation, lactation does not occur until estrogen levels fall precipitously after delivery. Multiple hormones, including thyroid hormone, insulin, growth hormone, placental lactogen, and cortisol in addition to prolactin, progesterone, and estrogen, prime the breasts to prepare for lactation by stimulating proliferative and secretory activity of the breast alveolar cells. Within 20 to 30 min of nursing, prolactin levels rise to 60 times normal. The discharge is milky, white, and thin and usually involves multiple ducts. Rarely, a bloody lactation, due to the high estrogen levels of pregnancy, may be seen. When weaning, it may take weeks for lactation to cease. However, if the nipples continue to be stimulated manually, the discharge may continue for years.

Galactorrhea is an inappropriate nonlactational milky white nipple discharge. Spontaneous galactorrhea usually indicates hyperprolactinemia, especially when there is concomitant amenorrhea. However, in approximately 30 percent of cases, prolactin levels are normal. Physiologic hormonal alterations that occur at menarche and early menopause can sometimes cause galactorrhea. Hormonal preparations can stimulate the breast tissue directly, elevating prolactin levels and stimulates milk production.

Increased prolactin levels can also be caused by nipple stimulation, chest wall trauma, reduction mammoplasty, breast augmentation, herpes zoster infection of the breast, and postherpetic neuralgia. Rare oncologic causes include ectopic secretion by renal adenocarcinoma, bronchogenic carcinoma, and other prolactin- or estrogen-secreting neoplasms. Increased physical exertion, sexual intercourse, seizures, and hypoglycemia can also stimulate prolactin release.

Pathologic hyperprolactinemia is a frequent cause of the amenorrhea-galactorrhea syndrome. As discussed above, prolactin secretion is predominantly inhibited by dopamine, which is transported along the hypophyseal stalk from the hypothalamus to the pituitary gland, where it directly inhibits synthesis and secretion. Any damage to the hypothalamus or hypophyseal stalk by lesions, such as tumors, radiation scarring, or trauma in addition to congenital, vascular, ischemia, or inflammatory lesions, may result in increased serum prolactin levels.[1]

Drugs that alter dopamine secretion can also cause hyperprolactinemia. The most common causes of hyperprolactinemia include psychotropic agents, such as phenothiazines, haloperidol, tricyclic antidepressants, and fluoxetine. Reserpine and a-methyldopa may cause hyperprolactinemia due to depletion of dopamine reserves. Other drugs shown to increase prolactin levels include calcium channel blockers, angiotensin-converting enzyme inhibitors, cocaine, opiates, marijuana, and H_2 antagonists. Although estrogen therapy can increase prolactin levels, typically oral contraceptives do not increase serum prolactin levels.

Certain medical conditions, such as chronic renal disease and, rarely, liver failure, can cause increased prolactin levels. Hypothyroidism can lead to

hyperprolactinemia, galactorrhea, and amenorrhea due to the effects of thyrotropin-releasing factor on the pituitary gland.

Prolactinomas, prolactin-secreting pituitary tumors, are a frequent cause of hyperprolactinemia. Pituitary adenomas secreting other hormones, such as growth hormone and ACTH along with prolactin, may also cause galactorrhea. Therefore, patients with galactorrhea should be evaluated for acromegaly and Cushing disease. Assessment includes visual field and extraocular movement testing. Cranial nerve involvement or diplopia could indicate extension of the tumor into the cavernous sinus. Patients with symptoms or signs of intracranial mass such as headache, nausea, vomiting, or visual abnormality, need immediate neuroimaging studies (computed tomography or magnetic resonance imaging) and neurosurgical consultation.

Routine determination of prolactin levels is not indicated in the emergency department without endocrinologic consultation. Pituitary tumors usually generate prolactin levels greater than 200 µg/L; however, random prolactin levels may not reflect an abnormality. Prolactin levels less than 100 µg/L units are usually not of tumor origin and are probably related to drugs.[1]

Management of galactorrhea in the emergency department should include determination of the urine or serum b-human chorionic gonadotropin level, evaluation for neuroophthalmologic abnormalities and imaging as previously discussed. Further hormonal workup, including serial determination of prolactin, thyroid-stimulating hormone, and growth hormone levels, can be left to the discretion of the primary care provider or specialist. The majority of patients require no intervention other than reassurance and perhaps cessation of drugs. Almost all patients with pituitary-induced hyperprolactinemia can be effectively treated with the dopamine agonist bromocriptine, which normalizes prolactin levels in 80 to 90 percent of patients, restores menses, and halts galactorrhea.[1] Bromocriptine is also useful for treating galactorrhea in patients with normal prolactin levels. Although an understanding of the basis and effects of such treatment is useful, it is not within the purview of emergency medicine.

NIPPLE DISCHARGE

Nipple discharge is a common complaint in benign breast disease. Pathologic processes must be distinguished from the more common physiologic ones. Physiologic discharges usually require manual compression, involve multiple ducts, and are bilateral. The fluid may be clear, white, yellow, or dark green. Discharges of long duration are less likely to be clinically significant.[2]

On the other hand, pathologic nipple discharge is spontaneous, usually unilateral, confined to a single duct, bloody, and associated with a mass. The most common cause of pathologic nipple discharge is intraductal papilloma, followed by duct ectasia (discussed below).[2] While most nipple discharges associated with cancer are bloody, cancer has been shown to be the cause of only 6 percent of cases of bloody discharge.[2]

The precise incidence of breast cancer in women with nipple discharge is unknown.[3] If a palpable mass is associated with a discharge, the likelihood of carcinoma is greatly increased. In a series of women presenting with nipple discharge, over 60 percent of patients with a palpable mass and spontaneous nipple discharge had carcinoma, compared to 6 percent in patients with nipple discharge only.[3]

Workup of spontaneous nipple discharge or a nipple discharge with a mass should include a complete breast examination and referral of all women over age 35 for a mammogram and evaluation by a breast surgeon. Nonspontaneous nipple discharge without a mass can be referred to a primary care provider for arrangement of a mammogram.[3] All postmenopausal discharges are significant. If practical, the discharge should be assessed for the presence of occult blood, which can be done using either a white gauze or reagent stick. Sending the discharge for cytologic analysis may be helpful if the results are positive; the absence of malignant cells does not exclude carcinoma.

SKIN DISORDERS AFFECTING THE NIPPLE AND BREAST

Any disorder of the skin can affect the breast. Some of the more important ones specific to the breast and nipple are discussed below.

Colonization of the nipples or the lactiferous ducts by *Candida albicans* may cause chronically sore nipples during or after lactation. The appearance of the nipple may be normal; however, more commonly, scaling, fissuring, and erythema are present. Predisposing factors for candidal colonization include antibiotic use, vaginal candidiasis, mastitis, and nipple trauma occurring in the early lactation period. Definitive diagnosis may be made by fungal culture, but that should not be necessary. The nipples may be treated with topical antifungal creams.[4] Vaginal candidiasis in the patient, as well as any clinically evident oral candidiasis in the infant, should also be treated.

Atopic dermatitis, which may affect one or both nipples, is manifested by areas of fissuring, weeping skin, or lichenification. This condition occurs in both pregnant and nonpregnant women, most commonly between the ages of 15 and 30. This dermatitis is more common in atopic individuals. Underlying causes of these skin changes include scabies, contact allergy, local medication reaction, and irritation secondary to friction.[5]

Paget's disease is an uncommon neoplastic disorder that usually begins at the nipple and spreads outward, secondarily involving the areola. This is an important distinction, since benign skin conditions begin on the areola. The appearance ranges from that of an eczema-like erosion of the nipple to a red, raw surface, with a copious, clear discharge. Both the areola and nipple have chronic, moist eczematous changes. Paget's disease is estimated to occur in 1 to 2 percent of breast cancers.[4] Most cases are diagnosed in postmenopausal women. Unfortunately, early symptoms, such as an itching or burning sensation of the nipple, may be subtle and may have been present for years before the diagnosis is made. Paget's disease is usually unilateral. Patients may note a small crusted area, with staining of the clothing, or an overt serous or bloody discharge from the nipples. Dermatologic changes of the nipple and areola progress slowly. In later cases, there may be a sharply demarcated area on the nipple areola complex. The nipple may become retracted or deformed.

The histology of Paget's disease is an intraductal carcinoma occurring in the large sinuses beneath the nipple. The carcinomatous cells invade across the nipple epithelium. Paget's disease of the nipple has an associated palpable underlying mass in 50 percent of cases, and 90 percent of these patients have invasive intraductal carcinoma of the breast. Seventy percent of these patients without a palpable mass have in situ intraductal breast carcinoma; the remainder are diagnosed with invasive disease at a later date.[6]

Treatment for intraductal carcinoma associated with Paget's disease is related to the underlying carcinoma. The long-term outcome for treated patients is excellent. Referral to a breast surgeon is mandatory. Topical steroids should never be prescribed because the anti-inflammatory effects may delay the diagnosis.

Mondor's disease of the breast is a superficial phlebitis of the veins in the subcutaneous tissue of the breast. This condition may occur postoperatively or after minor trauma. The patient presents complaining of a painful induration across the costal margin. A cord may be present. The phlebitis may be tender for several weeks. No treatment other than analgesia is required. Follow-up evaluation with a surgeon is indicated.[4]

An "orange-peel" appearance of the skin, or *peau d'orange,* is produced by skin edema emphasizing the skin sweat glands. Such a breast appearance indicates underlying breast carcinoma with both stromal infiltration and lymphatic obstruction, causing skin edema. Referral to a breast surgeon for appropriate diagnostic testing and treatment is always indicated.

Erosive adenomatosis of the nipple is an uncommon, benign tumor of the nipple that generally occurs in the fourth decade. It is a proliferation of the lactiferous ducts that usually occurs unilaterally but may occur bilaterally. The onset is insidious and may begin with a serous or bloody nipple discharge that worsens in the premenstrual period. Occasionally, there may be a palpable nodule, but usually the nipple appears eroded or eczematous. There is no accompanying axillary lymphadenopathy. The patient should be referred to a breast surgeon. Complete excision, which may include the entire nipple if it is involved, is curative.

BENIGN BREAST DISEASE

Benign breast disease is traditionally considered to be due to hormonal influence. Prolonged hormonal imbalance leads to proliferation of breast tissue, leading to edema and discomfort. The clinical characteristics of benign breast disease include mastalgia or cyclic breast pain, isolated unilateral or bilateral breast lumps (either cysts or fibroadenomas), bilateral nodularities in the perimenstrual period, fibrocystic disease, and nipple discharge, as discussed above.[7] The patient should be

referred to a breast specialist for confirmation of this diagnosis.

NONLACTATIONAL INFLAMMATION (MASTITIS)

Nonlactational mastitis and duct ectasia, or dilated ducts filled with stagnant secretions, make up a clinical complex. A discussion of the confusion in disease classification arising from these independently described conditions is beyond the scope of this chapter. Hughes provides a clear overview of the clinical conditions and their management.[8] Duct ectasia is generally a subclinical condition, with nipple discharge that is either serosanguineous or occultly positive for blood, as the most common clinical manifestation. Patients with mastitis have an average age of 40 years. In some series, up to one-third of patients have type II diabetes mellitus. [9]

Mastitis originates in the subareolar ducts and extends outward in the breast. The cause is generally infectious, and the organisms include gram-negative organisms and anaerobes in addition to *Staphylococcus aureus.* Occasionally, mastitis occurs in areas of cystic breast tissue without an infectious cause. Periductal mastitis may be an evanescent tender breast mass that resolves spontaneously or persistent inflammatory reaction that progresses to abscess formation. Mastitis is manifested by pain, erythema, and warmth of the overlying skin, with exquisite tenderness. Nipple retraction or fistula formation at the edge of the areola occurs frequently with recurrent episodes of periductal mastitis with or without abscess formation.

Management is generally conservative, with heat and antibiotics in an outpatient setting. Referral for mammography is impractical, given the degree of compression necessary to get an adequate image of the inflamed breast. For detection of an abscess cavity, breast ultrasound is more sensitive. Patients should always be referred to a breast specialist for follow-up, since the diagnosis of inflammatory carcinoma must be excluded. All cases should be followed for complete resolution of signs or symptoms.

BREAST ABSCESS

Pathophysiology

Breast abscess may be difficult to distinguish from breast mastitis, a more generalized cellulitis. Due to the compartmentalized structure of the breast, regions of necrosis and avascularity, the abscess may lie deep to the overlying tissues. Typical fluctuance may be difficult to appreciate. The pathophysiology of this entity is not precisely known. However, it has been suggested that it may be due to plugging of the ductal openings by keratin at the junction of squamous cell with cuboid epithelium or due to duct ectasia. Bacterial invasions, more commonly by *staphylococcus,* leads to abscess development. However, as in mastitis, other microorganisms have also been associated with breast abscess. In one case series, monomicrobial aerobic bacteria were most frequently identified with a significant percentage of *proteus mirabilis* isolates. Additionally, polymicrobial anaerobic cultures, most frequently *Peptostreptococcus spp.* and *Bacteroides sp.,* are commonly found in recurrent breast abscesses.[10] The most common site for breast abscesses to occur is in the subareolar tissue. These are difficult to treat and have a high incidence of recurrence.

Diagnosis

The diagnosis of breast abscesses should be considered in all patients who present with painful breast mass, particularly inflammatory conditions. Some recommend ultrasonographic assessment of suspected breast abscess as not all women have an obvious collection of focal pus. [11] Alternatively, as long as carcinoma is not suspected, aspiration for diagnosis can be attempted. A negative aspiration does not exclude the diagnosis of abscess. The technique of aspiration is the same as for suspected abscess at other near-surface body sites.

Treatment

Treatment is determined by the degree of inflamation and the stage of abscesses development. [12] Patients presenting to the ED with small, early subareolar abscess should be treated conservatively with antibiotics alone for a 2-week period. Broad spectrum antibiotics should be prescribed given the high percentage of anaerobes and other aerobes other than *staphylococcus aureus.* Warm compresses and analgesia should be prescribed for pain relief. More severe infections may require hospitalization with intravenous antibiotics, especially in patients with systemic toxicity, diabetes mellitus, or immunocompromise. The patient treated with antibiotics as an outpatient should be referred to a surgeon for follow-up within 24 to 72 h to monitor resolution of signs and symptoms.

The appropriate surgical management of breast abscess is debated. [12] If the patient presents with a fluctuant abscess, one that has drained spontaneously, or if the abscess cannot be treated by antibiotics alone, some recommend a procedure under general anesthesia with wide incision. [12] Commonly, a more conservative incision is recommended. Although some emergency physicians will perform an incision and drainage procedure in the ED, given the potential for multiloculation and the difficulty in achieving adequate analgesia required for appropriate drainage, this procedure is best performed by a breast surgeon under more ideal circumstances. Needle aspiration may be attempted. However, as noted, the abscess is usually multiloculated and the procedure is unlikely to be successful. Some recommend another conservative management approach to breast abscess with ultrasonographic assessment and aspiration. [11]

When evaluating a patient for breast abscess, search for a history of recurrent infection. Case series of women with subareolar abscesses have shown that recurrences occur both in patients treated with antibiotics alone and with incision and drainage in addition to antibiotics. [12] Recurrent infections may best treated by incision of the ducts, at the discretion of the breast surgeon.

LACTATIONAL MASTITIS

Postpartum mastitis is much more common than nonpuerperal mastitis. The pathophysiology involves obstruction of the duct, inspissation of milk, and secondary bacterial invasion. The patient has localized warmth and tenderness of the affected breast. She may even have systemic symptoms and signs, such as fever, malaise, and leukocytosis. The condition is so painful that it may threaten continuation of breast-feeding. Most authors recommend a conservative approach to mastitis in postpartum patients. Analgesia, warm or cold compresses, and increased pumping of the affected breast have all been recommended. The most commonly identified organism is *S. aureus*. Antibiotics are frequently recommended for lactational mastitis, and the best choice is a penicillinase-resistant penicillin. However, if abscess is present, anaerobes may be involved, and clindamycin is a better choice. Lactating mothers question whether it is safe to continue to nurse with mastitis. Clearly, emptying of the breast, either by a mechanical pump or manually, leads to quicker resolution of the condition. The affected breast milk will not harm the baby, although, with breast abscess, ongoing nursing on the unaffected side with expression of milk on the affected side seems to be the best management approach. [13]

MASTITIS VERSUS INFLAMMATORY CARCINOMA

The differential diagnosis of an inflamed breast in a lactating woman includes acute mastitis, abscess, and, very rarely, cancer. Breast infection in a nonlactating woman, on the other hand, is not as common. The differential diagnosis of inflammation includes duct ectasia, nonpuepural breast abscess, and cancer. Inflammatory breast cancer must be distinguished from mastitis. Whereas the breast tissue changes of mastitis are typically well circumscribed, inflammatory breast cancer generally involves at least one-third of the breast tissue, and edges are not well demarcated. [14] There may or may not be a palpable mass in inflammatory breast carcinoma. However, the breast usually increases in size. Due to the diffuse invasion of lymphatic channels by tumor cells, axillary nodal metastases are almost always present at the time of diagnosis. The classically described *peau d'orange* appearance of the breast is due to edema and thickening of the skin. The breast discoloration may have a uniform appearance or be seen in the dependent part of the breast. Nipple retraction, with dermatologic findings, may occur as the disease progresses. Prolonged use of antibiotics in patients thought to have mastitis may cause significant delays in the diagnosis and treatment of breast cancer. A breast specialist should be consulted for chronic breast infections. [14]

BREAST CANCER

The report by the American Cancer Society that one in eight women will develop breast cancer is actually misleading, in that the risk is cumulative, with half of the risk occurring after the age of 65. The risk for African-American women is only 7 to 8 percent. Such statistics contribute to the anxiety experienced by patients with a breast mass. While the specifics of diagnostics, treatment, and prognosis in breast carcinoma are beyond the scope of this chapter and beyond the purview of emergency medicine, the emergency physician should be familiar with general issues concerning risks, cancer type, and therapy in order to counsel patients in the

department.

The etiology of breast cancer is multifactorial. Family history is an important determinant if a mother or a sister develops breast cancer during the premenopausal years or when the disease occurs bilaterally. Genetic mutations have been identified. However, only 5 to 10 percent of all breast cancers are due to such mutations. [2] Specific risks for carrying the BRCA1 and BRCA2 mutations, and the subsequent risks for development of disease have been reviewed by others. [2] Such specifics are best left to genetic counselors or breast specialists, and genetic testing should not be ordered in the emergency department. Less well-defined, and more universally applicable risk factors for breast cancer include nulliparity, late first pregnancy or late menopause, increased fat intake, exogenous estrogen, and ethanol use.

The major subdivisions of breast carcinoma are noninvasive and invasive tumors. Ductal carcinoma in situ (DCIS) is a noninvasive cancer that remains in the ducts without invasion to the surrounding tissue. Presentations of DCIS include a mammographic mass, microcalcifications, nipple discharge, Paget's disease of the breast, or a palpable mass. Treatment options for DCIS include excision, excision and radiation, or mastectomy. The National Surgical Adjuvent Breast Protocol showed decreased recurrence in patients treated with irradiation, as compared to lumpectomy alone, and a recurrence rate equal to that of mastectomy. [15]

Infiltrative ductal carcinoma is the most common type of invasive breast cancer, accounting for 65 to 85 percent of cases. Infiltrative lobular carcinoma accounts for 5 to 10 percent of cases. Its presentation may be a subtle thickening of the breast, rather than a mass. For early-stage carcinomas, the National Cancer Institute Consensus has determined breast conserving therapy to be appropriate. [16] An important meta-analysis of 133 breast cancer trials involving 75,000 women has formed the basis of current recommendations for adjuvant chemotherapy in breast cancer. [17] Risk reduction depends on the patient's absolute risk for recurrence. Axillary node dissection for metastatic spread assessment clarifies the risk; however, 20 to 30 percent of node-negative women die of their disease. Emergency medicine management issues regarding the patient receiving adjuvant chemotherapy for breast cancer are included in Chap. 217, "Emergency Complications of Malignancy".

Evaluation of an Isolated Breast Mass

Detection of a palpable breast mass, solid or cystic, is of great concern to patients and may prompt an emergency department visit. The emergency physician should examine the patient systematically, as described above, and determine whether a true mass exists. The normal glandular breast tissue has a nodular consistency. Both the upper outer quadrant of the breast and the inframammary ridge have increased nodularity. When a nodularity is persistent throughout the menstrual cycle, it may well be a true mass and may represent a number of entities, including cyst, fibroadenoma, fibrocystic change, or carcinoma. Usually, a patient with a breast malignancy presents with a solitary mass in the upper outer quadrant. Poorly defined masses or thickenings may also be cancer. The breast may be indurated, with thickened skin and nipple retraction. A serosanguineous nipple discharge may be present.

The patient should always be referred for mammography and evaluation by a specialist, even if a mass cannot be detected on examination.

Aspiration of solid or cystic breast masses is best left to a specialist or a provider of continuity of care. A necrotizing breast carcinoma may present identically to abscess, and some authors recommend biopsy of the abscess wall at the time of abscess drainage, [9] a procedure clearly beyond the scope of emergency medicine practice. Some authors recommend that the same person who performs the fine-needle aspiration procedure be the evaluating cytopathologist, [18] especially since the feel of the lesion (e.g., the rubbery consistency of a fibroadenoma, the gritty consistency of a malignancy, or the resistant nature of a fibrocystic lesion) has diagnostic importance. In addition, nuances in technique are best left to the specialists (e.g., obtaining a dermal specimen when inflammatory disease of the breast is suspected). The consensus statement of a National Cancer Institute conference has identified the specific indications and training and credentialing recommendations for fine-needle aspiration of breast masses. [19]

107 UROGYNECOLOGIC DISORDERS AND GYNECOLOGIC ONCOLOGY

Michael Londner
Julia B. van Rooyen

This chapter discusses the urogynecologic problems of incontinence, prolapse, and urethral syndrome and reviews the more common gynecologic malignancies and their complications.

INCONTINENCE

Although different authors categorize incontinence in various ways, the four most common groupings are

1. Urinary stress incontinence
2. Urge incontinence
3. Total incontinence
4. Overflow incontinence

The six main anatomic structures contributing to continence are

1. The detrusor muscle, a meshwork of fibers surrounding the bladder.
2. The urethra, a 3- to 4-cm tube surrounded mainly by smooth muscle.
3. The urethral sphincter, which provides the secondary defense to urinary incontinence and about 50 percent of total urethral resistance.
4. Two posterior pubourethral ligaments, which suspend the urethra, holding it close to the pubic bone.
5. The autonomic nervous system, the parasympathetic and sympathetic nerves that supply the lower genitourinary tract. Parasympathetic fibers S_2 to S_4 cause detrusor contraction (cholinergic drugs do the same). Sympathetic fibers T_{1c} to L_2 have a- and b-adrenergic components. Alpha fibers stimulate the bladder neck and urethral contraction while relaxing the detrusor muscle. Beta fibers relax the urethra and the detrusor muscle.
6. Pudendal innervation provides voluntary urethral contraction.

Continence is maintained because intraurethral pressure exceeds intravesical pressure. The levator ani, surrounding fascia, and ligaments help maintain urethral anatomy in times of abrupt changes associated in intraabdominal pressure.

Stress urinary incontinence occurs when urine is involuntarily lost as a result of increased intraabdominal pressure, i.e., when the intraurethral pressure is less than the intraabdominal pressure. It is caused by multiparity, vaginal delivery, pregnancy, menopause, chronic cough (i.e., chronic obstructive pulmonary disease), or other forms of pelvic relaxation. Symptoms include leaking of urine during cough, straining, laughing, sneezing, running, or other causes of increased intraabdominal pressure. Diagnosis involves ruling out infection, neurologic disease, medications, or other systemic illness as possible causes of stress urinary incontinence. A thorough history and physical examination are required, including full vaginal examination with inspection of all the vaginal walls. Further workup by the consulting gynecologist includes stress testing and, if necessary, urodynamic testing. Treatment options are both nonoperative and operative. Nonoperative options include Kegel exercises, estrogen, a-adrenergic stimulants, intravaginal weights, and *urethral plugs.* Operative management is the approach used most commonly. The purpose of incontinence surgery is to correct the defect and restore the anatomy of the urethra. Surgery may be laparoscopic, vaginal, abdominal, or a combination of these. The list of procedures and variations are very long, but the most common include the Marshall-Marchetti-Kranz, Burch, Pereyra, Stamey, and Raz procedures, collagen injections, and sling suspensions.

Urge incontinence occurs in the setting of detrusor muscle instability. The incidence of this entity is around 15 to 20 percent of all women with incontinence but markedly increases with increasing age. It is often seen in conjunction with stress urinary incontinence also known as *mixed incontinence.* The precise etiology of urge incontinence is unknown, but it is seen in the presence of foreign bodies (suture inadvertently placed in the bladder), intravesical stones, and/or infection. Symptoms include urinary urgency, frequency, nocturia, and incontinence. Observing involuntary detrusor contractions during cystometrics or urodynamic studies is diagnostic. Treatment includes pharmacologic agents (e.g., anticholinergics, b-sympathomimetics, musculotrophics, TCAs, or dopamine agonists), bladder training, biofeedback, and functional electrical stimulation.

Total incontinence is usually the result of a urinary fistula. Fistulas usually occur as a result of pelvic surgery, radiation, and in underdeveloped countries, obstetrical injuries. Greater than 50 percent of fistulas occur after a hysterectomy. Patients present with constant, painless leaking of urine and/or recurrent infections. Placing a tampon into the vagina and instilling methylene blue into the bladder helps to make the diagnosis. In the event that a vesicovaginal fistulae is present, the tampon will stain blue. If there is no staining, then indigo carmine is injected intravenously. If the tampon then stains blue, a ureterovaginal fistula is present. An intravenouspyelogram (IVP) should be obtained in either situation to help define the anatomy and rule out other multiple fistulas. Treatment is initiated with insertion of a diverting Foley catheter and may lead to spontaneous healing if the injury is recent but probably will require operative repair.

Overflow incontinence is a result of urinary retention from a hypotonic detrusor muscle. This is seen in the setting of neuropathy secondary to diabetes, spinal cord injuries, outflow obstruction, postoperatively, or lower motor neuron diseases (i.e., multiple sclerosis). Symptoms include postvoid bladder fullness (the "feeling" of never having an empty bladder), small quantities on micturition, and leaking. Diagnosis is made through complete history and physical examination with emphasis on the neurologic examination and determination of postvoid residual volume. Therapy is directed at treating the underlying cause and teaching intermittent self-catheterization.

PROLAPSE

The female pelvic organs, i.e., vagina, uterus, bladder, and rectum, are held in proper alignment by supporting ligaments, fascia, and the pelvic floor muscles. When any or all of these structures fail, the pelvic organs may prolapse within and occasionally protrude through the vagina. This prolapse or displacement may occur singly or more commonly combined. Prolapse can be divided into two broad categories, uterine and vaginal.

Uterine prolapse is graded as first through third degree.

1. *First degree:* The cervix remains within the vagina.
2. *Second degree:* The cervix protrudes beyond the introitus.
3. *Third degree:* This implies descent of the entire uterus outside the vulva, also known as *procidentia.*

This classification system is actually slowly being replaced with staging of all pelvic prolapses through one pelvic organ prolapse quantification (POPQ) profile, now

standardized terminology.

A prolapsed, elongated, inflamed, edematous cervix may be mistaken for uterine prolapse if careful evaluation is not undertaken. Procidentia represents complete failure of all supporting structures. The vagina can prolapse without accompanying uterine prolapse, but the uterus cannot prolapse without bringing the upper vagina with it.

Vaginal prolapse is best subdivided into four basic quadrants:

1. Upper anterior vaginal wall: cystocele (represents weakness of the pubocervical fascia)
2. Lower anterior vaginal wall: urethral displacement
3. Upper posterior vaginal wall: enterocele (usually associated with herniation into the pouch of Douglas)
4. Lower posterior vaginal wall: rectocele

In addition, inversion of the vagina is known as *vault prolapse*. Most commonly prolapse results from attenuation of pelvic fascia, ligaments, and muscles following extensive stretching during vaginal delivery. However, prolapse can occur after easy labor or in the nulliparous woman, in which case it is considered a congenital or developmental weakness of pelvic connective tissue. Virtually any cause of repeated increased intraabdominal pressure may lead to prolapse, including chronic cough, ascites, heavy lifting, or habitual straining on defecation. These mechanisms should raise concern to search for occult malignancy, e.g., lung cancer in a person with chronic cough or colonic cancer in someone straining to defecate. Atrophy of the supporting tissue plays a significant role in initiation or worsening of this condition.

The degree of symptomatology is quite variable. The most common complaint is a "feeling of heaviness or fullness in the pelvis." Others may describe "something falling out." More diffuse complaints include backache, pelvic discomfort, and discomfort or straining with defecation or urination. Cystocele may present with frequency, urgency, incontinence, or ultimately, retention (especially if displacement causes kinking of the ureter), whereas rectocele may present with difficulty evacuating the rectal vault.[1] A characteristic not to be overlooked is the worsening of symptoms with prolonged standing followed by alleviation when lying down. Women may become extremely tolerant of prolapse symptoms and present with advanced complications such as infection of the prolapsed segment, decubitus ulceration, bleeding, and carcinoma of the cervix.

Diagnosis revolves around a thorough history and physical examination including vaginal examination. Use of a Sim's speculum or separating the two halves of the standard Grave's speculum and using the posterior blade allows for adequate vaginal inspection. Depress the posterior vaginal wall and ask the patient to bear down. This will demonstrate descent of the anterior vaginal wall in the setting of cystocele and/or urethral displacement. Reversing the speculum to elevate the anterior vaginal wall allows visualization of the intruding posterior wall during straining demonstrative of enterocele or rectocele. A rectal examination often will help to distinguish rectocele from enterocele.

Treatment modalities are grouped into nonoperative and operative.[2] The patient's age, future fertility, degree of sexual activity, and degree of prolapse must be considered in defining a management plan. Nonoperative treatments generally are tried first if future childbearing is desired, the degree of pathology is mild, or the patient is a poor surgical candidate. These options include Kegel (pelvic floor strengthening) exercises, pessaries, estrogen, and electrical muscle stimulation. Operative management options are used in patients failing nonoperative treatments, those with severe prolapse, and those who are symptomatic. The overall goal of surgery is to return the pelvic anatomy to as close to normal as possible. Procedures include anterior/posterior colporrhaphy, enterocele repair, hysterectomy, obliteration of the vaginal vault, urethropexies, urethral sling procedures, and/or suspension of the vaginal vault.

URETHRAL SYNDROME

The term *urethral syndrome* describes a complex of symptoms involving the lower urinary tract including urinary frequency, urgency, dysuria, suprapubic discomfort, postvoid fullness, incontinence, and/or dyspareunia with no objective findings of urologic pathology. Grandmultiparity, delivery without episiotomy, two or more abortuses, and pelvic relaxations appear to predispose.[3] The true incidence of urethral syndrome in the United States among adult women is unknown, as is the cause. The most widely accepted etiology of this enigmatic syndrome is an inflammatory process. Other etiologies include psychogenic factors, *Chlamydia* or *Mycoplasma* infection, atrophic urethritis in the perimenopausal/postmenopausal patient, fastidious organism bacterial infection, urethral stenosis and/or spasm, allergy, neurogenic, and trauma during intercourse. The diagnosis is one of exclusion founded on a thorough history and physical examination, followed by urine microscopic examination and culture. Referral is often obtained then for dynamic cystourethroscopy and urodynamic studies. Treatment encompasses many modalities because the etiology is uncertain.[4] The first approach is often pharmacologic, with antibiotics (doxycycline) or anticholinergics, followed by instillation of dimethyl sulfoxide, periurethral injection of triamcinolone, serial urethral dilation with or without massage, cryosurgery (internal urethrotomy and urethrolysis), bladder neck reconstruction, biofeedback, and psychotherapy. Recent research has led to the use of urethral suppositories with multiple medications including lidocaine, hydrocortisone, and topical estrogens. Lastly, supportive therapy is helpful in all patients.

GYNECOLOGIC MALIGNANCIES

The female reproductive tract cancers account for 13 percent of all cancers in women, following breast, lung, and colon cancer. Symptoms occurring as a result of natural progression of malignancy include bleeding, nausea and vomiting, obstructive uropathy, failure to thrive, and/or paraneoplastic syndromes. Treatment with surgery, chemotherapy, and radiation can themselves cause complications. Surgical complications include bowel and urogenital tract injury, thromboembolism, and bleeding. Chemotherapy-related complications include anemia, febrile neutropenia, thrombocytopenia, neuropathy, uropathy, nausea and vomiting, extravasation injury, and stomatitis. Radiation-related complications focus mainly on injury to the gastrointestinal and genitourinary tracts.

Ovarian Cancer

Cancers of the ovary and fallopian tube are discussed together because of the rarity of fallopian tube cancer and similarity in gross and microscopic appearance, pattern of spread, and disease process. Approximately 26,800 women were diagnosed with ovarian cancer in 1997 in the United States, with about half dying from the disease. A woman has a 1 to 2 percent chance of developing ovarian cancer in her lifetime with no family history. Peak incidence occurs between the ages of 55 and 65 although some types occur earlier. The following risk factors have been identified: infertility, low parity, high-fat diet, lactose intolerance, history of breast or colon cancer, and a family history of site-specific ovarian cancer or its associated syndromes. Oral contraceptives seem to be protective against ovarian cancer. Cancers of the ovary and fallopian tube come in three main histologic types: epithelial (85 percent), germ cell tumors (10 percent), and sex-cord stromal tumors (5 percent). Certain epithelial tumors may involve one ovary, and peak incidence is 10 to 15 years younger. Germ cell tumors include dysgerminomas, endodermal sinus tumors, embryonal carcinomas, immature and mature teratomas, choriocarcinoma, and mixed germ cell tumors. These are usually found in women under the age of 30. Sex-cord stomal tumors are usually divided into female and male types. Granulosa cell tumors secrete estrogen and may result in endometrial hyperplasia and/or cancer with average age of incidence about 50 years. Sertoli-Leydig tumors produce androgens, often resulting in masculinization and often occurring at age 25 years.

Patients often present after the disease has spread beyond the ovary, with symptoms such as abdominal pain, bloating, ascites, early satiety, weight loss, and/or respiratory distress secondary to effusion. It is most important to recognize that a woman presenting to the emergency department with ascites has a gynecologic malignancy until proven otherwise. As a first diagnostic step after pelvic examination, computed tomographic (CT) scanning can be done in the emergency department. Aspiration of ascitic fluid should not be done.

The single most important factor in the large death rate is the advanced stage at diagnosis. Diagnosis and staging of ovarian cancer are based on surgical evaluation. The International Federation of Gynecology and Obstetrics (FIGO) devised an extensive and universal staging classification. In summary (a simplification),

Stage I: Growth limited to one or both ovaries
Stage II: One or both ovaries with pelvic extension
Stage III: One or both ovaries with growth outside the pelvis
Stage IV: One or both ovaries with distant metastasis

Treatment of ovarian cancer may involve surgery, chemotherapy, and/or radiation therapy.

Uterine Cancer

Uterine cancer is the most common gynecologic malignancy. In 1997, 32,800 cases were diagnosed. The average age of incidence is 58 years of age. Endometrial cancer is the most common histologic type, and of these, the most common type is adenocarcinoma of the endometrium. Other histologic types of endometrial cancer that occur less frequently are papillary serous, clear cell, adenosquamous, and adenocanthoma. Sarcomas are malignancies of the uterine muscle. They behave very aggressively and have a worse prognosis than endometrial cancer.

Multiple risk factors have been associated with endometrioid adenocarcinoma of the uterus such as early menses, late menopause, nulliparity, obesity, diabetes, hypertension, and unopposed estrogen use. The use of progestins has drastically reduced the risk of endometrial cancer by 50 percent. Tamoxifen, an antiestrogen that competes with estrogen at its receptor site, has been shown to increase the risk of adenocarcinoma of the uterus.

The most common symptom of endometrial cancer is bleeding. Seventy-five percent of these cancers occur in postmenopausal patients, thus presenting with postmenopausal bleeding. Sarcomas, however, may present with bleeding but also with abdominal pain or prolapse of friable tissue through the cervical os.

The diagnosis of uterine cancer is made by sampling the endometrium. This may be achieved through office endometrial biopsy, a dilatation and curettage specimen, or hysteroscopy. A pathologic specimen must be obtained for proper diagnosis and further treatment planning. A sonogram measuring the endometrial stripe greater than 10 mm, in post-menopausal women, must be evaluated.

Staging for uterine cancer is as follows: (summary of staging)

Stage I: Confined to the uterine corpus
Stage II: Involvement of the cervix
Stage III: Extends to uterine serosa, ovary, vagina, and paraaortic/pelvic lymph nodes
Stage IV: Involvement of the bladder/bowel, inguinal/intraabdominal lymph nodes

Staging is surgical. Treatment involves surgery and also may include radiation and chemotherapy.

The vaginal cuff, vagina, and pelvis are common sites for recurrence. Patients with recurrence often present with vaginal bleeding, vaginal or pelvic masses, or uremia secondary to ureter obstruction. Pulmonary metastases are less common in recurrent uterine cancer but still need to be considered, in a women presenting with respiratory symptoms and a history of uterine cancer.

Cervical Cancer

Currently, 15,800 new cases of cervical cancer are diagnosed per year. The average age at the time of diagnosis is 54. Risk factors include early coitus, multiple sexual partners, high-risk male partners, smoking, human papillomavirus, and HIV infection (or other immunosuppressive states). The diagnosis of cervical cancer in an HIV-positive patient is now considered an AIDS-identifying illness. Smoking increases the risk of cervical cancer in women by 3.5 times, and even passive smoke increases the risk threefold. Approximately 90 percent of cervical cancers are of squamous histologic type, but adenocarcinoma, which comprises 5 to 10 percent of cervical cancers, is increasing and has a worse prognosis.

Cervical cancer, in decreasing order, most often presents with postmenopausal bleeding, abnormal vaginal bleeding, postcoital bleeding, vaginal discharge, pain, or leg swelling. Diagnosis must be made by cervical biopsy. Often, on speculum examination, a mass or ulcerative lesion is seen on the cervix. A Pap smear must never be done if a suspicious lesion is seen! Instead, the gynecologic consultant should be called to perform a biopsy, cone biopsy, or loup electrosurgical excision procedure (LEEP).

Staging of cervical cancer, as opposed to uterine and ovarian cancer, is performed clinically. Once a diagnosis is made by biopsy, a thorough physical examination must be performed, including an examination under anesthesia (cystoscopy and proctoscopy) of the parametrium, pelvic sidewalls, bladder, and rectum, and a chest x-ray. These results are combined to clinically stage the individual. The tumor tends to spread by direct extension causing parametrial thickening and by lymphatic spread to obturator nodes then to pelvic and paraortic nodes.

The staging of cervical cancer is complex, but the following is a brief overview:

Stage I: Confined strictly to the cervix
Stage II: Beyond the cervix but not to the pelvic sidewall
Stage IIA: No parametrial involvement
Stage IIB: Parametrial involvement
Stage III: Extends to pelvic sidewall
Stage IV: Beyond the true pelvis, bladder or rectum involvement

Treatment of cervical cancer requires a team of gynecologic oncologists and radiation oncologists. In stage I to IIA cervical cancer, radical hysterectomy or radiation therapy has demonstrated similar 5-year survival rates (90 percent). Any persons with stage IIB or greater must be treated with radiation.

Recurrent or persistent cancer causes devastating problems for patients, their families, and clinicians. Patients have a 1-year survival rate of 15 percent and a 5-year survival rate of 5 percent when recurrence occurs. Recurrent cervical cancer can be treated palliatively or with some hope of a cure. Curable lesions are those which are easily resected, i.e., single lesions located at the vaginal apex or in the lung or lesions located centrally in the pelvis without lymph node involvement. Curative, exenterative surgery is successful 50 to 60 percent of the time for patients with central recurrences. Pelvic exenterative surgery is very extensive surgery removing the bladder, rectum, uterus (if not already done), and vagina. A colostomy is required, and a neovagina and urinary diversion are created. Recurrent cervical cancers often present to the emergency department with vaginal bleeding, uremia secondary to ureter obstruction or invasion, deep venous thrombosis, leg swelling, or pain.

Vaginal Cancer

Vaginal cancer accounts for only 1 to 2 percent of all gynecologic malignancies. The true definition of primary vaginal cancer is that it must arise from the vagina and not be an extension or metastasis from the cervix or vulva. The main histologic type is squamous cell carcinoma, which comprise 80 percent of all vaginal cancers. Squamous lesions usually occur in postmenopausal woman, whereas other histologic types (rhabdosarcoma, endodermal sinus tumor, adenocarcinoma, and clear cell adenocarcinoma from diethylstilbestrol) usually occur in younger women. The last diethylstilbestrol (DES) administration was around 1971, which would place these women in their forties. The mean age of occurrence for vaginal cancer is 60 to 65 years of age. Epidemiologic factors contributing to the occurrence of vaginal cancer are immunosuppression, chronic irritation (long-term pessary use or prolapse of female organs), decreased socioeconomic status, radiation for cervical cancer, hysterectomy for dysplasia, multiple sexual partners, or DES exposure. The tumor usually presents in the posterior upper third of the vagina. Abnormal vaginal bleeding is the presenting symptom 50 to 75 percent of the time. Some complain of abnormal discharge or postcoital bleeding.

Staging for vaginal cancer is summarized as follows:

Stage I: Vaginal wall involvement
Stage II: Parametrial involvement
Stage III: Pelvic wall involvement
Stage IV: Bladder/rectum or beyond pelvic involvement

Most vaginal cancers are best treated with radiation therapy. The survival rate when radiation is used is 93 percent at 5 years and 87 percent at 10 years. Most

recurrences occur within 3 years, but later recurrences are also possible.

Embryonal rhabdomyosarcomas (sarcoma botryoides) occur in children less than 5 years of age and present with vaginal bleeding, discharge, or grapelike masses protruding from the vagina. These cancers respond very well to the chemotherapeutic regimen of vincristine, dactinomycin, and cyclophosphamide, with either surgery or radiation. Complications associated with vaginal cancers are bleeding, infections, fistulas, or complications from chemotherapy, radiation, or surgery.

Vulvar Cancer

Vulvar cancer is responsible for only 1 to 4 percent of all gynecologic malignancies and less than 1 percent of all cancers. Approximately 500 women die from vulvar cancer annually in the United States. Seventy-five percent of women diagnosed with vulvar cancer are greater than 55 years of age, with a third of them greater than 75 years of age. The most common histologic type is squamous cell carcinoma (90 percent), followed by melanoma, basal cell carcinoma, adenocarcinoma, sarcoma, Bartholin gland tumors, and metastasis. Luckily, the prognosis is generally good because recognizable symptoms allow for early diagnosis. The most common presenting symptoms include a mass, pruritus, pain, or ulceration (in decreasing order of frequency). The cause for vulvar cancer is still unknown, but there have been associations of vulvar cancers with other cancers of the anogenital tract. Human papillomavirus (HPV) types 16, 18, 31, 35, and 39 have all been suggested as causative factors.

It seems that the etiology is multifactorial, and HPV alone is not the culprit. Other possibilities include immunodeficiency, vulvar dystrophy, smoking, and exposure to aniline dyes such as benzene. Multicentric lesions are seen more commonly in younger women, whereas unifocal lesions are seen most often in older women. On physical examination, the lesions may appear white, pigmented, raised, thickened, nodular, or ulcerative. A vulvar biopsy should be performed liberally in women with any suspicious lesions. Treatment depends on the stage at the time of diagnosis. More recent years have welcomed the advent of more conservative treatment modalities. The treatment of choice is surgery with adjuvant radiotherapy in more advanced stages.

Staging is summarized as follows:

Stage I: Confined to the vulva or perineum and <2 cm
Stage II: Confined to vulva or perineum and >2 cm
Stage III: Any size lesion spread to lower urethra, vagina, or anus with unilateral positive nodes
Stage IV: Involvement of the upper urethra, bladder, rectum, or pelvic bone with positive bilateral nodes

Radical subtotal vulvectomy is the treatment of choice for patients with lesions less than 2 cm. The use of postoperative radiation may decrease the incidence of recurrence and improve survival in women with lesions larger than 2 cm and positive lymph nodes. The morbidity from surgery is groin wound breakdown and lymphedema from lymph node dissections. Recurrent vulvar cancer may be local, distant, or involve lymph nodes. Patients often present with bleeding, lymphedema, deep venous thrombosis, or metastasis (usually to bone or lung).

Gestational Trophoblastic Disease

Gestational trophoblastic disease (GTD) is a disease of trophoblastic placental tissue. GTD represents a spectrum of diseases ranging from benign to frank malignancy.[5] There are four forms of this process:

1. Hydatidiform mole
2. Invasive mole
3. Choriocarcinoma
4. Placental site tumors

The incidence of molar pregnancy is 1 in 2000 pregnancies; however, the incidence is much higher in Asian women, at 1 in 800. The risk of developing a second molar pregnancy is 1 to 3 percent, sometimes approaching 40 percent. Molar pregnancy is seen with a bimodal distribution. Persons younger than age 20 and older than age 40 are at greatest risk. GTD may be benign or malignant and, when malignant, can be divided into metastatic and nonmetastatic.

The benign form of this disease is hydatidiform mole, either partial or complete. This following summary table includes some of the major differences between partial and complete moles (Table 107-1).

	Complete Mole	Partial Mole
Symptoms	90% present with vaginal bleeding, 30% with uterine size greater than dates, 15% bilateral theca–lutein cyst enlargement, 10% hyperemesis, 1% preeclampsia (<20 weeks), hyperthyroidism, trophoblastic embolization, nonfetal heart tones auscultated	90% present with incomplete or missed abortion, 70% with vaginal bleeding, all the symptoms of complete abortion may be present but are very rare
Diagnosis	Ultrasonography reveals "snow storm" appearance coupled with a high βhCG level	Usually on histologic examination from tissue obtained from a missed or incomplete abortion

TABLE 107-1   Some Major Differences between Partial and Complete Moles

Treatment of hydatidiform mole is suction curettage or hysterectomy. Hyperthyroidism or hypertension must be stabilized prior to surgery. Follow-up is essential because dilation and curettage alone is curative in only 80 percent of patients, leaving 20 percent at risk for persistent trophoblastic disease.

Gestational trophoblastic neoplasm (GTN) includes invasive mole and choriocarcinoma. These tumors can progress to malignancy and ultimately death if left untreated. Luckily, they are highly responsive to chemotherapy, which in turn leads to a cure rate of 90 percent.

Invasive mole is the myometrial invasion of the hydatidiform mole. Common sites for metastasis of this cancer are the lungs and vagina, which occurs in 15 percent of patients. Invasive moles occur in 1 of 15,000 pregnancies, and 15 percent of hydatidiform moles result in invasive moles. Diagnosis is confirmed by consistently elevated or rising beta human chorionic gonadotropin (hCG) levels after a molar evacuation.

Choriocarcinoma is characterized by atypical trophoblastic hyperplasia with direct and vascular invasion into the myometrium and distant sites, most commonly the lungs, brain, liver, pelvis, or vagina. The incidence of choriocarcinoma is approximately 1 per 40,000 pregnancies. Twenty-five percent follow abortion or ectopic pregnancies, 25 percent are seen with term gestations, and the remaining 50 percent result from hydatidiform moles. However, only 2 to 3 percent of hydatidiform moles result in choriocarcinoma.

Symptoms of GTN are continued bleeding after dilation and curettage for hydatidiform mole or bleeding after a pregnancy event (e.g., vaginal delivery, cesarean section, ectopic pregnancy, miscarriage, or abortion). Patients with metastasis may present with dyspnea, cough, chest pain, central nervous system abnormalities, or vaginal mass. The most common site for metastasis is the vagina, followed by the lung.

Treatment depends on the presence of metastasis. Patients with no metastatic disease who wish to preserve their fertility are treated with single-agent chemotherapy, methotrexate, or dactinomycin; otherwise, hysterectomy is the treatment of choice. This initial therapy leads to cure in 85 to 90 percent of patients. When metastatic

disease is present, combination chemotherapy is given.

COMPLICATIONS

The complications of gynecologic malignancies are related to the natural progression of disease, surgery, chemotherapy, or radiation. Any combination of these complications can occur depending on the type and stage of neoplasm and treatment modality.

The complications related to the natural progression of disease often represent the symptoms that help to diagnose the disease. These include, but are not limited to, genital tract bleeding, gastrointestinal obstruction, masses or ascites, fistulas (both genitourinary and gastrointestinal), obstructive uropathy, metastasis, lymphedema, and hypercoagulable states leading to deep venous thrombosis or pulmonary embolism.

By far the most common oncologic complication (most frequently seen with cervical or uterine cancer) is bleeding. It may be acute or chronic, massive or minimal, external or internal. Sources include friable tissue, tumor erosion into iliac or femoral vessels, adnexal mass rupture, or coagulopathies that develop secondary to chemotherapy or radiation. Assessment and management begin with the principles of emergency care. Then a thorough history and physical examination including prior diagnoses and treatment should be undertaken to find the likely source and cause of bleeding. Where externally accessible sites of bleeding occur, apply direct pressure. If this fails to control the bleeding, next use topical silver nitrate or Monsel's solution. If bleeding persists, topical absorbable hemostat material can be applied such as Gelfoam, Instal, or Surgicel. Where the vagina is the source of bleeding, vaginal packing may become necessary. Use a long strip of continuous gauze, and place a Foley catheter to prevent retention. Regardless of the causes of bleeding, after stabilization, the gynecology service should be consulted.

Patients occasionally present with abdominal distention and discomfort. This often is concomitant with other complications of cancer and therefore may be accompanied by early satiety, nausea, vomiting, anorexia, weight loss, constipation or diarrhea, urinary frequency, urgency, incontinence, dyspnea, or orthopnea. As always, the first step is complete history and physical examination, including both pelvic and rectal examinations. Diagnostic testing may reveal worsening of known disease, recurrence of cancer, new cancer, torsion of a large ovary, bowel perforation, or intraabdominal hemorrhage. Consultation with a gynecologist, gynecologic oncologist, or surgeon is indicated.

Gastrointestinal complications include obstructions and fistulas. Obstruction is common as a progressive symptom of malignancy, especially with ovarian and uterine tumors that are associated with enlarging masses or ascites. The resulting obstruction may be mechanical or due to tumor ileus from encasement of the nerve plexus leading to dysfunction of a segment of bowel. Patients often present with nausea, vomiting, early satiety, abdominal pain, distention, constipation, and/or obstipation. The normal management scheme for obstruction applies (as discussed in Chap. 75 in more depth). Surgical palliation may give temporary symptomatic relief, but recurrence rates are extremely high. Consultation with a gynecologist, gynecologic oncologist, or surgeon is indicated to discuss and provide permanent proximal decompression and supplemental nutrition.

Fistula formation occurs secondary to bowel encasement or obstruction. Fistula may drain to the abdominal wall, peritoneal cavity, vagina, uterus, or bladder. Instillation of colored medium (e.g., charcoal, food dye in tube feeds), upper gastrointestinal series, barium enema, or a fistulogram often aids diagnosis. Consultation with a gynecologist, gynecologic oncologist, or surgeon is indicated to determine the best treatment.

Urinary tract complications also include obstruction and fistula. Ureteral obstruction classically is seen in cervical cancer but also occurs with progression or recurrence of other pelvic malignancies. Radiation also may cause permanent scarring of the lumen leading to obstruction. Patients may present with acute renal failure and require percutaneous or cystoscopic emergent decompression. A vesicovaginal or ureterovaginal fistula may develop at the site of untreated cancer or recurrent cancer or after radiation therapy. Fistulas follow radical pelvic surgery about 1 percent of the time and radiation therapy approximately 2.6 percent of the time.

Chronic mild lymphedema of the lower extremities often follows inguinal node resection. Pedal lymphedema is seen after pelvic radiation therapy. Aside from the associated discomfort, the greatest concern is deep veinous thrombosis, especially if lymphedema is unilateral. Duplex ultrasound is necessary. Lymphedema is treated supportively with elevation and support stockings.

Thromboembolic disease has long been associated with gynecologic malignancies and is discussed in Chap. 55.

Most of the side effects of chemotherapeutic agents are predictable and can be lessened with adjuvant medications. Risk factors for poor tolerability of chemotherapy are advanced age, advanced disease, poor nutritional status, or severe systemic involvement. Chemotherapeutic agents may have debilitating effects on many organ systems (Table 107-2).

TABLE 107-2   Chemotherapeutic Agents and Their Toxicities

The complications related to radiation are temporally divided into acute and chronic. The chronic manifestations may be further broken into gastrointestinal, genitourinary, and pulmonary. Acute findings include nausea, vomiting, diarrhea, cystitis, nephritis, pneumonitis, and myelosuppression. Gastrointestinal symptoms are often self-limiting and are controlled with supportive therapy including antiemetics, antidiarrheals, and avoidance of high-fiber diets. Newer studies point to glutamine-rich diets, and the use of sucralfate may further reduce diarrhea. The genitourinary symptoms range from infection to hemorrhagic cystitis with extreme pain. Treatment of these symptoms includes adequate hydration, surveillance for infection, and bladder irrigation with analgesia or steroids. Resolution of myelosuppression is often spontaneous and begins after radiation has been completed.

Chronic findings are divided into gastrointestinal, genitourinary, and pulmonary. The most common complication is radiation enteritis, which presents with chronic diarrhea, malabsorption, or digestive difficulty. Other chronic gastrointestinal complications include strictures, fistulas, perforations, obstructions, and hematochezia. These findings often occur within 2 years of treatment. Management should be a collaborative effort between the oncologist, surgeon, and gastroenterologist. Emergency management includes adequate hydration and symptomatic relief. Genitourinary complications include incontinence, fistula formation, stricture formation, and hemorrhagic cystitis. Incontinence and fistulas were discussed earlier. The most severe complication of stricture formation is obstructive uropathy. This always should be considered as recurrence of disease until proven otherwise and as a result of radiation by diagnosis of exclusion. Both hemorrhagic cystitis and stricture require cystoscopy for evaluation. An oncologist and urologist should institute appropriate treatment.

Lastly, secondary malignancies may arise from radiation therapy. This results from the local nonmalignant tissue being exposed to ionizing radiation. The resulting damage to genetic material leads to mutation that is the presumed mechanism for carcinogenesis. The secondary malignancy is often observed years after the initial radiation therapy, and accuracy in predicting its occurrence is difficult at best.

This chapter provides an overview of the common complications of gynecologic procedures that are likely to lead to an ED visit.

Because of convenience, cost effectiveness, and apparent safety, the number of ambulatory surgeries continues to increase. The indications appropriate for ambulatory surgery also continue to increase. These trends are accompanied by a decrease in the length of hospitalization following major gynecologic surgery. Unanticipated hospital admission after ambulatory surgery occurs in approximately 1 percent of cases and is an important measure of outcome. [1] Gynecologic outpatient surgery has been associated with an unscheduled admission rate of 3.64 percent, with postoperative emesis being the most common reason for admission.[2]

HISTORY AND PHYSICAL EXAMINATION

The most common reasons for emergency department visits during the postoperative period following gynecologic procedures are pain, fever, and vaginal bleeding. A focused but thorough evaluation should be performed. The history should include the surgical procedure performed (abdominal versus vaginal), the reason for it, time of symptom onset and its proximity to the surgery, complications already experienced, patient's postsurgical history, and medications prescribed. The interval between the surgery and the onset of symptoms is very important in determining their cause. For example, most cases of early postoperative fevers are not infectious, and causes may include pulmonary atelectasis, hypersensitivity reactions to antibiotics, pyogenic reactions to tissue trauma, or hematoma formation.

Relevant examination of all appropriate systems should then be performed. It should not be assumed that the etiology of the complaint is gynecologic. Other potential explanations of the symptoms should be investigated. The surgical wound should be examined, and a pelvic examination should be performed, including both a sterile speculum and a bimanual examination. The sterile speculum examination should visualize the cervix or, if it is absent, the vaginal cuff, and any evidence of bleeding, discharge, erythema, or cuff or labial cellulitis should be noted. Cervical cultures should be considered. Bimanual examination after a vaginal or abdominal hysterectomy should evaluate for tenderness, masses, and an intact cuff. Following hysteroscopy or dilation and curettage, cervical motion, uterine, and adnexal tenderness should be evaluated. A rectal examination should always be performed to evaluate tenderness or masses.

Laboratory studies should be directed towards the patient's complaints. A complete blood count with a manual differential count is almost always indicated. A serum b human chorionic gonadotropin level should be obtained for all women of childbearing potential. A catheterized urine specimen, along with urine, blood, wound, and cervical (if present) cultures, should be obtained if the patient is febrile. A chemistry panel may be necessary to evaluate hepatic and renal function.

Imaging procedures are often necessary. A chest radiograph can confirm pneumonia or inappropriate air under the diaphragm. Supine and erect abdominal series help confirm bowel obstruction. Pelvic sonogram remains the gold standard for visualizing the pelvic structures. However, a computed tomography (CT) scan may be necessary, especially if an abscess is suspected.

COMPLICATIONS OF ENDOSCOPIC PROCEDURES

Laparoscopy

Both diagnostic and therapeutic gynecologic laparoscopy accomplished by passing a rigid endoscope through a trocar that is inserted bluntly through a small subumbilical incision into the abdominal cavity after a Veress needle has been used to insufflate the abdomen with carbon dioxide. The pneumoperitoneum must be sufficient to displace the bowel and is maintained throughout the surgery. Additional trocars can be placed so that other accessories can be used during the surgery. Laparoscopy is almost always an ambulatory surgical procedure and is performed under general anesthesia with endotracheal intubation.

There are numerous indications for gynecologic laparoscopy, ranging from diagnosing gynecologic disorders (e.g., endometriosis or ectopic pregnancy) to performing complex gynecologic surgery. The most common surgical procedure in the United States is female sterilization, and more than 60 percent of the procedures are performed laparoscopically. In one study, 82 percent of diagnostic laparoscopies were performed because of infertility. [3] Laparoscopy is also used for lysis of adhesions, CO_2 laser ablation of endometriosis, uterine surgery (including myomectomy), tubal surgeries (including salpingectomy), ovarian surgery (including oophorectomy and oophorocystectomy), paraovarian cyst excision, laparoscopic vaginal hysterectomy, and retropubic urethroplexy.

All of these procedures entail the same potential complications, but more complex surgeries carry considerably more risk. The incidence of major complications in the United States for laparoscopy may be as low as 0.22 percent. [4] In 1993, the American Association of Gynecologic Laparoscopists reported complications for 45,042 procedures as follows: hemorrhage 1 percent, unintended laparotomy 1 percent, blood transfusion for hemorrhage 0.45 percent, and bowel or urinary tract injury 0.41 percent. In 1996, the overall incidence of complications in major operative laparoscopy was reported as 10.4 percent. [5] This rate is still significantly less than the 25 to 50 percent overall complication rate of abdominal surgery, such as hysterectomy or oophorectomy through abdominal incisions, although data related to the two approaches are not directly comparable because of other factors that may mandate a traditional surgical procedure.

The major complications associated with laparoscopy are thermal injury of the bowel, perforation of a viscus, bleeding or other vascular injury, ureteral or bladder injuries, and incisional hernia or wound dehiscence.

Thermal injury is the most serious potential complication. While many significant complications of laparoscopy are recognized in the operating room under direct visualization, patients with thermal injury may not develop symptoms for several days and up to several weeks postoperatively. Various series have reported the incidence of electrothermal injuries to be in the range of 0.5 to 3.2 per 1000 cases. Patient presentations may include bilateral lower quadrant pain and tenderness, fever, elevated white blood cell count, or peritonitis. Plain radiographs may show an ileus or free air under the diaphragm. Air or insufflated CO_2 should be completely absorbed by the third postoperative day. Patients with greater than expected pain after laparoscopy should be considered to have a bowel injury until proven

otherwise. Early gynecologic consult is critical if a thermal injury is suspected.

Traumatic injury to the bowel is usually less serious than thermal injury. The very small diameter Veress needle is usually the cause of a bowel perforation, which is recognized on withdrawal of the needle. A sharp trocar may cause more damage. Gastric perforation may result, usually due to stomach distention from aerophagia or a difficult intubation. The large or small bowel may also be perforated. These injuries are usually noted during the operation. On rare occasions, perforation may occur through a single loop of bowel adherent to the anterior abdominal wall. Complications include peritonitis, abscess, enterocutaneous fistula, and septic shock.

Vascular injury occurs between 0.1 and 6.4 per 1000 cases.[6] While such injuries may be immediately life threatening, they are almost universally recognized during the operation. Patients may present with a postoperative hematoma. Local compression, if feasible, is the initial treatment. If the mass enlarges or signs of hypovolemia occur, the wound must be explored by the gynecologist.

Bladder and ureteral injuries may occur from mechanical or thermal trauma. Trocar or dissection injuries to the bladder are typically recognized intraoperatively. Thermal injuries, however, may not be initially apparent and may present with peritonitis or fistula. The diagnosis of a ureteral injury is usually delayed. Thermal injury may present up to 14 days postoperatively with abdominal or flank pain, fever, and peritonitis. There may be an elevated white blood cell count, and an intravenous pyelogram (IVP) shows extravasation of urine or a urinoma. Mechanical obstruction of the ureter from sutures or staples may be recognized intraoperatively by direct visualization but may present up to 1 week postoperatively with fever and flank pain. An IVP helps define the site and degree of obstruction.

Incisional hernias and dehiscence are rare complications after laparoscopy. Incisional hernias are more common when defects larger than 10 mm are made. Intestinal hernia may develop within the first postoperative week. Patients may be asymptomatic or may present with pain, mass, evisceration, or signs and symptoms of a mechanical bowel obstruction. Fever may occur if the bowel is incarcerated, and peritonitis may develop following bowel perforation. Dehiscence usually involves protrusion of the omentum, and, in rare cases, the small bowel passes through the opening. Immediate incisional repair by a gynecologist is usually sufficient; however, a laparotomy may be necessary if the bowel is incarcerated or perforation is a risk.

Wound infection after laparoscopy is uncommon and often not a serious complication. Most are minor skin infections that can be managed expectantly, with oral antibiotics, or with drainage. The risk of infection after laparoscopy is much lower than that after abdominal or vaginal surgery. Excluding minor skin infections, pelvic infection is reported in fewer than 1 in 1000 cases. Pelvic cellulitis and abscess can occur, and severe necrotizing fasciitis, while rare, has been reported. Most infections are probably secondary to a subacute coexisting infection present prior to the procedure or secondary to skin contamination. Broad-spectrum antibiotics typically provide a rapid response.

Hysteroscopy

Hysteroscopy is the direct visualization of the uterine cavity using a rigid or flexible fiberoptic instrument. Hysteroscopy can be done as an office procedure under intravenous sedation or in an operating room under general anesthesia, spinal or epidural anesthesia, or intravenous sedation. Hysteroscopy is done for both diagnostic and therapeutic purposes. The most common indication for hysteroscopy is abnormal vaginal bleeding. Other indications include uterine leiomyomata, intrauterine adhesions, proximal tubal obstruction, removal of intrauterine devices, müllerian anomalies, and infertility evaluation. Therapeutic applications include directed biopsies, removal of small myomata, and endometrial ablation for menorrhagia. Complications of hysteroscopy occur in approximately 2 percent of cases and include fluid overload, uterine perforation with possible damage to intraabdominal organs, infection, toxic shock syndrome, anesthesia reaction, postoperative bleeding, and embolism.[7]

Fluid overload is rare but can occur from absorption of electrolyte and nonelectrolyte solutions during lengthy procedures. The entry of dextran into the circulation can lead to pulmonary edema and disseminated intravascular coagulation. For this reason, no more than 500 mL dextran should be used during a procedure. A lack of recovery of distention medium in excess of 1000 mL also places the patient at risk for fluid overload. If fluid overload is suspected, hyponatremia should be anticipated. A rapid decrease in the serum sodium level can result in generalized cerebral edema, seizures, and death.

Uterine perforation is a relatively common complication. A midline uterine perforation generally does not have significant sequelae. A lateral perforation may lacerate uterine vessels and cause substantial bleeding. Most often, the perforation is noted at the time of surgery, and a laparoscopy is done to investigate for bleeding and/or damage to bowel or bladder. If the complication is not noted at the time of surgery, the patient may present with peritoneal signs if the bowel has been injured or pain and/or bleeding if the vessels were lacerated.

Infection is very rare and most commonly occurs in patients with concurrent genital tract infections. Endometritis or even toxic shock can result.

Postoperative bleeding may be uterine or cervical in origin. Cervical lacerations may be caused by forceful dilation or tears from the tenaculum. Uterine bleeding can result from resection procedures. After hemodynamic stabilization of the patient, the gynecologist can place a Foley or balloon catheter into the uterine cavity and fill it with approximately 10 to 15 mL of water or saline solution. One technique is to remove one-half the fluid from the balloon after 1 h and the other half after 2 h. If bleeding remains stopped, the patient can usually be discharged. If bleeding persists, the patient should be admitted. The catheter is reinflated and left overnight, or occasionally reexploration is required.

Embolism is the most feared complication of using CO_2 gas as a distention medium. The risks of such an occurrence are low when the principles of low flow and low pressure are followed.

COMPLICATIONS RELATED TO MAJOR ABDOMINAL SURGERY

Complications from major abdominal procedures that lead to ED visits usually occur at least 3 days postoperatively. Expected complications include, but are not confined to, wound infection and related morbidity, phlebitis (both superficial and deep), urinary tract infection, bladder and ureteral injury, ileus and bowel obstruction, pneumonia, and atelectasis.

Hysterectomy remains one of the most common major surgical procedures in the United States. It also carries a significant morbidity, with postoperative infection rates reported between 3.9 and 50 percent for abdominal hysterectomies and 1.7 to 64 percent for laparoscopic vaginal hysterectomies. There are numerous risk factors for postoperative infections. Lower socioeconomic status is a risk factor for infection in gynecologic surgery, which may be related to inadequate nutrition or poor hygiene. Obesity also carries an increased risk of infection, possibly due to poor hygiene, altered nutrition, or increased operative time. Additional risk factors include altered immunocompetence, diabetes, lack of prophylactic antibiotics when indicated, premenopausal stage, or excessive amount of operative blood loss.

Wound Infection

CLINICAL FEATURES   Wound infections may occur early post-operatively or up to several months after the surgery. Greater than 90 percent occur within the first 2 postoperative weeks. Early infections are characterized by fever, tachycardia, increased wound tenderness, and local cellulitis. As the infection progresses, the wound may be fluctuant or indurated. Wound breakdown and dehiscence can occur if treatment is not initiated rapidly. The infected incision is swollen, erythematous, edematous, and tender. There may be spontaneous purulent drainage from the wound. Initial management consists of opening the incision, probing with a sterile cotton swab to maintain fascia integrity, vigorous cleaning with a fifty-fifty mixture of hydrogen peroxide and saline solution, and packing with saline-soaked wet-to-dry dressings. If staples have been placed, they should be removed. Aerobic and anaerobic cultures could be obtained. The operating gynecologist should always be informed about the patient. Late-onset infections are characterized by persistent low-grade fevers and purulent drainage from the incision. Local wound care, as described above, is appropriate.

DISPOSITION   Parenteral therapy with a penicillin-based antibiotic and aggressive local wound care are typically used for early postoperative infections, particularly when there is underlying cellulitis. Most patients are readmitted.

Infected Vaginal Cuff Hematoma, Cellulitis, or Abscess

CLINICAL FEATURES   A vaginal cuff is formed during a hysterectomy and is composed of the contiguous retroperitoneal space immediately above the vaginal apex

and the surrounding soft tissue. This cuff may become infected, leading to cellulitis, hematoma, or abscess.

Vaginal cuff cellulitis is a common complication following both abdominal and vaginal hysterectomy. Symptoms and signs usually present between postoperative days 3 and 5, and may begin in the hospital, or just after discharge. Patients often complain of lower abdominal pain, pelvic pain, back pain, fever, and abnormal vaginal discharge. Induration, tenderness of the vaginal cuff, and possibly a purulent discharge or labial edema or erythema are prominent during the pelvic examination. The white blood cell count is usually elevated.

A vaginal cuff abscess usually presents early in the postoperative course. Patients complain of fever, chills, pelvic pain, and rectal pressure. On examination, lower abdominal and vaginal cuff tenderness is present. A tender fluctuant mass near the cuff may be palpable, and purulent drainage from the cuff may be seen.

Infected cuff hematomas may present later in the postoperative course and are associated with a decrease in the patient's hemoglobin and hematocrit levels. The hematoma may not be palpable on examination.

DISPOSITION   Patients should be readmitted for drainage and intravenous antibiotics. Broad-spectrum antibiotics should be started early, with coverage for gram-negative, gram-positive, and anaerobic organisms. A CT scan may be necessary for diagnosis or to better define an abscess or hematoma.

Postoperative Ovarian Abscess

CLINICAL FEATURES   Patients with fever and abdominal and pelvic pain shortly after discharge from the hospital may have a pelvic abscess. Such abcesses are usually ovarian in nature. A sudden increase in pain may be a signal that the abscess has ruptured. This is a surgical emergency and requires a laporatomy. If time permits or the diagnosis is in question, a CT scan can aid in identifying the size and location of the abscess.

DISPOSITION   Patients with a pelvic abcess need to be admitted. Some abscesses respond to broad-spectrum antibiotics, and others may require drainage either by an interventional radiologist or by colpotomy.

Dehiscence and Evisceration

CLINICAL FEATURES   Wound disruption is a failure of normal healing and includes the breakdown of any layers of a surgical incision. Dehiscence is disruption of all layers, including fascia and peritoneum. Evisceration occurs when there is complete breakdown of the healing processes through all levels of the abdominal wall and the omentum or bowel presents through the incision.

The classic signs of impending dehiscence is the sudden outpouring of serosanguineous blood from the abdominal incision. Most often this occurs between postoperative days 5 and 8. The patient may describe a "pop" or tearing sensation. About one-third of the cases of wound dehiscence are associated with evisceration. While gynecologic surgery has a lower wound disruption rate than the 1 to 3 percent reported following major abdominal surgery, the mortality rate is high, with a median of 18.1 percent.[8,9 and 10]

DISPOSITION   When evisceration has occurred, the abdomen should be covered with moist sterile towels and supported with tape to prevent further extrusion of the gut.

The patient should be taken directly to the operating room for closure. In cases in which there is a sudden appearance of blood but no bowel, it is best to follow the same procedure because evisceration usually is imminent.

Ureteral Injury

CLINICAL FEATURES   Operative injury to the ureter results from one of three types of trauma: crushing, transection, or ligation. Each type of injury may be either partial or complete. This complication occurs more often during the performance of abdominal hysterectomy than during any other pelvic surgery. In patients who develop flank pain shortly after surgery, ureteral injury should be suspected. Patients may have fever and costovertebral angle tenderness. A urinalysis should be performed, and if obstruction is suspected, an IVP should be obtained. If obstruction is noted on IVP, it is usually near the ureterovesical junction.

DISPOSITION   Patients should be admitted for attempted ureteral catheterization under cystoscopic guidance and possibly exploratomy laporotomy. Percutaneous nephrostomy with delayed repair may also be considered.

OTHER COMPLICATIONS OF GYNECOLOGIC SURGERY

Urinary Retention

Urinary retention in a healthy female after gynecologic surgery is uncommon. However, many women experience either an inability to void or incomplete emptying of the bladder during the postoperative period. Urinary retention is usually a temporary result of pain or bladder atony resulting from anesthesia.

CLINICAL FEATURES   Inability to void is more frequent after operations that involve the urethra and bladder neck, i.e., anterior repair or any modification of the retropubic urethropexy. Most problems with voiding following any of these procedures resolve with time and without medication.

DISPOSITION   Retention can be initally relieved with insertion of a Foley catheter for 12 to 24 h. Most patients are able to void after this period. An alternative method is intermittent straight catheterization. Patients are instructed to attempt to void on a timed schedule at intervals of less than 3 h. Patients should be taught to perform self-catheterization if they are unable to void. Self-catheterization can be taught in the emergency department, and the patient should be reassured that voiding function will return in time. If a patient still has trouble voiding after temporary placement of a Foley catheter, the problem may be ureteral spasm, which can be treated with phenazopyridine or oxybutynin.

Vesicovaginal Fistula

CLINICAL FEATURES   Vesicovaginal fistulas may occur after total abdominal hysterectomy. Patients present 10 to 14 days after surgery with a watery vaginal discharge. The diagnosis can be confirmed by inserting a cotton tampon into the vagina and then instilling methylene blue or indigo carmine dye via a transurethral catheter. If the tampon stains blue, a vesicovaginal fistula is present. If no staining occurs, a ureterovaginal fistula must be ruled out by injecting 5 mL of indigo carmine dye intravenously. If a ureterovaginal fistula is present, the tampon should stain blue within 20 min.

DISPOSITION   Gynecologic consultation is necessary. A Foley catheter should be inserted for prolonged drainage if a vesicovaginal fistula is present. With continuous drainage, up to 15 percent close spontaneously within 4 to 6 weeks.

Osteomyelitis Pubis

CLINICAL FEATURES   Osteomyelitis pubis is a rare complication of pelvic surgery that presents 6 to 8 weeks after surgery with pain and tenderness along the symphysis pubis, especially with ambulation. Osteomyelitis pubis results from direct or contiguous seeding of the periosteum from pelvic surgery. It has been seen in the past following certain types of bladder neck suspension. Patients have a low-grade fever, elevated sedimentation rate, and leukocytosis. Blood should be drawn for culture, since the results are sometimes positive.

DISPOSITION   Patients should be admitted for parenteral antibiotics and possibly surgical debridement.

Wound Hematoma

CLINICAL FEATURES   Hematomas are a common complication of wound closure and are more frequent in transverse than in vertical incisions. The wound itself may swell and be painful.

DISPOSITION   In general, smaller hematomas can and should be managed expectantly. If there are any signs of infection, the wound should be opened and drained. An ultrasound examination of the incision may be helpful if hematoma is suspected. The patient should be instructed to return if signs of infection develop.

Wound Seroma

CLINICAL FEATURES   Wound seromas are relatively uncommon in gynecologic incisions, with the exception of groin dissection. A wound seroma is a collection of serous fluid and may drain spontaneously. In general, it is the presence of drainage, not fever or pain, that prompts patients to seek emergency care.

DISPOSITION   If the wound remains intact after gentle probing, the seroma can be watched and usually disappears. If the seroma has reached a large size, drainage can be performed by aspiration and light pressure over the lymphocyst. Wound infection precautions should be given.

Postconization Bleeding

CLINICAL FEATURES   High-grade squamous intraepithelial lesions of the cervix may be treated by loop electrocautery or cold-knife cone. The most common complication of these procedures is bleeding. If delayed hemorrhage occurs, it usually occurs 7 days postoperatively. Bleeding following this procedure can be rapid and severe.

DISPOSITION   Visualization of the cervix is the key to controlling such bleeding. Application of Monsel solution is a reasonable first step if it is readily available. If this is not successful, a gynecologist should be consulted for suturing of the bleeding arteriole. Often, the patient must be taken to the operating room for repair because adequate visualization is difficult in the emergency department.

Septic Pelvic Thrombophlebitis

CLINICAL FEATURES   Septic pelvic thrombophlebitis (SPT) is a diagnosis of exclusion complicating 0.1 to 0.5 percent of gynecologic procedures. The diagnosis is made when a patient with a postoperative fever does not respond to appropriate antibiotics in the absence of an undrained abscess or infected hematoma. Patients with SPT rarely present to the emergency department, since the complication typically presents in the hospital and delays discharge.

There are two forms of SPT. The classic form occurs 2 to 4 days after abdominal surgery and is characterized by fever, tachycardia, gastrointestinal distress, and unilateral abdominal pain. A palpable abdominal cord is seen in 50 to 67 percent of cases. The enigmatic form complicates vaginal delivery and pelvic surgery. Patients have spiking fevers despite clinical improvement on antibiotics. Findings upon pelvic examination may be normal in patients with either form.

DISPOSITION   Heparin for 7 to 10 days is the mainstay of treatment. Long-term anticoagulation is not needed unless septic pulmonary emboli have occurred. Antibiotics against heparinase-producing *Bacterioides* species should be given to all patients.

Induced Abortion

There are three major methods for termination of a pregnancy: instrumental evacuation by the vaginal route, stimulation of uterine contraction, and major surgical procedures. Complications occur in between 1 and 5 percent of cases,[11,12] and can be immediate, delayed, or late. Immediate complications, less than 24 h after the abortion, include bleeding and pain. Most immediate complications are arrested at surgery, but many present within 24 h to the emergency department. Retained products of conception, uterine perforation, and cervical lacerations are the most common causes of immediate bleeding and pain. Delayed complications occur between 24 h and 4 weeks post-abortion and include excessive bleeding, primarily due to retained products of conception, and post-abortive endometritis. Late complications include post-abortal amenorrhea, psychological problems, including depressions, and Rh isoimmunization.

If a cervical laceration is noted, treatment includes pressure followed by application of Monsel solution or use of silver nitrate sticks. Suturing may be necessary if there is no resolution of bleeding. Uterine perforation occurs in approximately 1 to 3 per 1000 abortion procedures. Most perforations are noted at the time of surgery and are asymptomatic. However, those that go unnoticed can present with pain and/or bleeding and possibly signs of shock. The incidence of retained products of conception is 0.5 to 1.0 percent. On physical examination, the cervical os is generally open. The uterus is usually boggy, enlarged, and tender. A pelvic sonogram should be obtained to evaluate the uterine cavity for retained products. Repeat dilatation and curettage is necessary. If coexistent endometritis is present, treatment with antibiotics is required for 10 to 14 days. Usual therapy includes "triple antibiotics" (ampicillin, gentamycin, and clindamycin) until the patient is afebrile for 24 to 48 h.

Post-abortal endometritis not associated with retained products of conception presents with a firm, yet tender uterus and closed cervical os. Uncomplicated endometritis requires antibiotics, as previously discussed, and possible reaspiration based on sonographic findings. Rh immune globulin should be given to Rh negative women after a spontaneous or induced abortion. If it is not prescribed, the overall risk of sensitization in the second pregnancy is approximately 3 percent.

Brachytherapy

Brachytherapy is the treatment of malignant tumors by radioactive sources that are implanted, typically under general anesthesia, close to (intercavitary) or within (interstitial) the tumor. It may be used as adjuvant therapy following surgery or as primary therapy if the malignancy is advanced. Currently, radiation therapy is geared mainly toward cervical and uterine cancers and remains limited in ovarian cancer.

The normal tissues of the cervix and uterus can tolerate very high doses of radiation. In contrast, the sigmoid, rectosigmoid, and rectum do not and, therefore, are more susceptible to radiation injury. Usually the small bowel is spared because it is in motion. Acute radiation cystitis can occur in the immediate postoperative period. Symptoms of cystitis are present but cultures are negative. Treatment is to increase oral intake and take a urinary analgesic. Chronic radiation cystititis with hematuria requires continuous bladder irrigation.

Radiation induced soft tissue necrosis can also be a significant complication. It is thought to be due to a progressive end arteritis leading to decreased blood flow and eventually hypoxia. Often this leads to inflammation, infection, tissue breakdown, and fistula formation. The use of hyperbaric oxygen has been shown to enhance healing.

Assisted Reproductive Technology

Transvaginal ultrasonographically guided aspiration of oocytes is used universally during in vitro fertilization. Previously, laparoscopic oocyte collection had been used, carrying the occasional complications of laparoscopic surgery, including those related to general anesthesia. Complications related to ultrasound-guided retrieval of oocytes are rare and include ovarian hyperstimulation syndrome, pelvic infections, intraperitoneal bleeding, and adnexal torsions.[13,14 and 15] However, the acute abdomen has developed hours to weeks after the procedure and has required prompt surgical intervention.

Ovarian hyperstimulation syndrome can be a life-threatening complication of induction of ovulation. The incidence in the moderate-to-severe form is 1 to 2 percent. Symptoms include abdominal distention, ovarian enlargement, and weight gain in the mildest form. In the most severe form, patients have massive third-spacing of fluids into the abdominal cavity, which can lead to ascites, electrolyte imbalances, pleural effusions, and hypovolemia. Clinically, one sees increased coagulability and decreased renal perfusion. The decreased renal perfusion leads to increased salt and water reabsorption in the proximal tubule, leading to oliguria. Abdominal and pelvic examinations are contraindicated due to extremely fragile ovaries that are at high risk of rupture or hemorrhage. Patients are also at high risk for ovarian torsion because of the size of their ovaries. Electrolyte studies, renal function tests, a complete blood count, coagulation studies, and blood for type and cross match should be obtained. An electrocardiogram to evaluate potential hyperkalemic changes should also be obtained. The gynecologist should be consulted for admission. Treatment is conservative, and diuretics are contraindicated. Volume repletion may be necessary.

109 PELVIC ULTRASONOGRAPHY

Robert F. Reardon
Dietrich V. K. Jehle

Ultrasonography is a standard diagnostic tool used in the evaluation of pregnancy and female pelvic pathology. [1] Bedside pelvic ultrasound is commonly used in the emergency department (ED) in order to guide the evaluation of women with pelvic pain, pregnancy problems, and maternal trauma. The use of early pelvic ultrasound is essential for the timely diagnosis of ectopic pregnancy and placenta previa. Recent studies have demonstrated that bedside transvaginal ultrasound performed by emergency physicians improves early detection and decreases morbidity of patients with ectopic pregnancy. [2,3 and 4] The availability of bedside pelvic sonography decreases the ED length of stay for women with early pregnancy.[5] This chapter describes many other indications for ED bedside pelvic sonography, all of which may be useful to the practicing emergency physician. Since training and experience with pelvic sonography is highly variable among emergency physicians, a cautious approach to "ruling out" serious conditions should be employed initially. For example, ordering a "formal" ultrasound to be performed in the radiology or ob/gyn department is reasonable when no intrauterine pregnancy is identified in a symptomatic pregnant patient.

IMAGING TECHNIQUES

General discussion of the principles of ultrasonagraphy are found in Chap. 295. Transabdominal and transvaginal imaging are complementary studies in evaluating the female pelvis. Transabdominal sonography gives a good overview of the pelvis but requires a full urinary bladder. When the bladder is full, it acts as an acoustic window to the pelvis for transabdominal scanning. If empty, retrograde filling of the bladder with 300 to 500 mL of saline, with careful avoidance of introducing air, may be necessary to obtain adequate visualization. In contrast, transvaginal sonography is performed with an empty bladder, which is more comfortable for the patient. Transabdominal scanning of the pelvis is usually performed with lower-frequency transducers (3 to 3.5 MHz) that provide a larger field of view and deeper penetration but with lower resolution. Transvaginal images generally provide better resolution with a smaller field of view, since the transducer is placed closer to the area of interest and utilizes a higher-frequency probe (5 to 7.5 MHz). The standard transabdominal views are longitudinal and transverse and the orientation of the pelvic anatomy is relatively simple (Fig. 109-1 and Fig. 109-2). Standard transvaginal views are sagittal and coronal; however, orientation of pelvic anatomy is initially more difficult (Fig. 109-3). Identifying the anatomy of the uterus before searching for other pelvic structures may assist in obtaining transvaginal images.

FIG. 109-1. Normal longitudinal pelvic anatomy. The uterus (*left*) and the vagina (*right*) are seen posterior to the anechoic bladder on a transabdominal longitudinal view. The cervix lies immediately posterior to the angle (deepest part) of the bladder.
FIG. 109-2. Normal transverse pelvic anatomy. The uterus is seen posterior to the bladder on a transabdominal scan in the transverse plane. The margins of the uterus are marked by plus signs and the arrow points to the endometrial stripe.
FIG. 109-3. Normal uterus. The midline endometrial stripe is seen at both ends of the uterus on a transvaginal sagittal view. The posterior uterine wall is clearly seen. The tip of the ultrasound probe is very close to the anterior wall of the uterus on this view.

SONOGRAPHIC PELVIC ANATOMY

Transabdominal versus Transvaginal Imaging

Transabdominal midline images of the pelvis in the longitudinal plane will show the long axis of the uterus posterior to the distended bladder. The cervix will be visualized immediately posterior to the angle of the bladder. The posterior cul-de-sac (pouch of Douglas) is a potential space where free intraperitoneal fluid may be found, posterior to the uterus (Fig. 109-4). When a normal anteverted uterus is imaged, the uterus meets the vagina at an angle of 90° or greater, dependent on the amount of bladder distention. Retroversion of the uterus is a normal variant and can make transabdominal visualization of the uterine fundus difficult. The position of the uterus is less important when the transvaginal probe is used.
FIG. 109-4. Free fluid. The markers indicate the uterine dimensions on this transabdominal scan in the longitudinal (sagittal) plane. The anechoic bladder is seen anteriorly and anechoic free fluid is seen posteriorly (pouch of Douglas) and on the left side of the image.

Uterus

Normal uterine size for a nulliparous menstruating female is up to 8 cm in length and 3 to 5 cm in transverse and AP diameter. Maximal uterine size for multiparous women may be 1 to 2 cm greater in each plane. The empty uterus is a thick-walled, muscular organ with moderate echogenicity. It contains a central hyperechoic (endometrial) stripe that represents the opposed surfaces of the endometrial cavity. In the nonpregnant patient, the appearance of the endometrium is variable depending on the phase of the menstrual cycle. Early in the cycle the proliferative endometrium usually measures 4 to 8 mm in width (Fig. 109-1). Later during the secretory phase, the endometrium generally measures 7 to 14 mm and displays increased echogenicity (Fig. 109-5). The echogenicity and size of the menstrual endometrium are variable and dependent on the amount of blood and clot present within the uterus. The endometrium of the postmenopausal patient without hormonal replacement therapy is generally less than 9 mm in width. The combination of postmenopausal vaginal bleeding and increased endometrial width is suspicious for endometrial carcinoma and requires further evaluation. A markedly thickened postpartum endometrium suggests the presence of retained products of conception.
FIG. 109-5. The uterus with a thickened and hyperechoic endometrial stripe (secretory phase) is visualized on this transabdominal image in the longitudinal plane. Two nabothian cysts can be seen at the cervix, immediately posterior to the angle of the bladder.

Ovaries

The ovaries can usually be found lateral to the body of the uterus, anterior to the internal iliac vessels, and anteromedial to the external iliac vessels (Fig. 109-6 and Fig. 109-7). There is variability in the position of the ovaries in women who have been pregnant. The distended bladder, which is required for transabdominal imaging of the ovaries, may displace them more cephalad. The size of each ovary is about 2 by 2 by 3 cm, although this may vary widely. Each ovary contains several small hypoechoic cysts, which are the maturing follicles. The sonographic appearance of the ovary changes throughout the menstrual cycle as several follicles are recruited and then a dominant follicle emerges, followed by the development of a corpus luteum.
FIG. 109-6. Anatomy of pelvis. This drawing shows the normal anatomic relationship between the ovary and the iliac vessels, with the iliac vessels drawn in longitudinal section. See Fig. 109-7.

FIG. 109-7. Ovarian cyst. Sonographic image of the structures drawn in Fig. 109-6. A large cyst is visualized in the left ovary (plus signs mark borders). This demonstrates the normal position of the ovary in relation to the iliac vessels.

NORMAL EARLY PREGNANCY

Ultrasound Findings

The first sonographic finding in early pregnancy is the gestational sac. This is a hypoechoic structure that is slightly eccentric in its location within the uterine cavity. The decidua capsularis and decidua vera are seen as two distinct hypoechoic layers surrounding the early gestational sac; this is known as the double decidual sac sign (Fig. 109-8). The yolk sac is the next embryonic structure to be visualized. It appears as a small ringlike structure within the gestational sac. Finally, the fetal pole can be recognized adjacent to the yolk sac (Fig. 109-9).[6] Cardiac activity can usually be observed if a fetal pole is present. The normal fetal heart rate seen in early pregnancy is 112 to 136 beats per minute, slower than heart rates observed in the second and third trimesters. If the ovaries are imaged early in pregnancy, a corpus luteum cyst may be seen (Fig. 109-9). These cysts usually measure 2 to 4 cm in diameter (can be up to 10 cm) with 3 to 4 mm walls. Corpus luteum cysts are generally anechoic; however, if they are hemorrhagic, they will contain internal echoes.

FIG. 109-8. Early intrauterine pregnancy. A gestational sac with a clear double decidual sign (*arrow*) between the two decidual layers on a transvaginal image in the sagittal plane.

FIG. 109-9. Early intrauterine pregnancy. The ovary with a corpus luteum cyst is seen adjacent to the uterus. A yolk sac and fetal pole are present within the gestational sac.

Pregnancy Testing

The biochemical diagnosis of pregnancy may be made very early with the use of qualitative serum bhCG tests of blood and urine. Modern tests can detect serum bhCG levels of 20 mIU/mL or lower in urine and can diagnose pregnancy within 7 to 10 days after conception, at 3 weeks of gestational age. Gestational age is measured from the first day of the last menstrual period. Quantitative serum bhCG levels correlate with the gestational age of the normal pregnancy. At any given gestational age, serum bhCG titers are markedly higher when twins (or multiple gestations) are present. Table 109-1 indicates the approximate gestational age at which different sonographic and serum markers appear in early pregnancy.[7] The standards shown in the table are those of the International Reference Preparation (IRP). Some institutions may use an older standard called the Second International Standard, with values approximately one-half of the IRP values.

Gestational Age	Transabdominal Landmarks	Transvaginal Landmarks	S BhCG Level, IRP*
4–5 weeks	±Gestational sac	Gestational sac	1000 mIU/mL
5 weeks	Gestational sac ± yolk sac	Gestational sac with yolk sac, ± fetal pole	1000–7000 mIU/mL
6 weeks	Yolk sac and fetal pole	Yolk sac and fetal pole with cardiac activity	10,000–23,000 mIU/mL

*IRP = International Reference Preparation.[7]

TABLE 109-1   Estimated Sonographic and Serum BhCG Landmarks[7]

Determining Gestational Age

When sonographic evidence of an early pregnancy is definitive, the gestational age of the pregnancy can be estimated by measurements of the gestational sac, crown-rump length, or biparietal diameter. Mean sac size and crown-rump length provides the best estimates of gestational age during the first trimester. Measurements of sonographic structures very early in pregnancy give better estimates of gestational age than later measurements because the growth of the embryo during the first trimester is consistent between individuals and not dependent on genetic or nutritional factors. Mean sac diameter (MSD) is the average of three gestational sac measurements in millimeters: MSD = (length + width + depth) /3; gestational age (days) = 30 + MSD. In measuring crown-rump length (CRL) it is important to obtain the maximal embryo length, excluding the extremities and yolk sac. Gestational age (weeks) = 6.5 + CRL when CRL is measured in centimeters. Both MSD and CRL give very accurate estimates of gestational age. A significant discrepancy between CRL and MSD suggests a failing pregnancy. After the first trimester, gestational age should be estimated by measuring the (biparietal diameter) BPD of the fetal skull. The BPD is a transverse measurement of diameter at the level of the thalamus. The markers are positioned at the inside of one side of the skull and the outside of the opposite skull surface. Modern ultrasound software is capable of calculating gestational age automatically when the above measurements are marked on the display.

ECTOPIC PREGNANCY

The diagnosis of (ectopic pregnancy) EP is among the most challenging for the emergency physician. Significant morbidity and mortality may result from a missed or delayed diagnosis. (See Chap. 100 for a detailed discussion of ectopic pregnancy.) About half of all ectopic pregnancies are missed on first presentation to the ED.[3,8] The use of protocols that rule out ectopic pregnancy incorporating transvaginal pelvic sonography and the bhCG discriminatory zone, can decrease the rate of missed ectopic pregnancies.[2,3,9]

Ectopic Location

EP occurs when the fertilized ovum implants anywhere except in the endometrium of the intrauterine cavity. Approximately 95 percent of EPs occur in the fallopian tube, with the ampulla being the most common location of implantation. Sites of implantation outside of the tube include uterine cornua, abdomen, ovary, and cervix. Cornual and abdominal ectopics may present late with profuse hemorrhage and probably represent the majority of pregnancies in which the patient dies before reaching the hospital. Cornual and cervical ectopics can be easily confused with a normal intrauterine pregnancy on the ultrasound examination. In addition, a cervical pregnancy may be confused with a nabothian cyst.

Initial Evaluation of Patients at Risk for EP

Female patients with complaints of vaginal bleeding, abdominal pain, dizziness, or syncope present very commonly in any ED. A high index of suspicion for EP is required, since about one-third of patients with EP are nontender on exam and about 10 percent have no complaint of abdominal pain.[9] A urine bhCG test should be the first step in the evaluation of such patients. Patients with a positive test require further evaluation. A negative urine test followed by a negative serum bhCG, virtually rules out the possibility of EP.[8] If the qualitative bhCG test is positive, an EP may be present. A protocol to rule out EP that includes bedside transvaginal sonography and a serum bhCG discriminatory zone allows emergency physicians to evaluate high-risk patients more quickly and effectively (see Chap. 100).[3,4 and 5]

Ultrasound Evaluation

Transvaginal sonography is more sensitive and specific than transabdominal sonography in evaluating first-trimester pregnancies. Transvaginal sonography can differentiate between intrauterine pregnancy (IUP) and EP in 75 percent of pregnant women who present with pain or bleeding. Transvaginal sonography has 69 percent sensitivity and 99 percent specificity for diagnosing EP.[9] If a definite IUP or EP is seen, the workup is complete. The finding of an IUP rules out the diagnosis of EP as long as there is a single gestation. Patients on fertility drugs may have multiple gestations. The presence of a yolk sac, fetal pole, or cardiac activity within an intrauterine gestational sac confirms the presence of an IUP. Visualization of a gestational sac alone should not be relied upon to make the diagnosis of an early IUP unless a double decidual sign is clearly seen. The presence of an EP is immediately established in about 15 percent, by either visualization of cardiac activity or an obvious gestational sac, yolk sac, and fetal pole outside of the uterus. The finding of a tubal ring in the adnexa is highly suggestive of an EP and may be frequently found in those with EP (Fig. 109-10). An EP is strongly suspected when pelvic free fluid and/or a complex adnexal mass is seen.[10,11 and 12] Consider ordering a "formal" pelvic ultrasound when no IUP is seen on bedside sonography, since the ancillary findings of EP may be subtle.

FIG. 109-10. Tubal ring. This represents hypertrophy of the left fallopian tube in a patient with an ectopic pregnancy.

Quantitative Serum bhCG and Discriminatory Zone

When no IUP is noted and no sonographic "ancillary findings" of EP exist, a quantitative serum bhCG should be obtained if not already done. In using quantitative serum bhCG in a protocol to rule out ectopic pregnancy, the concept of discriminatory zone is important. A discriminatory zone is the serum bhCG level above which an intrauterine pregnancy is expected to be visualized sonographically. A discriminatory zone serum bhCG level of 2000 mIU/mL is commonly used. [2,3 and 4] A pregnancy with a serum bhCG level above 2000 mIU/mL without sonographic evidence of an IUP should be considered an ectopic pregnancy until proven otherwise and an ob/gyn consult should be obtained. With a low serum bhCG (<2000) and no IUP or "ancillary findings," most gynecologists recommend a conservative approach with repeat serum bhCG titers and ultrasound studies in 3 to 7 days. [3] The discriminatory zone serum bhCG level may be adjusted depending on institutional variation and preference.

Potential Errors in the Diagnosis of EP

Several common errors should be avoided in evaluating a patient with a potential EP. Not considering the possibility of an EP is the first obstacle to making the diagnosis. A high index of suspicion for this diagnosis must be maintained. Reliance on the protocol to rule out EP, serum bhCG level, and pelvic sonography while ignoring significant physical signs can be a serious mistake. A history of "passing tissue" vaginally should not be considered evidence of a spontaneous abortion. [8] Only identification of chorionic villi or obvious fetal parts confirms abortion and rules out EP. Misinterpretation of pelvic sonography can lead to a delayed diagnosis of EP, with disastrous results. [8] An anechoic fluid collection without a clear double decidual reaction (gestational pseudosac) may be misinterpreted as an IUP. A gestational pseudosac is present in about 10 to 20 percent of patients who have an ectopic pregnancy. [8,13] A pseudosac is the result of endometrium that is stimulated by trophoblastic hormones and intrauterine bleeding (Fig. 109-11). The double decidual sac sign can be used to differentiate a true gestational sac from a pseudosac. [14] Finally, misjudging the intrauterine or extrauterine location of a pregnancy is a serious mistake. The location of the uterus should be clearly identified before a gestational sac, yolk sac, and/or fetal pole is called an IUP or EP. A normal pregnancy should be located in the fundus of the uterus. Interstitial and cervical pregnancies can be difficult to differentiate from IUP and should be considered when a patient presents in shock with an apparent IUP by ultrasound. Abdominal and ovarian pregnancies are obviously outside the uterus but may have the appearance of a viable fetus. Not recognizing the ectopic location of an apparently viable pregnancy is likely to have grave consequences, since an advanced EP is likely to cause severe hemorrhage upon rupturing.

FIG. 109-11. Pseudosac. There is a hypoechoic sac inside the uterus, without a double decidual sign, yolk sac, or fetal pole in a patient with an ectopic pregnancy.

Heterotopic Pregnancy

Usually the presence of an intrauterine pregnancy is sufficient evidence that an EP does not exist. However, in the case of patients who are taking progestational/fertility agents, this assumption should not be made. The incidence of simultaneous intrauterine and extrauterine pregnancy (heterotopic pregnancy) in the general population is now thought to be as high as 1 per 4000 pregnancies, although historically this was only reported in 1 per 30,000 pregnancies. Those taking medications to enhance fertility are at much higher risk for heterotopic pregnancy. Patients who have a history of in vitro fertilization may have an incidence as high as 1 per 100 to 200 pregnancies. [15] For this reason sonographic imaging of the entire pelvis should be completed even after identification of an obvious IUP.

Ectopic Pregnancy with Low Serum bhCG

Low-serum bhCG EPs are common, and this is the weakness of the protocol described above. Simply assuming that a patient has a very early IUP because of a low serum bhCG level can be a major mistake. All patients need to have transvaginal sonography, even if they have a very low serum bhCG level. About 50 percent of symptomatic patients with an EP have a quantitative serum bhCG level below the discriminatory zone. In fact EPs with serum bhCG levels < 100 mIU/mL have been reported. EPs with low serum bhCG levels may rupture and cause bleeding just like other EPs. [16] Patients with low serum bhCG and significant risk factors or findings suggestive of EP should be closely observed. (See Chapter 100 for a detailed discussion of risk factors.) Those with low serum bhCG and no risk factors or evidence of EP may be sent home with close follow-up in 24 to 48 h. Pelvic sonography and quantitative serum bhCG are repeated on follow-up. During a normal early pregnancy, the serum bhCG will double about every 2 days. Abnormal pregnancies, ectopic or intrauterine, have a prolonged doubling time. [17]

ABNORMAL FIRST-TRIMESTER INTRAUTERINE PREGNANCY

Spontaneous Abortion

Spontaneous abortion occurs in as many as 40 percent of gestational events and approximately 15 percent of clinically apparent pregnancies. Most pregnancy losses occur early in the first trimester and few are lost after fetal cardiac activity is noted sonographically. [6] A completed abortion occurs when all of the products of conception have left the uterus. After a completed abortion, the cervical os may be opened or closed. If the os is closed and products of conception are not clearly identified, one should be skeptical about the diagnosis. An incomplete abortion occurs when some of the products of conception have been expelled and some still remain within the uterus. After a completed abortion, an empty uterus should be visualized sonographically; thus a postpartum endometrial stripe greater than 10 mm in a symptomatic patient suggests the presence of retained products of conception (Fig. 109-12). An inevitable abortion occurs when the cervical os is open but the products of conception have not yet been expelled. [1] A missed abortion occurs when the fetus is dead and is retained for greater than 4 to 8 weeks.

FIG. 109-12. Retained products of conception. There is a very thick (hyperechoic) endometrial echo measuring approximately 3 cm within the uterus on this transabdominal midline longitudinal view. This represents retained products of conception in a patient who had aborted a 10-week IUP. (Courtesy of J. Mateer, M.B. Phelan, and the Department of Emergency Medicine, Medical College of Wisconsin.)

Threatened Abortion

Threatened abortion is vaginal bleeding in the pregnant patient before 20 weeks gestation. It complicates about 25 percent of all pregnancies. Vaginal bleeding is usually light and is accompanied by crampy pelvic pain. On examination, abdominal, adnexal, and cervical motion tenderness is usually absent and the cervix is closed. The pivotal step in the workup of a patient with first-trimester vaginal bleeding is pelvic sonography. If a live IUP is seen and there is a single gestation, expectant management is the rule. Although limitation of activity is recommended, there is no proven therapy for early threatened abortion.

Viability of an Early IUP

There are several sonographic criteria that can be used to decide whether an early IUP is viable or whether early fetal demise has occurred. Major criteria are those that uniformly predict fetal demise. Inability to visualize a yolk sac or embryo in a large gestational sac is a major criterion for demise; this is referred to as a blighted ovum (Fig. 109-13). Specifically, absence of a yolk sac when MSD is ³ 10 mm using transvaginal sonography (TVS) or when MSD is ³ 20 mm using transabdominal sonography (TAS) indicates certain fetal demise. [6] In addition, absence of an embryo when MSD is ³ 16 mm using TVS or when MSD ³ 25 mm using TAS predicts fetal demise with confidence.[6] Visualization of a grossly distorted gestational sac uniformly predicts fetal demise but is somewhat subjective (Fig. 109-14). A gestational sac located in the lower portion of the uterus adjacent to the cervix is probably in the process of aborting. [6] An irregular, thin, or weakly echogenic choriodecidual reaction surrounding the gestational sac, decreased amniotic fluid volume, or a fetal heartbeat below 90 beats per minute after 6 weeks gestational age are all suggestive but not diagnostic of a failing pregnancy.

FIG. 109-13. Blighted ovum. There is a large, regularly shaped intrauterine sac without yolk sac or fetal pole.

FIG. 109-14. Inevitable abortion. Irregularly shaped intrauterine sac low in the uterus.

Subchorionic Hematoma

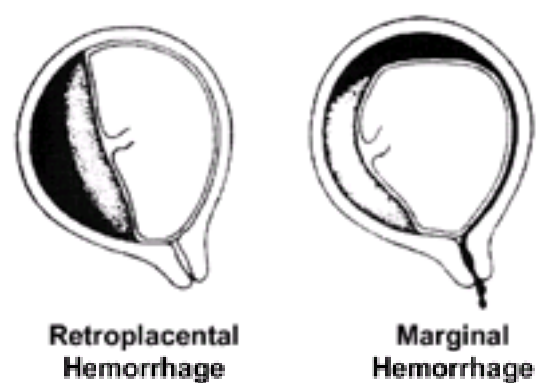
An intrauterine hematoma is present in about one-fourth of those with threatened abortion. In the first trimester, blood may accumulate in the endometrial cavity between the chorionic membranes and the uterine wall; this is known as a subchorionic hematoma or implantation bleed (Fig. 109-15 and Fig. 109-16). The presence of a subchorionic hematoma may more than double the chances of pregnancy loss in threatened abortion. The size and location are important factors in judging the significance of such bleeding. Small hematomas under the placenta are more important than larger hematomas elsewhere.


FIG. 109-15. Drawings of retroplacental and marginal hematomas.

FIG. 109-16. Subchorionic hemorrhage. The anechoic region adjacent to the edge of the placenta represents a subchorionic hemorrhage. The placenta is the

hyperechoic structure on the posterior wall of the uterus.

Vaginal Bleeding with No IUP

The sonographic finding of an empty uterus in a patient with vaginal bleeding and a positive pregnancy test poses a difficult diagnostic dilemma. Very early IUP and completed spontaneous abortion are possible, but about 25 percent of these patients will have an EP. [13] When echogenic material is seen within the uterus, retained intrauterine products from an incomplete abortion or from partial resorption after fetal demise may be present; this should not be confused with intrauterine blood and clots, which can occur with an ectopic pregnancy. Completed spontaneous abortion is confirmed only by passage of obvious products of conception or identification of chorionic villi pathologically. Serial quantitative serum bhCG levels may be helpful in this setting. After spontaneous abortion, serum bhCG levels fall rapidly during the first 7 days. Close follow-up with serial sonography and serum bhCG levels may be needed before a final diagnosis can be made.

Molar Pregnancy

Gestational trophoblastic neoplasia is a proliferative disease of the trophoblast. The incidence in the United States is about 1 per 1500 live births. Most cases (80 percent) present as a hydatidiform mole and follow a benign course. More malignant forms of the disease are invasive mole (12 to 15 percent) and choriocarcinoma (5 to 8 percent). Patients with a hydatidiform mole most commonly present with vaginal bleeding but may present with early preeclampsia or hyperemesis gravidarum. A larger-than-expected uterus for gestational age and markedly elevated serum bhCG level (>100,000 mIU/mL) are risk factors for malignant disease and are important clues to making this diagnosis. Most cases of molar pregnancy involve the entire placenta, but molar disease involving only part of the placenta or fetus have also been described. Pelvic ultrasound is the initial study of choice when a molar pregnancy is suspected. [1] Sonographically, a hydatidiform mole is an intrauterine echogenic mass with multiple small hypoechoic vesicles interspersed (Fig. 109-17). It is said to have a characteristic "snowstorm" appearance. However, the appearance of first-trimester moles may be confused with a blighted ovum or threatened abortion. A theca lutein cyst may be seen on examination of the ovaries in as many as half of the cases of gestational trophoblastic disease (GTD). They are large, multiseptated ovarian cysts caused by markedly high levels of serum bhCG. A benign mole usually resolves after evacuation of the uterus. Choriocarcinoma may metastasize to the lung, vagina, brain, or liver and is very sensitive to chemotherapy.
FIG. 109-17. Molar pregnancy. The two plus signs mark the borders of this molar pregnancy, which contains numerous grapelike hypoechoic structures.

Second- and Third-Trimester Pregnancy

Ultrasound evaluations of second- and third-trimester pregnancies are often done in order to evaluate fetal well-being when maternal problems arise. Maternal vaginal bleeding, preeclampsia, diabetes, drug abuse, and trauma may all compromise the fetus. Ultrasound can be used to quickly evaluate several important structures that may have a bearing on the final outcome of the pregnancy. Although emergency physicians are not relied upon to perform routine ultrasound examinations during late pregnancy, many of the structures and abnormalities seen in late pregnancy are easily recognizable, even to those with little ultrasound training.

Immediate Fetal Viability

The visualization of fetal movements and fetal heart rate (normal = 120 to 180 beats per minute) takes priority in the acute setting. [1] The diagnosis of fetal death is established by careful sonographic imaging of the fetal chest for at least 3 min, with lack of cardiac activity. Two experienced sonographers should confirm the diagnosis.

Oligohydramnios and Polyhydramnios

The amount of amniotic fluid should be estimated. Subjective estimates of amniotic fluid volumes are best left to experienced sonographers, but extremes of polyhydramnios and oligohydramnios may be obvious to the neophyte. Amniotic fluid volume is large compared with fetal volume in normal early pregnancy; this should not be mistaken for polyhydramnios. A single measurement of the length of the deepest pocket of amniotic fluid gives a gross estimate of the volume and may be the best method of measurement for the inexperienced sonographer. A pocket more than 8 cm deep indicates polyhydramnios and a pocket less than 1 cm deep indicates oligohydramnios. A four-quadrant index can also be used to estimate the volume of amniotic fluid. The uterus is divided into four quadrants and the deepest pocket in each quadrant is measured. If the sum of the four measurements is less than 5 cm, oligohydramnios is present. If the sum is greater than 20 cm, polyhydramnios is present. An obstetrician should be consulted immediately when oligohydramnios is found, since it is associated with fetal renal malformation, severe growth retardation, and fetal death. Polyhydramnios may be associated with fetal anomalies, preterm labor, and premature rupture of membranes, but it is generally considered less serious.

Umbilical Cord

Sonographic examination of the umbilical cord should reveal two arteries and a single larger vein (Fig. 109-18). A cord that contains only one artery is associated with a 25 to 50 percent chance of fetal abnormalities. The cord vessels are best counted at the cord insertion into the fetus, since the two umbilical arteries may normally fuse at the placental end of the cord.

FIG. 109-18. Umbilical cord. Three loops of cord are seen in this image. An umbilical vein and two smaller arteries are seen in each loop of umbilical cord.

Fetal Gender

Both male and female genitalia are easily recognizable but should be clearly identified before the gender of the fetus is revealed. Lack of visualization of the penis and scrotum without clearly identifying the female labia is not adequate, and in this case no estimate of fetal gender should be made. Errors in sonographic sex determination occur relatively frequently; thus emergency physicians should avoid forecasting gender, as it adds little to emergency care.

Fetal Structures and Abnormalities

Fetal anatomy can be visualized quite easily in the second and third trimesters. Identification of the fetal head, chest, abdomen, and extremities is possible even for those with little ultrasound experience. Most major fetal anomalies can be recognized if ultrasound examination is done during the twentieth week of gestation or beyond. More subtle abnormalities can be recognized when a specific anomaly is suspected and a targeted examination of a single anatomic region is performed. Most routine fetal ultrasound examinations and all targeted examinations are done by physicians who specialize in fetal sonography.

THIRD-TRIMESTER BLEEDING—PLACENTA PREVIA

During the evaluation of third-trimester bleeding, the greatest utility of sonography is to establish the presence or absence of placenta previa. Since the sensitivity of sonography for the diagnosis of placental abruption is very poor, a presumptive diagnosis of placenta abruption is often made after placenta previa has been ruled out. Placenta previa occurs when the blastocyte implants on the endometrium close to the cervical os and the placenta covers the os (Fig. 109-19). Painless vaginal bleeding in the third trimester is the classic clinical presentation. Placenta previa is fairly common and complicates about 0.5 percent of pregnancies at the time of delivery. Risk factors include multiparity, prior cesarean section, advanced maternal age, and abnormal fetal presentations. Attempted vaginal delivery in the presence of placenta previa may result in massive hemorrhage and death of the fetus, mother, or both. Cesarean section is required in complete placenta previa. Complete placenta previa is diagnosed when the placenta is implanted on both sides of the cervical os. A partial placenta previa covers part of the cervical os but does not bridge it. A marginal placenta previa abuts the cervical os but does not cover it. Since partial and marginal previas can both cause bleeding and ultrasound cannot distinguish between the two diagnoses, they are commonly grouped together. A low-lying placenta that does not cover or abut the cervical os may still cause bleeding, but not as frequently or severely as placenta previa.
FIG. 109-19. Placenta previa. The cervix is seen on the right side of the image and is covered by the edge of the placenta. The placenta is the homogeneous structure on the anterior wall of the uterus.

Ultrasound Exam for Suspected Placenta Previa

Ultrasound is highly sensitive in detecting placenta previa, but a significant number of false-positive examinations occur. Since the consequences of placenta previa are so serious, it is important not to underdiagnose the condition. The standard examination for placenta previa uses TAS and a longitudinal projection with a full urinary bladder. In order to rule out placenta previa, the cervical os must be clearly visualized and must be free of overlying placenta. Visualization of the placenta at a site distant from the os makes previa unlikely but does not rule it out, since an accessory placental lobe may also be present. When the relationship between the internal cervical os and the placenta cannot be clearly established using the standard examination, other sonographic approaches may be attempted. Traction on the fetal head with the patient in the Trendelenburg position may allow an improved view of the cervical os in late pregnancy. Completely emptying the urinary bladder may improve transabdominal images of the cervical os in some cases. Transvaginal sonography gives better visualization of the cervix and is preferred in patients who have not had vaginal bleeding. The theoretical risk of dislodging clots and causing significant bleeding by introducing a probe into the vagina has led some clinicians to use transperineal sonography instead. Transperineal sonography is performed by placing the abdominal transducer on the perineum between the urethra and the vagina. This method has been found to be very accurate for diagnosing placenta previa. [18]

False-Positive Diagnosis of Placenta Previa

Sonographic false-positive diagnoses of placenta previa may occur for a number of reasons. An overly distended urinary bladder may cause a low-lying placenta to appear as a previa. A myometrial contraction may mimic the placenta or push the edge of the placenta into the proximity of the cervical os. Diagnosing placenta previa at an early gestational age makes a false-positive diagnosis more likely. Many placentas that appear to cover or abut the cervical os during the second trimester are found to be a safe distance from the os on later exams. This apparent migration of the placenta is probably due to different growth rates of the placenta and the lower uterine segment. Most previas diagnosed before 20 weeks resolve prior to delivery.

THIRD TRIMESTER BLEEDING—PLACENTAL ABRUPTION

Premature separation of the placenta from the wall of the uterus is called *placental abruption.* Abruption can be severe or mild, acute or chronic, and retroplacental or marginal. Abruption causes varying degrees of pain and bleeding. Severe acute abruption classically causes severe, unremitting pain and vaginal bleeding, but bleeding may be mild or absent. Small abruptions may present as vaginal bleeding with little or no pain. Abdominal trauma, maternal hypertension, vascular disease, diabetes, smoking, fibroids, fetal anomalies, and cocaine use are thought to predispose patients to placental abruption. Abruption is found in about 5 percent of all placentas on pathologic examination; however, most small hematomas are asymptomatic and the clinical symptoms of abruption complicate only about 1 percent of all pregnancies. Sonography has very poor sensitivity for diagnosing placental abruption and lack of sonographic evidence certainly does not rule out abruption. However, a clinical presentation suggestive of placental abruption without sonographic evidence of a placenta previa should be assumed to be an abruption until proven otherwise.

Retroplacental Hematoma

Retroplacental hematoma separates the placenta from the uterine wall centrally and is likely the result of bleeding from spiral arteries (Fig. 109-20). Sonographically it appears as a hypoechoic stripe between the placenta and underlying myometrium, but it may have variable echogenicity depending on the age of the bleeding. An acute hematoma may be isoechoic with the placenta, so it may appear as simply a thickened region of the placenta. It will become hypoechoic in 1 to 2 weeks. A retroplacental contraction may mimic a hematoma, and an old heterogeneous hematoma may look like a retroplacental fibroid. Retroplacental hematomas cause placental infarction and may result in fetal growth retardation, fetal death, and massive maternal hemorrhage. When a retroplacental hematoma is apparent sonographically, fetal mortality is directly related to the size of the hematoma.

FIG. 109-20. Placental abruption. This retroplacental hemorrhage is visualized in a patient during the third trimester of her pregnancy. Retroplacental abruptions carry a poorer prognosis than marginal abruptions. See Fig. 109-15.

Marginal Hematoma

Marginal hematomas occur at the edge of the placenta in the subchorionic plane. They are probably the result of bleeding from veins at the margin of the placenta. They are generally associated with less severe complications than retroplacental hematomas, but bleeding may still be severe. Some physicians have claimed that marginal hematomas are of no consequence to the fetus; however, some studies have shown that large hematoma volumes are associated with poor fetal outcomes.

TRAUMA IN PREGNANCY

When trauma occurs during pregnancy, the first priority is the stabilization of the mother. The most common cause of fetal death is maternal death. Ultrasound of the maternal abdomen should be accomplished early after significant blunt trauma.[1] The uterus is well protected within the pelvis during the first trimester of pregnancy; however, during the second and third trimesters, it is at much greater risk of injury due to its intraabdominal position. The sonographic appearance of intraperitoneal blood may be noted in the pelvis before it is detected in the Morison's pouch or elsewhere. Signs of fetal distress may be the first warning sign of occult maternal hemodynamic compromise. After maternal stabilization, the well-being of the fetus should be evaluated. Placental abruption and direct fetal injury must be suspected following significant maternal trauma in the second and third trimesters.

Fetal Sonographic Evaluation

Ultrasound can be used to assist in the initial evaluation of the fetus after maternal trauma.[1] First, ultrasound can aid in making a quick estimate of gestational age. Knowledge of the gestational age is important, since subsequent management decisions will be based on it. Next, a sonographic determination of immediate fetal viability can be made. If the fetus is dead (no cardiac activity and no fetal movement), the management of the mother will become the sole priority. Gross injury to the fetus, placenta, or uterus may be apparent on the initial ultrasound examination. Oligohydramnios following maternal trauma suggests uterine injury or premature rupture of the membranes. Large placental abruptions may be visualized and fetal distress (fetal heartbeat above 180 or below 120) may indicate unrecognized maternal, fetal, or placental injury. Urgent delivery of the significantly compromised fetus is indicated if the gestational age is at least 24 to 26 weeks. Traumatic uterine rupture is usually accompanied by massive bleeding and requires repair or hysterectomy regardless of gestational age. Although sonographic imaging may detect some large abruptions and gross fetal injury, cardiotocographic monitoring is a much more sensitive indicator. Fetal bradycardia, late decelerations, and loss of beat to beat variation are signs of distress. Fetal distress and frequent uterine contractions nearly always appear within 4 h following significant traumatic placental abruption.

PELVIC MASSES

Uterine Masses

A leiomyoma (uterine fibroid) is a benign proliferation of the smooth muscle and connective tissue of the uterus. It is the most common cause of uterine enlargement not related to pregnancy. Fibroids have a variety of sonographic appearances, ranging from hypoechoic masses with irregular uterine contours to echogenic structures with distinct calcified borders (Fig. 109-21). When a fibroid degenerates, multiple small cystic spaces are visualized within the fibroid. Fibroids can be intramural, submucosal, subserosal, or pedunculated. A fibroid may outgrow its blood supply, leading to necrosis and severe pain, especially during pregnancy. Rarely a fibroid degenerates into a uterine sarcoma. In addition, endometrial or ovarian carcinoma may invade the myometrium. Therefore complex or cystic uterine masses require further investigation.
FIG. 109-21. Early intrauterine pregnancy. A yolk sac is seen within gestational sac (*left*). On the right side of the image, there is a calcified fibroid in the anterior wall of the uterus. Acoustic shadowing is seen posterior to the fibroid.

Cervix and Vagina

The vagina and cervix are best visualized with transabdominal sonography. Visualization of the cervix with the transvaginal probe requires that the probe be withdrawn into the distal vagina. Nabothian cysts are benign growths that can commonly be seen in the region of the cervix (Fig. 109-5). Gartner duct cysts are also benign and may be seen at the anterior and lateral walls of the vagina. Imperforate hymen causes primary amenorrhea, lower abdominal pain, and urinary symptoms during puberty. A tender lower abdominal mass may be palpable on physical examination and pelvic sonography will confirm that the vagina is filled with blood; this is called *hematocolpos.* A distended urinary bladder and a blood-filled distended uterus, or *hematometra,* may also be noted (Fig. 109-22). Perineal examination will reveal a bulging hymen; incision and drainage are required.
FIG. 109-22. Hematometra. A large amount of hypoechoic blood (clot) is seen within the uterus. This can be seen with an imperforate hymen or as a postoperative complication of gynecologic surgery.

Adnexal Masses

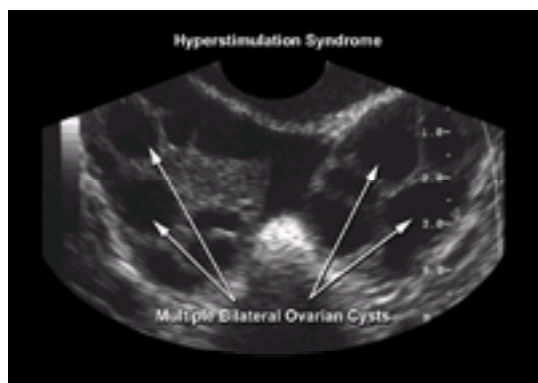
Developing ovarian follicles may measure up to 2 cm at midcycle. Functional ovarian cysts measure greater than 2.5 cm and are well defined, thin walled, and anechoic. Most simple ovarian cysts resolve spontaneously, and serial sonographic exams are helpful to follow their progression. In postmenopausal patients, even well-defined anechoic ovarian cysts require further workup, especially if they are greater then 5 cm in diameter. Sonographically, polycystic ovary disease appears as bilaterally enlarged ovaries with multiple small follicles or a small number of very large follicles (Fig. 109-23). In some cases, the follicles are so tiny that they cannot be seen sonographically; thus a normal appearance of the ovaries does not rule out the diagnosis.


FIG. 109-23. Ovarian hyperstimulation syndrome. Multiple large anechoic cysts are visualized in both ovaries in this image. Ovarian hyperstimulation syndrome or polycystic ovary disease may have this appearance.

Complex Adnexal Masses

Hemorrhagic ovarian cysts have a variable appearance but are often difficult to differentiate sonographically from endometriomas, tuboovarian abscesses, benign ovarian tumors, or malignancies (Fig. 109-24). Dermoids appear sonographically as focal bright echoes in a complex adnexal mass. In general, septated, complex, irregular, and hyperechoic adnexal masses are more commonly malignant and require further investigation. The combination of a large, complex adnexal mass and ascites makes the likelihood of ovarian carcinoma very high.

FIG. 109-24. Complex mass. This adnexal mass (plus signs mark borders) has multiple hypoechoic and hyperechoic regions. This could represent a tubo-ovarian abscess, ectopic pregnancy, hemorrhagic ovarian cyst, or ovarian tumor.

OTHER CONDITIONS

Pelvic Inflammatory Disease and Tuboovarian Abscess

The diagnosis of pelvic inflammatory disease (PID) is usually made clinically, without the aid of ancillary studies. Ultrasound findings are unlikely to be noted early in the course of PID. In cases of severe PID, the ultrasound examination may demonstrate free fluid in the cul-de-sac or pyosalpinx. Pyosalpinx is an enlarged pus filled fallopian tube, which appears sonographically as a distinct circular structure with low-level echoes in the lumen when imaged in cross section. Pyosalpinx may appear to be a multicystic mass if multiple loops of distended tube are lying adjacent to one another. Sonographic evidence of pyosalpinx has been shown to be specific for the diagnosis of PID.[19] Tuboovarian abscess (TOA) is a complication of PID that can be accurately diagnosed using pelvic ultrasound. An abscess will appear sonographically as a complex mass with both cystic and solid components (Fig. 109-24). Percutaneous or transvaginal drainage of a TOA may be facilitated by ultrasound guidance.

Ovarian Torsion

Doppler ultrasound is commonly used for the evaluation of suspected ovarian torsion; however, the diagnostic accuracy of Doppler studies for ovarian torsion is poor. When torsion is present, the lack of internal ovarian blood flow on Doppler examination probably indicates that an ovary is beyond salvage. Also, the absence of blood flow to the ovary can be seen in a variety of cystic ovarian lesions when torsion is not present. Massive ovarian edema is an entity caused by intermittent or partial adnexal torsion. Doppler flow is present and resolution of the edema often occurs after detorsion of the adnexa. Simple gray-scale pelvic sonography is helpful when adnexal torsion is suspected, since most cases of torsion are secondary to large ovarian cysts or masses. The finding of a normal-sized ovary makes adnexal torsion unlikely.

110 FEVER

Carol D. Berkowitz

Fever is the single most common chief complaint of children presenting to the emergency department, accounting for about 30 percent of pediatric outpatient visits. Physicians evaluating febrile children must differentiate mildly ill from seriously ill children, a challenge that may be compounded when no focus of infection is apparent. The extent of the diagnostic workup and the institution of appropriate management, including the use of antibiotics and the need for hospitalization, must be determined. Many factors—such as clinical assessment, physical findings, age of the patient, and height of the fever—influence the evaluation and management decisions.

PATHOPHYSIOLOGY

Fever is defined as a rise in deep body temperature associated with a resetting of the body's thermostat. [1] This thermostat is located in the preoptic region of the anterior hypothalamus near the floor of the third ventricle. Exogenous fever-producing substances (pyrogens)—such as bacteria, bacterial endotoxin, antigen-antibody complexes, yeast, viruses, and etiocholanolone—may stimulate the formation and release of endogenous pyrogens. Endogenous pyrogens are produced by neutrophils, monocytes, hepatic Kupffer cells, splenic sinusoidal cells, alveolar macrophages, and peritoneal lining cells and are believed to induce the synthesis of prostaglandins in the hypothalamus. Endogenous pyrogens include interleukin 1, interleukin 6, and tumor necrosis factor. [2] The body's thermostat is then reset at a higher setting, and the patient, whose own temperature is below that of the body's thermostat, experiences a chill. Peripheral vasoconstriction, shivering, central pooling, and behavioral activity (e.g., putting on a sweater or drinking hot tea) lead to an increase in body temperature.

CLINICAL FEATURES

The possible beneficial effects of fever have been debated for many years. [3] Aside from these considerations, it is important to recognize that fever represents a symptom of some underlying disease, and one must determine what this disease is.

An initial question is "What degree of temperature elevation represents a fever?" One survey conducted among pediatric training programs revealed a wide variability in the temperature considered a "fever" in infants younger than 2 months of age. [4] This figure has ranged from 38° to 39.4°C (100.4° to 103°F). It is important to recognize that oral temperatures are generally 0.6°C (1°F) lower than rectal temperatures and axillary temperatures are 0.6°C (1°F) lower than oral temperatures. Temperatures taken using infrared thermometers that scan the tympanic membrane are of variable reliability and reproducibility. [5] Body temperature normally varies from morning to evening with the body's circadian rhythm. The degree of variation, which is greater in young women and small children, is about 1.1°C (2°F).

Current practice guidelines suggest a temperature of 38°C as a sufficient fever to warrant an evaluation. [6] The relationship between height of fever and incidence of bacteremia is discussed below. In general, higher temperatures are associated with a higher incidence of bacteremia. [7] A retrospective study of hyperpyrexia reported that the incidence of meningitis was twice as high in children with fever above 41.1°C (105.9°F), compared with children with fever between 40.5° and 41.0°C (104.9° and 105.8°F). [8] The incidence of pneumonia and bacteremia was the same in the two groups.

Other studies, many of which have also been retrospective, have had variable results and indicated that children with higher temperatures have more diagnostic studies ordered but the same incidence of different diseases. [9,10 and 11]

INFANTS UP TO 3 MONTHS

Diagnosis

The age of the patient influences the extent of the workup. Early studies suggested that infants younger than age 3 months were at high risk for life-threatening infection. [12,13] Recent studies based on outpatients show that the incidence of serious bacterial infection, including bacteremia and meningitis, is about 3 to 4 percent, although serious nonbacterial infections (e.g., aseptic meningitis) are a frequent cause of fever in this age group. [14,15 and 16]

Presentation History

The history often provides a clue to the diagnosis. When evaluating infants younger than the age of 1 to 2 months, it is critical to review the birth history because the etiology of the infant's infection may be birth related. The key points to question include the length of the gestation, the use of antibiotics in the mother or infant, and the presence of any neonatal complications, such as fever or tachypnea. Although an organ-specific list of inquiries may be helpful in treating older infants, it is less useful in younger ones because the signs and symptoms of sepsis may be very nonspecific. For instance, vomiting and diarrhea accompany many problems, including gastroenteritis, otitis media, urinary tract infections, and meningitis. [16] Cough or respiratory symptoms would be consistent with a respiratory infection. Frequency of urination is important to assess as a measure of the state of hydration.

Physical Examination

Infants should be undressed completely to enable a full assessment. Vital signs are important to evaluate. For instance, tachypnea may be a clue to lower respiratory tract infection. Crying and the ease of consolability should be evaluated. Inconsolable crying, or increased irritability when handled, is frequently seen in infants with meningitis. Although fullness of the anterior fontanelle may be noted in some of these infants, other signs of meningeal irritation, such as nuchal rigidity, are most often absent. A head-to-toe evaluation should be carried out to determine whether there is a focus of infection, such as an inflamed eardrum or evidence of cellulitis.

Clinical assessment of the severity of illness of young, febrile infants is, however, problematic. Young infants lack social skills, such as the social smile, and their ability to interact with examiners is limited. There is a report in the literature of an infant with group B streptococcal bacteremia who was judged by house staff and faculty to be clinically well. [12] The absence of any diagnostic abnormalities in the medical history or on physical examination suggests the need for extensive laboratory tests to detect occult infection. These tests would include a complete blood count (CBC) and differential, erythrocyte sedimentation rate (ESR), blood culture, lumbar puncture, chest x-ray, urinalysis and culture, and a stool culture if there is a history of diarrhea, particularly if leukocytes are noted on a stool smear. Some authors also recommend a quantitative C-reactive protein as an index of serious bacterial infection. [17,18] Urinary tract infections may not produce symptoms other than fever, and so a urinalysis and culture should be included routinely in the evaluation. Urinary tract infections may be associated with bacteremia in up to 30

percent of infected infants [19,20] and are the single most common bacterial infection in this age group.

The recognition of occult serious infection in well-appearing young, febrile infants is problematic. Most investigators agree that no single variable can correctly identify these infants. Combinations of variables are more helpful in the differentiation process. Criteria have been identified by a number of investigators, but are generally referred to as the Rochester criteria for low risk for serious bacterial infection in infants younger than 3 months of age. These criteria include nontoxic appearance, no soft tissue infection, white blood cells (WBCs) between 5000 and 15,000/mm^3, bands less than 1500/mm^3, normal urinalysis, and stool with less than 5 WBCs/hpf (high power field) in infants with diarrhea. [17,18] The risk of serious bacterial infection in the absence of these variables is about 0.2 percent.

Management

The appropriate management of young febrile infants presents another area of disagreement. [21] There appears to be no "community standard of practice" regarding the need for hospitalization; some physicians hospitalize all febrile infants younger than age 3 months, and others hospitalize only those under age 1 month. Because the differentiation between sick and well infants is so difficult, all such febrile infants need extensive septic workups. The decision not to hospitalize a small febrile infant must be made after careful clinical and appropriate laboratory assessment and after ensuring the reliability of follow-up.

Current management strategies include the administration of ceftriaxone at a dose of 50 mg/kg to febrile infants between 1 and 3 months of age who are judged to be at low risk for serious bacterial infection when the above criteria are used. [22] A caretaker with a telephone is an additional criterion for such outpatient management. Similarly, Baskin and colleagues [23] proposed inpatient management of febrile infants who are between 2 and 4 weeks of age and also judged to be at low risk, using parenteral ceftriaxone and only 24 h of observation. Infants could be discharged if cultures were negative after 24 h.

INFANTS OF 3 TO 24 MONTHS

Diagnosis

Many of the considerations noted in the evaluation of infants younger than 3 months of age apply for older infants. Patients between 3 and 36 months have been the focus of considerable research because this group appears to be at higher risk for occult bacteremia. These studies have sought to identify clinical and laboratory characteristics of bacteremic patients. [7,24,25]

Clinical judgment appears to be more reliable in the assessment of older infants. Characteristics that evaluating physicians should note are willingness of patients to make eye contact, playfulness and positive response to interactions, negative response to noxious stimuli, alertness, and consolability. Toxic infants will not respond appropriately. [26]

Presentation History

Again, the medical history and physical examination will frequently reveal the source of infection. Viral illnesses, including respiratory infections and gastroenteritis, account for the majority of febrile illnesses and usually have system-specific symptoms, such as vomiting, diarrhea, rhinorrhea, cough, or rashes. In this age group, such symptoms are more often indicative of an organ-specific infection. Bacterial infections of the respiratory tract include most notably otitis media, pharyngitis, and pneumonia. Otitis media is generally caused by *Streptococcus pneumoniae* or *Haemophilus influenzae*, and antibiotic therapy, such as amoxicillin, should be directed at these organisms. [27] Although pneumonia is commonly of viral etiology, it is appropriate to institute antibiotic therapy with amoxicillin or erythromycin. The physical signs of meningitis, such as nuchal rigidity and Kernig or Brudzinski signs, may be inapparent in children even up to the age of 2 years. A bulging fontanelle, vomiting, irritability that increases when the infant is held, inconsolability, or a febrile seizure may be the only signs suggestive of meningitis. Infants with aseptic meningitis should generally be hospitalized and ensured adequate long-term follow-up because they are at higher risk for subsequent neurologic and learning disabilities. The presence of petechiae on physical examination should alert physicians to the potential presence of a serious underlying infection. Up to 20 percent of children may have bacteremia or meningitis most frequently with *Neisseria meningitidis* or *H. influenzae*. [28,29] Petechiae in association with high fever (³40°C), ESR at or above 30 mm/h, and WBCs of at least 15,000/mm^3 are most frequently correlated with bacteremia.

Bacteremic infants may or may not have an obvious focus of infection. The height of the fever is a clue to which infants are bacteremic. Although bacteremia may be seen at lower temperatures, a temperature of over 39.5°C (103.1°F) in infants aged 3 to 36 months is associated with a higher incidence of bacteremia. Certain laboratory tests have been recommended to assist in further identifying bacteremic patients. WBCs over 15,000/mm^3, band counts of at least 500/mm^3, total polymorphonuclear counts at or above 10,000/mm^3, and band plus polymorphonuclear counts equal to or greater than 10,500/mm^3 are associated with an increased incidence of bacteremia, although bacteremia also occurs in the absence of these findings. [30] The incidence of bacteremia in children 3 to 24 months of age with a temperature of 39.5°C (103.1°F) or over is about 5 to 6 percent. The incidence increases to 12 to 15 percent in patients with WBCs of 15,000/mm^3 or over. An ESR at or above 30 mm/h has the same significance as WBCs of 15,000/mm^3 or greater. [7,25,26] The organism most commonly causing bacteremia in this age group is *S. pneumoniae. Haemophilus influenzae* has been rarely implicated in cases of occult bacteremia since the availability of *H. influenzae* vaccine.

Is it important to perform a blood culture to detect occult bacteremia? [31] Opinions vary on the answer to this question. It is apparent that bacteremic patients do better if they receive antibiotics early on. [32] Many bacteremic children do have a focus of infection and so are treated anyway. Additionally, in at least 25 percent of bacteremic patients with no focus of infection, the bacteremia is resolved without any antibiotics. Others develop soft tissue infections, which are then appropriately managed. The ability of oral antibiotics to prevent the development of meningitis in bacteremic children is still unclear. The blood culture appears to be useful for following patients who may not be returning for periodic evaluations. Therefore, from a medical and epidemiologic standpoint, blood cultures are indicated in high-risk infants or those in whom the physician suspects an infection.

Management

Is there a role for the use of expectant antibiotics in children suspected of having occult bacteremia? Retrospective studies have all shown that early antibiotics diminished the incidence of persistent bacteremia. In a prospective randomized study comparing oral penicillin to no antibiotics, no improvement was reported in any bacteremic child who did not receive antibiotics. [33] Other investigators report more equivocal results. Outpatient daily injections of ceftriaxone are being used by some physicians for children at increased risk of occult bacteremia. Controlled trials investigating the efficacy of this therapy have demonstrated a reduction in the incidence of meningitis in bacteremic children treated with ceftriaxone compared with those treated with oral or no antibiotics. Parenteral ceftriaxone should never be initiated without appropriate antecedent diagnostic studies. Treatment should be discontinued if cultures are negative. The risk from the overuse of ceftriaxone is the emergence of resistant organisms, a phenomenon that has already been observed. [34] Current recommendations suggest that well-appearing infants between 3 and 36 months of age, with no focus of infection, and fever greater than or equal to 39.5°C (103.1°F) and WBCs over 15,000 or a temperature over 40.0°C (104°F), regardless of the white count, may be candidates for expectant antibiotic treatment with ceftriaxone at a dose of 50 mg/kg given twice 24 h apart. If cultures are negative after 48 h, no further treatment is needed. Any child who appears ill or toxic should be admitted to the hospital. Likewise, children who are felt to be at risk for a serious bacterial infection, and do not have reliable follow-up or the ability to return to the hospital, should also be admitted for inpatient management. [35]

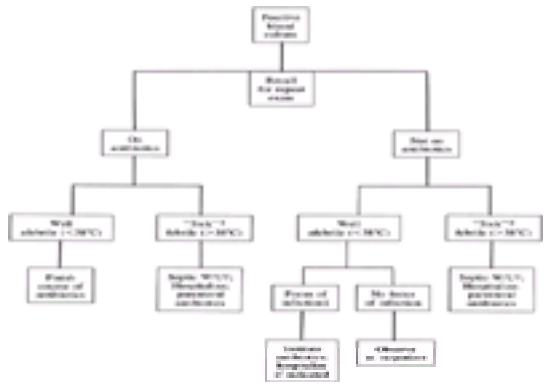
An additional dilemma surrounds the management of positive blood culture results. All patients with positive blood cultures should be recalled for repeat evaluation. If they are receiving appropriate antibiotics, are clinically well, and have been afebrile, they should be instructed to complete the course of therapy. If they are afebrile and clinically well but have never been treated with antibiotics, opinions differ regarding the need for additional blood cultures and antibiotic therapy. Generally, neither is necessary unless the child has developed a specific focus of infection. However, any patient who remains febrile or does poorly even if on antibiotics should receive complete septic evaluation (CBC, blood culture, lumbar puncture, chest film, and urine culture), be hospitalized, and receive parenteral antibiotics (Fig. 110-1).


FIG. 110-1. Management of bacteremic children; 1"Sick": irritable, lethargic, anorexic, vomiting; †septic W/U (workup): blood culture, lumbar puncture, chest x-ray, complete blood count, differential, urinalysis, urine culture; ‡focus of infection: otitis media, pneumonia, cellulitis.

OLDER FEBRILE CHILDREN

Diagnosis

Children over the age of 3 are easier to evaluate. They can specify their complaints and have illnesses similar to younger children, particularly upper respiratory infections and gastroenteritis. The risk of bacteremia appears lower in this age group, but the incidence of streptococcal pharyngitis is higher, especially in children between the ages of 5 and 10 and those with hyperpyrexia.[11] Infectious mononucleosis may present with fever, tonsillar hypertrophy, and exudate, like streptococcal pharyngitis. Marked lymphadenopathy or hepatosplenomegaly would support the diagnosis. Pneumonia in this age group may be caused by *Mycoplasma pneumoniae*. These children present with cough and fever. Rales may not be apparent early in the illness, although the chest film would show evidence of an infiltrate. Bedside cold agglutinins, if positive, provide a clue to the correct diagnosis. Children with pneumonia secondary to mycoplasma should be treated with erythromycin, 30 to 40 mg/kg per day (maximum dose, 1 g).

EMERGENCY DEPARTMENT CARE

Managing the Fever

Once the issue of fever as a symptom has been addressed, it is appropriate to determine the need for fever-reducing measures.

Many parents are concerned about the harmful effects of the fever; many are aware of the risk of febrile seizures. Children who are prone to febrile seizures are not benefited by antipyretics alone because the seizure frequently occurs early in the illness, often before the parents are aware that the child is ill. Aside from febrile seizures, fever is not known to produce any harmful effects in children. Many children, however, feel uncomfortable during the fever, and so it is appropriate to institute measures directed at symptomatically reducing the fever.

The body loses heat in four ways: (1) radiation (60 percent), heat loss from the body to the air in the surrounding environment; (2) evaporation (25 percent), heat loss through the evaporation of perspiration, water, or any liquid applied to the body surface; (3) convection (10 percent), heat loss when air currents blow over the skin; and (4) conduction (approximately 5 percent), heat loss through contact with solid surface. Heat loss through conduction is increased by the use of cooling blankets.

One can facilitate heat loss in children by using any combination of these measures. Unwrapping a bundled child increases heat loss through radiation, and rehydrating a dehydrated child will increase the heat loss through evaporation. Sponging also helps to reduce fever by evaporation. Sponging should be done slowly, using tepid water only. Very rapid cooling by sponging can result in peripheral vascular collapse, and death among small, critically ill infants, has been reported. Sponging with ice water is uncomfortable for children and results in shivering, and sponging with alcohol carries the risk of intoxication, hypoglycemia, and coma. Vigorous rubbing of the skin induces vasodilatation and improves heat loss.[36]

Studies have shown that sponging and antipyretics used together are more effective than either modality used alone. Acetaminophen, ibuprofen, and aspirin are equally effective and appear to work centrally to block prostaglandin synthesis. Heat is lost through peripheral vasodilatation and sweating.

Drug dosage for aspirin or acetaminophen is 10 to 15 mg/kg per dose at 4-h intervals (maximum dose, 600 mg). Increasing the dose does not result in a better or more-sustained effect. Administration of either drug by rectal suppository results in a slight delay in absorption. No studies have evaluated the efficacy of alternating the two drugs at 2-h intervals in an effort to avoid the recrudescence of fever. Administration of the drugs simultaneously at the usual dosage produces a reduction in temperature that is sustained for 6 h rather than 2 to 4 h.[37] The dosage of ibuprofen is 5 mg/kg for fevers less than 39°C (102.2°F) and 10 mg/kg for fevers over 39°C (102.2°F). Ibuprofen may be given every 6 to 8 h, with a maximum daily dose of 40 mg/kg.[38] The key to assuring a good outcome is judicial management, follow-up, and reassessment. It is not appropriate to simply administer ceftriaxone and assume that any infection an infant may have has been appropriately covered. Emergency physicians must be certain that infants can be reevaluated to assure that other problems have not emerged.

The use of aspirin has been curtailed following reports linking aspirin and Reye syndrome. Aspirin should not be used in children with chickenpox or with influenza-like illnesses. The effects of aspirin are cumulative, and more than half of the reported overdoses involve therapeutic misuse. Other side effects of aspirin include gastrointestinal upset and hemorrhage and coagulation disturbances. Acetaminophen is also toxic if taken in inappropriate doses, but there is no cumulative effect, and children are less prone than adults to hepatotoxicity. Side effects of ibuprofen are similar to those of aspirin and include gastrointestinal ulceration, bleeding, and perforation. Platelet disturbances are also reported but are felt to be reversible with cessation of therapy.

111 ASSESSMENT OF THE CHILD IN THE EMERGENCY DEPARTMENT: A PRACTICAL APPLICATION OF NORMAL CHILD DEVELOPMENT

Peter Mellis

Children account for approximately 30 percent of visits in most emergency departments. The majority have minor or self-limited illness, which may optimally be cared for in a nonemergent setting. However, the differentiation of critically ill pediatric patients from the larger number of less ill children with similar complaints represents one of the most important and challenging diagnostic skills for emergency physicians. The key to mastering this process of identifying ill children is a knowledge of child development as applied to the emergency setting.

GENERAL PRINCIPLES OF THE DEVELOPMENTAL APPROACH

Although there are many specific aspects of the developmental approach, a few general principles are applicable to all age groups of children and their families.

Communicate with the Child

Children are best approached in a positive and gentle manner, with an awareness that the first impression sets the tone for the encounter. Review the emergency record for patient name and age so that an introduction and a developmentally structured interaction may be planned. An awareness of the child's age-related communication skills and perspective will result in a more meaningful evaluation. Whenever possible, look at the child from his or her own eye level. Use the child's motor skills, vocabulary, and specific life experiences as reference points. Hunger, discomfort, fear of separation or pain, and feelings of loss of control should be directly addressed. Recognize that the emergency department is a strange and threatening environment and, whenever possible, isolate the child from the sights and sounds of other patient care experiences that may heighten their own anxiety. Most importantly, be honest with children regarding expectations for their experience so that trust can be established.

Communicate with the Family

Assess and treat the child in the context of his or her family, avoiding separation whenever possible. Emergency department policy should encourage parental accompaniment of children to the clinical area. It is optimal to consider that there are two patients, child and parent(s), each with expectations that must be addressed. Caregivers have essential historical information and, in the case of infants and toddlers, are physically necessary to the performance of a meaningful physical assessment. At all ages, children watch their parents for cues with respect to how to respond to the medical staff. Parents who understand and accept the sequence of events involved in emergency care become allies in enlisting their child's cooperation. Whenever possible, parents should be encouraged to remain present during procedures, maintaining visual and physical contact from a sitting position. Appropriate exceptions include parental discomfort and critical illness. Finally, because parents are intimately familiar with their child's range of verbal and nonverbal behavior, the examiner must take the phrase "this is not my child" as parental concern for abnormal level of consciousness. This reliance on parental knowledge is particularly applicable to the assessment of a child with developmental delay.

Assess by Means of Observation

Every effort should be made to gain information regarding a young child prior to interacting with him or her directly. Infants and young children communicate a normal level of consciousness through age-appropriate motor and social responses to their environment. Observe the child's behavior from a distance, preferably without his or her awareness. This can often be accomplished while obtaining the history from the caretakers. Antipyretic therapy and satisfying hunger are often crucial to achieving this period of optimal observation. Often more is learned regarding neurologic status from a brief period of observation than from the traditional physical examination. Nonemergent, uncomfortable examination components and procedures should be performed last.

Obtain Meaningful Vital Signs

Normal ranges for heart rate, respiratory rate, and blood pressure vary significantly with age and must be interpreted in the context of a child's activity at the time (Table 111-1). Anxiety, pain, fever, and crying will increase all values, and these states should be documented if present. Optimal vital signs are obtained without eliciting an adverse reaction to the examiner (e.g., respiratory rate taken by observing abdominal movements, and heart rate auscultated through clothing). If fever is a concern, temperature should be obtained rectally in infants, toddlers, and uncooperative children, because the oral, axillary, and tympanic routes are less reliable. Temperature measured by the oral route is likely to be feasible and accurate in children by 4 to 5 years of age. Blood pressure should be measured on previously well children who are 5 years of age and older (school age), children with chronic disease associated with hypertension (e.g., renal disease), and all children who are critically ill. Weight is a pediatric vital sign because of dosing considerations and the importance of growth as an indicator of chronic disease in children. Appropriate scales and growth charts should be available in emergency departments. For resuscitation purposes, bedside estimates of weight are frequently inaccurate, and length-based resuscitation resources (e.g., Broselow tapes) are recommended.

Age	Heart Rate/min, Upper Limit	Respiratory Rate/min, Upper Limit	Blood Pressure,* Lower Limit	Weight,† kg
0–1 Month	190	60	60/40	3–4
2–12 Months	160	50	70/45	5–10
12–24 Months	140	40	75/50	10–12
2–6 Years	120	30	80/55	13–25
6–12 Years	110	20	90/60	25–40
>12 Years	100	20	90/60	40–60

*May be estimated by
  systolic blood pressure (5th percentile) = 70 + [2 × (age in years)]
†May be estimated by
  ≤12 months: weight (kg) = 4 + (age in months/2)
  1–12 years: weight (kg) = 10 + [2 × (age in years)]

TABLE 111-1   Pediatric Vital Signs (Awake and Resting)

GROWTH AND DEVELOPMENTAL STAGES

The process of development is not unique to children, but the pace at which change occurs and the implications for patient care are maximal during this period of life. *Developmental stages* are described with associated age ranges, but these are best viewed as a sequence of events with significant individual variation in rate of progression. For purposes of facilitating patient care in the ED, two aspects of each developmental stage must be considered. *Physical aspects* include growth and physiologic parameters unique to a given developmental stage, a knowledge of which is essential to provide excellent care. *Neurologic aspects* include motor, language, and social/psychological milestones that impact on both patient assessment and responses during acute illness or injury. These milestones and their related strategies are summarized in Table 111-2. Based on a knowledge of these, the examiner is well equipped to proceed with a developmentally *age-specific approach.*

Stage	Milestone	Strategy
Early infancy (0–6 months)	Motor: lifts head, reaches; Verbal: cooing; Social: responsive smile	Observation; Examine in parent's arms; Direct approach
Late infancy (6–18 months)	Motor: reaches/obtains, sits, walks; Verbal: jargon, few words; Social: stranger anxiety/dependence	Observation; Examine in parents arms; Indirect approach
Toddler (18–36 months)	Motor: walks well, scribbles; Verbal: speaks in phrases; Social: stranger anxiety/autonomy	Observation; Indirect approach
Preschool (3–5 years)	Motor: runs well, colors; Verbal: speaks in sentences; Social: magical thinking	Indirect or direct approach; Explain briefly just prior to procedures
School age (5–12 years)	Motor: schoolwork, sports; Verbal: concrete reasoning; Social: task oriented	Direct approach; Explain in detail prior to procedures
Adolescence (12–17 years)	Motor: adult; Verbal: abstract reasoning; Social: autonomy, rebellion	Direct approach; Confidentiality; Treat as adult

TABLE 111-2   Developmental Stages and Emergency Department Assessment Strategy

Early Infancy (0 to 6 Months)

PHYSICAL ASPECTS   Rapid growth rate is a characteristic feature of young infants, for whom the major work is eating. After a 5 to 10 percent loss over the first 3 days of life, term infants regain birth weight by 10 days of age. A 20- to 30-g/day weight gain is the best overall sign of health. Normal infants double their birth weight by 5 months. Young infants have a high surface area to body mass ratio with a proportionally large head, resulting in a high rate of heat loss and risk of hypothermia. The normal anterior fontanelle is slightly depressed when a child is upright. Young infants are obligate nose breathers and may experience partial airway obstruction with abnormal positioning or viral upper respiratory tract infections. Normal neonates may exhibit periodic breathing, or 5 to 10 s pauses followed by tachypnea, due to immature central control of respiration. Both cardiac output and minute ventilation are relatively rate dependent in early infancy. A heart rate greater than 180/min and a respiratory rate greater than 60/min should be considered abnormal. Blood pressure is well maintained by compensatory mechanisms at this age, with hypotension a very late finding in shock. The pulmonary vascular bed dilates over the first 6 weeks of life, so that congenital heart lesions resulting in a left-to-right shunt, for example, ventricular septal defect, will present after this age. Finally, the primary series of immunizations, including diphtheria-pertussis-tetanus (DPT), oral poliovirus (OPV), and *Haemophilus influenzae* type b (HIb), are completed by 6 months of age (Table 111-3). The rotavirus vaccine had been added to the primary immunization series, but recent reports of possible association with intussusception have resulted in temporary cessation of use.

Age	DTP	OPV	Hib	MMR	HepB	VZV	RotV
Birth					HepB		
2 Months	DTP	OPV	Hib		HepB		RotV
4 Months	DTP	OPV	Hib				RotV
6 Months	DTP		Hib		HepB		RotV
12–15 Months			Hib	MMR			
15–18 months	DTP	OPV				VZV	
4–6 Years	DTP	OPV					
11–12 Years				MMR			
14–16 Years	Td						

TABLE 111-3   Recommended Schedule of Childhood Immunizations*

NEUROLOGIC ASPECTS   Motor development is the major indicator of neurologic health and proceeds in a cephalocaudal fashion. Neonates demonstrate involuntary "primitive" reflexes, such as the suck, grasp, and Moro (startle) responses, which may be elicited to demonstrate muscle tone and should always be symmetric. By 1 month of age, infants can lift their heads, follow a moving object, and demonstrate a social smile. By 4 months, head control is steady, the child will reach for and grasp objects with the whole hand, a cooing response may be elicited, and rolling over has begun. During this period, normal infants learn trust from their parents and will respond positively to a gentle examiner. This is the period of least parental confidence, and many emergency department visits are made because of lack of knowledge and a need for reassurance.

AGE-SPECIFIC APPROACH   Assessment is optimally made by direct interaction using a pleasant, confident tone of voice and smiling face directed toward the infant. Observation of muscle tone, spontaneous activity, eye contact, responsive smile, and recognition of parents is most important. Examination of the infant is best performed in the parent's lap, with use of brightly colored or pleasant-sounding objects to elicit a motor response. Feeding the infant or eliciting the sucking reflex with a finger will often result in greater cooperation. Optimal examination is done in order of least to most invasive interactions, i.e., observation, auscultation, and palpation, being careful to avoid uncomfortable procedures such as ear and throat examination until the child's level of consciousness is established. Parental confidence should be directly reinforced. Young infants should be carefully monitored during procedures involving conscious sedation or abnormal positioning, because of the risk of airway compromise. Finally, the motor abilities of young infants result in a limited potential for self-inflicted accidental injury. Whenever an injury is developmentally inconsistent with the stated mechanism, the potential for child abuse must be investigated.

Late Infancy (6 to 18 Months)

PHYSICAL ASPECTS   Normal infants triple their birth weight by 1 year of age, but the rate of growth slows during this period. The primary teeth begin to erupt by 6 months of age, with an average rate of acquisition of one per month. Head size, center of gravity, and surface area to mass ratio remain large in comparison to adults. The anterior fontanelle is closed by 18 months of age. The measles-mumps-rubella (MMR) vaccination is given at 12 to 15 months of age, and the varicella vaccine is given at 12 to 18 months of age. The DPT and HIb boosters are given during this same period (Table 111-3).

NEUROLOGIC ASPECTS   The normal infant sits with minimal support, transfers objects from hand to hand, and babbles by 6 months. By 9 months of age, the infant is crawling, pulling to a standing position, and verbalizing with nonspecific jargon. By 12 months, the infant has a mature pincer-type grasp, begins to walk, and acquires specific words. The developmental combination of mobility and grasp results in increasing risk of toxic and foreign-body ingestion. Between 9 and 12 months, a strong sense of "stranger anxiety," related to fear of separation from parents, is acquired and complicates every aspect of physical assessment. Conversely, the failure of an older infant or toddler to recognize and preferentially respond to parents suggests significant disease.

AGE-SPECIFIC APPROACH   Assessment of an older infant and toddler begins with observation, preferably without the child's awareness of the examiner's presence. The child should be undressed to obtain a meaningful respiratory rate and to observe the work of breathing. Spontaneous motor activity, such as sitting and pulling up, and purposeful responses to parental overtures, such as reaching for objects and smiling, are indicators of a normal level of consciousness. The child

should see the examiner approach gradually and engage his or her caretakers first. An entire examination requiring any degree of cooperation is best performed while the child is held on the parent's lap or shoulder so that perception of separation is avoided. As for younger infants, the examination proceeds from least to most invasive interactions. Procedures in this age group require adequate physical restraint. Although parental restraint is acceptable for nonpainful examination procedures, parents should not be asked to immobilize their child for invasive procedures. Caretakers should be encouraged to remain present to reassure their child during procedures if it is their desire to do so. The high level of anxiety at this age frequently results in persistently uncooperative behavior despite adequate analgesia. Sedation for procedures may require a significantly higher per-kilogram dose of anxiolytic/analgesic drug to achieve the desired effect.

Toddler (18 to 36 Months)

PHYSICAL ASPECTS   Decelerating growth rate and decreased appetite are seen during this period, although the head approaches its adult size. The 20 primary teeth are in place by 36 months, and dental caries are common. High center of gravity, mobility, and curiosity lead to increasing risk for head and orthopedic injuries. A toddler's open growth plates are far more likely to sustain epiphyseal fracture than ligamentous injury. Traction injuries to the arm will frequently result in subluxation of the annular ligament of the radial head (i.e., "nursemaid's elbow").

NEUROLOGIC ASPECTS   By 18 months of age, most children can walk well, feed themselves, follow simple commands, and use four to six words to indicate their desires. Stranger anxiety peaks at this age but remains important throughout the toddler period. By 24 months, most children can run, climb stairs, and speak with three-word phrases, although only 50 percent of speech is intelligible to nonfamily members. Toddlers understand far more than their spontaneous speech would indicate and learn by imitating the behavior of their family members. When given opportunity to draw, a toddler will scribble with a brief attention span. Parents consistently underestimate the mobility and problem-solving ability of a toddler, resulting in a peak risk for falls and ingestions at this age.

AGE-SPECIFIC APPROACH   An examination strategy of indirect observation followed by direct interaction in the safety of the parent's arms should be followed, as described for older infants. The examiner should encourage the parent to have the toddler walk and follow commands as an important component of the assessment for acute systemic or neurologic disease. Allow the child a favorite object, such as a doll or blanket, for comfort during the examination. Talk to the child in simple language about what you will do and offer to let the child touch or hold the examination instruments in order to gain their trust. Older toddlers may indicate the site of pain specifically, but many will be unable to communicate localized pain or tenderness. As described above, perform the physical assessment in order of least to most invasive examination components. As for older infants, restraint is routinely indicated for painful procedures and a higher per-kilogram dose of anxiolytic/analgesic drug may be required. Because of likelihood of epiphyseal fracture, a young child with tenderness over the growth plate following injury should be immobilized with a splint, even if x-ray films are negative.

Preschool Age (3 to 5 Years)

PHYSICAL ASPECTS   Growth rate slows significantly during this period, and appetite decreases further. Children develop a more lean body habitus. The incidence of injuries increases with increasing activity. The preschool child is no longer restrained in a car seat and is at risk for defined injury complexes from improperly fitting lap and shoulder belts. A DPT booster is given shortly before beginning school, between the ages of 4 and 6 (see Table 111-3).

NEUROLOGIC ASPECTS   Preschool children develop progressive autonomy in terms of mobility and self-care. Attraction to books, drawing, and coloring is common. Expressive language skills expand rapidly, and children this age are often able to identify site(s) of specific complaint. However, a strong sense of fear of pain remains, and the level of anxiety remains high in the emergency setting. Preschool children live in the present and have a limited sense of time and history, so that prior symptoms are frequently forgotten. Self-centered "magical" reasoning is the rule, so that many preschool children believe that emergency department care is punishment for misbehavior. This is occasionally reinforced by parents who state they will "have the doctor give you a shot," which should be discouraged.

AGE-SPECIFIC APPROACH   Many preschool children may be directly approached and examined in the traditional systematic fashion. However, some will require the indirect approach described for toddlers, and the nearby presence of a parent is typically essential for cooperation. The examiner should always talk directly with the preschooler to establish rapport and confirm the general complaint. Identification of recent positive experiences such as birthdays or favorite cartoon characters is frequently helpful in gaining cooperation. However, preschool children should be expected to identify only the current complaint, and reliance on parental history should remain. Cooperation during the physical examination is likely, although less comfortable components are still best performed at the end. The performance of painful procedures requires a careful approach. It is always best to be honest regarding discomfort, but information should be given immediately before performing the procedure to minimize the effects of fantasy regarding pain and causality as well as delaying tactics. Comfort and distraction by the parent is frequently effective for minor procedures; however, restraint as for toddlers is typically necessary. Rewards such as verbal praise and a sticker for bravery often significantly enhance the memory of the experience for the child and family.

School Age (5 to 12 Years)

PHYSICAL ASPECTS   The school years represent the slowest period of growth in childhood, and the body habitus is typically slender. The primary teeth are loosening and the secondary teeth erupt. The lymphatics reach maximal dimensions relative to body size by 6 years of age. There is increased physical activity, including organized sports, during this period, and injuries become common.

NEUROLOGIC ASPECTS   School-age children experience rapid language growth and maturing motor ability. Concrete reasoning ability emerges with an ability to understand cause and effect. The child is increasingly aware of his or her body and develops a sense of modesty. Task-oriented behavior is common, and school and sports activity are typically the central events of the child's life. School-age children are eager to please and often reluctant to express their fears of pain and death.

AGE-SPECIFIC APPROACH   The direct examination approach is typically successful for school-age children. Parental accompaniment and respect for modesty should be maintained. Historical information should be elicited from child as well as parent. An effort to inquire about school or extracurricular interests will enhance rapport. Change in school performance is a helpful indicator of chronic disease. Painful procedures are best preceded by explanations to both parent and child, given well in advance with honesty regarding discomfort. The child should be given some degree of choice in the manner in which the procedure is completed, such as a comfortable position, in order to minimize the sense of loss of control.

Adolescence (12 to 17 Years)

PHYSICAL ASPECTS   The teen years mark a second period of rapid growth, beginning at age 10 in girls and age 12 in boys. Secondary sexual development begins shortly after beginning the growth spurt, with menarche starting between 10 and 16 years in girls. Sexual activity and drug use are common during adolescence, and many teens are parents themselves, complicating both the differential diagnosis and issues of maturity and reliability in carrying out the follow-up plan.

NEUROLOGIC ASPECTS   Abstract reasoning ability progressively develops during adolescence, paired with a self-centered worldview and self-consciousness regarding appearance. Feelings of immortality and denial of the consequences of risky behavior are common. Loss of autonomy is the greatest fear of an adolescent, and mistrust of and rebellion toward authority is normal. Previously well-controlled chronic disease frequently becomes unstable as a result of these developmental issues. Psychiatric disease and suicidal behavior are increasingly recognized in this age group. The parents of teenagers are frequently angered by these changes and may project these feelings on the emergency department staff.

AGE-SPECIFIC APPROACH   The traditional history and physical examination with respect for modesty is effective in the assessment of adolescents. The examiner should communicate to the teenager that he or she will be treated "like an adult." Choices must be allowed, such as parental presence during the examination, with proper limit setting regarding cooperative behavior. The parent's concerns must be addressed individually and, if necessary, in private. Confidentiality should be stressed, particularly as the law requires with respect to pregnancy and sexually transmitted disease.

MEDICAL CONSENT AND THE TREATMENT OF MINORS

Consent for evaluation and treatment must be obtained for medical care to be delivered in a lawful manner. State laws vary regarding the age of majority at which consent may be given by a patient, varying between 18 and 21 years of age. In the case of minor children, consent must be obtained from the legal guardian (typically a parent, unless custody has been removed) prior to initiation of treatment. This does not apply, however, to triage and examination, and children should be evaluated without delay to determine the nature of the illness or injury. If the child is not accompanied by persons able to provide consent, the parent or guardian should be contacted by phone and witnessed consent obtained. Such attempts should be documented in the medical record. Written documentation from the parent or legal

guardian granting consent may suffice in many states, but this should not obviate attempted phone contact for permission to treat. In the absence of consent, the patient should be evaluated sufficiently to determine the presence or absence of an emergent situation. In the setting of an emergency situation in which delay in treatment may threaten the life or health of the child, consent can be assumed and care initiated with ongoing attempts to locate the parent or guardian. If any doubt exists, the emergency physician and patient are best served by providing treatment with documentation of efforts to determine the presence of an emergency and obtain consent for treatment. In the absence of an emergency, further care should not be provided unless specifically permitted under state law (Table 111-4). Most states permit minors to seek treatment for child abuse, substance abuse, sexually transmitted diseases, and pregnancy-related complaints without parental consent. Most states consider a child "emancipated" and able to provide consent if a member of the armed forces, married, or self-supporting and living on his or her own. Some states permit older minors to give consent for nonemergent care. Many states have a process for obtaining concurrent judicial review and consent. Emergency physicians are encouraged to become familiar with the specific state laws applicable to consent issues. [2] As a matter of courtesy and necessity, verbal consent should be obtained from older minors as well, typically at age 12 and older.

The age of majority varies by state. A minor should not receive care in an emergency department without consent obtained by parent or legal guardian with the following exceptions:
1. Life-threatening emergency
2. State-protected rights to treatment
   Child abuse
   Pregnancy
   Sexually transmitted disease
   Substance abuse
3. State-defined "emancipated minor" status
   Married
   Member of armed forces
   Self-supporting and living on his or her own

TABLE 111-4   Consent for Treating Minors

Parental refusal of consent for care in the setting of possible life-threatening emergency or child abuse presents emergency physicians with a significant challenge. If parental consent cannot be obtained, a court order should be obtained through the appropriate local mechanism to to allow the provision of necessary care for the well-being of the child.

112 COMMON NEONATAL PROBLEMS

M. Yousuf Hasan
Niranjan Kissoon

The assessment of neonates in the emergency department is more difficult than that of older children and adults. Symptoms are usually vague and nonspecific. Signs are usually subtle and, even when recognized, may not be helpful in pinpointing a diagnosis. For example, respiratory distress may be due to primary respiratory or cardiac disease, generalized sepsis, abdominal pathology, or metabolic derangements. Examination of neonates is time-consuming and requires special skills in the approach to the infant as well as the anxious parent.

The prerequisites for the proper evaluation of neonates are a great deal of patience and an appreciation of the marked variations in normal vegetative functions. Many visits are initiated because of parental concerns related to feeding patterns; weight gain; stool frequency, color, and consistency; and breathing patterns. Physicians involved in the care of neonates in the emergency department should therefore be knowledgeable about patterns of normal vegetative functions in the neonatal population.

NORMAL VEGETATIVE FUNCTIONS

Feeding Patterns

The feeding of infants requires practical interpretation of specific nutritional needs and the widely varying limits of a normal baby's appetite and behavior regarding food. Variation in times between feedings is to be expected in the first few weeks during the establishment of a self-regulation plan. By the end of first month, more than 90 percent of infants establish a suitable and reasonably regular schedule. Most healthy bottle-fed infants want six to nine feedings every 24 h by the end of first week of life; breast-fed infants prefer shorter intervals. [1,2]

Feedings should be considered as having progressed satisfactorily if the infant is no longer losing weight by 5 to 7 days and is gaining weight by 12 to 14 days. Parents usually need reassurance that their infant is obtaining adequate nutrition because of the wide variation in the intakes of normal infants. It is important to appreciate that infants cry for reasons other than hunger and that they need not be fed every time they cry.

Weight Gain

While it is difficult to precisely judge the caloric intake of breast-fed infants and feeding frequency varies widely, intake is adequate if the neonate is gaining weight appropriately and appears content between feedings. Normal newborns may lose 5 to 8 percent of their birth weight during first 3 to 7 days of life. A weight loss of up to 10 percent is acceptable if the infant's examination findings and behavior are normal. On average, infants gain between 20 and 30 g/day in first 3 months of life and 15 to 20 g/day for the next several months. It is important to weigh the infant completely undressed.

An infant's weight between 3 and 12 months of age can be calculated approximately by the following formula:

$$\frac{age\ (months) + 9}{2} = expected\ weight\ (kg).[3]$$

Stool Patterns

The number, color, and consistency of bowel movements may vary greatly in the same infant and among infants regardless of diet or environment. Breast-fed infants frequently will have 6 or 7 stools per day, while formula-fed infants generally have 1 to 2 stools per day. The first stool, which consists of meconium, is usually passed within first 24 h after birth. Transition stools, which are greenish brown, appear after initiation of milk feeding and are replaced by typical milk stools 3 to 4 days later. Infrequent bowel movements do not necessarily mean constipation, since breast-fed infants may occasionally go 5 to 7 days without a bowel movement. Stool color has no significance unless blood is present. Occasionally, an infant may not have a bowel movement on a given day. The stools of breast-fed infants are softer than those of formula-fed infants. Excessive intake of human milk or maternal use of laxatives further increases the water content of the infant's stool. Overfeeding or use

of formula that is too concentrated or too high in sugar content also can produce loose stools. [2,4]

Breathing Patterns

The respiratory rate ranges between 30 and 60 breaths per minute in infants. For premature infants it is higher and fluctuates more widely. Because fluctuations are rapid, the respiratory rate should be counted for a full minute with the infant in full resting state, preferably asleep. A rate consistently over 60 breaths per minute during periods of regular breathing should be evaluated further.

Since the breathing of newborn infants is almost entirely diaphragmatic, the soft front of the thorax usually is drawn inward during inspiration, while the abdomen protrudes. In a quiet infant, this paradoxical pattern has no clinical significance, but when it changes to predominantly thoracic breathing, intraabdominal or intrathoracic pathology should be suspected. On the other hand, an increase in abdominal breathing suggests pulmonary disease.

Newborn infants, especially those born prematurely, may exhibit periodic breathing, characterized by alternating periods of breathing at a normal rate and periods of a markedly slow rate of respiration, which may cease three or more times for 3 s or longer. Such alternating respiratory patterns have been observed in 30 to 95 percent of premature babies during sleep, but less frequently in term infants. Periods of apnea greater than 20 s or accompanied by bradycardia or cyanosis should be evaluated. [5,6]

Sleeping Patterns

Infants are not born with the ability to sleep through the night. Instead, they awaken every 20 min to 6 h, and sleep periods are spread evenly across day and night. By 3 months of age, most of their sleep occurs at night, and by 6 months, most infants are sleeping through the night.

Night waking is defined as waking and crying once or more between midnight and 5 A.M. at least four of seven nights per week for at least four consecutive weeks. This occurs in approximately 25 percent of infants usually under 12 months of age. This prevalence rises to about 50 percent among breast-fed infants. When the child cries during the night, parents can check to ensure that there is no physical reason for the crying. Having determined that there is no physical problem, parents should ignore the crying so that the child learns to fall asleep on his or her own. If parents usually feed the child at that time and the child is older than about 6 months, the volume of the night feedings should be tapered until they are discontinued and all nourishment is given during the daytime. [7,8]

REASONS FOR EMERGENCY DEPARTMENT VISITS

A review of presenting complaints in our pediatric emergency department, a tertiary-care referral center, over a 6-month period indicates the spectrum most likely to be seen by the emergency physician (Table 112-1). Complaints in neonates are usually not single; rather, they are often symptom complexes. Such symptom complexes reflect the nonspecific nature of signs and symptoms in neonates and the similar presentation of many diseases of diverse etiology.

Crying, irritability, lethargy (see Table 112-2)
Gastrointestinal tract symptoms
    Feeding difficulties
    Regurgitation
    Vomiting
    Diarrhea
    Abdominal distention
    Constipation

Cardiorespiratory symptoms
    Rapid breathing
    Cough and nasal congestion
    Noisy breathing and stridor
    Apnea, periodic breathing
    Blue spells, cyanosis

Jaundice

Eye discharge, redness

Diaper rash, oral thrush

Fever and sepsis

Sudden infant death

TABLE 112-1   Common Presenting Complaints

Crying, Irritability, and Lethargy

The symptom complex of crying, irritability, and lethargy is fairly common yet difficult to treat, even in the presence of an identifiable cause. Most neonates exhibit varying degrees and periods of crying during a 24-h period. However, infants who present with an episode of acute, inconsolable crying should be observed closely for an underlying cause (Table 112-2). [2]

Intestinal colic
Traumatic conditions
    Battered child syndrome (e.g., fractures, burns, etc.)
    Falls (e.g., skull or extremity fractures)
    Open diaper pin
    Strangulation of digit or penis
    Corneal abrasion or foreign body

Infections
    Meningitis
    Generalized sepsis
    Otitis media
    Urinary tract infection
    Gastroenteritis

Surgical
    Incarcerated hernia (umbilical or inguinal)
    Testicular torsion
    Anal fissure

Improper feeding practices

TABLE 112-2   Conditions Associated with Uncontrollable Crying, Irritability, and/or Lethargy in Neonates

Intestinal Colic

Colic is a paroxysm of crying for 3 h/day or more for 3 days/week or more over a 3-week period. The incidence of colic is about 13 percent, with no seasonal variation. Colic is a symptom complex consisting of the sudden onset of paroxysmal crying lasting several hours, a flushed face, circumoral pallor, tense abdomen, drawn up legs, cold feet, and clenched fists. It usually begins soon after birth but seldom lasts beyond 3 months of age. A careful history is important in diagnosis of colic; findings upon physical examination are normal, and laboratory tests are not required. However, when the diagnosis is unclear, a careful history, physical examination, and appropriate laboratory investigations are necessary to rule out conditions listed in Table 112-2. In doubtful situations, admission for observation or return for reassessment is reasonable.

The cause of colic is unknown. Proposed causes include excessive intake of air, insufficient intake of fluid, allergy to protein, and maternal stress. Just as the cause remains obscure, no single treatment has been proven effective for all infants who have colic. Changing formula, applying heat to the abdomen, decreasing external stimulation, and rocking the infant all have been advocated as useful interventions by various authorities at various times. Administration of drugs (including sedatives) rarely is beneficial or indicated. Reassuring the parents that colic is a common, self-limited problem in young infants and encouraging them to share care-giving responsibilities during this time can be helpful.

The emergency physician can also be helpful by making the following suggestions:

- Changes in care-taking styles (e.g., increased carrying and rocking, feeding more frequently, and use of a pacifier)
- Changes in environment (e.g., background music or car and stroller rides)
- Changes in feeding for refractory cases (e.g., removal of cow's milk from the diet of an infant who has visible peristalsis, persistent regurgitation, and symptoms after ingesting cow's-milk protein; removal of cow's milk from the diet of a mother of a breast-fed baby; but not switching to formula from breast milk or changing formula).[8,9 and 10]

Abuse and Trauma

Distinguishing between accidental and intentional injuries is vital. By making an accurate determination, the practitioner achieves two equally important objectives:

- Protecting victims of abuse from future harm, which is often more severe than the present injuries; and
- Avoiding the damage done by unwarranted suspicion of abuse and the time-consuming investigative process that ensues.

Recognition of abuse and neglect is likely only if the possibility is entertained in the differential diagnosis of the presenting condition. The approach to the family should be supportive, empathic, and nonaccusatory. (See Chap 289 for a detailed discussion.)

Approximately one-third of the cases of child abuse occur in extrafamilial settings, such as with a babysitter or friend. Suspected abuse of a child should trigger immediate concern for the safety of the child's siblings. Spousal abuse often occurs with the abuse of the child. Particular attention should be given to the general appearance of the child and all growth parameters, especially in cases of failure to thrive. Nonorganic failure to thrive and physical or sexual abuse can coexist in the same child.

An inconsistent or implausible history may lead the physician to strongly suspect the diagnosis of child abuse, while the physical examination may reveal unexplained injuries (e.g., bruises of varying ages, skull fractures, extremity fractures, or cigarette burns). If the diagnosis is suspected, the child should be admitted for protection and further investigation.

Intentional trauma to the central nervous system remains the most serious injury, with high rates of morbidity and mortality. Unintentional head injuries in children younger than 2 years of age are common, but motor vehicle accidents and falls from extreme heights typically cause severe brain injury. Scalp hematomas, lacerations, or head bruises should alert the physician to the possibility of inflicted head trauma and brain injury. Vigorous shaking (shaken baby syndrome) may lead to epidural, subdural, and subarachnoid hemorrhages with no external signs of trauma and can be life threatening. The modes of presentation may vary, depending on the severity of central nervous system injury. In acute, severe cases the presenting complaints include choking, apnea, respiratory distress, seizures, altered level of consciousness, or cardiopulmonary arrest. When the injury is milder, presentations may be less acute, with one or more of the following: vomiting, irritability, an inappropriate increase in head circumference with split cranial sutures, failure to thrive, and developmental delay with more social than motor findings.

Physical findings in shaken infants may also include lethargy, poor sucking, irritability, rhythmic eye opening, eye deviation, bicycling movements, decerebrate or decorticate posturing, full fontanel, seizures, and alterations in muscle tone and responsiveness to voice, touch, or pain. An examination of the eye, although difficult, is essential, since presence of retinal hemorrhage, especially in the absence of external signs of trauma, suggests a whiplash injury due to severe shaking. When central nervous system injury is strongly suspected, imaging studies, such as a head computed tomography scan, should be done for confirmation. In addition, a skeletal survey should be done to rule out other injuries. Multiple skeletal fractures at various stages of healing, metaphyseal chip or bucket-handle fractures, and posterior rib fractures in infants are highly suggestive of intentional injuries.

Physical injuries and sexually transmitted disease, if present, should be treated immediately. Children with failure to thrive on the basis of emotional neglect need to be placed in a setting where they can be fed. In every state of the United States, practitioners (and many other professionals who come in contact with children) are "mandated reporters." If abuse or neglect is suspected, a report must be made to a local or state agency designated to investigate such reports. Emergency departments would be well served if protocols for management of such conditions were available. [11,12,13 and 14]

Infections

Neonatal infections are manifested by a variety of symptoms and signs, such as feeding difficulties, fever, jaundice, and respiratory distress. Neck rigidity and Kernig and Brudzinski signs are usually absent in neonates with meningitis. A septic neonate may present with a normal or subnormal temperature. Urinary tract infections are often associated with nonspecific signs, such as irritability, diarrhea, or poor feeding, and diagnosis is established by urine culture rather than urinalysis. There is general consensus that all neonates with possible sepsis should be hospitalized and given broad-spectrum antibiotic therapy pending results of appropriate cultures (e.g., urine, blood, and cerebrospinal fluid). See "Fever and Sepsis" below.

Surgical Lesions

Surgical conditions in neonates can present with wide variety of symptoms, including respiratory distress, fever, lethargy, weight loss, and poor feeding. Progression of symptoms can be helpful in decision making but may not be easily or accurately elicited from an infant or poorly observant parent.

The surgically correctable causes of respiratory distress in newborns are less frequent and include choanal atresia, micrognathia (Pierre Robin syndrome), laryngomalacia, tracheomalacia, tracheoesophageal fistula, and vascular rings. Most of these anomalies are identified in the newborn nursery, but in the emergency department these possibilities should be entertained in any infant with respiratory distress. In the neonate with abdominal symptoms, the most common diagnoses include necrotizing enterocolitis and congenital anomalies such as malrotation with midgut volvulus, duplication, gastroschisis, and omphalocele. Pyloric stenosis typically presents between 2 and 6 months of age. Incarcerated inguinal hernias and intussusception are most common after 2 months of age. Incarcerated hernia and intussusception account for most of abdominal surgical emergencies in the 2-month-old to 1-year-old group; the former decreases in incidence after 1 year of age.

The diagnosis of abdominal emergencies is challenging in the emergency department. A systematic approach helps to minimize missed diagnoses. The most common signs are irritability and crying, followed by poor feeding, vomiting, constipation, and abdominal distention. Prudent and directed use of laboratory and imaging studies will minimize misdiagnosis. The early involvement of a surgeon in the care of pediatric patients who have significant abdominal symptoms is recommended. [15,16]

Improper Feeding Practices

Improper feeding practices may result in an irritable infant with periods of inconsolable crying. These symptoms usually result from overfeeding without adequate burping during feedings. The infant swallows large amounts of air, resulting in bowel distention and occasionally respiratory distress. Instruction in proper feeding practices usually alleviates the problem. [1]

GASTROINTESTINAL TRACT SYMPTOMS

Common presenting gastrointestinal symptoms are listed in Table 112-1.

Feeding Difficulties

Most visits for feeding difficulties are due to parental perception that the infant's food intake is inadequate. The neonate's pattern of intake is not fully established until about 1 month of age. If weight gain is satisfactory and the infant is satisfied after feedings, intake is adequate. Parents can usually provide accurate information of the intake of bottle-fed infants. The weighing of breast-fed infants before and after feedings is not advised, since weights may be inaccurate. In addition, weighing may

have adverse psychological effects on a mother whose infant is doing poorly.

Rarely, anatomic abnormalities can cause difficulty in feeding and swallowing. A careful history usually pinpoints such difficulties as having occurred from birth. The infants appear malnourished and dehydrated. The most likely causes are esophageal obstruction (e.g., stenoses, strictures, laryngeal clefts, or cleft palate) and compression of the esophagus or trachea by a double aortic arch. Infants with a recent decrease in intake have an acute disease, usually an infection. [1]

Regurgitation

Regurgitation of small amounts is common in neonates due to reduced lower esophageal sphincter pressure and relatively increased intragastric pressure. Parents may confuse regurgitation with vomiting. Vomiting results from forceful contraction of the diaphragm and abdominal muscles, whereas regurgitation is independent of any effort and probably represents the ultimate degree of gastrointestinal reflux. If the neonate is thriving, parents can be reassured that regurgitation is of no clinical significance and will decrease as the infant grows. Infants who are not thriving or having respiratory symptoms should be investigated for anatomic causes of regurgitation or chronic aspiration.

Regurgitation rarely results from pathologic processes, such as intrinsic compression of the esophagus or occasionally compression of the trachea, in which case it is usually accompanied by stridor and cough. Dysphagia, irritability, anemia due to chronic blood loss, and malnutrition are sequelae of chronic regurgitation with esophagitis, but this condition is rare. Investigations such as scintigraphy, pH monitoring, endoscopy, and biopsy are utilized to confirm the diagnosis of reflux esophagitis. These invasive tests are not justified in patients who are healthy and are not done on an emergency basis. Such infants usually respond well to thickening of feedings. The infant's upper body can be elevated after feedings added if thickening of feedings alone does not resolve the regurgitation. [4,17]

Vomiting

Vomiting results from a variety of causes and is rarely an isolated symptom. ++During the first few weeks of life, vomiting is uncommon and is often confused with regurgitation. Vomiting from birth is most likely due to an anatomic abnormality, such as tracheoesophageal fistula, upper gastrointestinal obstruction, or midgut rotation. More commonly, acute vomiting may be part of the symptom complex of some diseases (Table 112-2), especially increased intracranial pressure, and infections (e.g., sepsis, urinary tract infections, and gastroenteritis).

Projectile vomiting is usually seen in infants with pyloric stenosis and usually assumes its characteristic pattern after the second and third week of life. This condition usually occurs in firstborn males and is characterized by projectile vomiting at the end of feeding or shortly thereafter. The vomitus does not contain bile or blood. Examination of these infants should be done with the infant relaxed and the stomach empty. Prominent gastric waves may be seen going from the left to right. A firm olive mass may be felt by palpating under the liver edge. Malnutrition and dehydration may be evident. Hospitalization is necessary for rehydration and surgical treatment.

In any infant who is vomiting, signs of dehydration and candidiasis of the mouth should be sought. Hepatobiliary (e.g., jaundice), urinary tract, and central nervous system disease can also cause vomiting. Vomiting due to inborn errors of metabolism may present with hypoglycemia and metabolic acidosis. Infants who are vomiting should be admitted for evaluation and therapy. [18,19]

Diarrhea and Dehydration

Diarrhea refers to stools that are abnormally frequent and liquid. The modifier *abnormal* is critical because stools can normally be frequent and liquid in young children. Acute diarrheal illnesses account for more than 3 million ambulatory pediatric visits, 10 million sick days, and 100,000 hospital admissions per year in the United States. In the United States, rotavirus predominantly affects infants between 3 to 15 months. The peak incidence is in the winter months, and rotavirus accounts for as many as 50 percent of the cases of acute diarrhea in winter. Enteric adenoviruses (serotypes 40 and 41) are the second most common viral pathogen in infants. In summer most of the cases of diarrhea are caused by bacteria (including *Escherichia coli, Salmonella,* and *Shigella*). Parasitic causes of diarrhea are rare in neonates. A history of bloody diarrhea strongly suggests a bacterial pathogen, particularly in an older infant or a child. It is important to know that, in infants less than 6 months of age, the most common causes of blood in the stool are cow's milk intolerance and anal fissures.

In diarrheal illness, the history and physical examination serve as an initial screen to narrow the diagnostic possibilities. The choice of laboratory tests depends on the results of the history and physical examination. The history should assess the infant's state of hydration and possible causative agents. Information regarding oral intake, frequency and volume of stools, general appearance of the infant, mental status, and frequency of urination can help in assessing hydration. The parent should be asked about fever, antibiotic therapy, and exposure to day care or other children and adults with diarrheal illness.

All children with diarrhea should be carefully weighed unclothed for comparison of previous weight and to provide a baseline for monitoring subsequent weights during the course of the disease. In an infant, the normal extracellular fluid volume is 25 percent of body weight; therefore, a loss of 8 percent of body weight as extracellular fluid would result in manifestations of severe dehydration. The actual weight loss is greater than that because of concomitant loss of cellular water.

The physical examination should begin with a global assessment, with particular attention to the state of hydration (Table 112-3). Mucous membranes, more than the lips, should be evaluated for moistness. The appearance of the anterior fontanel and eyes should be assessed. The skin hydration and turgor may give a sense of the degree of dehydration. The finding of doughy and tented skin is associated with hypernatremic dehydration. Finally, the child's mental status with regard to interaction with the examiner and the parent can be used as a measure of seriousness of illness and dehydration.

Signs and Symptoms	Mild Dehydration	Moderate Dehydration	Severe Dehydration
Body weight loss, %	3-5	6-9	10 or more
General appearance and condition; infants and young children	Thirsty, alert, restless	Thirsty, restless or lethargic but irritable to touch or drowsy	Drowsy, limp, cold, sweaty, cyanotic extremities; may be comatose
Radial pulse	Normal rate and strength	Rapid and weak	Rapid, feeble, sometimes impalpable
Respiration	Normal	Deep, may be rapid	Deep and rapid
Anterior fontanel	Normal	Sunken	Very sunken
Systolic blood pressure	Normal	Normal or low	Low, may be unmeasurable
Skin elasticity	Pinch retracts immediately	Pinch retracts slowly	Pinch retracts very slowly
Eyes	Normal	Sunken	Grossly sunken
Tears	Present	Absent or reduced	Absent
Mucous membranes	Moist	Dry	Very dry
Urine flow	Normal	Reduced amount and dark	Anuria, severe oliguria
Capillary refill	Normal	≥2 s	>3 s
Estimated fluid deficit, mL/kg	30-35	60-90	100 or more

TABLE 112-3   Clinical Assessment of Severity of Dehydration

Temperature, pulse, and blood pressure all provide information concerning the degree of illness. The rest of the physical examination should focus on signs of concurrent viral illness, such as upper respiratory tract infections, that may be associated with gastroenteritis, as well as abdominal findings. A rectal examination is often useful in obtaining a stool sample for detection of occult blood, culture, examination for leukocytes, measurement of pH, and detection of reducing substances. It can also rule out anal fissures as the cause of bloody stools.

Serum electrolyte levels, particularly sodium and bicarbonate levels, should be assessed in any child considered significantly dehydrated. A markedly elevated blood urea nitrogen concentration with a relatively normal creatinine value may indicate recent or rapid dehydration. Serum creatinine values tend to be low in infants and young children, and a creatinine value of 1 mg/dL in this age group may represent a doubling in the normal value. The rest of the diagnostic workup should include a stool sample for the abovementioned tests and a urine sample for culture and analysis.

The decision to rehydrate the child as an inpatient or outpatient or orally or intravenously is dependent upon several factors. Children with greater than 10 percent dehydration, hypernatremic (Na > 150 meq/dL) dehydration, or symptomatic hyponatremia (Na < 130 meq/dL) should be admitted to the hospital. Oral hydration for

these children may be attempted in the hospital, depending on the circumstances and cardiovascular stability of the patient. However, if there are any indications of significant peripheral vascular compromise or pending shock, intravenous hydration is mandatory. For a child who is isotonically 5 to 10 percent dehydrated, the choice of inpatient versus outpatient management is dependent on the ability of the person caring for the child to administer oral fluids. Children with this degree of dehydration tend to do well with oral hydration, and this approach may be attempted initially.

Contraindications to oral rehydration are severe vomiting or a required regimen of oral feedings. For the child with less than 5 percent dehydration, oral rehydration should be attempted. If the infant has been breast-fed, feeding should be continued and oral electrolyte-glucose solution given in addition until diarrhea subsides. If the infant has been fed a cow's-milk-based diet, feedings should be resumed slowly after initial feedings with oral rehydration solutions as tolerated, preferably with a lactose-free formula. Increased stool output may occur as feedings are increased, but a gradual increase of caloric intake over 4 or 5 days should avoid exacerbation of diarrhea. The total fluid intake of oral electrolyte solution and regular diet should be approximately 150 mL/kg/day. [20,21,22,23,24 and 25]

Abdominal Distention

Abdominal distention is normal in neonates and is usually due to lax abdominal musculature and relatively large intraabdominal organs. It may also be accentuated by excessive gas within the bowel. If the infant is comfortable and feeding well and the abdomen is soft, there is no need for concern. Abdominal distention may also occur in association with bowel obstruction, constipation, or ileus due to sepsis or gastroenteritis. Congenital organomegaly (e.g., hepatomegaly, splenomegaly, or renal enlargement) undetected in the perinatal period may also present as abdominal distention. [4,26]

Constipation

Infrequent bowel movements in neonates do not necessarily mean that the infant is constipated. Breast-fed infants may occasionally go without a bowel movement for 5 to 7 days and then pass a normal stool. However, if the infant has never passed stools, the possibility of intestinal stenosis or atresia, Hirschsprung disease, or meconium ileus or plug should be considered.

Constipation occurring after birth but within the first month of life suggests Hirschsprung disease, hypothyroidism, or anal stenosis. The diagnosis of Hirschsprung disease is supported by absence of feces on rectal examination and abrupt change in bowel luminal size on barium enema and is confirmed by a rectal biopsy demonstrating absence of ganglion cells. Infants with hypothyroidism present with feeding problems; a weak, hoarse cry; hypothermia; hypotonia; and peripheral edema. The child should be admitted for further evaluation and treatment. [27]

CARDIORESPIRATORY SYMPTOMS

Neonates are prone to respiratory problems for a variety of reasons. Anatomic causes are a barrel-shaped chest, a flattened diaphragm, limitation of diaphragmatic movement by abdominal compression, smaller airway diameter, and higher closing volumes. The high compliance of the chest wall, low compliance of the lungs, and less fatigue-resistant fibers in the diaphragm and intercostal muscles are also significant contributory factors. Cardiorespiratory symptoms are also more common in this age group since structural and functional abnormalities of the airway and heart are more likely to present at this time.

Cardiorespiratory symptoms in neonates are nonspecific and may be due to primary organ failure (cardiovascular or respiratory) or secondary to a variety of systemic diseases, such as sepsis, metabolic acidosis, abdominal pathology, and severe meningitis. Regardless of the cause, the assessment and stabilization of the airway, breathing, and circulation are priorities and should be accomplished before or concurrently with establishing a diagnosis.

Rapid Breathing

Rapid breathing can be due to minor problems, such as abdominal distention, or life-threatening illnesses, such as sepsis. Rapid breathing or grunting should always be considered a medical emergency. Admission for investigations, monitoring, and therapy should be considered in all but the mildest cases. When a cause cannot be identified on initial presentation, a full sepsis workup (full blood count, blood culture, urinalysis, chest x-ray, and cerebrospinal fluid examination) should be done and broad-spectrum antibiotics administered (Table 112-4).

TABLE 112-4   Causes of Rapid Breathing in Neonates

Pneumonia

The lungs are the most common site of infection in neonates. Group B streptococcus is the most common cause of lower respiratory infection in newborns. The infection is most likely acquired in utero from a contaminated amniotic environment. Affected infants frequently develop fulminant illness within hours of birth. Other common bacterial pathogens in newborns and infants include *Streptococcus pneumoniae* and *Haemophilus influenzae* serotype B. Chlamydial pneumonia usually occurs after 3 weeks of age and is accompanied by conjunctivitis in 50 percent of cases. Infants with bacterial as well as viral pneumonia may present with fussiness, stuffy nose, decreased appetite, abrupt onset of high fever (<39°C), nasal flaring, grunting, retraction, tachypnea, and tachycardia.

Patients with chlamydial pneumonia are usually afebrile and tachypenic and have a prominent cough. Respiratory syncytial virus (RSV), adenovirus, and parainfluenzavirus can also cause pneumonia in otherwise well infants. In addition, infections with *Bordetella pertussis* may cause paroxysms of cough in an otherwise well-appearing infant. The cough may not be accompanied by characteristic whoop. Pertussis always must be considered in infants who have severe, paroxysmal cough and posttussive vomiting. Because many adults are susceptible to infection with pertussis, such an infection should be ruled out if the caretaker has a persistent cough.

The approach to febrile infants with suspected bacterial pneumonia should include a full evaluation for potential sepsis (blood and urine cultures, chest radiographs, and complete blood count). The blood culture results are typically negative, but obtaining two culture samples instead of one during the initial evaluation may increase the diagnostic yield fourfold. A lumbar puncture should be done if there are no contraindications.

Infants who have fever and pneumonia should be hospitalized and receive parenteral antibiotics against staphylococci and potential gram-negative pathogens. Infants suspected of having chlamydial or *B. pertussis* pneumonia should receive erythromycin or sulfamethoxazole. Infants who are afebrile with pneumonia may be treated as outpatients when a viral pathogen is suspected. Inability to eat, respiratory distress, and hypoxemia are criteria for hospitalization. Patients observed on an outpatient basis should be seen daily until symptoms are resolving. [28,29]

Bronchiolitis

Bronchiolitis is acute wheezing-associated respiratory illness in early life preceded by signs and symptoms of an upper respiratory infection. Bronchiolitis is a highly

seasonal disease, with comparatively few cases seen during summer months and activity peaks during winter months. Serious cases of bronchiolitis occur most commonly in infants younger than 1 year of age, particularly in the first 3 months of life. In the general population of the United States, the incidence of bronchiolitis is 11.4 cases per 100 children-years during the first year of life. Bronchiolitis is more commonly seen in families of low socioeconomic status or infants who have not been breast-fed.

RSV is the most common cause and is probably transmitted by direct contact with nasal secretions of infected individuals much more frequently than by aerosol spread. Shedding of the virus can be documented 1 to 2 days before symptoms occur and for 1 to 2 weeks thereafter. Those exposed are probably not contagious for the entire period of time but should be considered contagious 24 to 48 h before the onset of symptoms and for several days thereafter.

A number of other viral agents also can cause bronchiolitis, although the illness is milder. The parainfluenza viruses are the second most common cause of bronchiolitis and are responsible for autumn and spring epidemics, usually preceding and following RSV outbreaks. Influenza type A virus can also precipitate bronchiolitis, along with adenovirus, rhinovirus, and *Mycoplasma pneumoniae*. The latter two agents are responsible for an increasing number of cases of wheezing-associated respiratory illness with increasing age, but RSV and parainfluenza viruses have been shown to provoke wheezing at all ages.

Acute bronchiolitis presents in infancy with serous nasal discharge accompanied by sneezing. These symptoms are followed by diminished appetite, cough, dyspnea, irritability, and, commonly, periods of apnea. Apnea is more common in neonates and usually presents within the first 3 days of illness. Physical examination reveals a rapid respiratory rate (>60 breaths per minute), cyanosis, air hunger, hyperinflation, intercostal and subcostal retractions, and a palpable liver and/or spleen due to hyperinflation of the lungs. Fever is usually low grade or absent, except in the presence of otitis media, when a temperature as high as 40°C may be present. Chest x-rays usually show hyperinflation with patchy atelectasis.

The diagnosis of bronchiolitis is usually made clinically. A wheezing infant with a history of the aforementioned symptoms for several days, particularly during the peak season for RSV, can be assumed to have bronchiolitis. Previous recommendations of a trial of subcutaneous epinephrine to distinguish bronchiolitis from asthma in wheezing infants is now discouraged because a small number of infants who have true bronchiolitis respond to first-course of b-adrenergic agents, while many patients with status asthmaticus do not. Immunofluorescence or enzyme-linked immunosorbent assays performed on respiratory secretions are very sensitive and specific for detection of RSV. Other diagnostic tests, such as blood gas analysis or cell counts, are directed by clinical assessment but rarely necessary.

Most cases of bronchiolitis are mild and can be managed without hospitalization. Infants recover without b-adrenergic agents or other medications used for relief of wheezing. The decision to hospitalize an infant with bronchiolitis should be based on a number of clinical criteria in addition to other considerations, such as reliability of parents, duration of present illness, and likelihood of obtaining acceptable follow-up. Infants who are born prematurely, have underlying heart or lung disease, are in first 3 months of life, or have low initial oxygen saturation (<92 percent) are more likely to develop progressive or life-threatening illness. In addition, infants who are not feeding well or who are dehydrated should be considered for hospitalization. If respiratory distress is not severe and the infant is feeding reasonably well, hospitalization is not needed.

Infants for whom hospitalization is being considered should receive at least one course of b-adrenergic agent [albuterol 0.1 to 0.15 mg/kg/dose, up to 5 mg, hourly as required for the first few doses, then every 4 to 6 h]. If the response is good, the drug may be continued. The continued use of such agents in the absence of an initial beneficial response is controversial. It is not possible to predict which individuals with bronchiolitis will respond well to b-adrenergic agents. The hazards of administrating these agents are relatively minor; therefore, it is reasonable to administer b-adrenergic agents by aerosol, at least during first 24 h of hospitalization, and to continue to do so if the response is good.

The use of corticosteroids has never been evaluated adequately. Although a beneficial role for corticosteroids cannot be excluded, most infants with bronchiolitis respond satisfactorily without them. The use of antibiotics generally does not affect the clinical course of bronchiolitis because bacterial infection is almost never simultaneously present. The presence of unexplained high fever in the course of illness may be an indication for temporary antibiotic coverage. [3C,31 and 32]

ILLNESS INVOLVING OTHER ORGAN SYSTEMS

The search for pathologic conditions in other organ systems is mandatory, since the presence of respiratory symptoms may divert attention from a significant underlying problem. For example, generalized sepsis, meningitis, gastroenteritis, and metabolic acidosis may present with respiratory distress as the predominant symptom.

CONGENITAL DISEASES

Respiratory Disease

Occasionally an H-type tracheoesophageal fistula may present in the first month of life or later with recurrent pneumonia, respiratory distress after feedings, and problems in clearing mucus. Tracheal stenosis may present initially with noisy breathing or a high-pitched cry and tremendous respiratory difficulty even after mild upper respiratory infections. Similarly, neonates with chronic respiratory insufficiency, such as bronchopulmonary dysplasia, may present in respiratory failure even after mild upper respiratory infections. [33,34]

Heart Disease

Rapid breathing due to cardiac disease is usually not associated with significant retractions and use of accessory muscles. As a general rule, a well-developed neonate who presents with unexplained cyanosis and tachypnea should be suspected of having congenital cardiac disease. In neonates with transposition of the great arteries and ventricular septal defect or critical coarctation of the aorta, congestive cardiac failure may be the presenting feature. Signs of heart failure may be very subtle but are life threatening and require emergency referral. [35]

Neuromuscular Disease

Any form of muscle weakness may be associated with shallow breathing and an increase in respiratory rate as a compensatory mechanism.

Cough and Nasal Congestion

Cough may be a prominent feature of most of the primary respiratory conditions listed in Table 112-4. It may also be the initial presentation of a variety of congenital anomalies, including cleft palate, laryngotracheomalacia, laryngotracheal cleft, tracheal webs, tracheoesophageal fistula, tracheal hemangiomas, and vascular rings. Although congenital malformation resulting in cough and nasal congestion is more likely to occur in neonates, in most instances, cough is due to a viral upper respiratory infection and may be associated with sneezing and nasal congestion. It may also be a prominent feature of bronchiolitis and chlamydial and pertussis infections. Treatment of the underlying condition is required. Cough suppressants should be used with extreme caution in neonates. Nasal congestion is best treated with instillation of saline drops when necessary. [32]

Noisy Breathing and Stridor

Noisy breathing is a common presenting complaint in neonates and is usually benign. Stridor is usually due to congenital anomalies (e.g., webs, cysts, stresia, stenosis, clefts, or hemangiomas) extending anywhere from the nose to the trachea and bronchi. Infants who were intubated in the neonatal period are prone to develop subglottic stenosis. Infection (e.g., croup, epiglottis, and abscess) as a cause of stridor in neonates is rare. Stridor worsening with cry suggests laryngomalacia or subglottic hemangioma; stridor and feeding difficulties suggest vascular ring, laryngeal cleft, or tracheoesophageal fistula; stridor with hoarseness suggests vocal cord paralysis. Laryngomalacia is the most common cause of stridor in the neonate. It is characterized by noisy, crowing inspiratory sounds, which usually improve during the first year of life. When the cause is in doubt, the infant should be admitted for evaluation to determine the cause. [36,37]

Apnea and Periodic Breathing

Periodic breathing, which may occur in normal neonates, should be differentiated from apnea. However, periodic breathing may precede apnea, and both may occur in the same patient. Apnea is a cessation of respiration for 10 to 20 s with or without bradycardia and cyanosis. It signifies critical illness and warrants prompt investigation and admission for monitoring and therapy.

Apnea may be precipitated by any of the disease conditions listed in Table 112-4 and usually indicates respiratory muscle fatigue and impending respiratory arrest. Resuscitation, including airway support and ventilation, should be followed by a thorough search for the inciting condition. If no obvious cause is found, the neonate should be assumed to be septic. Cultures should be obtained and broad-spectrum antibiotics started. [38,39]

Cyanosis and Blue Spells

An infant with cyanosis and blue spells usually presents a diagnostic challenge, since such findings may be due to many disorders. If breathing is rapid but not labored, the most likely cause is cyanotic congenital heart disease with right-to-left shunting. Methemoglobinemia, although rare, may have a similar presentation. Irregular or shallow breathing may be associated with sepsis, meningitis, cerebral edema, or intracranial hemorrhage and may also be accompanied by cyanosis. If breathing is labored (e.g., grunting or indrawing), pulmonary disease (e.g., pneumonia or bronchiolitis) is likely. All infants with cyanosis should be admitted for monitoring and further investigation. [40,41]

Jaundice

Jaundice (Table 112-5) may appear at varying times during the neonatal period and requires a complete diagnostic evaluation. Jaundice during the first 24 h rarely presents to the emergency department. The commonest causes of jaundice seen in the emergency department are physiologic jaundice, jaundice due to sepsis, or breast-milk jaundice. Occasionally, infants with hemolysis due to autoimmune congenital causes may present to the emergency department.

<24 h	ABO, Rh incompatibility
	Sepsis
	Congenital infections (e.g., rubella, toxoplasmosis, cytomegalovirus infection)
	Excessive bruising from birth trauma (cephalhematoma or intramuscular hematoma)
2–3 days	Physiologic
3 days to 1 week	Septicemia
	Syphilis, toxoplasmosis, cytomegalovirus infection
>1 week	Septicemia, congenital atresia of bile ducts, serum hepatitis
	Congenital hemolytic anemias (sickle cell anemia, spherocytosis)
	Hemolytic anemia due to drugs (e.g., in glucose-6-phosphate dehydrogenase deficiency)
	Rubella, herpetic hepatitis
	Hypothyroidism
	Breast-milk jaundice

TABLE 112-5 Causes of Jaundice in Neonates

Physiologic jaundice is due to the breakdown of fetal red blood cells, and bilirubin rises at a rate of less than 5 mg/dL per 24 h, with a peak of 5 to 6 mg/dL during the second to the fourth day of life, returning to <2 mg/dL by 5 to 7 days. Septic infants with hyperbilirubinemia also have other features of sepsis, such as vomiting, abdominal distention, respiratory distress, and poor feeding. Jaundice associated with breast-feeding is thought to be due to the presence of substances that inhibit glucuronyl transferase in breast milk; it may start as early as the third to fourth day and reaches a peak of 10 to 27 mg/dL by the third week of life. Cessation of breast-feeding causes rapid decline in 2 to 3 days.

A proper history and physical examination provide clues to the causes of jaundice. A well-looking child who is gaining weight and feeding well is unlikely to be septic. Laboratory evaluation should include a full blood count to test for anemia, a smear for hemolysis, direct and total bilirubin determinations, a reticulocyte count, and a Coombs test. Admission to the hospital, appropriate cultures, and antibiotics are ordered for neonates who are unwell and have any of the signs or symptoms listed in Table 112-5. In all cases, arrangements should be made for monitoring of bilirubin and hemoglobin levels. While most well infants can be monitored out of the hospital, infants who are anemic or have bilirubin levels approaching transfusion levels (approximately 20 mg/dL) should be admitted. [42,43 and 44]

Eye Discharge, Redness, and Conjunctivitis

Neonates with red eyes are most likely suffering from conjunctivitis. Neonatal conjunctivitis occurs in 1.6 to 12 percent of newborns during the first month of life. The chemical irritation from antimicrobial prophylaxis against bacterial infection is the most frequent cause, followed by *Chlamydia trachomatis* infection. Other important pathogens in this setting are *H. influenzae* and *Streptococcus pneumoniae*. *Neisseria gonorrhoeae* is no longer a major cause of neonatal conjunctivitis in the United States because of mandated use of neonatal ocular prophylaxis. The failure rate of antimicrobial prophylaxis is 1 percent. However, because *N. gonorrhoeae* can damage the eye severely, it is important to always test for this pathogen as the possible cause of neonatal conjunctivitis. Viruses rarely cause isolated neonatal conjunctivitis as an isolated problem. They usually cause conjunctivitis as part of a generalized viral syndrome affecting many organs. For example, herpes simplex virus causes neonatal keratoconjuctivitis as part of a generalized viremia with infection at other sites such as skin, mucous membranes, or with disseminated disease. The finding of vesicles anywhere on the body in association with neonatal conjunctivitis suggests the possibility of herpes simplex infection.

An important consideration in the evaluation of neonatal conjunctivitis is the time of onset. Chemical conjunctivitis secondary to ocular prophylaxis usually occurs on the first day of life. Gonococcal conjunctivitis generally has its peak time of onset between 3 and 5 days after birth. By the end of first week of life and throughout the first month of life, *Chlamydia* becomes the most frequent cause of conjunctivitis. It is important to note that these times of onset assume rupture of amniotic membrane at or near the time of delivery. The conjunctiva can be inoculated before birth by an ascending bacterial infection.

Chlamydial conjunctivitis can vary in severity, ranging from mild-to-severe hyperemia with a thick mucopurulent discharge and psuedomembrane formation. Gonococcal conjunctivitis can present as typical bacterial conjunctivitis. However, in its full-blown form, it presents as hyperacute conjunctivitis with profuse discharge. There often is severe edema of both lids. In marked contrast to other forms of bacterial conjunctivitis, *N. gonorrhoeae* has the capacity to invade superficial layers of the conjunctiva, causing ulceration of the cornea. If it is not treated, it can result in the loss of eye from corneal complications.

A Gram stain and culture should always be obtained in instances of neonatal conjunctivitis to make certain that the conjunctivitis is not due to *N. gonorrhoeae.* Since isolation of *C. trachomatis* requires specialized tissue cultures, proper technique should be employed in collecting those specimens (e.g., Dacron swabs) and specimens for antigen detection.

Gonococcal opthalmia neonatorum is treated best with ceftriaxone (25 to 50 mg/kg per day intravenously or intramuscularly, not to exceed 125 mg) given once or a single dose of cefotaxime (100 mg/kg intravenously or intramuscularly). When disseminated disease is suspected, the duration of treatment is 7 days. Cefotaxime is recommended for hyperbilirubinemic infants. If meningitis is documented, treatment should be continued for 10 to 14 days. Infants with gonococcal opthalmia should have their eyes irrigated with saline solution immediately and at frequent intervals until the discharge is eliminated. Topical antibiotic treatment alone is inadequate and is unnecessary when recommended systemic antibiotic treatment is given.

Chlamydial conjunctivitis and pneumonia in young infants are treated with oral erythromycin (50 mg/kg/day in four divided doses] for 14 days. Oral sulfonamides may be used after the immediate neonatal period for infants who do not tolerate erythromycin. Topical treatment of conjunctivitis is ineffective and unnecessary. Since the efficacy of erythromycin therapy is approximately 80 percent, a second course is sometimes required. A specific diagnosis of *C. trachomatis* infection in an infant should prompt the treatment of the mother and her sexual partners.

The neonate with a red eye and irritability may also be suffering from a corneal irritation or abrasion, usually due to an eyelash. Acute glaucoma, although rare, also presents as a red, teary eye. In these instances, the cornea may be stained or cloudy, the anterior chamber shallow, and the intraoccular pressure increased. Prompt

opthalmologic referral of all suspected cases of glaucoma is mandatory. Infectious causes should be treated (Table 112-6) and follow-up care ensured.[45,46,47 and 48]

TABLE 112-6   Antibiotic Therapy for Infections

Diaper Rash and Oral Thrush

Candidal diaper dermatitis is an erythematous plaque with a scalloped border and a sharply demarcated edge that is studded by satellite lesions. It usually occurs in the moist, occluded diaper area and intertriginous zones and usually results from the action of organisms harbored in the gastrointestinal tract. Treatment consists of a topical anticandidal agent with each diaper change or four times daily. Protection of the area with zinc oxide paste overlying the cream will prevent friction, and local treatment with Nystatin cream will prevent spread of the infection. In addition, an oral course of Nystatin is usually warranted to prevent colonization of the gut (Table 112-6).

Oral lesions are white and flaky, covering the tongue, lips, gingiva, and mucous membranes. These lesions are common in debilitated infants and in those on antibiotics. Oral lesions may affect oral intake because of pain and discomfort. Treatment of ill infants consists of treating the underlying pathology, oral antifungal therapy, and an anesthetic gel prior to feeding. Cool liquids may prevent discomfort and pain. [49,50]

Fever and Sepsis

Fever (Table 112-6) is most commonly due to acute infections. Fever is present when an infant's rectal temperature is 100.4°F or greater, as reportedly measured by a caretaker, or 38°C or more, as measured by a health care professional. The risk of infection rises with the height of fever, especially in infants over 4 weeks of age. The risk is about 3 percent with fever above 39.4°C, 6 percent with fever over 40°C, 13 percent with over 40.5°C, and 26 percent with fever over 41.1°C.

Recognizing neonatal bacterial sepsis early is a difficult task. Neonates have about twice the risk of serious bacterial infection as do infants 4 to 8 weeks of age. Neonatal sepsis tends to appear as either an "early-onset" or a "late-onset" syndrome, but some cases are difficult to classify. Early-onset disease is seen in first few days of life, tends to be fulminant, and is usually associated with maternal or perinatal risk factors, such as maternal fever, prolonged rupture of membranes, and fetal distress. On the other hand, late-onset disease usually occurs after 1 week of age, tends to develop more gradually, and is less likely to be associated with risk factors. Septic shock and neutropenia are more common with early-onset syndrome, and meningitis is more common in late-onset disease.

Clinical signs of either type of sepsis are not specific (Table 112-7). Septic infants may exhibit any of a variety of symptoms, including lethargy, poor feeding, vomiting, temperature instability (hypothermia more often than hyperthermia), unexplained apnea, respiratory distress, seizures (with or without meningitis), cyanosis, tachycardia, bleeding diathesis, and hypotension.

Temperature instability

Central nervous system dysfunction

Respiratory distress

Feeding disturbance

Jaundice

Rashes

Fever, hypothermia

Lethargy, irritability, seizures

Apnea, tachypnea, grunting

Vomiting, poor feeding, gastric distention, diarrhea

TABLE 112-7   Signs and Symptoms of Neonatal Sepsis

The bacterial causes of neonatal sepsis tend to reflect the organisms that colonize the female genital tract and nasal mucosae of caregivers. In general, the two groups of pathogens most frequently encountered have been gram-positive cocci, such as b-hemolytic streptococci, and enteric organisms, such as *E. coli* and *Klebsiella* species, and *H. influenzae. Listeria monocytogenes,* a gram-positive rod, is a very common pathogen that causes sepsis and meningitis in neonates. Viral infections are also common and are most likely due to enteroviruses (coxsackievirus and echovirus) acquired at the time of delivery or RSV and influenza A virus acquired postnatally.

When a neonate is thought to be septic, microscopic analysis of cerebrospinal fluid, blood, and urine, and cerebrospinal cultures should be obtained. The infant should be admitted and intravenous antibiotics started. Initial treatment of a neonate with suspected bacterial septicemia or meningitis entails a combination of ampicillin and an aminoglycoside. An alternative regimen of ampicillin and a cephalosporin (e.g., cefotaxime or ceftazidime) is active against most etiologic gram-negative bacilli and can be used in cases when gram-negative meningitis is strongly suspected.

Febrile infants between 4 to 8 weeks of age who satisfy the following criteria are candidates for outpatient management:

- No focus of bacterial infection (middle ear, skin, soft tissue, bone, or joint) on physical examination
- Well appearing (alert, active, and with good muscle tone), well hydrated and tolerating oral fluids adequately, no respiratory distress (respiratory rate <60 breaths per minute, no grunting respiration or retractions)
- Cerebrospinal fluid total white blood cell count less than 10/µL, complete blood count total white blood cell count less than 15,000/µL, urinalysis white blood cell count less than 10 cells/hpf, and negative results for bacteriuria, leukocytes, esterase, and nitrite
- No pulmonary infiltrates on chest radiograph
- Reliable caretaker ensuring close outpatient follow-up.

The decision to administer empiric ceftriaxone pending culture results depends largely on the physician's level of comfort. We prefer to treat, since potentially serious complications, such as focal bacterial infection progressing to bacteremia and septicemia, and seeding of central nervous system can result from misdiagnosed ("occult") serious bacterial infection that is not treated promptly. Therefore, the therapeutic benefit of administering ceftriaxone pending culture results outweighs both therapeutic risk and cost considerations. It should be emphasized that thorough and frequent reevaluations of these infants are essential to monitor changes in the

clinical course and culture results.[51,52,53,54,55 and 56]

Apparent Life-Threatening Events

An apparent life-threatening event (ALTE) (Table 112-8) is an "episode that is frightening to the observer and is characterized by some combination of apnea (central or occasionally obstructive), color change (usually cyanotic or pallid but occasionally erythematous or plethoric), marked change in muscle tone (usually marked limpness), choking, or gagging. In some cases the observer fears that the infant has died."

Infectious	Viral (e.g., RSV, other respiratory viruses)
	Bacterial (e.g., sepsis, pertussis)
Gastrointestinal	Gastroesophageal reflux with or without obstructive apnea
Respiratory	Airway abnormality (e.g., vascular rings, pulmonary slings, tracheomalacia)
	Pneumonia
Neurologic	Seizure disorder
	Central nervous system infection (e.g., meningitis, encephalitis)
	Vasovagal response
	Leigh's encephalopathy
	Brain tumor
Cardiovascular	Congenital malformation
	Dysrhythmias
	Cardiomyopathy
Nonaccidental trauma	Battering
	Drug overdose
	Munchausen-by-proxy syndrome
No definable cause	Apnea of infancy

TABLE 112-8 Differential Diagnosis of Acute Life-Threatening Episodes

ALTE is not a diagnosis. It is simply a description of a characteristic clinical presentation. The usual age of occurrence is 2 to 3 months, but ALTE can occur at any age. Approximately 1 to 3 percent of infants in the general population are reported to experience ALTEs. The incidence is increased among infants who die of sudden infant death syndrome (SIDS) to about 5 to 6 percent. It can be reassuring to families that only about 1 of 20 SIDS cases occurs in the population who experience ALTE and, except for the most severe ALTE episodes, fewer than 1 to 2 percent of these infants succumb to SIDS. Most infants presenting with the history of ALTE have had relatively mild events and probably are not at increased risk of subsequent infant death compared with general population. Data do indicate a high risk of subsequent infant death following more severe ALTE presentations. The risk of subsequent infant death among all infants who experience an ALTE probably is 1 to 2 percent, but the risk increases to 8 to 10 percent for the relatively rare subgroup of infants who present with ALTE occurring during sleep and who are perceived to require some form of cardiopulmonary resuscitation. Those who experienced more than one such severe episode requiring either cardiopulmonary resuscitation or vigorous stimulation were reported in one study to have a 28 percent subsequent mortality rate despite the prescription of home monitors.

An ALTE may be caused by anything that could give the impression that the infant is extremely ill and in danger of dying. The most common general categories of the causation for ALTEs and their prevalence among ALTE infants are infection (5 to 40 percent, depending on the season), gastroesophageal reflux (GER) and other causes of laryngeal chemoreceptor stimulation (20 percent), seizures and other neurologic disorders (15 to 20 percent), and idiopathic (40 to 60 percent). Because most infants who have significant GER do not experience ALTEs, establishing the diagnosis of GER does not prove that it is the cause of ALTE. An unusually strong laryngeal chemoreceptor reflex can significantly increase an infant's susceptibility to ALTE due to GER, even with only minor reflux. This reflex is stimulated by acid or nonisotonic fluids, and the reflex response is apnea, bradycardia, and central pooling of blood.

Another type of ALTE, infantile breath-holding response, is also known as prolonged expiratory apnea or infantile syncope. Normal infants, both premature and full term, often perform a Valsalva maneuver in response to pain or fright, during vigorous activity, and during crying, coughing, and defecation. This maneuver normally decreases minute ventilation but is usually without consequence. However, some infants perform prolonged Valsalva maneuvers that persist until cyanosis, unconsciousness, and even seizures develop. These spells are presumed to be a more severe version of the simple breath-holding spells in which a crying child holds his or her breath until cyanosis develops but resumes breathing. Severe breath-holding spells have been estimated to occur in up to 5 percent of normal children at some time before 6 years of age.

There is no routine evaluation for ALTE. In general, after obtaining vital signs and history and performing a physical examination, further diagnostic testing should be individualized, depending on initial findings and clinical suspicions. If the infant appears to have cardiovascular and respiratory symptoms at the time of presentation, a very careful history should be taken and physical examination performed. If at all possible, a detailed description of the infant at the time of discovery, the specific stimulation and resuscitation measures used, and the infant's response should be obtained directly from those present at the time. Great care must be taken to ensure that the terms used by lay observers to describe the event are interpreted appropriately by the physician. It is useful to determine whether the infant has been chronically ill or essentially well. A report of several days of poor feeding, temperature instability, or respiratory or gastrointestinal symptoms suggests an infectious process.

Reports of "struggling to breathe" or "trying to breathe" imply airway obstruction. Association of the episode with the feeding implies uncoordinated swallowing, GER, or airway obstruction. Episodes that typically follow crying may be related to breath holding. Association of the episode with sleeping may also suggest GER or apnea of infancy. Attempts should be made to determine the duration of episode, but this is often difficult. The physician should also search for past medical problems and any family history of such problems. In addition to a normal, careful physical examination, particular focus should be directed toward the neurologic examination, observation of breathing during sleep and feeding, and evidence on cardiac examination of pulmonary hypertension or structural cardiac abnormalities.

Most infants who present acutely after an ALTE should be hospitalized for monitoring and further evaluation. Some episodes occur in clusters; if they occur in the hospital, observation by medically trained observers may help clarify the severity and cause of the episodes, and availability of trained medical personnel may be necessary for resuscitative efforts. In addition, the family and caretaker may be extremely anxious about the vulnerability of their infant and may benefit from reassurance, assessment, and counseling.[36,57,58,59,60,61 and 62]

Sudden Infant Death Syndrome

Neonates may occasionally present in cardiorespiratory arrest. Although SIDS should be considered, catastrophic deterioration is more likely to be due to infectious causes (e.g., septicemia or meningitis), trauma (e.g., intracranial bleeding or child abuse), and inborn errors of metabolism (e.g., medium-chain acyl dehydrogenase deficiency).

In most cases, cardiopulmonary resuscitation is unsuccessful, since the myocardium has suffered severe hypoxic ischemic damage. The physician's role in such cases is to provide supportive care for the family. In most cases, this entails reassurance that all appropriate efforts were made to save their child's life and that the infant has been treated with dignity. Other personnel (e.g., chaplain, social worker, or family physician) may also be required to provide support.

When the cause of death is not known, physicians should obtain appropriate samples (blood, urine, skin biopsy, etc.) and obtain permission for an autopsy. Such postmortem studies are very important because of the genetic implications of metabolic disease. A postmortem protocol for sudden neonatal deaths should be available in all emergency departments.[63,64]

113 THE NICU GRADUATE

Daniel G. Batton

Graduates of the neonatal intensive care unit (NICU) may be frequent visitors to the emergency department and often require rehospitalization during the first few months following discharge.[1,2 and 3] Most NICU graduates are low-birth weight infants who may have a variety of complications related to prematurity. These infants should be evaluated based upon *postconceptional,* not chronologic, age. For example, a 32-week-gestation premature infant with an 8-week chronologic age since birth is evaluated as a term infant.

Premature infants are usually discharged from the hospital at a postconceptional age of 33 to 38 weeks, although a few infants are well beyond 40 weeks. The normal respiratory rate at this age is 30 to 40 breaths per minute, although an infant with bronchopulmonary dysplasia may breathe 60 to 70 times per minute. The heart rate ranges from 120 to 160 beats per minute but can be considerably lower during quiet sleep. Most laboratory values are similar to adults' values, although the hematocrit can be as low as 20 to 25 percent because of physiologic anemia. Neurodevelopmental milestones most appropriate for a given infant are those corresponding to the postconceptional age. When caring for NICU graduates, attention must be paid not only to the presenting signs and symptoms but also to general problems related to prematurity.

GENERAL CONSIDERATIONS

Cold Stress

Following hospital discharge, premature infants remain susceptible to cold stress when exposed to lower environmental temperatures, primarily because of decreased subcutaneous tissue.[4] Infants who are cold-stressed are not capable of responding by shivering but, rather, attempt to maintain body temperature by increasing their metabolism of brown fat, which results in heat production. However, this increases oxygen consumption and can lead to hypoglycemia. If this compensatory increase in metabolic rate is insufficient to overcome the low environmental temperature, then body temperature will fall. A normal body temperature, however, does not eliminate the possibility of cold stress, since body temperature may be maintained at considerable metabolic expense. The best way to avoid cold stress is to provide an adequate environmental temperature for the infant who is being evaluated in the emergency department. If the room temperature cannot be adjusted appropriately, a heat lamp should be available. Commercial heat lamps are available that have automatic timers and can be adjusted to provide varying amounts of heat. Such lamps should be standard equipment in emergency departments that treat infants and children.

Hypoglycemia

Premature infants are at risk of developing hypoglycemia with an acute illness. This risk may be due in part to increased glucose consumption, cold stress, poor enteral intake during the illness, or suboptimal glycogen stores. [4] Since hypoglycemia can have severe consequences, glucose testing is necessary for all premature infants presenting with an acute illness. If the blood sugar is less than 45 mg percent, intravenous glucose therapy (10% dextrose in water at 100 mL/kg/day) should be initiated.

Hypertension

Longitudinal studies of convalescing premature infants have demonstrated that systemic hypertension may develop in as many as 9 percent. [5] The possible causes include thromboembolic renal artery occlusion following umbilical artery catheterization and bronchopulmonary dysplasia. [6] Although the normal range is age dependent, a systolic blood pressure greater than 120 mmHg or a diastolic pressure greater than 75 mmHg warrants consideration of systemic hypertension. [7]

Fractures

Because of decreased bone mineralization (osteopenia) related to prematurity, fractures of the long bones and ribs are not uncommon in premature infants during their initial hospitalization. Usually by the time of hospital discharge, bone mineralization has improved to such an extent that new fractures are uncommon, but there may be evidence of healing fractures on x-ray examination. This fact should be kept in mind if fractures are incidentally noted on an x-ray, to avoid possible misinterpretation as signs of child abuse. Comparison of current x-rays with previous films may help to clarify the issue.

Failure to Thrive

The establishment of consistent weight gain with oral feedings is a standard criterion for discharge from the hospital for most premature infants. However, this does not ensure that the pattern of weight gain will continue following discharge. Failure to thrive may occur either because of an ongoing chronic disease (e.g., bronchopulmonary dysplasia, malabsorption, or central nervous system disease) or because of dysfunctional parenting. NICU graduates should be consuming at least 150 mL/kg/day of a standard formula if not breast feeding and should be consistently gaining approximately 20 to 30 g/day. A comparison of the current weight with the discharge weight (which parents usually remember) allows for a quick evaluation of this problem, or appropriate growth curves can be utilized. [8,9] Any infant with failure to thrive requires a thorough diagnostic evaluation and often hospitalization for accurate documentation of caloric intake. It should be remembered that prematurity itself is not an adequate explanation for postdischarge failure to thrive.

Immunizations

The recommendation by the American Academy of Pediatrics is to immunize premature infants on the same schedule as normal full-term infants. [10] However, because of prolonged hospitalization and complicated follow-up, it is possible that immunizations might be missed. Inquiry about the immunization status may uncover such a situation. Although it may not be desirable to immunize an infant during an acute illness, appropriate recommendations for follow-up should be made.

ACUTE RESPIRATORY DETERIORATION IN INFANTS WITH BRONCHOPULMONARY DYSPLASIA

Although acute respiratory deterioration can occur in any NICU graduate, this discussion focuses on those infants with ongoing pulmonary disease, such as bronchopulmonary dysplasia (BPD). BPD is usually a sequela of prematurity, hyaline membrane disease, and mechanical ventilation, although it may be associated with other conditions. [11] Features of BPD include tachypnea, hypercarbia, suboptimal oxygenation, and sometimes reactive airway disease. In more severe cases, pulmonary hypertension, pulmonary edema, and cor pulmonale are prominent. The cornerstones of therapy for BPD are oxygen and nutrition. It is essential to take a medication history, since chronic use of diuretics or bronchodilators is seen in selected patients, although their value remains poorly defined. Systemic glucocorticoids are used more commonly as chronic therapy and can lead to adrenal suppression.

Acute deterioration in patients with BPD is usually manifested by an increase in respiratory rate, an increase in respiratory effort, a decrease in oxygenation, and poor

feeding. The most common causes of acute respiratory deterioration in infants with BPD are listed in Table 113-1 . A careful history can usually delineate the likely cause. For example, a history of an upper respiratory infection or fever suggests an infectious cause, which is the most common reason for an acute respiratory deterioration in a patient with BPD. Although many viruses or bacteria can be responsible for such infections, respiratory syncytial virus (RSV) infection is particularly common in premature infants with BPD.[2,12] It is important to recognize how quickly infants with BPD can deteriorate during an RSV infection due to acute bronchospasm. Such infants usually require rehospitalization for close observation, since many worsen to the point of requiring mechanical ventilation. Although the recent recommendation to use RSV immunoglobulin prophylactically in premature babies with BPD is designed to decrease the frequency of RSV infection, [13,14] it is likely to remain an important cause of acute respiratory deterioration in NICU graduates, particularly those with underlying BPD.

Respiratory infection

Aspiration
    Gastroesophageal reflux
    Incoordinate sucking or swallowing

Bronchospasm

Pulmonary edema

Dehydration
    Gastroenteritis
    Diuretic therapy

Anemia

Cor pulmonale

TABLE 113-1   Causes of Acute Respiratory Deterioration in Infants with BPD

Sudden respiratory deterioration in a patient with BPD is usually due to aspiration, either from gastroesophageal reflux or to a poorly coordinated suck/swallow reflex. Exposure to cigarette smoke or other environmental pollutants may precipitate acute bronchospasm. An increase in pulmonary edema is usually accompanied by the development of peripheral edema and excessive weight gain.

Dehydration is an important cause of acute respiratory deterioration, since many infants possess an altered myocardial compliance (Starling curve shifted to the right), making cardiac output more dependent on end-diastolic filling. Therefore, if an infant becomes dehydrated secondary to vomiting and diarrhea or to aggressive diuretic therapy, cardiac output will decrease and secondary respiratory deterioration will follow. When evaluating and treating an infant with BPD with respiratory distress, there is often a temptation to use diuretics. However, one must be sure that the infant is not already hypovolemic, since in that case diuretics make the infant worse.

Anemia may also exacerbate respiratory distress in an infant with BPD and is suggested by the presence of pallor. Acute cor pulmonale can develop secondary to hypoxemia from any of the above-mentioned causes, and deterioration can be very rapid. The only effective way to treat acute cor pulmonale in infants with BPD is to treat the hypoxemia and its underlying cause.

The usual evaluation of an infant with BPD who has acute respiratory deterioration includes a complete blood count, arterial blood gas determination, appropriate cultures, and a chest x-ray. However, the chest x-ray can be difficult to interpret because of the presence of chronic abnormalities. Therefore, it is essential to compare the current x-ray with previous films to identify acute changes.

Therapy should be directed toward the specific cause of deterioration, but oxygenation is the cornerstone of treatment. Although BPD infants often have chronic CO_2 retention, there is no evidence that respiratory drive is decreased with oxygen administration. Therefore, oxygen should be used liberally while definitive diagnosis and treatment are debated. Specific therapies for BPD have recently been extensively reviewed. [11] Care in an emergency department often centers on the treatment of acute bronchospasm. The most commonly used medications for acute bronchospasm are aerosolized b_2 agonists (e.g., albuterol and terbutaline) with or without glucocorticoids. The majority of infants with BPD who deteriorate sufficiently to need acute bronchodilator therapy require hospitalization and observation.

APNEA AND HOME APNEA MONITORS

Most infants resolve apnea of prematurity before discharge and do not require apnea monitoring at home. [15] However, home monitoring is sometimes utilized for premature infants with severe apnea or if apnea persists beyond 38 weeks' postconceptional age. [16,17] Infants may be brought to an emergency department because of an actual apneic episode or because the parents are not sure of the significance of an alarm. Studies have demonstrated that the majority of alarms at home are not associated with a change in cardiorespiratory status and probably represent monitor dysfunction, such as loose leads. [16] However, caution must be exercised before attributing an alarm to a mechanical problem with the monitor.

All episodes associated with cyanosis or bradycardia, directly observed episodes of apnea, and any episode requiring intervention, such as stimulation or mouth-to-mouth resuscitation, should be thoroughly evaluated and require admission. A recurrence of apnea in a premature infant who was discharged apnea-free warrants admission and a thorough search for the cause. The differential diagnosis (Table 113-2) includes respiratory infection (especially with RSV or pertussis), sepsis, gastroesophageal reflux and aspiration, aspiration with feedings, anemia, and metabolic problems, such as hypoglycemia. Other, more unusual causes include seizures, cardiac dysrhythmias, and posthemorrhagic hydrocephalus. Therapy is directed toward the specific cause.

Respiratory infection (RSV or pertussis)

Sepsis

Gastroesophageal reflux and aspiration

Aspiration with feedings

Anemia

Hypoglycemia

Seizures

Cardiac arrhythmias

Posthemorrhagic hydrocephalus

TABLE 113-2   Most Common Causes of Apnea and Bradycardia at Home in NICU Graduates

POSTHEMORRHAGIC HYDROCEPHALUS

Premature infants who have had an intraventricular hemorrhage may develop posthemorrhagic hydrocephalus in the newborn period. [18] Hydrocephalus can progress during the initial hospitalization, in which case the infant is usually discharged with a ventriculoperitoneal shunt in place, or hydrocephalus may develop gradually following discharge. Such infants may present to an emergency department because of progressive hydrocephalus if unshunted, or shunt obstruction or infection. Infants with infection usually have nonspecific signs, such as poor feeding, lethargy, irritability, fever, and vomiting, similar to those of any other child with central nervous system infection. Infants with obstructed shunts most often have a tense fontanelle and a history of vomiting, although the infant usually does not appear particularly ill. A comparison of the current head circumference with the head circumference at discharge (if available) is helpful in evaluating for progressive hydrocephalus. A computed tomography scan may be necessary to properly evaluate the size of the ventricles. Empiric antibiotic therapy should be utilized whenever a shunt infection is suspected, pending culture reports. Shunt infections usually require removal of the foreign body, although successful treatment without removal

has been reported for *Staphylococcus epidermidis* infections. For both shunt infections and hydrocephalus, neurosurgical consultation is required.

THE EXPECTED HOME DEATH

Some infants are discharged for the NICU with lethal conditions for which further medical intervention is futile, and the parents are expecting the child to die at home. In many cases the parents are instructed to take the infant to the emergency department to be pronounced dead by a physician. The parents should be given a letter at the time of the original hospital discharge by their physicians delineating the infant's problems to provide guidance to the emergency physician facing such a situation.

This is a very traumatic time for the parents, and a futile resuscitation effort is not indicated and can prolong the parents' agony. However, it is very important to request autopsy permission to completely delineate the infant's problems and to provide optimal counseling for future pregnancies.

114 SUDDEN INFANT DEATH SYNDROME

Carol D. Berkowitz

Sudden death may affect persons of any age, but it is especially devastating when it affects previously healthy individuals. In the past, between 5000 and 10,000 infants (1 to 2 per 1000 live births) succumbed yearly to sudden infant death syndrome (SIDS), also known as "crib death." With recent changes related to infant position during sleep, the number of deaths has decreased to about 3000 and the rate to about 0.8 deaths per 1000 infants.

The term *SIDS* was officially designated in 1963 to describe a syndrome of unexpected death in infants under 1 year of age for which no pathologic cause could be determined by a thorough postmortem examination. The syndrome has been a leading cause of death of infants between 1 month and 1 year of age.[1]

An understanding of SIDS is essential for emergency physicians so that they can recognize the syndrome, initiate resuscitation, manage infants who have experienced an apparent life-threatening event (ALTE, previously termed *"near miss" SIDS*) and counsel the family of the victim.[2]

PATHOPHYSIOLOGY

Over 70 different theories for SIDS has been proposed, including suffocation from sleeping with a parent, milk allergy, and thymic enlargement (status thymicolymphaticus). The main disturbance in some victims appears to be with the infant's ventilatory response, and SIDS and infantile apnea appear related, although the exact nature of this relation is uncertain.[3] Death is due to respiratory rather than cardiac arrest, and some potential SIDS victims may be successfully resuscitated with ventilation alone. Dysrhythmias probably occur only as a terminal event, and syndromes such as prolonged QT interval or Wolff-Parkinson-White syndrome are rare associations.[4] Prospective studies monitoring normal infants showed no antecedent dysrhythmias in infants who eventually succumbed to SIDS. Conversely, approximately 2 percent of premature and low-birth-weight infants experienced bradycardia (fewer than 50 bpm) without apnea 1 week after discharge.[5]

Information implicating ventilation disturbances and hypoxemia has been obtained from two sources: autopsies of infants who succumbed to SIDS, and studies of those who experienced an ALTE but survived. This later group represents infants who were found limp, cyanotic, pale, and lifeless, without any respiratory effort, but who were successfully resuscitated.

Autopsies of some SIDS victims reveal pathologic changes initially felt to be indicative of long-standing hypoxemia. These changes include smooth muscle thickening in small pulmonary arteries, right ventricular hypertrophy, hematopoiesis in the liver, increase in periadrenal brown fat, adrenal medullary hyperplasia, and abnormalities of the carotid body. The only marker now reported with regularity is brainstem gliosis.[6]

Recently, much attention has been given to SIDS and sleeping in the prone position.[7,8,9 and 10] Epidemiologic studies indicate that the incidence of SIDS is lower in countries where infants sleep supine or in the side-down position, and that a reduction in the incidence of SIDS follows a reduction in prone sleeping. Concern about aspiration in infants sleeping in the supine position are unfounded. Two mechanisms linking SIDS to prone sleeping are noted. With prone sleeping, infants will assume a face-down position, particularly in response to a cold stimulus on the face. This may result in upper airway obstruction. However, upper airway obstruction has not been observed in clinical trials; rather, it has been noted that infants rebreathe expired air and experience hypercarbia.[11] Because of these observations related to the prone position, the American Academy of Pediatrics now recommends a supine or side sleeping position for normal infants.

The link between child abuse, SIDS, and ALTE has also received renewed interest.[12,13,14,15 and 16] Familial cases of SIDS raise the possibility of abuse. Some investigators report that 10 percent of SIDS cases are due to abuse. Some children with ALTE have been purposefully asphyxiated, and in some cases the complaints have simply been fabricated. These problems are referred to as *Munchausen syndrome by proxy*. Child abuse is the diagnosed cause of death in 2000 cases a year. The presence of bruises, long-bone fractures, rib fractures, internal hemorrhages, evidence of physical neglect, or trauma around the nares suggests abuse. Rib fractures in infants are not induced by cardiopulmonary resuscitation. A history inconsistent with the usual events surrounding a SIDS death may also raise the suspicion of abuse. An interesting report on death-scene investigations revealed that in 23 of 26 infants studied, circumstantial evidence of accidental death was present.[17] It is beyond the scope of emergency physicians to conduct such investigations. However, more and more communities are convening Child Death Review Boards to assure the full evaluation of sudden and unexpected death among children. It is important, however, to be aware of the possible role of accidental or intentional trauma in some SIDS victims.

SIDS and Apnea

Four groups of infants who appear at increased risk of SIDS have been identified: (1) term infants who have had a life-threatening episode of apnea, or ALTE; (2) premature infants of low birth weight; (3) siblings of infants who have succumbed to SIDS; and (4) infants of substance-abusing mothers.[18,19 and 20]

Studies of infants with ALTE may reveal (1) hypoventilation ($P_{CO_2} > 45$ mmHg) and chronic hypoxemia, (2) a depressed ventilatory response to CO_2 breathing, (3) prolonged sleep apnea (>15 s, associated with cyanosis or pallor), (4) bouts of frequent short apnea, (5) increased periodic breathing (characterized by repeated 3-s pauses in breathing followed by normal breathing for less than 20 s with bradycardia), (6) obstructive apnea, and (7) mixed obstructive and central apnea.[21]

Southall has described three separate components associated with respiratory abnormalities in infants.[22]

First, there is central apnea, in which immaturity, tumor, head injury, infection, or congenital malformation leads to primary failure of respiratory center control. In addition, peripheral chemoreceptors act abnormally, particularly in response to hypercarbia and hypoxia. The dive reflex may contribute to apnea on a central basis. Young monkeys receiving a cold or wet stimulus to the face in the area of the trigeminal nerve stop breathing. This situation may be analogous to a young infant lying in a regurgitated feeding. Alternatively, this stimulus may lead to a face-down sleeping position and airway obstruction.

Airway obstruction is a second component. Obstructive apnea may occur in response to nasal occlusion, as with an upper respiratory infection, and is noted with tonsillar enlargement, hypotonia of the hypopharynx, or glossoptosis. It is a contributing factor in about 5 percent of ALTE episodes. It is detected by the presence of increased chest wall movement, with bradycardia and decreased P_{O_2} (by surface oximeter). It is a contributing component to SIDS in infants with upper respiratory infection.

The third and most significant component is expiratory apnea. Prolonged expiratory apnea is associated with sudden atelectasis. Ventilation perfusion inequalities, hypoxia, and sudden cyanosis occur within 5 to 10 s. There is a rapid loss of consciousness. These episodes may occur even in the face of nasotracheal intubation. In older children, they may occur with crying, as cyanotic breath-holding spells.

Acute hypoxic episodes are felt to occur in 80 percent of SIDS cases.

EPIDEMIOLOGIC FACTORS

The diagnosis of SIDS is confirmed by autopsy, but many clinical and epidemiologic features characterize the syndrome. Although the overall incidence is now about

0.8 per 1000 live births, there is variation among different ethnic groups, with an incidence of 0.51 per 1000 among Asian Americans and 5.93 per 1000 among Native Americans. Victims range in age from 1 month to 1 year, with peaks at $2\frac{1}{2}$ months and at 4 months. The infant frequently has been premature or small for gestational age. Although initial reports suggested a higher incidence of SIDS among premature infants with bronchopulmonary dysplasia, this association has not been confirmed by more recent studies.[23,24]

The syndrome is rare in the first month of life, probably because the neonate has a better anaerobic capacity for survival, and with a gasp may be able to raise his or her arterial P_{O_2} over 20 mmHg and continue breathing. Of the infants who are otherwise healthy, 30 to 50 percent have some acute infection, usually of the upper respiratory tract, at the time of the event. Infection with respiratory syncytial virus has been associated with apnea, particularly in premature infants and those with an antecedent history of apnea.[25,26] Otitis media and gastroenteritis have also been associated with SIDS. Infected infants tend to be older than noninfected infants, and males outnumber females in the infected group by 2:1. The sex ratio is equal in the noninfected group. There is a disproportionate number of babies from the lower socioeconomic group, although this is true for deaths in infancy from all causes. Mothers frequently are younger than 20 years of age and unwed, smoke, use drugs, and have made few prenatal and postpartum visits. Both prenatal and postnatal maternal smoking increase the incidence of SIDS.[27,28] SIDS is more likely to occur during the winter months and when the infant is asleep.

CLINICAL FEATURES

A number of scenarios may confront physicians in the emergency department. These scenarios mirror the range of problems that may be broadly categorized under the heading of SIDS or of ALTE.

Some infants are completely well appearing at the time they are examined, and the parents relate a history of cessation of respiration. The physician must then determine whether the event represented an episode of apnea, was severe enough to be life-threatening, or represents a different disorder.

The sequence of events prior to the episode may be a clue to the cause (see Table 114-1). If the infant stiffened or exhibited clonic movements, the cessation of respiration may have been postictal apnea following a seizure. With a seizure, an infant is frequently awake before becoming apneic. Gastroesophageal reflux may lead to apnea and also may occur in awake infants following a feeding. A history of an upper respiratory infection followed by paroxysmal cough with an apneic episode would be suggestive of pertussis. Hypoglycemia may also be associated with apnea, with or without a seizure. The differential diagnosis also includes infection (sepsis or meningitis) and cardiomyopathy. Infantile botulism may be the cause in 5 to 10 percent of SIDS victims.

Cardiac arrhythmias/anomalies
Child abuse
Gastroesophageal reflux
Infantile botulism
Inborn errors of metabolism
Intracranial hemorrhage
Pertussis
Respiratory syncytial virus infection
Seizure
Sepsis

TABLE 114-1   Conditions that May Present as an Apparent Life-Threatening Event

The evaluation of healthy-appearing infants with a history of apnea is problematic. Occasionally, parents may have misinterpreted acrocyanosis, postprandial regurgitation, or color changes with stooling as an episode of apnea. The parents should be carefully questioned about what they did to revive the baby, for example, stimulation or mouth-to-mouth resuscitation. No resuscitative efforts suggest a benign event. Conversely, the need for mouth-to-mouth resuscitation bespeaks a more serious event. The finding of irregular respiration or poor muscle tone on physical examination would assist in the diagnosis of an ALTE.

Some infants who have experienced an ALTE have not been fully resuscitated in the field. They should receive the benefit of vigorous cardiopulmonary resuscitation, unless signs of irreversible death (livedo reticularis, blood pH of 6, or boxcar venous pooling in the fundi) are apparent. Frequently the heart will resume beating after prolonged arrest. The infant heart is a remarkably resistant organ and may be revived after irreversible brain damage.

DIAGNOSIS

The evaluation of an infant who has experienced an ALTE should include a complete medical history, particularly of the event itself, and take into account the perinatal and epidemiologic factors associated with SIDS and ALTE. A history of other infant deaths in the family should be obtained because of the familial incidence of SIDS. Familial cases of SIDS suggest the possibility of child abuse, as noted above, or of inborn errors of metabolism, such as disorders of fatty acid metabolism.[29,30] Autopsy results in a small subset of infants who have succumbed to SIDS reveals findings such as microvesicular steatosis of the liver, a sign of a disorder of fatty acid metabolism. Sometimes, sudden unexpected death has occurred in other siblings within these affected families. Initial reports suggested that siblings of SIDS victims are at increased risk (about 10-fold) for subsequent SIDS. More recent studies show at most a twofold increase in the incidence of SIDS among SIDS siblings.[31,32]

The physical examination should be complete, with special emphasis on the neurologic evaluation and the presence of any injuries. The initial laboratory assessment should include a complete blood cell count; determination of levels of serum electrolytes, blood sugar, calcium, phosphate, and magnesium; and a 12-lead electrocardiogram. A septic workup including blood culture, cerebrospinal fluid analysis, urine culture, and chest x-ray is indicated in most cases, although studies have shown a negligible yield in the absence of associated findings such as fever. In an infant with an ALTE, the stool should be sent for clostridial culture and botulinum toxin testing, expecially if hypotonia is present. Other studies should be done if suggested by the history and physical examination; these include determination of serum ammonia, urinary organic acids, sleep and awake electroencephalograms, skull x-rays, barium swallow, and computed tomography.

TREATMENT

Initial treatment in the emergency department involves continued resuscitation of the infant, if necessary, and stabilization. In general, all ALTE victims and infants with a history of apnea and/or cyanosis should be admitted to the hospital. The evaluation of these infants is designed to rule out treatable causes of apnea and to determine whether, in the absence of these other causes, the infant is at risk for SIDS, an event reported in from 20 to 100 percent of infants with an ALTE.

Apnea should be monitored in the hospital. Most hospitals are able to obtain pneumograms, which provide evidence of abnormalities related to periodic breathing or episodes of apnea. Polysomnography measures the amount of air flowing in at the mouth and nose and can detect obstructive apnea; the test is complicated and is generally done in a sleep laboratory. Certain tertiary care centers are equipped to evaluate responses to CO_2 breathing and diminished inspiratory oxygen.

HOME MONITORING

Two major treatment modalities are recommended for infants who have experienced an ALTE or are at risk for SIDS. Xanthine derivatives such as caffeine and theophylline are used frequently in treating apnea of prematurity because of their central excitatory effect. Their use is associated with the normalization of the respiratory pattern in over 80 percent of such children. Their efficacy in the prevention of SIDS is unclear. A pragmatic approach to the use of theophylline would be to limit it to infants with abnormal pneumograms. Reversal of these abnormalities with theophylline would be an indication for its use. Theophylline is given at 6 mg/kg per day, and a serum level of 5 to 15 mg/mL should be maintained.

Home apnea monitoring is the second modality that can be offered. Three groups have been defined in a National Institutes of Health Consensus Statement in 1986 as being candidates for home monitoring.[33] Group 1 consists of term infants with unexplained apnea of infancy, usually manifested by a life-threatening episode and/or abnormal pneumogram. The absence of an abnormal pneumogram does not preclude home monitoring. The second group consists of preterm infants who have continued to manifest apnea beyond term (i.e., after 40 weeks postconception). The third group consists of subsequent siblings of two or more SIDS victims, but not of one SIDS victim. Twins of SIDS victims were reported in the past to have a 20-fold increase in their risk for SIDS. More recent studies suggest their chance is the same as for nontwin siblings. Additional candidates for home monitoring include infants with bronchopulmonary dysplasia, especially if oxygen dependent, and infants who require tracheostomy for airway support.

Home-monitoring devices usually measure chest wall movement and heart rate. The detection of bradycardia is particularly important in infants with an obstructive component because chest wall movement is not diminished with obstructive apnea. Parents must be instructed in equipment maintenance, interpretation of the alarm, and cardiopulmonary resuscitation. Home monitoring does not mean simply supplying a family with a mechanical device. It involves the development of a medical team to support the family, interpret any episodes of apnea, and decide when home monitoring can be discontinued. Technicians who are available 24 h a day to maintain the equipment are also required.

Emergency physicians are frequently consulted about monitor alarms. Infants are brought to the emergency department because of alarm triggering. Physicians must be able to differentiate a false alarm from a true episode. The need for vigorous stimulation or mouth-to-mouth resuscitation again suggests a serious episode. If there is concern about equipment malfunction, technical assistance should be obtained from the monitoring company.

The use of home monitors has increased dramatically in recent years. The estimated cost of monitoring (including initial assessment) ranges from $3000 to $5000 per infant, with monthly rental and maintenance costs ranging from $150 to $300. Although parental anxiety is frequently reduced, the reduction in the incidence of subsequent SIDS in monitored infants is questioned. Reports have shown a mortality rate of as high as 50 percent among infants on home monitoring. In many cases, technical errors and parental noncompliance contributed to the infant's demise. Some infants, however, simply failed to respond to aggressive cardiopulmonary resuscitation.

The decision to discontinue monitoring is usually made by an infant's primary physician. In general, most infants remain on a monitor for 6 to 8 months. Criteria for discontinuing the monitor include 2 to 3 months with no episodes requiring stimulation or resuscitation, 3 months without apnea of 20 s or longer, no apnea associated with an upper respiratory infection or immunization, and an improvement in any neurologic problem for which the monitoring was instituted (e.g., apnea associated with seizures).

THE SIDS VICTIM

The management of a nonresuscitatable SIDS infant and his or her family is equally challenging for a physician. The emergency department physician is confronted by the distraught mother who had fed her infant several hours earlier, went to check the sleeping infant, and found the baby cold, blue, and lifeless. Frequently, valiant though unsuccessful efforts are carried out in the emergency department, or the infant is revived briefly, only to succumb after several hours in the intensive care unit.

The major responsibility of the physician is then to notify, counsel, and educate the family. In most jurisdictions, victims of sudden and unexplained deaths must be referred to the coroner's office, where an autopsy is performed at the coroner's discretion. [35] Some jurisdictions have infant death teams that fully evaluate the circumstances surrounding the unexpected death of young infants. If the physician believes the infant is a victim of SIDS, the family should be so advised but told that the final confirmation awaits the autopsy report. The emergency physician should assure the family about their lack of responsibility for the infant's death and assuage their feelings of guilt. He or she should then serve as a facilitator maintaining contact with the family to advise them of the autopsy results. The hospital chaplain or social worker may provide additional support, but the physician's empathy is especially supportive to the family. Most communities have organizations for parents of SIDS victims, and information about these organizations can be obtained from the National Foundation for Sudden Infant Death, 101 Broadway, New York, New York 10036. Parents should be referred to these organizations. Additional information can be obtained from the National Sudden Infant Death Syndrome Resource Center, 8201 Greensboro Drive, Suite 600, McLean, Virginia 22102, telephone (703) 821-8955.

115 PEDIATRIC HEART DISEASE

C. James Corrall

Pediatric cardiovascular disorders are decidedly uncommon in emergency medicine. The incidence of congenital heart disease is only about eight cases per 1000 live births and contrasts sharply with the increasing prevalence of cardiovascular disease in adult populations. [1] Because of the relative unfamiliarity of such disorders, most emergency medicine physicians have encountered these disorders only in their initial training. The combination of the low incidence and the age-related differences in clinical presentation make timely recognition, stabilization, and appropriate tertiary referral a challenge for primary care physicians. In the emergency department, problems may range from an asymptomatic discovery of a murmur to the life-threatening presentation of a cyanotic infant in cardiogenic shock.

Congenital heart disease is usually classified based on physiology (presence or absence of cyanosis, with or without persistent fetal circulation) or on the nature of the anatomic defect (shunt, obstruction, transposition, or complex). Most pediatric heart disease is congenital, but acquired conditions also occur and include complications secondary to rheumatic fever, Kawasaki disease, and severe chronic anemias, as well as myocarditis, pericarditis, endocarditis, and the tachydysrrhythmias.

Pediatric heart disease can also be classified by clinical presentation. The six common clinical presentations to primary care physicians are cyanosis, congestive heart failure, pathologic murmur in asymptomatic patients, abnormal pulses, hypertension, and syncope. Table 115-1 lists the most common lesions in each category. While this is informative in the formation of a broad differential diagnosis in very ill pediatric patients, it is perhaps best to classify heart disease according to the clinical presentation in the emergency department. Most often, this presentation is in children with previously undiagnosed heart disease and to a lesser degree in those with previously diagnosed heart disease or reparative surgery for the same.

Cyanosis	TGA, TOF, TA, Tat, TAVR
Congestive heart failure	See Table 115-3
Murmur/symptomatic patient	Shunts: VSD, PDA, ASD
	Obstructions
	Valvular incompetence
Abnormal pulses	
Bounding	PDA, AI, AVM
Decreased with prolonged amplitude	Coarctation, HPLV
Hypertension	Coarctation
Syncope	
Cyanotic	TOF
Acyanotic	Critical AS

TABLE 115-1 Clinical Presentation of Pediatric Heart Disease

Children with previously undiagnosed heart disease can be broadly classified into three categories: unstable, stable but symptomatic, and stable and asymptomatic. Unstable infants usually require immediate and decisive stabilization and aggressive management before diagnostic studies or tertiary referral can be made. Pediatric cardiology consultation should be emergently sought from the regional tertiary care center before pharmacologic intervention, if at all possible. Stable and symptomatic infants require less aggressive measures, so there is time to focus on physiologic derangement and correction of abnormalities of oxygenation and metabolism and time for tertiary referral. A baseline electrocardiogram (ECG) and chest radiograph are indicated in such infants particularly when a murmur appears to be pathologic (grade 3 or louder, holosystolic or diastolic in timing, and/or radiating away from the heart). Stable but asymptomatic infants can easily be referred routinely based on findings on general examination. Such infants can be electively evaluated without specific testing in the emergency department. Recent, well-publicized cases of pediatric sudden death from unrecognized pediatric heart disease are rare, but such infants arrive in extremis at the emergency department. This represents a final presentation type of pediatric heart disease that is tragic because such infants cannot often be resuscitated, even by physicians with expertise in pediatric heart disease.

Children with known heart disease arrive at the emergency department for treatment of routine illnesses as well as for problems related to their unique disease. Rarely, they arrive with acute life-threatening cardiovascular complications. Once the knowledge of preexisting heart disease is known, the physician can anticipate complications related to the unique disease, such as hemoconcentration due to polycythemia, bacterial endocarditis, or embolism. Only infrequently do such infants have abnormal immune systems, and most handle routine pediatric illnesses well.

CARDIOVASCULAR PHYSIOLOGY

It is important to understand the interplay between normal cardiovascular dynamics in pediatric patients and the age-related changes that occur during transition to

the extrauterine environment. This understanding is necessary in order to recognize the signs and symptoms of pediatric heart disease and to plan therapy appropriate to the physiologic derangement.

Perhaps the most dramatic change that occurs at birth is the transition from fetal to postnatal circulation. Immediately following birth, flow through the umbilical arteries ceases and the venous flow through the cord slows and then stops. These vascular changes are mediated by the rapid increase in arterial oxygen partial pressure (P_{AC_2}) that occurs during lung inflation. Following lung expansion, pulmonary vascular resistance falls and pulmonary blood flow increases. The pulmonary vascular resistance will continue to fall with increases in blood flow over the next 30 to 45 days of extrauterine life. The ductus arteriosus also closes with the rise in arterial P_{O_2}, and blood shunted through a patent foramen ovale ceases. In time, these shunt channels permanently close but, until then, may reopen under conditions of decreased P_{O_2} or other stresses.[2]

Cardiac output, which is the amount of blood that the heart pumps each minute, is normally the product of the heart rate and the stroke volume of the ventricles. Physiologically, the role of the heart is to facilitate and maintain a cardiac output that is adequate for the metabolic needs of the body by the provision of substrates for adequate cellular function and removal of by-products of metabolism. Since neonates and small children have limited ability to increase stroke volume due to the relatively noncompliant ventricular walls, they rely on changes in heart rate to adjust the cardiac output. Thus, sinus tachycardia is usually the first response to stress in infants and children and is mediated by the intrinsic pacemaker in the sinoatrial node and by various adrenergic, hormonal, and neural mediators.

Several physiologic terms are important to understand, particularly with regard to therapy. *Preload* is normally considered the amount of blood that the heart receives to distribute to the body. Decreasing the amount of blood flowing into the heart lowers the cardiac output. Preload can be reduced due to pharmacologic means such as by the use of intravenous nitrates or by blood loss. Similarly, increasing the amount of blood into the heart will increase the cardiac output in accordance with Starling forces, until the point of maximum compliance of the ventricular wall. At this point, cardiac output decreases dramatically and congestive heart failure occurs. *Afterload* refers to the resistance to blood flow out of the heart. Afterload may be increased anatomically in neonates by an obstructive lesion, such as aortic stenosis or critical coarctation of the aorta. Afterload depends on the size of the ventricle and its compliance or elasticity. The compliance in the neonatal heart is limited, so afterload reaches critical values early. Afterload also depends on the amount of arteriolar resistance in the case of pediatric hypertension unrelated to obstructive lesions in the proximity of the heart and great vessels. Treatment of afterload problems is directed at arterial vasoconstriction or vasodilatation. *Contractility* or *inotropy*, which is the ability of the cardiac muscle to pump blood out of the heart, refers to the force or power of the contraction and determines the amount of work that the heart can perform. Increasing the cardiac contractility increases the stroke volume and hence the cardiac output.

Cardiac contractility is normally regulated by neural or humoral mechanisms. It may be altered pharmacologically by such medications as digoxin or dobutamine. *Cardiac rate* or *chronotropy* is the ability of the heart muscle to pump blood out of the heart per fixed unit of contraction. In the typical circumstance, chronotropy and inotropy can not be differentiated with regard to therapeutic maneuvers. Typically, both the cardiac rate and the relatively fixed contractility of the neonatal heart contribute to the overall cardiac output, with the former contributing more of the output. In pediatric hearts older than 4 to 5 years, there is a more balanced contribution to cardiac output, with the contractility playing a much more prominent role.

THERAPEUTIC IMPLICATIONS

All of the medical management provided to children with heart disease is directed toward increasing cardiac output in low-output states by alteration of the heart rate, preload, afterload, or inherent contractility. As mentioned previously, some of these parameters may be rather fixed due to the inherent limitations of the neonatal ventricular noncompliance.[3]

Heart rate is the most malleable of the cardiac physiologic parameters. Symptomatic bradycardias of all types are treated with oxygenation, atropine and, in severe cases, with epinephrine and/or isoproterenol followed by transthoracic pacemaker and transvenous pacemaker usage. Symptomatic tachycardia must be differentiated into sinus, supraventricular, or ventricular before specific therapy can be initiated.

Preload disorders are common in children and are most frequently due to shock states with resultant hypovolemia that causes the decreased preload. The hypovolemia may be due to increased loss of total body water, such as occurs in excessive diarrhea or vomiting, or it may be a relative loss of volume due to maldistribution. In the latter circumstance, distributive forms of shock such as in sepsis, neurogenic spinal shock, or anaphylaxis produce relative hypovolemia secondary to increased vasodilation and decreased venous return to the heart. In congestive heart failure, preload is markedly increased when the left atrial pressure becomes elevated. The resulting Starling forces produce pulmonary edema and its resultant hypoxemia. The hypoxemia reduces contractility, further increasing the left atrial pressure and accentuating the increased preload state. Treatment of such a state requires diuretics and vasodilation to reduce preload.

Adequate oxygen delivery is necessary for the myocardium during the diastolic filling phase. The oxygen supply depends on the P_{O_2} of the blood, the hemoglobin concentration, and the coronary perfusion pressure. Hypoxemia results from deoxygenated venous blood entering the systemic circulation by vascular shunts that may be present at any location. Hypoxemia caused by most vascular shunts responds poorly to increasing ambient inspired oxygen. In contrast, most respiratory causes of hypoxemia respond to increasing oxygen.

Anemia profoundly decreases the amount of oxygen available to the tissues by decreasing the amount of oxygen bound to hemoglobin per unit of cardiac output. Transfusions of 10 mL packed red cells per kilogram will raise the hemoglobin approximately 1.5 g/dL and provide improved oxygen-carrying capacity to the tissues. In special circumstances, other competing agents, such as methemoglobinemia and carboxyhemoglobinemia, with increased affinity for oxygen must be excluded.

Myocardial perfusion can only occur during the relaxation phase provided during diastole. The perfusion is markedly impaired under conditions of low cardiac output. Because the coronary perfusion pressure is the difference between the diastolic pressure minus the coronary sinus venous pressure, it follows that any situation that lowers diastolic pressure to 30 to 40 mmHg can lead to poor coronary perfusion, myocardial ischemia, and subsequent ECG changes reflecting injury. Treatment of low diastolic pressure includes infusion with a-adrenergic agents such as phenylephrine, norepinephrine, and epinephrine to raise the diastolic pressure and coronary artery perfusion.

Other factors are also important to augment contractility, but are not as amenable to therapy by emergency physicians. Acidosis adversely affects myocardial contractility and may be persistent after hypovolemia has been corrected. Sodium bicarbonate may rapidly improve contractility in such situations. If acidosis is due to respiratory failure, airway control with endotracheal intubation and mechanical ventilation is useful to correct the hypercapnia and decrease the metabolic demand generated by trying to overcome respiratory failure. Temperature control is also important because elevations can cause an increase in oxygen consumption by 400 percent, causing a marginal cardiovascular system to fail. Ideally, a neutral thermal environment should be maintained to avoid such stress. Hypoglycemia frequently occurs during stressful events, and neonates are less able to respond because of decreased glycogen stores and minimal fat necessary for gluconeogenesis. Low serum glucose of less than 40 mg/dL should be corrected with an infusion of either 25% or 10% dextrose solution. Electrolyte disturbances can interfere with both inotropic and chronotropic responses to decreased cardiac output. Appropriate monitoring of concentrations of potassium, calcium, magnesium, sodium, chloride, phosphate, and bicarbonate is prudent. Finally, attempts must be made to minimize stress in ill neonates. Alleviation of external stressors such as tubing manipulation or skin care should be minimized to increase oxygen availability by decreasing agitation. All attempts to provide for parental care and the minimization of blood drawing are crucial to this goal.

PHARMACOLOGIC ENHANCEMENT OF CARDIAC OUTPUT

In addition to the normalization of preload and metabolic parameters, patients with severe heart failure or cardiogenic shock require aggressive pharmacologic support with vasoactive infusions to enhance contractility and output. From a historical perspective, dopamine hydrochloride has served as the first-line treatment of low cardiac output. In lower dosages of 2 to 5 µg/kg/min, blood flow to the kidney and bowel is increased, and a paradoxical fall in blood pressure is noted. Midrange dosages of 6 to 10 µ/kg/min result in b-adrenergic effect, and heart rate and contractility are improved. In dosages in excess of 10 µ/kg/min, a effects predominate, and vasoconstriction results in correction of hypotension.

Epinephrine has replaced dopamine as the initial infusion of choice in hypotensive states. Predominant b-adrenergic effects are noted at lower dosages of 0.05 to 0.5 µ/kg/min, whereas a-adrenergic effects are noted at higher dosages, which can result in rapid reversal of hypotension. Dobutamine is another useful drug that increases contractility without increasing heart rate or systemic vascular resistance. Its vasodilatory effects and lack of a effect at higher dosage ranges limit its usefulness as a single agent to counteract extremely low cardiac output with normal blood pressure. Nitroprusside can be useful in increasing stroke volume by the mechanism of afterload reduction. It is administered by continuous infusion with arterial and central venous pressure monitoring to detect hypotension and the need

for volume expansion. Its use, in doses of 0.5 to 5 µ/kg/min, is always reserved for intensive care situations.

Isoproterenol administration produces a marked decrease in total peripheral vascular resistance predominantly due to vasodilation in skeletal muscle vascular sites. Diastolic and mean blood pressures fall. The effects on the heart are similar to those with epinephrine, but with enhanced heart rate and stroke volume due to the decrease in mean blood pressure and reflexively decreased vagal tone.

Norepinephrine causes marked vasoconstriction of all vascular beds on both the venous side and the arterial side. Consequently, there is a net increase in total peripheral vascular resistance that results in a marked rise in both systolic and diastolic blood pressure. Due to complex actions on the heart, which depend in part on the amount of parasympathetic activity, the overall contribution to chronotropy is negligible and the inotropic response is only minimally increased.

Phenylephrine, which is not a naturally occurring catecholamine, has actions similar to those of norepinephrine, with minimal activity on chronotropic or inotropic function. Like norepinephrine, it causes marked increase in systemic vascular resistance due to direct vasoconstriction of all vascular beds. The difference between this drug and norepinephrine is predominantly in its metabolism. Overall, it has activity that is two to three times the duration of norepinephrine, making it highly effective in situations in which blood pressure elevation is likely to be depressed for long intervals. It is seldom used today, because of its narrow therapeutic window of benefit and its toxicity.

ASSESSMENT OF CHILDREN SUSPECTED OF HAVING HEART DISEASE

The initial evaluation of ill children begins with the process of assessment and triage. Often, children present with symptoms unrelated to the underlying disease, and careful neurologic, pulmonary, and cardiac assessment must be performed to determine the stability of patients and the need for supportive care. From a cardiovascular perspective, this assessment determines whether the cardiac output is low, normal, or hyperdynamic. Concurrent conditions often exist, making definition of physical findings challenging. For instance, the symptoms and signs of increasing pulmonary venous pressure and the signs of a viral upper respiratory tract infection appear similar. What appears to be a feeding disorder with easy fatigue during routine feeds may represent congestive heart failure, particularly if diaphoresis is present with labored breathing.

The physical examination of children with significant congenital heart disease is often not as dramatic as the diagnosis of congestive heart failure in adolescents. In the author's experience, unrecognized congenital heart disease in small infants is often not diagnosed until the second or third visit to the emergency department for the same illness. Most often, that illness is misdiagnosed as a viral upper respiratory illness or a feeding intolerance.

When a child with known cardiac problems presents to the emergency department, the historical information that must be obtained by the emergency physician is problem focused and directed toward known complications of the congenital defect. A detailed history of medications administered and recent changes in dosages and timing of administration are important in such children. New illnesses, particularly of the upper respiratory tract, should be identified. Simple common pediatric illnesses such as croup, pneumonia, or bronchiolitis may cause sudden decompensation in a child with limited cardiac reserves. These illnesses may be difficult or impossible to differentiate clinically from an exacerbation of known cardiac disease. The symptoms and signs of increased right heart failure and critical pulmonary venous pressure states and respiratory illness often overlap and are indistinguishable without echocardiography.

Exertional dyspnea is often present, but overlooked, in older children with cardiac disease. In infants, feeding intolerance is the most reliable marker of exercise tolerance. Historical evidence of slow feeding, increased tachypnea with feeding, persistent staccato cough with feeding, and diaphoresis at midfeeding all suggest borderline cardiac reserves.

In small infants, tachypnea is often the first sign manifested, followed by rales that are more typical of congestive heart failure. Hepatomegaly usually develops late and is always in excess of splenomegaly. In small infants, edema is usually generalized and not associated with jugular venous distention. Accurate blood pressure measurement in infants requires an appropriately sized cuff (approximating two-thirds of the extremity). Ideally, blood pressure should be measured in both upper and lower extremities. Cardiac murmurs should be graded according to location, timing in the cardiac cycle, and loudness. There may be significant cardiac pathology in the absence of murmur and, conversely, a very loud murmur may be innocent and nonpathologic. The pediatric-sized stethoscope bell and diaphragm should be used to discern the exact location of murmurs. Heart sounds should also be assessed particularly for fixed splitting of the second heart sound.

Focused cardiac examination must address the difference between pathologic and innocent cardiac murmurs. Typically, 30 percent of children will have innocent flow murmurs that are incidental findings on routine examination. Usually, innocent flow murmurs are of low intensity and do not radiate. They are brief in the cardiac cycle and usually systolic in timing. They are never holosystolic and are usually accentuated by head position or Valsalva maneuver. [4]

The Still's murmur, which is the most common innocent murmur, is usually early systolic in timing, located at the apex or the lower left sternal border, and is often confused with the murmur of a ventricular septal defect (VSD). It usually does not radiate to the back like the murmur of a VSD. Pulmonary systolic ejection murmur, which is equivalent to the Still's murmur, is extremely harsh and is usually heard loudest in the second and third intercostal spaces on the left. A unique murmur, often heard in neonates, is that of peripheral pulmonic stenosis. This murmur is usually of low intensity, is usually heard in both axillae and the back, and usually vanishes by 3 to 6 months of age. It is often misdiagnosed as a congenital lesion in sick infants and results in inadvertent administration of cardiotonic medication. Significant cardiac murmurs are usually holosystolic, continuous or diastolic in timing and usually associated with radiation. [5]

Laboratory studies are usually not initially helpful in acutely ill, hemodynamically unstable patients, but may be of some benefit in more stable pediatric patients. Such studies are usually confined to chest radiograph, ECG and, in some centers, bedside emergency ultrasound.

Chest radiographic studies are essential in assessing the size and shape of the heart and in evaluating pulmonary blood flow. The chest radiograph also provides some information about the position of the aortic arch, which should be normally left sided. In the normal left-sided aortic arch, there is rightward displacement of the esophagus and trachea to the right. An abnormal right position of the aortic arch may be a clue to the diagnosis of the congenital cardiac lesion. Right-sided aortic arches are seen in truncus arteriosus, transposition of the great vessels, tetralogy of Fallot, tricuspid atresia, and total anomalous pulmonary venous return. The chest radiograph is critical to the assessment of pulmonary vascularity. In small left-to-right shunts, the pulmonary vascularity is normal. Pulmonary vascularity can also be normal in conditions that cause pulmonary stenosis, such as valvular pulmonic stenosis or functional pulmonic stenosis associated with tetralogy of Fallot. Increased pulmonary vascularity may be seen with any cause of left-to-right shunting or in any cause of left-sided failure, such as ischemia or outflow obstruction.

The ECG is useful to evaluate cardiac conduction and, in particular, the rhythm, electrical axis, chamber size. Such information is clearly age related and will require one to have access to a standard text of normal values of pediatric ECG voltages and criteria for ventricular hypertrophy. [6] The electrical force axis most often defines abnormal chamber diameters and usually does not suggest cardiac ischemia as in the adult population.

Hemodynamically Unstable Patients

Clinical signs of low cardiac output are manifested by signs of dysfunction of one or more organ systems. Shock is diagnosed by determination of skin perfusion and mental status appropriate for age. Additional information may be obtained by assessment of the distal pulse quality, amplitude, and duration. Pallor, cyanosis, and skin mottling are usually present. The infant's hands and feet appear cold, and there is delayed capillary refill that is very distinct from acrocyanosis present in some infants. Mental status changes appear as fluctuating signs of apathy, irritability, or failure to respond to painful stimuli or to parental presence. Body positioning is that of prostration with loss of head control and is preferred to that of upright sitting or standing. Sinus tachycardia is the first response to maintenance of cardiac output, followed by tachypnea in an attempt to correct the acidosis of poor perfusion and oxygen delivery. Hypotension occurs late, is dramatic in its onset, and can occur without warning. Laboratory studies are unhelpful because their results are usually normal.

Noncardiac causes of shock and low cardiac output states must be considered, diagnosed, and treated in tandem with delineation of the possibility of congenital heart disease. Congenital heart lesions that present with low cardiac output are usually classified as shunt dependent and must be treated definitively and quickly. Up to 1 percent of infants are born with one or more congenital heart anomalies. Many of these lesions are of trivial or mild consequence, but a significant number are severe enough to become incompatible with life once the ductus arteriosus begins to close. As this occurs, blood can no longer reach the lungs and distal circulation. These infants present in shock within the first 2 weeks of life. Both cyanotic and acyanotic lesions may present in this fashion. The former include severe coarctation of the aorta, critical aortic stenosis, and hypoplastic left ventricle. Transposition of the great vessels, pulmonary atresia, and hypoplastic right heart syndrome are examples of the latter presentation.

Shunt-dependent lesions mandate immediate surgical referral for repair or palliation of the anatomic condition. It may be necessary to stabilize and restore some function to the shunt-dependent lesion while awaiting transport to a tertiary care facility. One method of providing this care is with the use of prostaglandin infusion to reopen the shunt pharmacologically. Prostaglandin E$_1$ infusions are successful in reopening the ductus arteriosus in nearly 95 percent of such patients and may allow for less emergent repair of the underlying defect. It is infused at a rate of 0.05 to 0.1 μg/kg/min initially. If there is no improvement within several minutes, it is increased progressively in 0.2 μg/kg/min increments. The minimal effective dosage should be used, because of adverse effects that include fever, skin flushing, diarrhea, and periodic apnea. Intubation and ventilatory support are often necessary as well.

Cardiogenic shock can also occur as a result of dysfunctional myocardium and may mimic the signs and symptoms seen with shunt-dependent anatomic lesions. Such cardiomyopathies are uncommon in pediatric patients, but can be easily confused with anatomic lesions. Cardiomyopathies are usually defined into two groups in children: dilated and hypertrophied. Presentation varies from asymptomatic cardiomegaly discovered on routine chest radiograph to congestive heart failure, cardiogenic shock, or sudden death. Typically, such children self-limit their activities at home and then, during an acute febrile illness, decompensate rapidly and arrive in profound shock. The dilated cardiomyopathies more often cause congestive heart failure, whereas the hypertrophied cardiomyopathies cause sudden death. Emergent medical management includes supportive care as previously outlined in an attempt to enhance contractility. Tragically, little can be done to assist those unfortunate children who suffer sudden death.

TETRALOGY OF FALLOT   Although not in itself a cause of hemodynamic instability due to sudden loss of blood flow, tetralogy of Fallot often presents in a dramatic fashion due to hypercyanotic episodes or "tet spells" that mimic other more significant structural lesions. Tetralogy of Fallot is the most common cause of cyanotic congenital heart disease in children older than 4 years of age. Anatomically, it is characterized by obstruction of the right ventricular outflow tract, VSD, dextroposition of the aorta, and right ventricular hypertrophy. Functionally, obstruction of the right ventricular outflow tract and the presence of VSD have the greatest physiologic consequences. Due to the outflow tract obstruction, blood is forced from right to left, resulting in desaturation and compensatory polycythemia and hyperviscosity.

The other cardinal features on physical examination are a holosystolic VSD murmur in the third intercostal space at the left sternal border and a diamond-shaped systolic murmur of pulmonary stenosis in the second intercostal space at the left sternal border. The history may reveal exercise intolerance relieved by squatting. The main radiographic findings are a boot-shaped heart with decreased pulmonary vascular markings. A right-side aortic arch is present in 25 percent of tetralogies. Right ventricular hypertrophy with right axis deviation is the primary ECG abnormality.

The greatest threat to these patients is the hypercyanotic or tet spells. These episodes, dramatic in presentation, are characterized by episodes of paroxysmal dyspnea with labored respiration, increased cyanosis, and syncope. These episodes in concert with polycythemia lead to seizures, cerebrovascular accidents, and death. They occur due to exertion of feeding, crying, or straining at stool and last from a few minutes to hours. The rapid, deep hypernea results from an increase in cardiac output with exertion against fixed right ventricular outflow tract obstruction. The fixed obstruction causes increased shunting across the VSD and increased hypoxia, hypercarbia, and acidosis. The hypoxia and acidosis cause a decrease in systemic vascular resistance that further potentiates the shunt and stimulates the respiratory center to maintain and deepen the hypernea. [7]

Management of hypercyanotic spells consists of positioning and pharmacologic management. Infants should be placed in a knee-chest position. This positioning allows for an increase in venous return to the heart and an increase in systemic vascular resistance. Pharmacologic management includes administration of oxygen to decrease the hypoxemia, and injection of morphine sulfate subcutaneously or intramuscularly at a dosage of 0.2 mg/kg/dose. Many consider the administration of propranolol a contraindication to bypass surgery, so it should not be given without consultation. In extreme cases, phenylephrine infusion 10 μg/kg initial infusion, followed by infusion of 0.5 to 2 μg/kg/min] is used to increase the systemic vascular resistance and increase blood pressure.

Lack of recognition of the hypercyanotic episode and timely intervention could result in significant complications, including seizures, cerebral thrombosis, profound lactic acidosis, deterioration in cardiac rhythm, and subsequent death.

TRANSPOSITION OF THE GREAT VESSELS   This is the most common cyanotic defect that appears in the first week of life. Infants with this defect who are brought to the emergency department usually have dusky lips noted by parents or have an increased respiratory rate or feeding difficulty. While not as dramatic in presentation as a hypercyanotic spell of tetralogy of Fallot, the defect is easily missed on a single emergency department visit, because of the lack of cardiomegaly or murmur.

Anatomically, in transposition of the great vessels, the aorta originates from the right ventricle, and the pulmonary artery originates from the left ventricle. The systemic veins drain as they usually do into the anatomically correct right atrium, and the pulmonary veins drain into the left atria. Thus, in transposition, the systemic and pulmonary blood flows are not admixed and exist in parallel unless alternative flow is established. To maintain life, mixing of blood occurs either at the level of the atria via an atrial septal defect or at the level of the ventricles by a VSD. If neither of these is present, flow must be maintained by a persistent ductus arteriosus.

Clinically, cyanosis and tachypnea appear within the first several days of life, but may be prolonged when a patent ductus arteriosus fails to close. Ironically, cardiomegaly is often absent and no murmur is noted. The chest radiograph is usually normal, but may show a narrow, small heart due to the overlapping of the abnormally positioned aorta and pulmonary artery. The ECG shows normal right-sided-force dominance. Rarely, depending on the anatomy, frank congestive heart failure will be present.

Treatment of this condition is initially palliative in the cardiac catheterization laboratory and involves the creation of a large artificial atrial septal defect by using a balloon catheter (Rashkind septoplasty). Initially, most emergency physicians who suspect this entity are justified in beginning an infusion of prostaglandin E$_1$, as previously outlined, while arranging transport to a facility capable of palliation. The definitive surgery that is performed later is the Mustard operation, in which an artificial baffle is created at the atrial level to direct systemic venous return into the left ventricle and the pulmonary return to the right ventricle. The left ventricle then pumps blood to the lungs, and the right ventricle pumps blood to the systemic circulation. [8]

LEFT VENTRICULAR OUTFLOW OBSTRUCTION SYNDROMES   No clinical presentation can match the rapidity of onset of cardiogenic shock, hypotension, and acidosis as seen in infants with this group of disorders. In these infants, systemic blood flow depends on a large contribution of shunted blood via a patent ductus arteriosus. When the ductus closes, cardiac output falls, perfusion becomes negligible, and a state of profound cardiogenic shock ensues. Such lesions are often complex, but include hypoplastic left heart syndrome, tricuspid atresia, and critical coarctation of the aorta. Other variants include transposition of the great vessels, as discussed previously, and some tetralogy of Fallot variants. [9]

Such infants present with decreased or absent perfusion, hypotension, and severe acidosis. When these infants present in the first week of life, they must be considered for an infusion of prostaglandin E$_1$, as outlined earlier. The infusion is begun at 0.1 μg/kg/min preferably by a central line, although any access in such ill infants is acceptable. The dosage may be reduced as perfusion and color return. Side effects of the infusion include hypotension and mandate close observation of blood pressure. Other effects are apnea, focal seizures, and fever that may mimic sepsis. Due to the critical nature of these infants, immediate referral and transfer to a tertiary care facility are necessary.

Hemodynamically Stable, Symptomatic Patients

Some infants arrive at the emergency department with respiratory distress and are found on examination to have findings suggestive of congenital heart disease, usually with evidence of congestive heart failure. These infants have near normal blood pressure and usually display normal skin perfusion, but may have cyanosis. Several congenital cardiac conditions may present in this fashion.

TRUNCUS ARTERIOSUS   This congenital anomaly is characterized by a single, large arterial trunk originating from the ventricular portion of the heart. This common vascular trunk supplies blood to both the systemic and the pulmonary circulation. A large VSD is usually present and may account for the murmur that is often heard. Because of the large amount of flow from both ventricles into the single large arterial conduit, flow to the pulmonary tree is greatly enhanced due to decreased flow resistance. This results in little or no cyanosis until pulmonary resistance increases and then cyanosis appears.

Clinically, these infants present with signs of increased pulmonary blood flow, dyspnea, and, occasionally, frank congestive heart failure. Chest x-ray demonstrates cardiomegaly and increased pulmonary vascularity or pulmonary edema. The ECG is initially normal until pulmonary vascular resistance increases and then signs of

strain, left ventricular hypertrophy, or biventricular hypertrophy are evident.

VENTRICULAR SEPTAL DEFECT   This is the most common cardiac defect, and symptoms displayed depend on the size of the defect. Small defects are often found on routine physical examination. More than 60 percent of these close spontaneously in older childhood.

Moderate-sized VSDs cause elevated right ventricular pressure and subsequent increased pulmonary artery pressure. Infants with this defect present with increased cough with mild upper respiratory tract infections and may have mild increase in pulmonary vascularity and early congestive heart failure. Typically, the chest radiograph is interpreted as mild congestive heart failure, and treatment consists of furosemide and, occasionally, digoxin.

Large VSDs present with congestive heart failure early in infancy, resulting in early and severe pulmonary artery pressure that, if uncorrected, will result in pulmonary hypertension. Such pulmonary hypertension will result in reversal of left-to-right shunt and frank cyanosis in a condition known as the Eisenmenger complex. Originally felt to be surgically irreversible, some centers now are routinely repairing such defects in adolescents who had inadequate management in infancy. [10]

COARCTATION OF THE AORTA   This represents localized narrowing of the aortic lumen, most often distal to the origin of the left subclavian artery and in close proximity to the ductus arteriosus or its postnatal remnant, the ligamentum arteriosus.

In infancy, symptomatic infants present with congestive heart failure and feeding difficulty. Decreased pulse amplitude and duration are noted in the lower extremities, and hypertension is noted in the upper extremities. Cardiac examination reveals a systolic ejection murmur at the cardiac base, with interscapular radiation.

Older children present with decreased exercise tolerance and, occasionally, claudication to the lower extremities. In children older than 6 to 7 years of age, a characteristic rib notching of the inferior border of posterior ribs is evident. Such notching is bilateral and usually caused by hypertrophied collateral vessels. [11]

Hemodynamically Stable, Asymptomatic Patients

This class of patients presents to the emergency department for reasons that are not referable to the heart and are discovered to have findings suggestive of cardiac disease. Some of the more common cardiac defects have already been mentioned including mildly affected tetralogy of Fallot, small to moderate-sized VSDs, and coarctation of the aorta. Several common structural defects warrant mention here.

ATRIAL SEPTAL DEFECT   Most children remain symptomatic throughout childhood until adolescence, when signs of increased pulmonary hypertension develop. Characteristically, the physical examination of such children reveals a split second heart sound that does not vary with inspiration. Often a soft systolic murmur heard at the upper left sternal border may mimic the pulmonary flow murmur mentioned earlier. Initially, the chest radiograph is normal but, with time, shows an increased size of the right atria and later the right ventricle. The ECG shows a characteristic prolongation of the PR interval and a incomplete or complete right bundle branch block pattern. Cardiomegaly represents a late finding that is usually seen in adults. [12]

CONGENITAL AORTIC STENOSIS   This is a less dramatic form of left-sided outlet obstruction than described previously. Children with this defect usually arrive at the emergency department with fatigue, decreasing exercise tolerance, exertional dyspnea, or syncope. The diagnosis is suspected based on the greatly diminished pulse amplitude and duration and the characteristic murmur, which is usually systolic in timing and loud with radiation to the neck. Treatment consists of decreasing activities, particularly sports, and referral for evaluation of surgical intervention. In all circumstances, these children should refrain from any significant physical activity, as sudden death can result. [13]

CONGESTIVE HEART FAILURE

Recognition

The most common cause of congestive heart failure (CHF) in children is congenital heart disease, which often masquerades as other problems, such as pneumonia or sepsis. The distinction between pneumonia and congestive heart failure in infants requires a high index of suspicion. Pneumonia can cause a previously stable cardiac condition to decompensate, so that both problems exist simultaneously. The predominant symptoms include poor feeding, excessive diaphoresis, irritability or lethargy with feeding, weak cry and, in severe cases, grunting and nasal flaring. Pulmonary congestion with rales, ronchi, and wheezing may mimic common lower respiratory viral infections. Gallop rhythms may be difficult to ascertain due to the presence of tachycardia. The common symptoms and signs of an infant with congestive heart failure are outlined in Table 115-2.

	Right Sided Failure	Left-Sided Failure	Both
Cardinal Signs	Hepatomegaly	Tachypnea Dyspnea and sweating on feeding Rales	Cardiomegaly Failure to thrive Tachycardia
Unusual Signs	Jugular venous distension Peripheral edema Anasarca		

TABLE 115-2   Recognition of Congestive Heart Failure in Infants

Both increased pulmonary blood flow in left-to-right shunts and pulmonary edema decrease lung compliance and thus cause tachypnea in an attempt to maintain minute ventilation. Tachypnea is a cardinal sign of left-sided failure in infants. Unlike tachypnea caused by respiratory viruses, this tachypnea is usually effortless in children with congestive heart failure, due to lack of airway obstruction. Since feeding is the infant's primary form of exertion, dyspnea and sweating during feeding can often be elicited in the history. Peripheral edema, jugular venous distention, and rales are unusual and late signs in infants.

Hepatomegaly appears long before ascites, anasarca, or peripheral edema in right-sided failure in infants, but is usually a late sign. Hepatomegaly exists when the liver is more than 2 cm below the right costal margin in the absence of downward displacement by hyperexpanded lungs. In hepatomegaly, the liver border is rounded rather than sharp.

In congestive heart failure, the details of any murmur detected on physical examination contribute to the diagnosis. The chest radiograph may reveal cardiomegaly, increased or decreased vascular markings, or pulmonary edema. Often, due to the presence of a thymic shadow, the cardiac size is not readily apparent on routine posterior-anterior radiographs of the chest, but can be assessed on the lateral view by obliteration of the retrocardiac window by the enlarged heart. On the posterior-anterior view, the thymic shadow can be distinguished from the cardiac silhouette by the "sail sign," if present, and by the scalloped border that is produced by compression of the thymus against the rib cage. The ECG is often nonspecific, but may reveal only evidence of abnormal electrical axis, rhythm disturbances or, more often, chamber hypertrophy.

Physiologic Correlates of Congestive Heart Failure

Typically, most cases of congestive heart failure in children are caused by afterload increases in the pressure dynamics of one or both chambers of the heart. In these conditions, pressure builds in one chamber of the heart due to an obstructive lesion in the outflow tract of the affected chamber. Several of the more common entities early in the first weeks of life are the left ventricular outflow obstruction syndromes, followed by congenital aortic stenosis and moderate-to-severe coarctation of the aorta. With these lesions, the systemic circulation has inadequate perfusion, and renal flow is diminished. The combination of increased fluid retention and chamber

dilatation results in cardiac failure. Treatment of afterload increases is aimed at vasodilatation with either specific load-altering medications, such as nitroprusside or nitroglycerin, or the use of furosemide, which has both a diuretic effect and a vasodilatory effect. Correction of the mechanical obstruction is viewed as the ideal solution.[14]

Less often, congestive heart failure can be related to increases in preload representing an overall volume overload without obstructive pressure consequences. Typical entities include large VSDs, and persistent patent ductus arteriosus in premature infants. Anemias of different etiologies should be considered, especially iron deficiency anemia in small cow-milk-fed infants. Sickle cell anemia and thalassemia variants should also be considered. In the former group of conditions, decreasing the vascular volume with diuretics is beneficial. In addition, the use of digoxin may be beneficial prior to surgical repair. In the latter cases, transfusion is warranted along with judicious use of fluid restriction and diuresis.

Poor contractility is not usually considered a major cause of congestive heart failure in small infants, because the ventricular walls are still relatively noncompliant. In older pediatric patients, though, poor contractility becomes an issue. Kawasaki syndrome, idiopathic endocardial fibroelastosis, pulmonary hypertension associated with Eisenmenger syndrome, and toxic-metabolic causes should be considered in adolescent patients with congestive heart failure. Less frequent inflammatory causes include myocarditis, constrictive pericarditis, and collagen vascular diseases. Treatment is geared toward increasing contractility with dobutamine or digoxin.[15]

Differential Diagnosis

CONGENITAL ANATOMIC HEART DEFECTS   Once congestive heart failure is recognized, age-related categories simplify further differential diagnosis as outlined according to time of development in Table 115-3. In the first few minutes of life, congestive heart failure occurs from a variety of noncardiac origins such as asphyxia, acidosis, hypoglycemia, hypocalcemia, anemia, or sepsis. In critically ill premature neonates, a patent ductus arteriosus is the most common cause of congestive heart failure. Among full-term newborns, a hypoplastic left ventricle is the most common cause in the first week of life and coarctation of the aorta is the most common cause in the second week of life. Transposition of the great arteries presents within the first 3 days of life, with either cyanosis or congestive heart failure.[16]

Age	Spectrum	
1 min	Noncardiac origin: anemia, acidosis, hypoxia, hypoglycemia, hypocalcemia, sepsis	Acquired
1 hour		
1 day	PDA in premature infants	
1 week	HPLV	
2 weeks	Coarctation	Congenital
1 month	Ventricular septal defect	
3 months	Supraventricular tachycardia	
1 year	Myocarditis	
	Cardiomyopathy	Acquired
	Severe anemia	
10 years	Rheumatic fever	

For meanings of acronyms, refer to Table 115-1.

TABLE 115-3   Differential Diagnosis of Congestive Heart Failure Based on Age of Presentation

VSDs alone do not cause congestive heart failure in the first weeks of life but, when complicated by transposition of the great arteries, truncus arteriosus, critical aortic stenosis, or coarctation can present with failure at any time during the first few weeks of life. Large, uncomplicated VSDs can present with congestive heart failure after weeks 3 to 4 of life as pulmonary artery pressure continues to fall, increasing the left-to-right shunt. Onset of failure is insidious between 1 and 3 months of age, when the left-to-right shunt increases as the pulmonary vascular resistance decreases further from the high fetal values.

Clinical assessment also involves estimation of the degree of severity of the congestive heart failure. For example, depending on the size of the defect, a VSD may present in a variety of ways, ranging from mild tachypnea to chronic compensated congestive heart failure accompanied by growth failure and frank pulmonary hypertension in later years. The finding on clinical examination of a small VSD is often out of proportion to the size of the VSD: a small VSD may have with a loud holosystolic murmur that is hemodynamically insignificant, and a large defect may produce no murmur initially.

In contrast to the gradual onset of heart failure with a VSD, coarctation of the aorta can present with abrupt onset of congestive heart failure precipitated by a delayed closure of the ductus arteriosus during week 2 of life. The severity of the symptoms is directly proportional to the degree of obstruction and can vary from mild tachypnea to cardiogenic shock. Milder degrees of coarctation, on the other hand, present later in life with isolated hypertension and diminished pulses in the lower extremities.

The onset of congestive heart failure after 3 months of age usually signifies acquired heart disease as opposed to congenital heart disease. The exception to this rule occurs when pneumonia, subacute bacterial endocarditis, or other complicating factors cause a previously stable congenital lesion to decompensate. Before 2 years of age, myocarditis, cardiomyopathies, and severe anemia are the most common diseases in the differential diagnosis. Rheumatic fever, once a common cause of congestive heart failure, is seen among children who are 8 to 12 years of age. It is unusual now, except in certain ethnic groups.

MYOCARDITIS AND CARDIOMYOPATHIES   Myocarditis affects children of all ages and is the leading cause of end-stage cardiomyopathy requiring transplantation. Viral etiologies include enteroviruses (coxsackie, echovirus, and poliovirus), as well as mumps, influenza virus, and *Varicella zoster*. An emerging cause is HIV-associated myocarditis and chronic Epstein-Barr myocarditis. Many bacterial species have been associated with myopericarditis, but not myocarditis alone. Noninfectious causes include lupus erythematosus, toxins such as tricyclic antidepressants, and cocaine. Myocarditis is often preceded by a viral respiratory illness and needs to be differentiated from pneumonia. As with the latter diagnosis, presenting signs and symptoms are often respiratory distress, fever, tachypnea, and tachycardia. Clues that suggest myocarditis include generalized malaise, fever, and myalgias in age-appropriate children.[17,18]

Cardiomyopathies are uncommon, but significant due to the high mortality and severe disability that they produce. They are usually classified into two groups: either dilated or hypertrophic. The dilated cardiomyopathies display impaired cardiac contractility and ventricular dilation. Most cases are idiopathic or viral in etiology. Most infants who arrive at the emergency department have respiratory symptoms, and a chest radiograph reveals an enlarged heart and vascular congestion. In a small percentage of these infants, acute cardiovascular collapse can result from severe congestive heart failure or dysrhythmia. Infants become acutely symptomatic when their disease is accentuated by intercurrent febrile illness. The hypertrophic cardiomyopathies display thickened myocardium and very plastic immobile contractile state. Often, minor febrile illness may result in sudden unexplained death that could not have been predicted by a previous examination.[19]

Chest radiographs show cloudy lung fields either from inflammation or pulmonary edema. ECG may reveal ST-T-segment changes that are generalized to all leads or rhythm disturbances. Evidence of ectopy signals severe diffuse disease and a high risk of sudden death. Cardiomegaly with poor distal pulses and prolonged capillary refill, however, distinguish it from common pneumonia. Once cardiomegaly is discovered, admission and echocardiogram are warranted. The latter will show a dilated, poorly contracting left ventricle with a low ejection fraction with or without a pericardial effusion. In dilated cardiomyopathies, both ventricles are usually affected and substantial dilatation is apparent at diagnosis.

At this point, the cause of myocarditis must be further delineated in a hospital, and endomyocardial biopsy may be warranted to do so. Parents must be thoroughly versed in cardiopulmonary resuscitation and be aware that a lethal dysrhythmia could cause sudden death. Infants are best kept comfortable in an upright position in an infant seat. Oxygen is administered in a nonthreatening fashion appropriate for age, and a neutral thermal environment is established. If congestive heart failure is apparent, a diuretic is administered. Severe congestive heart failure is initially treated with inotropic infusions (for example, dopamine hydrochloride or dobutamine) along with fluid restriction, diuresis, and supplemental oxygen. Intubation and mechanical ventilation often become necessary during the hospital phase of the illness. Treatment is directed to the underlying cause in addition to the supportive therapy outlined previously.

Such infants require management by pediatric cardiologists in an intensive care setting. Digoxin therapy is often initiated. Intravenous immune serum globulin is used by some experts. Definitive proof of treatment effect is lacking in such therapy in controlled trials. In severe cases, failure of improvement in left ventricular function in weeks 1 to 6 can lead to death unless cardiac transplantation is sought, and remains the only definitive treatment.

PERICARDITIS   Usually, this presents as cardiomegaly that is discovered incidentally on chest radiograph. Clinical signs such as chest pain, muffled heart sounds, and a friction rub may be present. In older patients and adolescents, classic pleuritic or positional chest pain, abdominal pain, and tachycardia may be seen. An echocardiogram is performed on an urgent basis to distinguish a pericardial effusion from dilated or hypertrophic myocarditis. The most common etiology is in association with coxsackie viral myocarditis. Bacterial pericarditis from *Haemophilus influenzae* is rare today and was uncommon even before the availability of *H. influenzae* type B conjugated vaccines. Typically, most cases of bacterial pericarditis present with profound toxicity and muffled heart sounds and jugular venous distention. If not appropriately drained in addition to antibiotic treatment, constrictive pericarditis will result in tamponade. Pericarditis that accompanies rheumatic fever, lupus erythematosus, or chronic renal failure is usually secondary and does not produce the main symptomatology. Since diagnostic pericardiocentesis can be complicated by hemorrhage, cardiac tamponade, and arrest, it is usually deferred to a pediatric cardiologist or intensivist for drainage. Pericardiocentesis with an 18-gauge over-the-needle catheter is indicated in the emergency department if an infant with large heart becomes rapidly unstable with loss of pulse. As in adults, the needle is placed in the subxiphoid region and aimed toward the left shoulder. As little as 30 to 50 mL pericardial fluid can cause tamponade, and removal with immediate improvement is diagnostic.[20]

Typically, uncomplicated pericarditis responds to a prolonged course of anti-inflammatory medication and decreased activity or bed rest. Most cases are self-limited and require specialty consultation only for the initial evaluation.

COR PULMONALE   If an infant presents in pure right-sided congestive heart failure, the primary problem is most likely to be pulmonary in origin. Hepatomegaly and anasarca may be present, but most often, in early stages, lid edema is the first noticeable sign. Moreover, the lid edema is likely to be appreciated by the parents more than by the physician and must be specifically searched for on examination. Often it will have to be elicited by asking "Do your child's eyes look puffy?" If the underlying problem is bronchopulmonary dysplasia resulting from prematurity and infantile respiratory distress syndrome, the infant may already be on appropriate home oxygenation and diuretic therapy. Upper airway obstruction from hypertrophied adenoidal and tonsillar tissue can produce cor pulmonale, presenting as edema or anasarca. The clinical features of airway obstruction, however, are subtle; a careful history will reveal continuous mouth breathing while awake and sleeping, with or without snoring. Sleep studies and tonsillectomy are indicated. Cor pulmonale from upper airway obstruction in infants usually responds to diuresis and oxygen alone, without the need for digoxin.

Initial Stabilization

The degree and severity of congestive heart failure dictate the types of therapeutic interventions necessary for the initial stabilization phase. Infants who present with mild tachypnea, hepatomegaly, and cardiomegaly simply need to be seated upright in a comfortable position and kept in a neutral thermal environment to minimize preload and to avoid metabolic stress. If the work of breathing is appreciably increased by an increased pulmonary blood flow, 1 to 2 mg/kg furosemide parenterally is indicated. If pulmonary edema is present, then the hypoxemia can usually be corrected by fluid restriction, diuresis, and an increase in ambient oxygen.

Severe degrees of congestive heart failure can present with signs of low cardiac output or cardiogenic shock. Aggressive management is often necessary in secondary derangement, including respiratory insufficiency, acute renal failure, lactic acidosis, disseminated intravascular coagulation, hypoglycemia, and hypocalcemia.

For definitive diagnosis and treatment of congenital lesions presenting in congestive heart failure, cardiac catheterization followed by surgical intervention is often necessary. Stabilization and improvement of left ventricular function can often first be accomplished with inotropic agents. Digoxin is used in milder forms of congestive heart failure. Initial digitalization is performed intravenously, giving one-half the daily dosage followed by one-fourth of the daily dosage intravenously at 6- to 8-h intervals. Maintenance dioxin consists of one-eighth the daily dosage given intravenously or orally at 12-h intervals. For full-term infants up to 2 years of age, the dosage is 0.03 to 0.05 mg/kg/day. Hence, 0.02 mg/kg would be the appropriate first digitalizing dose to be given in the emergency department.

At some point, congestive heart failure progresses to cardiogenic shock, in which distal pulses are absent and end-organ perfusion is threatened. In such situations, continuous infusions of inotropic agents such as dopamine or dobutamine are indicated instead of digoxin. The initial starting range is 5 to 10 µg/kg/min. The "rule of six" simplifies the necessary calculations. A total of 6 mg/kg of body weight of either dopamine or dobutamine is placed in a microdrip chamber and filled to 100 mL with 5% dextrose in water (D_5W) or normal saline; 1 mL/h equals 1 µg/kg/min, so it is administered via a pump initially at 5 mL/h (5 µg/kg/min). Prior to starting a continuous inotropic infusion such as this, the acid-base status should be checked by arterial blood gas analysis. Any abnormality should be corrected with 1 to 2 mEq/kg of sodium bicarbonate as needed and cautious volume expansion with 10 mL/kg of normal saline if necessary.

If inotropic support is inadequate, the use of combination therapy with vasodilatory therapy is warranted. The combination of dopamine and nitroprusside has been used extensively in situations of low cardiac output and low ejection fraction states. Another combination is nitroglycerin, which is readily available to even the smallest emergency departments.

When pharmacologic management is unsuccessful, other measures must be considered. Typically, most emergency physicians will be able to support ventilation with endotracheal intubation and positive end-expiratory pressure. Further care after tertiary referral includes balloon-assist counterpulsation devices or membrane oxygenation until definitive surgical care of the underlying cardiac defect can be undertaken.

DYSRHYTHMIA

This may rarely cause congestive heart failure. Most often, disorders of rate and rhythm are relatively benign except in postoperative cardiac patients. In general, children are able to tolerate higher rates without the usual ischemic phenomenon often present in adults. The treatment in children is usually directed at the underlying structural aspect of the intracardiac conduction system and less at prevention of cardiac ischemia related to rate.

Dysrhythmia appears to be increasing in incidence due to the increase in successful postoperative cardiac repair and survival. The fact that many of these children are now returned to the care of their primary care physicians makes it extremely likely that emergency physicians will encounter them and have the opportunity to deal with the dysrhythmias. Dysrhythmias can occur in the absence of any underlying structural heart disease or metabolic condition. Many conditions that occur in the adult population—such as hypoxia, electrolyte imbalance, collagen vascular diseases, and overzealous use of sympathomimetic agents—rarely occur in children. Because much of the prognosis with regard to the reoccurrence of a dysrhythmia depends on the nature of any underlying structural cardiac defect, noninvasive study is mandated in all first-time occurrences of dysrhythmia.[21]

Recognition of dysrhythmia is age dependent, and dysrhythmia often masquerades as other cardiac entities. In small infants, poor feeding and irritability may be the only signs of illness, with signs of poor cardiac output at higher rates evident later as edema and poor capillary refill. Older children may have more specific symptoms because of their increased ability to verbalize. In such instances, more classic adult symptoms of palpitations may be elicited, as well as syncope due to increased rate.

Typically, dysrhythmias are classified as in adults and are ideally viewed as rates that are either too slow or too fast for adequate cardiac output.

Slow Cardiac Rates

FIRST- AND SECOND-DEGREE ATRIOVENTRICULAR BLOCKS   First-degree atrioventricular (AV) block is seen frequently and has no real serious consequence unless it occurs in the presence of another cardiac anomaly such as an atrial septal defect. Second-degree AV block requires a more thorough evaluation. Typically, Mobitz type I second-degree AV block is of no consequence and can be a normal variant. Mobitz type II, however, is always of significance and always requires a minimum noninvasive evaluation and prolonged monitoring.[22]

COMPLETE ATRIOVENTRICULAR BLOCKS   Complete AV block can occur and can be either congenital or acquired. Congenital complete AV block is associated with congenital heart disease or may occur independently. In the former, the prognosis is extremely guarded until the underlying defect is corrected. Often the associated congenital defect is so severe (common AV canal) that it is uncorrectable. In the latter condition, AV block occurs during gestation and is usually secondary to maternal connective tissue disease with autoimmune destruction of the AV tracts in infants. The diagnosis is usually suspected prenatally, and treatment is instituted during gestation. Postnatal therapy includes transthoracic pacemaker and transvenous pacemaker use. Acquired AV block can occur without cause in older children, occur as a manifestation of inflammatory diseases of the myocardium, or occur postpartum in adolescent patients. In this category, syncope is usually

the initial presenting complaint, and prompt recognition and referral are mandatory. Treatment is with an implantable pacemaker to prevent sudden death. [23]

Fast Cardiac Rates

SINUS TACHYCARDIA   Although usually a benign event, the differentiation from the more significant supraventricular tachycardia (SVT) is difficult. Typically, ventricular rates in excess of 230 bpm are highly unusual and should be presumed to be the latter entity. The rate in SVT is usually fixed, with little variability with manipulation of the infant. Vagal maneuvers may be attempted to try to slow the cardiac rate. If slowing can be accomplished, P waves may be visible. The presence of P waves during slowing supports the diagnosis of sinus tachycardia. Other causes of sustained high-rate sinus tachycardia must be sought, including diarrheal dehydration, febrile illness, hyperthyroidism, sepsis, and drug effect from substance abuse or iatrogenic medication administration.

SUPRAVENTRICULAR TACHYCARDIA   This is the most common dysrhythmia in the pediatric age range. In infants, SVT presents with a 4- to 24-h history of poor feeding, tachypnea, pallor, and lethargy. In older children, palpitations and chest pain can be prominent in the symptomatology. Physical examination reveals weak pulses and a tachycardia that can be too rapid to be counted accurately. Depending on the time since onset of SVT, other physical signs can vary from congestive heart failure to cardiogenic shock with pending arrest. Low cardiac output is secondary to inadequate ventricular diastolic filling time.

Most children younger than 3 or 4 months of age will have no cause for the tachycardia that can be easily identified. Children over this age often have underlying structural defects or precipitators, such as fever or exposure to sympathomimetic cold remedies. Older children and adolescents are more likely to have accessory pathways. Recurrence rates for accessory pathway disease are as high as 90 percent, and recognition allows for more directed therapy at the AV node.

An ECG rhythm strip shows an unvarying ventricular rate between 220 and 360 bpm, as opposed to a range of 150 to 200 bpm in adults with SVT. The QRS complexes are narrow and regular. P waves are absent or abnormal. Any wide complex rhythm that is seen is considered ventricular in origin, because SVT with aberration is usually extremely rare in children.

SVT must be distinguished from sinus tachycardia, which is the most common tachyarrhythmia in children. In sinus tachycardia, P waves are present. The normal range for heart rate in newborns is 120 to 200 bpm. Under age 5, it is not unusual to find a sinus tachycardia up to a rate of 200 bpm, due to fever, stress, or hypovolemia. The latter requires prompt recognition and adequate volume expansion. [24]

Initial management of *unstable* patients with narrow complex tachycardia consists of immediate synchronized cardioversion at 0.5 J/kg with increases in power output to 2 J/kg as needed. Cardioversion should be undertaken at the lowest possible output in children on digoxin. There is a greater risk of subsequent ventricular fibrillation in such patients, so prophylactic lidocaine hydrochloride should be administered in a dose of 1 mg/kg before cardioversion. If cardioversion is unsuccessful, overdrive pacing is indicated. Once cardioversion is completed, suppressive therapy with digoxin is required.

Intravenous adenosine (0.1 mg/kg followed by 0.3 mg/kg boluses every 1 to 2 min until tachycardia resolves) is now the standard treatment in most pediatric cardiology centers. Because the half-life of adenosine is a matter of seconds, it is administered as a rapid bolus via a peripheral intravenous line. Two syringes can be timed in delivery of the medication: the first syringe contains the adenosine, and the second contains 5 to 10 mL of saline flush. Both syringes can be sequentially emptied in less than 5 s. A brief (3 to 10 s) period of asystole is sometimes seen before return of a normal sinus rhythm. If necessary, the dosage can be doubled, tripled, or quadrupled to convert the rhythm (maximum dosage, 12 mg). [25]

Vagal maneuvers to convert SVT can be attempted, but are usually not successful until after the first dose of digoxin. The diving reflex, which is elicited by submersing the face in ice water, usually produces the greatest vagal tone. An alternative to submersion is to place the ice water in a plastic bag that can be lowered briefly on the infant's face.

Digoxin has been the time-honored standard of medical management of SVT in infants. Since it takes 4 to 6 h before the rhythm converts, however, it is used more for chronic management than for acute conversion. The dosage is the same as that previously listed for congestive heart failure.

Management of a stable SVT in any child over 1 year of age presents a management dilemma, particularly if therapy with adenosine has failed. Verapamil may be used in a dose of 0.1 mg/kg bolus in older children, with preparation for any associated hypotension with calcium chloride at 10 mg/kg ready at the bedside. If verapamil fails, then pharmacologic cardioversion with either propranolol or procainamide should be attempted. Propranolol administration prolongs conduction at the AV node in both antegrade and retrograde fashion and thus is extremely useful in Wolff-Parkinson-White syndrome. It is administered at a dosage of 0.1 mg/kg/dose every 6 h. Procainamide blocks only retrograde conduction and may be beneficial if the rhythm appears to be ventricular in origin. It is administered as a 5- to 15-mg/kg bolus over 20 to 30 min. [26]

ATRIAL FLUTTER   This is associated with congenital heart disease approximately 90 percent of the time. The atrial rates generated typically range from 200 to 300 bpm in practice but rates as high as 500 bpm have been reported. With such high rates, the flutter waves are often difficult to visualize unless vagal maneuvers result in slowing long enough to capture the flutter waves. Conduction to the ventricles is variable and can be as high as 1:1 to a more usual 3:1 or 4:1 block.

In the stable patients, control of rate is a first priority and can usually be accomplished by the use of digitalization to slow the ventricular response. The ultimate goal of therapy is to eliminate the flutter waves and to decrease the conducted response of the atria. Evidence suggests that patients with congenital heart disease have a four to five times higher rate of sudden death if flutter persists. In 50 percent of patients, digoxin alone is effective, but other patients require combination therapy with digoxin, usually with procainamide. Combination therapy is usually never appropriate for emergency physicians to undertake, because slowed junctional bradycardia or asystole may occur. [27]

ATRIAL FIBRILLATION   This is another supraventricular rhythm that is seen in children. Unlike adult atrial fibrillation, which is usually secondary to ischemic heart disease or pulmonary disease with chamber dilatation, childhood disease is secondary to rheumatic heart disease or dilated cardiomyopathy. Atrial fibrillation in children usually manifests as an irregular rhythm with variable conduction. Rate control is rarely problematic unless rates are in excess of 200 bpm. In unstable patients, immediate cardioversion is usually successful at energy levels of 0.5 J/kg. Overdrive pacing is useful for those that do not convert.

Unlike adult cardioversion, anticoagulation is never necessary prior to the termination of atrial fibrillation. Medical therapy with digoxin is rarely effective, and not enough experience is available with newer agents such as diltiazem or ibutalide. Even in stable patients, cardioversion is usually required. Rarely, electrophysiologic studies are warranted and ablation of the focus is required. [28]

VENTRICULAR TACHYCARDIA   This is usually seen in the presence of underlying congenital heart disease. Intentional or inadvertent drug overdose should also be suspected. Occasionally, ventricular tachycardia may be idiopathic and discovered on routine examination in asymptomatic children. In the latter case, complete investigation should include a search for myocarditis, cardiomyopathy, or the prolonged QT syndrome.

Despite the poor prognosis that this rhythm holds in adults, stable asymptomatic children are usually left untreated if the heart is normal. Symptomatic children who present with syncope or chest pain require further study, but treatment should not be instituted by emergency physicians until after these studies are performed.

If patients are unstable in any way, synchronized cardioversion should be performed at an energy of 1 to 2 J/kg. If stability for transfer is uncertain, medical management with lidocaine hydrochloride is warranted. The dosage is usually 1-mg/kg loading followed by a 0.5 mg/kg reload in 20 to 30 min and then a maintenance infusion of 0.01 to 0.04 mg/kg/min infusion. Procainamide can also be used, but must be given over 30 to 60 min at a dose of 15 mg/kg intravenously. Other considerations include phenytoin or propranolol administration. [29]

VENTRICULAR FIBRILLATION   As in adult patients, this rhythm is incompatible with life and mandates immediate defibrillation. The initial energy for defibrillation is 2 J/kg and can be doubled, if necessary. Other causes include hypoxia, acidosis, and underlying cardiomyopathy, and their correction may increase the success of defibrillation. A trial of bretylium given as a 5-mg/kg infusion followed by defibrillation may be warranted followed by doubling of the dosage. Failure to respond after two infusions of bretylium followed by three defibrillation attempts usually indicates that the heart is unresuscitatable. Electrophysiology studies are indicated for any children who survive such a rhythm. [30]

CONGENITAL LESIONS THAT PRODUCE SYNCOPE

A child's sudden loss of consciousness is usually due to a previously unrecognized seizure and seldom due to dysrhythmia. When syncope does occur, children are often brought to the emergency department for initial evaluation. An accurate history from a reliable witness is essential to establish cardiac causes as the exact etiology. Typically, the history describes a child who has an initial change in skin color with or without cyanosis, a controlled fall, and then loss of consciousness.

The differential diagnosis includes tetralogy of Fallot, critical aortic stenosis, sick sinus syndrome, hypertrophic cardiomyopathy, and prolonged QT syndrome. Each are discussed in detail next.

Tetralogy of Fallot

This common cyanotic lesion may escape detection in the nursery, so it is important for emergency medicine physicians to recognize this lesion, as well as to recognize and treat hypercyanotic spells as discussed earlier. The degree of cyanosis is directly proportional to the severity of the pulmonary stenosis. In fact, cyanosis may be subtle or absent at rest and clinically obvious only when infants are active or crying.

Dynamic obstruction below the pulmonary valve can lead to an acute increase in the right-to-left shunt, producing a hypercyanotic spell or syncope with cyanosis. Prolonged or recurrent syncope due to tetralogy of Fallot can be a life-threatening emergency, so referral after initial stabilization is indicated for further diagnostic evaluation and possible urgent surgical intervention.

Critical Aortic Stenosis

This noncyanotic lesion can be life threatening and may present at any age. Older children may have a history of exercise intolerance with easy fatigability and chest pain. Prominent physical findings are a systolic ejection click and a diamond-shaped murmur that radiates to the neck and is associated with a suprasternal thrill. Left ventricular hypertrophy with strain can be present on ECG, and the chest x-ray may show poststenotic dilatation of the aorta, although neither of these signs is present consistently.

Syncope without cyanosis caused by critical aortic stenosis can portend a sudden life-threatening dysrhythmia. Patients should be kept strictly at rest and should be sedated, if necessary. Immediate referral for further diagnosis and possible urgent surgical repair is indicated.

Sick Sinus Syndrome

This is a pleomorphic group of dysrhythmias that result from enlargement of the right atrium, which typically is poorly distended due to the low-pressure state of the chamber. Enlargement can occur due to diseases of the lung, in particular, bronchopulmonary dysplasia and cystic fibrosis that result in the adult equivalent of cor pulmonale. Anatomic enlargement can occur in Epstein anomaly, an abnormal atrialization of the right ventricle. Such conditions result in wandering atrial pacemakers and sinus arrest. Occasionally, bursts of atrial flutter result in low-output states that may result in syncope.

Hypertrophic Cardiomyopathy

This can occur in children of any age, but is most often seen in adolescents. Nearly one-half have abnormal ECG findings, usually of a supraventricular origin (atrial flutter or fibrillation are most common). The disease is caused by a primary hypertrophied, undilated left ventricle without structural lesion and is usually inherited, so a family history will be helpful. Typically, most children present with chest pain, exertional dyspnea, and syncope. Occasionally, sudden death is the only clinical finding.

The cause of most cases of sudden death is unknown and may be the consequence of hemodynamic, structural, and electrophysiologic consequences. Although supraventricular rhythms are more common, electrophysiologic studies indicate that ventricular dysrhythmias are the cause of sudden death.

Once recognized, therapy should be instituted with b blockade to ameliorate symptoms. The goal of therapy is to improve left ventricular filling during diastole. b Blockade results in heart rate reduction to allow for more time for diastolic filling. Blockade also decreases myocardial muscle tension and improves compliance and eases filling. Other agents may be useful, but are usually instituted after conduction studies are performed. Surgery may be useful to eliminate some of the symptoms. Neither surgery nor medical management will prevent sudden death. There is not enough evidence to suggest that implantable defibrillation devices will prevent the sudden death of these children. [31]

Prolonged QT Syndrome

This is searched for more than any other etiology as a cause of syncope in young healthy children. In nearly all cases, the syndrome is inherited and is associated with deafness in about 75 percent of cases. Secondary, noncongenital cases result from anorexia, bulimia, or chronic ingestion of antidysrhythmic medications. Undiagnosed, untreated, or undertreated congenital prolonged QT syndrome results in a mortality rate in excess of 90 percent.

The syndrome is characterized by episodes of paroxysmal ventricular tachycardia often with torsades de pointes morphology. The usual precipitators, which include emotional lability or stress, can progress to ventricular fibrillation and sudden death without warning. The syndrome is thought to arise from an imbalance of sympathetic innervation to the heart with left-side predominance. Other considerations include electrolyte channel defects.

Therapy is directed toward prevention, and patients should be treated with b blockade to prevent the asymmetric sympathetic activity. Treatment is continued for life, and compliance must be stressed to adolescents, because lack of compliance can result in sudden death. Other medical management includes phenytoin administration. Implantable pacemakers or internal defibrillators may prove beneficial.

Treatment of the life-threatening ventricular tachycardia includes synchronized cardioversion and magnesium sulfate intravenously for refractory torsades de pointes. Referral for emergency cardiology consultation is mandatory for previously unrecognized cases. [32]

ANTICIPATING PROBLEMS IN CHILDREN WITH CONGENITAL HEART DISEASE

Children with congenital heart disease are brought to the emergency department for routine accident care, as well as for childhood illnesses. Some childhood illnesses may predispose patients to acute cardiovascular complications. A significant number of these children are treated with digoxin, diuretics, and anticoagulants that can make care of acute problems difficult. Special problems must be anticipated and complications of therapy for other conditions avoided.

Hypoxemic Spells

Most emergency department procedures involve fear and apprehension, as well as pain in the preparation of wounds and fracture splint placement or reduction. Infants with uncorrected tetralogy of Fallot can have hypoxemic episodes when total oxygen demand during painful procedures exceeds that which the restricted pulmonary blood flow can support. Strain also increases the right-to-left shunt through a VSD, as well as the reduced pulmonary blood flow. As described previously, loss of consciousness can result. Pediatric consultation should be obtained, if at all possible, before attempting conscious sedation.

Surgical Shunt Dysfunction

Due to palliative shunt procedures performed in the neonatal period prior to definitive operative repair of complex congenital heart disease, shunts can malfunction. Typically, infants in such a situation are in acute distress with increasing cyanosis. Although not as dramatic as with ductus-dependent lesions, symptoms develop when the shunt flow narrows to less than 50 percent of usual. Ordinarily, a continuous murmur is heard over the side of the shunt. Diminution or disappearance of the murmur suggests occlusion of the shunt. Typically, emergency physicians can do nothing for these infants. Palliative therapy with 100 percent oxygen is utilized, and

transfer to a tertiary center is expedited. The use of thrombolytic therapy has been tried, but should be used by only pediatric cardiologists by direct shunt instillation or systemically. In all cases, possible replacement of the shunt or definitive surgical repair might be the only option.

Pulmonary Hypertensive Crisis

Many children with congenital heart disease have increased pulmonary artery pressure, particularly those with large VSDs. With painful procedures, these patients can experience pulmonary vasospasm. In such conditions, cyanosis and lethargy can develop and can mimic the hypercyanotic episodes of tetralogy of Fallot. Treatment is directed toward alkalinization with intravenous sodium bicarbonate and 100 percent oxygen to facilitate pulmonary vasodilation. Anxiolysis and analgesia are useful.

Diuretic Complications

Diuretics may be inadequate for the weight of the child because of normal growth and present as congestive heart failure. Conversely, during times of excess extraneous losses such as diarrhea or vomiting, dehydration can occur with subsequent hemoconcentration that could compromise cardiac function or shunt integrity. Careful monitoring of potassium levels is imperative during such losses.

Digoxin Toxicity

Because of the narrow therapeutic window between treatment and toxicity, digoxin toxicity can easily develop. In infants, toxicity is manifested most often by bradycardia and occasionally by other dysrhythmias. The usual adult patterns of atrial and ventricular tachycardia are not seen, except in adolescents. It is always good practice to monitor digoxin concentrations expectantly during any visit where blood will be drawn.

Usually, increased serum concentrations can be managed by withholding dosages of digoxin. Rarely, pharmacologic intervention is required for bradycardias. Ventricular dysrhythmias are managed medically with lidocaine or phenytoin. For severely intoxicated children, the use of digoxin immune globulin is indicated and will reverse toxicity rapidly. Usually, the dosage can be calculated readily based on the amount of digoxin elevation in nanograms above normal (see Chap. 168, "Digitalis Glycosides"). A 1-ng increase in digoxin is assumed to reflect a burden of 1 mg digoxin. Each vial of digoxin-specific antibody binds 0.4 mg digoxin. Therefore, a digoxin level that is 5 ng above expected would require 12.5 vials of digoxin-specific antibody. Care should be taken to avoid volume overload.

Anticoagulation Problems

Some children with congenital heart disease are on anticoagulant therapy to prevent shunt occlusion or thrombosis of surgically implanted valves or grafts. The risk of serious bleeding is small with routine emergency department visits, but must be considered for any elective repair of fractures or lacerations. Prothrombin time and the international normalized ratio (INR) must be monitored. Reversal of anticoagulation with the administration of either vitamin K or fresh-frozen plasma should be undertaken only after consultation with a pediatric cardiologist.

Anemia and Polycythemia with Cyanotic Congenital Heart Disease

Children with this problem require an increase in hemoglobin concentration to compensate for hypoxemia. Children develop tachycardia, feeding difficulty, or congestive heart failure when hemoglobin concentrations fall to normal. Often, anemia will be compensated for by polycythemia, which will cause increased viscosity and the potential for cerebrovascular complications. Iron supplementation is important for prevention of anemia. When polycythemia occurs, therapeutic phlebotomy may be warranted.

Viral Infections with Congenital Heart Disease

Although few normal children have problems with common viral pathogens such as influenza virus, parainfluenza virus, or respiratory syncytial virus, children with congenital heart disease are at unique risk for major sequelae. Distinguishing minor early infections with these agents and differentiating them from the symptoms of congestive heart failure is a challenge, even for seasoned clinicians. Children with lesions that increase pulmonary blood flow are far more at risk because of pooling of alveolar secretions. The pooled secretions allow for stasis and secondary bacterial overgrowth. Dramatic increases in mortality and morbidity are evident among affected infants. No effective therapy is available for parainfluenza and influenza virus, and prophylaxis against influenza B with amantadine analogues is not approved for small children. Hospitalization and specific treatment of infants affected by respiratory syncytial virus has been difficult to justify due to conflicting studies regarding efficacy of the antivirals and ribavirin and the expense of respiratory syncytial virus-specific immune globulin. Most infants will benefit from admission for bronchodilator therapy, but the prophylactic use of antibiotics to prevent secondary bacterial pneumonia is not justified. Admission may help sort out the distinction between congestive heart failure and underlying pulmonary infection. [33]

Subacute Bacterial Endocarditis

Children with congenital heart disease are at great risk of developing endocarditis. Transient bacteremia produced by iatrogenic procedures such as dental work or gastrointestinal or urologic manipulation can lead to localized colonization and infection. Although the thrust of most primary care providers is toward prevention of this disease, cases still occur. Typically, the usual presentation is of unexplained fever in children with known congenital heart disease. Appropriate evaluation includes multiple blood cultures, urine culture and analysis, and complete blood count. Parenteral or oral antibiotics should be administered in consultation with a pediatric cardiologist familiar with the child's history. In cases of known source of infection, such as otitis media or pneumonia, multiple blood cultures should be obtained, and appropriate therapy should be directed at the site of primary infection.

Acutely ill children with high fever mandate hospitalization, multiple blood cultures, and echocardiographic study of the heart. Usually, treatment is instituted following the obtainment of cultures and is directed toward the most common pathogens. Established diagnosis is followed by 4 to 6 weeks of intravenous antibiotic therapy. [34]

ENDOCARDITIS PROPHYLAXIS PRIOR TO PROCEDURES

Prophylactic treatment is recommended for patients with congenital heart malformations and rheumatic fever with valvular disease who are undergoing surgical or dental procedures and instrumentation involving mucosal surfaces. The administration of the medication should be timed such that an effective serum level will be present during the 15 min after the mucosal manipulation, when the transient bacteremia occurs. Amoxicillin 50 mg/kg (maximum, 2 g) is given 1 h before the procedure and 25 mg/kg (maximum, 1.5 g) 6 h later. For patients with valvular disease, 2 mg/kg gentamicin is given intravenously or intramuscularly 30 min before the procedure and 8 h later, in addition to the amoxicillin. Erythromycin 20 mg/kg orally (maximum, 800 mg erythromycin ethylsuccinate or 1 g stearate) can be given 2 h before the procedure, with half the dose given 6 h later.

The indications for prophylaxis and treatment options are well outlined in the American Heart Association guidelines for prophylaxis of endocarditis. Cases of endocarditis can occur despite appropriate prophylaxis. Vigilance in performing appropriate blood cultures is warranted in any children with symptoms suggestive of endocarditis. [35]

EVALUATION OF FEVER IN INFANTS WITH HEART DISEASE

Infants and children with known heart disease are prone to the same illnesses as other children. When they are brought to the emergency department for treatment of febrile illnesses, they are most likely to be hemodynamically stable and capable of handling the illness. Any signs of congestive heart failure are indications for an admission. Otherwise, blood cultures should be obtained, as well as a complete blood count, as would be performed for any infant between the ages of 6 months and 24 months. Although occult bacteremia has the same probability for occurrence in a child with congenital heart disease, concern for bacterial endocarditis must be greater. Oral or parenteral antibiotics should be administered with great care if presumptively treating early bacteremia or subacute bacterial endocarditis. It is more prudent to arrange admission, repeated cultures, and expectant therapy for such infants than to begin antibiotic therapy blindly simply because of the presence of congenital heart disease. A follow-up visit is mandatory in 12 to 24 h for any children who are discharged home without hospital admission.

116 OTITIS AND PHARYNGITIS IN CHILDREN

Kimberly S. Quayle
Susan Fuchs
David M. Jaffe

OTITIS MEDIA AND EXTERNA

Otitis Media

Otitis media, or inflammation of the middle ear, is one of the most common pediatric diagnoses. Each year there are 24.5 million office visits and over 3.7 million emergency department visits, with direct and indirect costs of $5.7 billion a year. [1,2 and 3] Acute otitis media (AOM) (acute suppurative, purulent, or bacterial) is associated with signs and symptoms of inflammation of the middle ear, such as otalgia, otorrhea, fever, irritability, anorexia, or vomiting. [4] Otitis media with effusion (OME) (secretory, nonsuppurative, serous, or mucoid) is a relatively asymptomatic collection of fluid in the middle ear. The duration (not the severity) of OME can be divided into acute (<3 weeks), subacute (3 weeks to 3 months), and chronic (>3 months). [5] The most important distinction between OME and AOM is that the signs and symptoms of acute infection (otalgia, otorrhea, and fever) are lacking in OME, but hearing loss may be present in both conditions. [5]

ACUTE OTITIS MEDIA   Infants and young children are at greatest risk for the development of otitis media, with the peak incidence occurring between 6 and 18 months. [1] By 3 years, more than two-thirds of children have had at least one episode of AOM, and one-third have had three or more episodes. [6] The incidence is higher in males, Native Americans, Alaskan and Canadian Eskimos, and children who attend day care, are exposed to tobacco smoke, have a cleft palate or other craniofacial anomaly (e.g., Down syndrome), sleep in a prone position, use a pacifier, have older siblings or parents with a history of ear infections, had their first episode of AOM at less than 6 months of age, or have congenital or acquired immunodeficiency. [1] The incidence is lower in breast-fed infants. [1]

Middle ear effusion may persist for weeks to months after an episode of AOM. Antibiotic therapy generally sterilizes the effusion but does not clear it from the middle ear space. After the first episode of AOM, 70 percent of children still have a middle ear effusion at 2 weeks, 40 percent at 1 month, 20 percent at 2 months, and 10 percent at 3 months. [4]

Etiology   Bacteria are the most common cause of AOM and can be isolated in a pure culture from the middle ear exudate in 60 to 75 percent of cases. These organisms colonize the nasopharynx and enter the middle ear via the eustachian tube. *Streptococcus pneumoniae* and *Haemophilus influenzae* are the most common pathogens [*Strep. pneumoniae* 30 to 50 percent (most common serotypes, 19, 23, 6, 14, 3, and 18), *H. influenzae*—primarily nontypable strains—15 to 30 percent], and *Moraxella* (formerly *Branhamella*) *catarrhalis* the third most common organism (7 to 20 percent). [6] Of importance is a major change in the increased prevalence of b-lactamase-producing *M. catarrhalis* (70 to 90 percent) and *H. influenzae* (30 to 40 percent), which affects antibiotic therapy decisions. [7] *Strep. pyogenes* (group A) and *Staphylococcus aureus* are each found in 2 percent of cultures. [4] *Chlamydia pneumoniae* may also be a causative organism, especially in those less than 6 months of age. [8] However, in infants 6 weeks or less, gram-negative enteric bacilli and *S. aureus* account for 10 to 20 percent of isolates. Although viruses are rarely recovered from middle ear effusions, recent studies have shown an increased risk of OME following an upper respiratory tract infection due to rhinovirus, respiratory syncytial virus, adenovirus, and influenzavirus A or B. [4,6]

Pathophysiology   Abnormal function of the eustachian tube appears to be the dominant factor in the pathogenesis of middle ear disease. Two types of tube dysfunction may result in otitis media: obstruction and abnormal patency. Obstruction can result from persistent collapse of the eustachian tube due to increased tubal compliance, an inadequate active opening mechanism, or both. Infants and younger children are susceptible to eustachian tube obstruction because the cartilage that supports the eustachian tube is less stiff than in adults. In addition, an upper respiratory tract infection or allergies can obstruct the eustachian tube and decrease its function. The obstructed eustachian tube prevents equilibration of air pressure between the middle ear and the atmosphere and creates conditions favorable to the development of purulent or sterile effusions. The other type of dysfunction is abnormal patency, which may allow reflux of nasopharyngeal secretions. [5]

Clinical Features   Classic signs and symptoms of AOM include ear pain (otalgia), otorrhea, and fever; however, ear pulling and irritability may be the only clues in an infant. The most important diagnostic tool is the pneumatic otoscopic examination. Before adequate visualization of the external canal and tympanic membrane (TM) can be achieved, cerumen must be removed from the canal by blunt curettage or by irrigation with warm water. [9] The presence or absence of discharge and the position, color, and degree of translucency and mobility of the TM must be assessed. The light reflex is of no diagnostic value. The normal eardrum is translucent and pearly gray but may become reddened with crying. The eardrum should be freely mobile in response to positive and negative pressure by the pneumatoscope; however, retracted TMs have reduced mobility. The TM of AOM is usually opaque, hyperemic, and sometimes bulging, and bony landmarks (long and short process of the malleus) are not easily discernible. However, the most significant sign is the loss of or decrease in mobility of the TM. [5,9]

Tympanometry is a noninvasive diagnostic technique used to determine the compliance of the TM and the middle ear. A fixed tone at a given intensity is delivered through a probe snugly placed in the external ear canal as the air pressure in the canal is varied from positive to negative. The tympanogram is a recording of the acoustic compliance of the middle ear, and patterns obtained are useful in distinguishing a normal ear from one with an effusion. [5,9] Acoustic reflectometry is a technique that in the uncooperative infant or child is easier to perform than tympanometry (since the instrument does not need to seal the auditory canal). When fluid is present in the middle ear, sound reflection is increased. [6]

Aspiration of the middle ear is the most definitive method of verifying the presence and type of middle ear effusion and infecting organism; however, its use for this purpose in the emergency department setting is rarely practical. It may be beneficial in (1) children with overwhelming sepsis, (2) immunologically deficient children, (3) neonates, (4) children with persistent symptoms of AOM after more than 48 to 72 h on antimicrobial therapy, or (5) otitis media with confirmed or potential suppurative complications. [5] Diagnostic tympanocentesis may be performed by inserting an 18-gauge spinal needle or catheter over a needle attached to a syringe through the inferior portion of the TM. The aspirate should be cultured in blood culture broth and on blood and chocolate agar plates. When therapeutic drainage is required, a myringotomy should be performed. The incision should be made in the lower half of the TM and should be large enough to allow adequate drainage and aeration of the middle ear. Myringotomy may relieve unusually severe otalgia, either at initial examination or at any time during the course of the disease. In addition, it should be performed when a suppurative complication (e.g., meningitis, facial paralysis, or mastoiditis) is present. [5,6]

Treatment   Selection of the appropriate antibiotic is based on several factors: (1) knowledge of the likely etiologic agent or recovery of a specific pathogen from middle ear fluid, (2) the efficacy of certain antibiotics against the organism responsible for AOM, (3) antibiotic penetration into middle ear fluid, (4) a history of drug allergy, (5) compliance issues, (6) drug side effects, and (7) treatment failure or success of previous drug regimens for that child. [1,4] Despite the approval of 14 antibiotics by the US Food and Drug Administration for the treatment of AOM (see Table 116-1 for doses and frequency) and the changing antibiotic susceptibility patterns that have emerged over the past few years, amoxicillin [40 to 50 (mg/kg)/day divided tid for 10 days] remains the drug of choice. The preference for this drug is based on calculations that show that amoxicillin would result in clinical treatment failure in 8 to 10 percent of cases of AOM (based on data on organism prevalence, spontaneous clearance rates, and antimicrobial resistance). [1]

TABLE 116-1 Treatment Options for Acute Otitis Media

However, if b-lactamase-producing *H. influenzae* or *M. catarrhalis* is suspected or documented, appropriate antibiotics include trimethoprim-sulfamethoxazole (TMP-SMZ; Bactrim or Septra), erythromycin and sulfasoxazole (Pediazole), cefaclor (Ceclor), amoxicillin-clavulanate (Augmentin), cefuroxime axetil (Ceftin), and cefixime (Suprax). Other oral agents include ceftibuten (Cedax), cefproxil (Cefzil), cefpodoxime (Vantin), loracarbef (Lorabid), azithromycin (Zithromax), and clarithromycin (Biaxin), since all are active against b-lactamase-producing organisms. [1,4,10]

In infants 6 weeks of age or less, several factors should be taken into account. If the infant is younger than 2 weeks (or is older but has remained in a newborn nursery for a prolonged period), group B streptococcus, *Staph. aureus* and gram-negative bacilli are the most likely pathogens. A child of this age warrants a full septic workup (complete blood count, blood culture, urinalysis, urine culture, lumbar puncture with cerebrospinal fluid analysis and culture, and possibly a chest radiograph) and admission for parenteral antibiotics (ampicillin plus gentamicin, cefotaxime, or ceftriaxone). For infants between 2 and 6 weeks of age who have been discharged for more than 2 weeks from a nursery, *Strep. pneumoniae* and *H. influenzae* are the most likely organisms. [5] While a full septic workup is warranted, decisions about admission and treatment options are based on the results of these tests, the appearance of the infant, availability of close follow-up, and prevailing policies.

If the child is allergic to penicillin, erythromycin and sulfoxazole in combination, TMP-SMZ, clarithromycin, or azithromycin are recommended. When deciding which antibiotic to use, there are several issues to consider:

1. The efficacy of cefaclor is lower than that of amoxicillin-clavulanate, cefuroxime axetil, or cefixime. [10]
2. The efficacy of cefixime and ceftibuten against *Strep. pneumoniae* is less than that of other cephalosporins, but former are preferred when a b-lactamase-producing organism is suspected. [10]
3. When *Strep. pneumoniae* is suspected, cefproxil, erythromycin, clarithromycin, and azithromycin have superior activity.
4. The recent approval of intramuscular ceftriaxone may be of benefit when a child cannot take oral antibiotics due to emesis, when absorption of an oral antibiotic is in doubt (e.g., with malabsorption or inflammatory bowel disease), or when compliance is questionable. [11,12 and 13]

There has been a great increase in the prevalence of *Strep. pneumoniae* resistant to penicillin (and amoxicillin) in Europe as well as the United States in the past few years. Recent data demonstrate resistance levels of 16 to 41 percent in US cities. [8,14,15] Some key pieces of information to consider are the degree of resistance in the community and data on relative-resistance versus high-resistance organisms (since highly resistant *Strep. pneumoniae* are also resistant to TMP-SMZ, erythromycin, most cephalosporins, and ciprofloxacin). [8,14,15] Initially in the United States, the distribution of the two types of organisms was equal, but it has begun to follow the pattern in Europe, where relative resistance is two- to threefold higher than high resistance. [8]

The risk of being colonized or infected with penicillin-resistant *Strep. pneumoniae* is higher in younger children, those who have had several episodes of AOM, and those who have received multiple courses of antibiotics. [8] Some of the recent resistance patterns include the following:

1. Second-generation cephalosporins have good in vitro activity against penicillin-resistant *Strep. pneumoniae* and group A streptococcus. [8]
2. Cefprozil, cefpodoxime, and cefuroxime axetil are the only oral agents with some activity against penicillin-resistant *Strep. pneumoniae,* but the first 2 days are not effective against highly resistant strains. [8]
3. Although there is apparent resistance in vitro against azithromycin and clarithromycin for highly resistant *Strep. pneumoniae,* middle ear fluid concentrations exceed the minimum inhibitory concentrations (MIC) needed to eradicate it. [8]
4. At least 3 days of intramuscular ceftriaxone are needed to successfully treat highly penicillin-resistant *Strep. pneumoniae.*[14]

In areas where drug resistant *Strep. pneumoniae* has become a concern, amoxicillin remains the drug of choice for the treatment of acute otitis media. However, since the standard dose (40 mg/kg/day) may not eradicate penicillin resistant organisms, a higher dose, (80 to 90 mg/kg/day) has been recommended for high-risk patients. These include those less than 2 years of age, those with recent (prior month) antibiotic exposure, and attendance in day care. (Of note, the Food and Drug Administration has not approved amoxicillin at these higher doses.) [16]

Although there is recent literature to support a short-course (5-day) therapy for selected children (those >2 years of age with a mild episode and an otitis-free history), the standard length of treatment remains 10 days, except for azithromycin, which is given for 5 days. [16,17]

In the numerous trials of antibiotics in the treatment of otitis media, adverse reactions requiring the discontinuation of the drug have occurred in fewer than 5 percent of patients. With ampicillin, amoxicillin, and amoxicillin-clavulanate, diarrhea is the most common side effect, followed by rash. TMP-SMZ can also cause diarrhea and skin rash (including Stevens-Johnson syndrome), but the major concern is the development of neutropenia and thrombocytopenia. In addition, a patient with glucose 6-phosphate dehydrogenase deficiency should not receive sulfonamides. Erythromycin often causes gastrointestinal symptoms, including abdominal cramps, nausea, vomiting, and diarrhea. Besides possible cross-sensitivity in patients with penicillin allergy, cefaclor can cause a serum sickness–like reaction consisting of a rash, arthralgia or arthritis, and fever. [1]

Additional therapy, including antipyretics and analgesics, may be helpful in alleviating some of the acute symptoms. A topical analgesic [antipyrine, benzocaine, and glycerin (Auralgan)] instilled into the external ear canal often provides some relief from otalgia, but it should not be used when a TM perforation is present. [18] Decongestants, antihistamines, or glucocorticoids have no demonstrable role in the treatment of AOM. [4] With appropriate antimicrobial therapy, most children with AOM are significantly improved within 48 to 72 h. Persistent or recurrent pain or fever after 48 to 72 h indicates a need for reexamination of the child and the possible selection of another antimicrobial agent. Reasons for response failure include a resistant organism, noncompliance, and host-related structural or immunologic abnormalities. [6,18]

Standard practice has been that children with an uncomplicated course should be reexamined within 10 to 14 days of the completion of antibiotic therapy. Recent studies have demonstrated that this visit may be delayed to 3 to 6 weeks in certain cases. [1,18] However, in view of the fact that an emergency physician is not usually providing long-term follow-up care for such patients, phone contact with the patients' physician to arrange for a follow-up visit is recommended.

Recurrent AOM   Many children have repeated episodes of AOM. Recurrent AOM is three or more episodes of AOM in 6 months or four episodes in 12 months, with at least one episode within the past 6 months. [4] Some children develop symptoms and a new ear effusion, often associated with an upper respiratory tract infection, after a previous effusion has resolved, while others develop symptoms of AOM with no documented resolution of a previous effusion. There is a correlation between such "otis-prone" children and the onset of AOM before 1 year of age. Other risk factors include day-care attendance and genetic susceptibility: a sibling or parent with a history of severe or recurrent AOM. Due to the risk of long-term sequelae, such as hearing loss and speech impairment, prevention of further episodes is desirable. [19] A more thorough physical examination and laboratory x-ray studies should be performed to rule out sinusitis, allergies, immune deficiencies (C3 and C5 deficiency), submucous cleft palate, or a tumor of the nasopharynx. If none of these is present, the preferred method of prevention for this particular group of patients is prophylaxis with antibiotics: amoxicillin [20 (mg/kg)/day at bedtime] or sulfasoxazole (75 mg/kg in one or two divided doses) for 3 to 6 months, with rechecks every 1

to 2 months. Prophylaxis is especially important during the fall and winter, when respiratory tract infections tend to occur; for children less than 2 years of age; and for those in day care. Although there is concern that the use of prophylaxis results in increased nasopharyngeal carriage of resistant pneumococci in this population, the benefits must be weighed against the risks and other options. [17] Active immunization is still being studied. Some investigators have had success with the use of the current 23-valent capsular polysaccharide pneumococcal vaccine in children greater than 2 years of age with recurrent AOM. Others have used an influenza A vaccine and shown a decreased incidence of AOM in children in day care. [1,18]

Myringotomy with tympanostomy tube insertion is the next step for children who fail antibiotic prophylaxis, although some physicians would have chosen myringotomy instead of antibiotic prophylaxis. Adenoidectomy is recommended at the time of myringotomy tube placement for children with severe nasal obstruction. [1]

Persistent AOM   Persistent AOM is defined as the persistence of AOM within 6 days of initiating therapy or the recurrence of signs and symptoms within a few days of completing a 10-day course of antibiotics. This condition may be caused by the same pathogen (relapse) or a new bacterial species (reinfection). [5] Ideally, tympanocentesis for culture and identification of the organism should be performed, although this is not always feasible. A search for a suppurative complication of otitis media (e.g., mastoiditis) or a concurrent infection (e.g., meningitis) should be done before changing antibiotic therapy. If these conditions are not present, another medication can be prescribed, taking into account the spectrum of the initial choice (specifically, coverage of b-lactamase-producing organisms), as well as the antibiotic resistance patterns in the community. If penicillin resistant *Strep. pneumoniae* is an issue, the best antibiotic choices are: high dose amoxicillin-clavulanate (80 to 90 mg/kg/day of the amoxicillin component; with 6.4 mg/kg/day of clavulanate), cefuroxime axetil (30 mg/kg/day) or intramuscular ceftriaxone. [16] The patient should be followed closely, with a recheck in 2 to 3 days and another after 10 to 14 days. [5,6]

Chronic Suppurative Otitis Media   The persistence (greater than 6 weeks) of a chronic purulent ear discharge in the presence of a nonintact TM is known as chronic suppurative otitis media. It is thought to be a sequela of partially treated or untreated AOM or recurrent AOM. *Pseudomonas aeruginosa,* gram-negative bacilli, and *S. aureus* are the most common causative organisms, although anaerobes have also been cultured. [5,19] It is thought that the organisms gain access to the middle ear through the perforated TM and become pathogens in the middle ear. A thorough examination is imperative, since chronic ear drainage can be a manifestation of a cholesteatoma (which requires surgery). In the absence of a cholesteatoma, recent studies suggest that the following steps result in a more rapid improvement in ear drainage and a decreased need for tympanomastoid surgery: (1) parenterally administered broad-spectrum, antipseudomonal antibiotics [ticarcillin, ticarcillin-clavulanate (Timentin), mezlocillin, or ceftazidime (Fortaz, Tazicef, or Tazidime)] either on an inpatient or an outpatient basis; and (2) daily cleansing and aspiration of the external and middle ear followed by instillation of ear drops [Cortisporin suspension (polymyxin B, neomycin, and hydrocortisone) or Coly-Mycin (colistin, neomycin, and hydrocortisone)]. [5,7,19]

Complications and Sequelae of Otitis Media   The complications and sequelae of otitis media predominantly involve the middle ear and adjacent structures within the temporal bone, but in rare instances intracranial complications may occur. The aural or intratemporal complications and sequelae include hearing loss, perforation or retraction pocket of the TM, tympanosclerosis, adhesive otitis media, ossicular discontinuity and fixation, chronic suppurative otitis media, cholesteatoma, mastoiditis, petrositis, labyrinthitis, and facial paralysis. Suppuration in the middle ear, mastoid, or both may extend into the intracranial cavity, producing the following intracranial complications: meningitis, extradural abscess, subdural empyema, focal encephalitis, brain abscess, and lateral (sigmoid) sinus thrombosis. These complications are uncommon except in neglected cases. [5,19]

OTITIS MEDIA WITH EFFUSION   OME is a collection of fluid in the middle ear, without acute clinical signs and symptoms, that often follows an episode of AOM. [3] Hearing loss is by far the most prevalent complication and morbid outcome of OME. The extent of hearing loss is dependent on the volume of the effusion rather than the physical properties of the effusion and OME is associated with a mild-to-moderate conductive hearing loss of 20 dB or more. [18] Audiometry is of limited value as a diagnostic method for the identification of OME, but it can be helpful in the evaluation of the effect of middle ear disease on hearing. [20] The relationship between persistent or episodic conductive hearing loss and impairment in the cognitive linguistic and speech development of children has been reported. However, the degree and duration of the hearing loss required to produce such deficits have not been defined. [3,18]

Other factors that should be considered in addition to hearing loss when deciding whether to treat OME include (1) occurrence in young infants, since they are unable to communicate their symptoms and may have suppurative disease, (2) an associated acute purulent upper respiratory infection, (3) permanent conductive or sensorineural hearing loss, (4) vertigo, (5) alterations in the tympanic membrane (severe atelectasis and/or a deep retraction pocket in the posterosuperior quadrant or the pars flaccida), (6) middle ear changes, such as adhesive otitis or ossicular involvement, (7) persistence of the effusion for more than 3 months (chronic OME), (8) occurrence of the episodes so close together that the child has OME for 6 out of 12 months, (9) the presence of craniofacial abnormalities, and (10) impaired or deficient immunologic status. [1,20] A thorough search for an underlying cause (e.g., sinusitis, allergy, submucous cleft, or tumor) should be attempted before treatment is begun.

There are several management options for children between 1 and 3 years of age with OME that persists for less than 3 months: observation (no treatment) or treatment with an antibiotic for 10 to 14 days. [3] Because most episodes of OME clear spontaneously and because of the concern for antibiotic resistance, the no-treatment option is currently preferred. [16,17] However, if antibiotic therapy is chosen, since bacteria that cause OME are similar to those found in AOM, the antibiotics used are the same. Amoxicillin, amoxicillin-clavulanate, trimethoprim-sulfamethoxazole, cefaclor, erythromycin, and sulfasoxazole. [3]

The Agency for Health Care Policy and Research (AHCPR) recommends that, for children with an effusion for 3 months and a hearing loss of 20 dB or more, referral to an otolaryngologist for myringotomy with tympanostomy tube placement is another option (in addition to the abovementioned options). [3] However, many reserve myringotomy and tube placement for patients who have failed an antibiotic trial first. [1,16,18,20]

The other nonsurgical methods available, including the use of decongestants, antihistamines, and immunotherapy, have not been shown to be effective in clinical trials. [20] The addition of an oral corticosteroid [prednisone 1 (mg/kg)/day in two doses for 7 days] to the use of oral antibiotics for 14 to 21 days remains controversial. Steroids should not be used in a susceptible child who has been exposed to Varicella in the past month, due to a risk of disseminated disease. [18]

Myringotomy with tympanostomy tube placement improves the conductive hearing loss for longer periods of time than myringotomy alone. [4,5] Tympanostomy tubes remain in place for a few weeks to several years, with an average of 6 months. Possible complications of myringotomy tubes are scarring (tympanosclerosis), localized atrophy, persistent perforation, and the rare development of a cholesteatoma. [4] For children 4 years old or more who have recurrent chronic otitis media with effusion and who have had one or more myringotomy and tympanostomy tube operations in the past, adenoidectomy is a reasonable option. [3] The presence of upper airway obstruction, recurrent acute or chronic adenoiditis, or both is another indication to consider adenoidectomy. [1,20]

Otitis Externa

External otitis (OE) is any inflammatory condition of the auricle, external ear canal, or outer surface of the TM. It can be caused by infection, inflammatory dermatoses, trauma, or combinations of the three.

PATHOPHYSIOLOGY   The flora of the normal ear canal are the same as those of normal skin. They include *Staphylococcus epidermidis,* diphtheroids, b-hemolytic streptococcus, *Staph. aureus,* anaerobes, and fungi. [21,22] Compromise of any of the protective features of the ear canal (e.g., shape and cerumen) can lead to OE due to colonization and invasion by pathogenic organisms, especially gram-negative enteric bacteria, *Pseudomonas,* and fungi. Causes include (1) high environmental temperature and humidity, (2) hyperhydration and maceration of epithelial tissue in the canal, (3) absorption of moisture by the stratum corneum, (4) lack of cerumen through blocked gland ducts and/or mechanical removal (scratching), (5) obstruction of gland ducts by edema and keratin debris, (6) invasion by exogenous or endogenous organisms through breaks in the damaged epithelial surface, and (7) trauma. [21,22]

CLINICAL FEATURES   The mildest form of OE is characterized by itching or a sense of fullness in the ear. As it progresses, increasing pain, itching, redness, swelling, tenderness of the canal, and cheesy or purulent discharge occur. Inward pressure on the tragus or pulling the auricle up and back usually results in discomfort. If the TM can be visualized, it is often red, thick, and covered with the flat vesicles or areas of desquamating epithelium. [21] In the severe stage, pain is intense and can be caused by any movement of the jaw or the ear. There is often disseminated infection, with the presence of enlarged and tender lymph nodes. Further anterior spread of the infection affects the parotid gland and subcutaneous tissue. Posterior spread involves the mastoid, and medial spread involves cranial nerves IX through XII, with possible osteomyelitis of the skull. [21,22]

When there is localized OE (furunculosis), although pain, itching, and signs of infection, such as erythema, are present, a localized abscess is often seen. The organism responsible is usually *Staph. aureus.*[22] When OE is caused by fungi (otomycosis), intense itching is usually present. [21,22]

DIAGNOSIS   The hardest part of the diagnosis is to distinguish between OE and otitis media. Ideally, clinical inspection of the TM with a pneumatic otoscope helps establish the diagnosis; however, the TM of a child with OE may be as red and distorted as that of a child with otitis media, although mobility of the TM is normal or slightly decreased in OE. In addition, visualization of the TM may be difficult because of edema of the canal in OE. Tympanometry can be helpful if the canal is clear and a tight seal for the earpiece can be formed without too much discomfort. Parotitis, periauricular adenitis, mastoiditis, dental pain, and temporomandibular joint dysfunction should be considered when the discomfort is poorly localized and the ear canal and TM appear normal. In addition, pain can be referred from pharyngitis or tonsillitis, but such pain is often made worse by swallowing or eating. Foreign bodies in the ear can also cause OE. [21]

TREATMENT   A thorough and atraumatic cleansing of the ear canal is the most important part of therapy. For mild infections, dry mopping using a small tuft of cotton attached to a wire applicator is sufficient and may be curative. If the canal is inflamed, edematous, and occluded by debris, cleansing can be done with gentle suctioning: a soft plastic infant feeding tube (with an opening at the tip) attached to a DeLee trap can be used. If there is no perforation of the TM, irrigation with warm hypertonic (3%) saline solution, or 2% acetic acid in Burow's solution (Otic Domeboro) is helpful. Acidified isopropyl alcohol (equal parts vinegar and alcohol) or hydrogen peroxide can also be used, followed by drying with suction, compressed air, or a hair dryer. The use of cotton swabs to clean the ears should be strongly discouraged.[21,22] If the canal cannot be cleaned sufficiently, an otowick can be placed in the canal to act as a passage for the use of drops. It can be left in place for 2 to 3 days, at which point reexamination and removal can be performed. [21,22]

Acetic acid ear drops are the easiest and least expensive way to eliminate the infecting agent. A 2% solution is effective and available commercially in aqueous (Otic Domeboro) or propylene glycol (Vosol or Orlex) solutions. These drops should be used three to four times a day for at least 1 week. However, when OE is accompanied by a TM perforation, burning or stinging will occur with the use of acid- or alcohol-containing medication; thus, an antibiotic preparation containing neomycin, polymyxin B, and hydrocortisone (Cortisporin Otic suspension) is less irritating. Another option is the use of Cortisporin ophthalmic suspension, which is free of both acid and alcohol. Ophthalmic gentamicin or tobramycin are alternative drugs; however, when these agents are administered systemically, they have ototoxic properties, although hearing loss due to their topical use has not been documented. [21] Another option is the use of ophthalmic quinolone drops (ciprofloxacin, ofloxacin, and norfloxacin, all 0.3%). [22] Although quinolones are not approved for children via the oral route, these drops can be used in children over 1 year of age. Otic chloramphenicol should be avoided because of the risk of aplastic anemia. Swimming should be prohibited during the course of treatment. After brief showers (with infrequent hair washing), drops should be instilled into the ear.

The basic treatment of otomycosis is similar to that for acute bacterial OE, with cleansing followed by 2% acetic acid or M-cresyl acetate (25%) preparations. Patients who do not respond can be treated with topical ophthalmic suspensions of miconazole, nystatin, clotrimazole, or amphotericin B. Glucocorticoids are present in many topical otic preparations, but their value is unproven. Topical benzocaine and lidocaine may be useful to reduce the itching, but they are inadequate for the relief of moderate to severe pain, for which oral analgesics may be required. [21,22]

Children who fail to respond within 48 h of treatment should be reexamined. If the ear is not clear and dry, other causes, such as cellulitis, abscess, sensitization to the antibiotic, local dermatoses, or even noncompliance, should be excluded. [21] In some cases, oral antibiotics active against *Staph. aureus* (e.g., dicloxacillin or cephalexin) may be required (ciprofloxacin, the only oral antipseudomonal drug, is not approved for children <18 years of age). [22]

Patients with progressive, unresponsive, or severe infection may require parenteral (intravenous) therapy. Cultures of canal secretions should be taken and a combination of an aminoglycoside (gentamicin or tobramycin) and an antipseudomonal penicillin (ticarcillin or piperacillin) started. If the clinical findings and course of the illness suggest an infection due to *Staph. aureus,* a penicillinase-resistant antibiotic [nafcillin, oxacillin, vancomycin, or ampicillin sulbactam (Unasyn) for those over 12 years of age] should also be given. [21]

PHARYNGITIS

Pharyngitis, infection of the pharynx and the tonsils, is a very common pediatric problem. It is estimated that $300 million are spent annually in its diagnosis and treatment.[23] Despite physicians' long-standing familiarity with pharyngitis, there remains wide variability in approach. Controversies and new developments pertain to (1) selection of patients for throat culture and antibiotic treatment, (2) use of rapid diagnostic tests for group A b-hemolytic streptococcus (GABHS), (3) increased incidence of serious systemic streptococcal disease, and (4) occurrence of bacteriologic and clinical failure with penicillin treatment of GABHS.

Nonstreptococcal Pharyngitis

ETIOLOGY   Most cases of acute pharyngitis in children are caused by viral infections. Examples include adenovirus, Epstein-Barr virus (see below), influenza virus, parainfluenza virus, rhinovirus, herpes simplex virus, and enterovirus. Although many of these viruses cause symptoms in addition to sore throat and fever, such as cough, coryza, conjunctivitis, or mucosal ulcerations, some viral infections can be clinically difficult to distinguish from GABHS.

Mycoplasma and *Chlamydia* have been suggested as uncommon causes of pharyngitis in adults and adolescents, however neither organism appears to be an important cause of pharyngitis in children. [24,25] Many organisms—viral, bacterial, fungal, and even protozoal—have been associated with pharyngitis; however, only a relatively few are of practical significance to the emergency evaluation of pharyngitis in the immune competent child. Recent studies have suggested that *Arcanobacterium haemoliticum* (formerly *Corynebacterium haemoliticum*) might be a cause of non-GABHS tonsillopharyngitis with or without a scarlatiniform rash. [26] Erythromycin is the treatment of choice; however, no prospective therapeutic studies are available. Among bacterial pathogens, GABHS is clearly the most important, accounting for 15 to 40 percent of all pharyngeal infections in school-age children. GABHS pharyngitis is unusual in children under 3 years of age, and rheumatic fever is rare in this age group. [25,27]

DIAGNOSIS AND TREATMENT   The few non-GABHS organisms that occasionally require specific diagnosis are *Corynebacterium diphtheriae, Neisseria gonorrhoeae,* EBV, and human immunodeficiency virus type 1. Despite the many etiologic possibilities, in school-age children the diagnostic task is most often reduced to distinguishing GABHS, which requires specific antibiotic therapy, from nonstreptococcal pharyngitis.

Diphtheria is a rare but serious cause of pharyngitis in developed countries. Immunization in infancy with an alum-precipitated toxoid combined with pertussis antigen and tetanus antigen (DPT) has been effective in nearly eliminating diphtheria in childhood, but it can occur in crowded conditions where there are socioeconomic barriers to immunization. Morbidity occurs because of both infectious and toxic reactions. Infectious invasion and spread occur with enough tissue necrosis to produce a pseudomembrane that can progress to cause airway obstruction. The *C. diphtheriae* bacteria also produce an exotoxin that can cause widespread organ damage, including myocarditis and cardiac dysrhythmia, neuritis with both bulbar and peripheral paralysis, nephritis, and hepatitis. Diagnosis must be clinical in order to expedite effective therapy; however, the bacteria can be grown on Loeffler media. Treatment is directed at both killing the bacteria and neutralizing the exotoxin. Therefore, both antibiotic (penicillin or erythromycin) and horse-serum antitoxin must be given.

N. gonorrhoeae is an infrequent but important cause of pharyngitis in sexually active adolescents. Gonococcal pharyngitis in younger children strongly suggests child sexual abuse. Gonococcal pharyngitis may either be asymptomatic or cause very mild symptoms with occasional exudative tonsillitis and/or cervical lymphadenopathy. Pharyngeal throat swabs should be plated on Thayer-Martin medium to recover the organism. Rectal and vaginal or urethral cultures as well as serum to test for syphilis and hepatitis B should be obtained whenever gonorrhea is suspected or documented. Gonococcal pharyngitis in children and adolescents should be treated with ceftriaxons (125 mg intramuscularly once). Children who cannot tolerate ceftriaxone may be treated with a 5-day regimen of trimethoprim-sulfamethoxazole. Children 9 years or older should also receive oral doxycycline (100 mg bid for 7 days) for presumptive *Chlamydia* infection. Children 8 years or younger should receive erythromycin 40 mg/kg/day in divided doses]. Azithromycin (20 mg/kg, 1 g maximum) orally in a single dose is an alternative treatment for *Chlamydia* in all age groups. [28]

EBV is a herpesvirus that is a common cause of infection in childhood and adolescence. While EBV has been associated with a variety of clinical syndromes, most children infected with EBV are asymptomatic or have only mild nonspecific symptoms. EBV can cause isolated tonsillopharyngitis and pharyngitis as a manifestation of infectious mononucleosis (IM). Clinically, the classic IM syndrome begins with malaise, fatigue, and sore throat. Fever and adenopathy are the most common signs. Splenomegaly and hepatomegaly are also present in the majority of infected children, while skin rash, enanthem, eyelid edema, and jaundice occur much less commonly. Pharyngitis occurs in nearly all children with IM. The appearance of the throat can resemble that of bacterial GABHS disease. Dual infection with EBV and

GABHS has also been documented. Classic IM is much less common in children under the age of 2 years, when EBV tends to cause a nonspecific febrile illness. However, recently IM has been reported to occur in toddlers more commonly than was once thought. These younger children most often have a syndrome characterized by fever, tonsillitis, lymphadenopathy, and hepatosplenomegaly. [29,30]

The laboratory can be helpful in establishing the diagnosis of IM. There is an increase in both the proportion and the absolute number of atypical lymphocytes in the peripheral blood smear (generally ³50 percent lymphocytes and ³10 percent atypical lymphocytes). Liver transaminase levels show moderate elevation [generally aspartate aminotransferase (AST) is <600 U/dL]. The heterophil antibody is present (and can be demonstrated by rapid slide test methods) in over 90 percent of children over the age of 5 with IM, but in only 75 percent between the ages of 2 and 4, and in fewer than 30 percent under the age of 2. EBV-specific serologic testing can provide information as to the likelihood of acute, postacute, old quiescent, and reactivation-type infection. These determinations are made on the basis of the presence of specific patterns of IgM and IgG responses to viral capsid antigen and IgG responses to EBV early antigen and the Epstein-Barr nuclear antigen. [31]

IM is generally a benign, self-limited, but somewhat prolonged illness. In general, treatment involves nonspecific supportive modalities (fluids, acetaminophen, and rest). Fatal complications are rare. Death can be caused by neurologic complications (e.g., meningoencephalitis or Guillain-Barré syndrome), splenic rupture and hemorrhage, and bacterial and fungal sepsis. Immunocompromised children may have unusual susceptibility to fulminant EBV infection. Airway obstruction secondary to tonsillar hypertrophy can also occur. This complication responds rapidly to glucocorticoid administration (dexamethasone 1 mg/kg to 10 mg maximum; then 0.5 mg/kg every 6 h) and rarely requires intubation. Airway obstruction is the only complication for which the use of steroids is widely accepted.

Human immunodeficiency virus type 1 is a recently recognized cause of acute pharyngitis. Primary retroviral infection can produce a mononucleosis-like illness with fever, sore throat, and lymphadenopathy that can last for a few days or a few weeks. Such findings as gastrointestinal symptoms or mucocutaneous lesions occur more commonly with acute HIV infection and are very unusual with mononucleosis caused by EBV. Primary HIV infections should be considered in high-risk populations. [32]

Streptococcal Pharyngitis

GABHS pharyngitis is the most common treatable cause of pharyngitis in children. The peak months of infection are January to May, but, because of the high frequency of occurrence in school-age children, the beginning of school in the fall is also associated with GABHS pharyngitis in many areas. The peak ages are 4 to 11 years, with GABHS infection being uncommon under the age of 3 years.

DIAGNOSIS   No set of symptoms or signs is completely specific for GABHS. Nonetheless, there are findings that are typically, but not exclusively, associated with GABHS. Generally, the infected child experiences sudden onset of sore throat and fever. The tonsils and pharynx appear markedly red and have a moderate-to-large amount of exudate. The soft palate and uvula are also red and may have petechiae. The anterior cervical lymph nodes are enlarged and tender. The presence of a scarlatiniform rash and pharyngitis is virtually diagnostic of GABHS. Headache, vomiting, abdominal pain, meningismus, and torticollis can occur as well. These are of little diagnostic importance but must be recognized as possibly attributable to GABHS. The presence of significant coughing, rhinorrhea, or both suggests an alternative diagnosis. Diagnostic accuracy on the basis of clinical findings alone is reported at about 50 to 75 percent for children thought to have GABHS and 75 to 85 percent for children thought not to have GABHS. [33] There is general agreement that clinical diagnosis alone would result in an unacceptably high rate of misdiagnosis.

The mainstay of laboratory diagnosis is still the throat culture, although rapid antigen-detection techniques are gaining popularity in pediatric offices and emergency departments. The tonsil or posterior pharyngeal wall should be swabbed vigorously. In many centers, the swab is sent to the laboratory in appropriate culture medium for further handling. The sample is plated on a blood agar culture medium with neomycin and nalidixic acid added. Colonies that show b hemolysis are identified as group A by bacitracin disk tests, fluorescent antibody staining, or latex agglutination. The rate of false-negative results from single throat culture is about 10 percent. Recovery rates are maximized by good swabbing technique, multiple cultures (rarely actually performed), and incubation in a carbon dioxide-enriched environment. Positive cultures may indicate either an acute GABHS infection or the carrier state. Rates of GABHS carriage vary with the season but have been reported to be as high as 15 percent. There is imperfect correlation between the amount of growth (generally reported on a scale of 1+ to 4+) and the likelihood of true infection. Chronic carriers of GABHS are not at increased risk for developing true GABHS pharyngitis or suppurative and nonsuppurative (e.g., rheumatic fever and nephritis) sequelae, nor do they pose an increased risk for disease transmission.

Incubation of throat cultures takes 24 to 48 h, during which time management must occur with uncertainty as to the diagnosis. Antigen-detection procedures are often available in emergency departments and practitioners' offices. The tests involve extraction of group A carbohydrate antigen from a throat swab and then combining the antigen with a latex agglutination, coagglutination, or enzyme-linked immunosorbent assay. Recently a chemilluminescent DNA probe test and optical immunoassay have become commercially available. The nonculture tests take 10 to 30 min to perform and are generally more expensive per test than direct plate culturing. Sensitivity under controlled laboratory conditions using the culture as the gold standard ranges from 85 to 90 percent, and specificity ranges from 98 to 100 percent. Unfortunately, when measured in the field under less well-controlled circumstances, sensitivity of the latex agglutination test has been as low as 50 percent. [34] In other words, the false-positive rate is low, but the false-negative rate may be unacceptably high. Recent reports have shown that the optical immunoassay tests are nearly as sensitive as blood agar plate culture and more sensitive than other rapid tests for GABHS; this includes one study done in an office-based setting. [35,36] Any emergency department or office planning to use a rapid diagnostic test must assess the performance of the test on site. A safe and commonly used approach is to obtain swabs for both throat culture and rapid test simultaneously. Children with positive rapid test results are treated for GABHS. If the results are negative, the throat culture is processed and the children are managed according to an acceptable strategy while awaiting throat culture results. Some have advocated using optical immunoassay tests alone without culture confirmation of negative antigen test results; [35,37] however, as of this writing, the American Heart Association and the American Academy of Pediatrics have not yet supported that policy. [38]

TREATMENT   The objectives of treatment for GABHS are (1) to prevent rheumatic fever, (2) to prevent suppurative complications (e.g., peritonsillar abscess and cellulitis, suppurative cervical lymphadenitis, and retropharyngeal abscess), and (3) to hasten clinical recovery. GABHS is highly sensitive to penicillin, and there has been no evidence of development of resistance in vitro despite decades of use. A single dose of intramuscular penicillin G benzathine—600,000 U if the patient weighs 27 kg (60 lb) or less and 1.2 million U if the patient weighs more than 27 kg—is effective but causes significant local discomfort in over 50 percent of recipients. A preparation containing 900,000 U of penicillin G benzathine and 300,000 U of penicillin G procaine (CR Bicillin 900/300, introduced in 1976) is effective for children who weigh 64 kg (140 lb) or less and significantly reduces the magnitude and frequency of local reactions. Oral penicillin V is a popular alternative. A regimen of 250 mg two to three times daily for 10 days effectively eradicates infection and prevents rheumatic fever. [38,39] Variable levels of compliance have been reported. Improvements in compliance can be achieved with careful parent education at the time of discharge. If compliance or follow-up are problematic, the intramuscular route should be used. Alternatives to penicillin for children with penicillin allergy include erythromycin, cephalosporins, clindamycin, azithromycin, and clarithromycin.

An increased number of apparent treatment failures with penicillin have been reported. [40] GABHS remains susceptible to penicillin in vitro. Alternative explanations for these findings may involve children who are carriers of GABHS and develop a viral pharyngitis, patients who reacquire the organism from a family member or another close contact, or patients who are noncompliant with the prescribed penicillin. Other proposed mechanisms include development of GABHS penicillin tolerance and the production of b lactamases from other normal pharyngeal flora. [41,42] The evidence does not support the diminished efficacy of penicillin therapy for GABHS pharyngitis. Reports of the proposed therapeutic failures have prompted many recent studies comparing the efficacy of penicillin to that of other antibiotics. In general, penicillin remains the recommended antibiotic of choice based on past experience, cost, and historically successful prevention of rheumatic fever. [38,41,43]

The overall incidence of rheumatic fever has been declining in the developed countries and is now less than 1 per 100,000 in the continental United States. [44] A number of scattered outbreaks of acute rheumatic fever were reported in the United States during the latter part of the 1980s. [45,46] There is ample justification for adherence to the American Heart Association recommendations that one of the abovementioned antibiotic regimens for documented GABHS pharyngitis must be provided. Antibiotic treatment begun within 9 days of the onset of infection is effective in preventing rheumatic fever.

Poststreptococcal glomerulonephritis is a nonsuppurative complication of GABHS disease that is not preventable with antibiotic therapy. Its occurrence is related to infection with nephritogenic strains of streptococci.

Research has also clearly demonstrated the beneficial effects of early antibiotic therapy on reduction of signs and symptoms of GABHS pharyngitis. [47] In addition, because it is recommended that children with GABHS receive antibiotics for 24 h prior to returning to school or day care, early treatment benefits both the children and their parents, especially parents who work outside the home. Based on these considerations, many strategies for testing and treatment have been proposed,

ranging from treating all children with pharyngitis with antibiotics to withholding antibiotics from all pending culture results. Cost-effectiveness studies employing decision-analysis methods have been performed to compare some of these strategies. [37,48] The best strategy for a given institution depends on the local prevalence of GABHS, the availability and accuracy of rapid antigen testing, and the ability to follow up successfully on untreated children found to have positive culture results. A widely accepted strategy that incorporates the latest technology is to perform rapid antigen testing on all children with pharyngitis and to treat all with positive results. In addition, children with classic clinical findings or a scarlatiniform rash should be treated regardless of the result of rapid testing. Those with a negative rapid test result and equivocal or atypical clinical features for GABHS should have a throat culture performed, but treatment may be withheld pending culture results. Positive culture results indicate the need for treatment. It is not necessary to reculture to test for eradication of GABHS in asymptomatic children. Children with recurrent or persistent symptoms and those with previously documented rheumatic fever do require reculturing. Children with persistent positive culture results in this context can be treated with a different antibiotic such as amoxicillin-clavulanate, a cephalosporin, or clindamycin. The asymptomatic carrier state need not be treated except in certain circumstances. These exceptions include a family history of rheumatic fever, an outbreak of rheumatic fever or glomerulonephritis, or multiple documented symptomatic episodes of streptococcal pharyngitis occurring within a family or closed community. Clindamycin, amoxicillin-clavulanate, or a combination of penicillin and rifampin have been shown to be effective in eradicating GABHS in carriers. [49]

Some authors have suggested that early treatment of GABHS pharyngitis due to the availability of a positive nonculture test may lead to more frequent recurrences, possibly secondary to suppression of the immune response. [50] Other studies have not supported this view. [51] An intentional delay in the initiation of penicillin therapy for GABHS pharyngitis is not recommended at present.

Indications for tonsillectomy remain uncertain and controversial. One study showed that, for children with many recurrent episodes of pharyngitis (seven or more episodes in 1 year, five or more annually for 2 years, or three or more annually for 3 years), tonsillectomy reduces the incidence of pharyngitis for the subsequent 2 years compared with nonsurgical management. However, five of six children in the nonsurgical groups experience significant improvement as well. [52] The decision regarding tonsillectomy for such children should be individualized to account for various considerations of risks, benefits, and quality of life, including the quality of available anesthetic and surgical services, impact of recurrent illness versus surgery on the child and parents, school performance, and comparative costs to the family.

Recent outbreaks of pharyngitis caused by groups G and C streptococci have been reported often associated with contaminated food sources. [53,54 and 55] Although the acute clinical syndromes associated with these organisms are identical to those of GABHS pharyngitis, they are unlikely to cause preventable nonsuppurative sequelae. However cases of acute glomerulonephritis following infection with group G streptococci have been described. [56]

A recent resurgence of invasive GABHS infections has been noted. [44,57,58,59] Serious illnesses include septicemia, toxic shock–like syndrome, pneumonia, cellulitis, lymphangitis, and nerotizing fasciitis. Such systemic infections may produce an extraordinarily virulent syndrome progressing rapidly to shock and death. Data suggest an appearance of new serotypes of GABHS but also an increased strain-associated virulence, rather than virulence related to a given serotype. The pathogenetic mechanism by which these virulent strains produce severe disease is not well understood.

Symptomatic therapy for both GABHS and nonstreptococcal pharyngitis includes acetaminophen for analgesia. A throat spray (e.g., Chloraseptic) can be used before meals and bedtime if further analgesia is required. Lozenges should be avoided in the children under 5 years because of the possibility of aspiration.

117 SKIN AND SOFT TISSUE INFECTIONS

Richard Malley

This chapter discusses several of the more common skin and soft tissue infections of childhood, including conjunctivitis, impetigo, sinusitis, and cellulitis. Because of its particular severity, orbital/periorbital cellulitis will be highlighted in a section separate from the general discussion of cellulitis; however, the pathophysiology and clinical manifestations that are shared will not be repeated.

CONJUNCTIVITIS

Definition

Conjunctivitis is an inflammation of the conjunctivae, the membranes that line the surface of the eye. This inflammation may be the result of infection, allergy, or mechanical or chemical irritation. Keratoconjunctivitis involves the cornea as well as the conjunctivae.

Etiology

The etiology of infectious conjunctivitis differs between the newborn and the older child (Table 117-1). In the newborn, pathogens that reside in the birth canal play a major role in ocular infections. *Chlamydia trachomatis* is the most frequent, but *Neisseria gonorrhoeae* poses the greatest threat to the integrity of the eye. Later in childhood, the respiratory tract pathogens predominate, particularly *Hemophilus* species. Trachoma, a recurrent chlamydial conjunctivitis seen in tropical regions, will not be discussed.

Frequency	Neonate	Child
Very frequent	*Chlamydia trachomatis*	Adenoviruses *Hemophilus* species
Moderately frequent	*Streptococcus pneumoniae* *Streptococcus fecalis* (enterococcus) *Neisseria gonorrhoeae*	*Streptococcus pneumoniae*
Infrequent	*Hemophilus influenzae* Herpes simplex *Staphylococcus aureus*	*Neisseria gonorrhoeae* *Neisseria meningitidis* *Chlamydia trachomatis* Herpes simplex *Staphylococcus aureus* *Corynebacterium diphtheriae*

TABLE 117-1 Etiology of Infectious Conjunctivitis

Epidemiology

Conjunctivitis is the most common ocular infection of childhood. It may occur at any age. Neonates acquire most infections during passage through colonized birth canals; in older children, respiratory tract pathogens spread from person to person. Conjunctivitis is usually a sporadic disease, but epidemics of viral illness may occur.

Pathophysiology

Pathogens introduced into the conjunctival sac may proliferate and produce hyperemia and an inflammatory exudate. This exudate may be purulent, fibrinous, or serosanguineous. With certain organisms, corneal involvement (keratitis) also may occur.

Clinical Features

Older children with conjunctivitis may complain of photophobia, ocular pain or pruritus, a sensation of a foreign body in the eye, crusting of the eyelids, or conjunctival erythema. Infants and young children are usually brought by their parents for "pink eye" or crusting. The duration of symptoms with infectious conjunctivitis is most often 2 to 4 days but may be longer in cases which are untreated or resistant to therapy.

As with any ocular complaint, the physician should perform a thorough examination of the structure and function of both eyes, including, when age appropriate, examination of visual acuity, visual fields by confrontation, extraocular muscle function, periorbital area, eyelids (with eversion), conjunctivae, cornea with fluorescein staining, pupillary reflex, anterior chamber, and fundus. Erythema and increased secretions characterize conjunctivitis. Chemosis may be seen. Intense erythema and purulent discharge are more common with an infectious rather than an allergic cause. The cornea does not stain with fluorescein in children with conjunctivitis unless an associated keratitis has developed, as with herpes simplex or adenoviruses. Most importantly, visual acuity is normal.

Fever and/or other systemic symptoms do not occur with isolated conjunctivitis. However, conjunctivitis may be only one manifestation of a viral upper respiratory tract infection, in which case the temperature may be elevated.

Diagnosis

The diagnosis of infectious conjunctivitis rests primarily on the clinical examination. A Gram stain, which should be performed in neonates or in confusing cases, usually shows more than five white blood cells per oil immersion field and, in many cases, bacteria. The finding of gram-negative intracellular diplococci presumptively identifies *N. gonorrhoeae* in the first few weeks of life. Conjunctival scrapings and/or cultures may be performed in selected circumstances to diagnose *C. trachomatis* or specific viral and bacterial pathogens.

Differential Diagnosis

The differential diagnosis of the "red (or pink) eye" includes conjunctivitis, orbital/periorbital infection, foreign body, corneal abrasion, uveitis, and glaucoma. Periorbital and orbital infections cause obvious swelling and tenderness around the eye and/or loss of ocular mobility. Foreign bodies should be visible on direct examination, often only following eversion of the upper eyelid. Thus the differential diagnosis usually revolves around four conditions: conjunctivitis, corneal abrasion, uveitis, and glaucoma (Table 117-2). Both uveitis and glaucoma are uncommon. The erythema in these conditions is concentrated around the limbus, and the discharge consists primarily of tears. Additionally, the vision is decreased in glaucoma, and the cornea may be cloudy. A corneal abrasion is easily identified by the uptake of fluorescein.

	Conjunctivitis	Corneal Abrasion	Uveitis	Glaucoma
History	URI	Trauma, contact lens	JRA, sarcoid, trauma	Prematurity, Marfan's syndrome, homocystinuria
Visual acuity	Normal	Normal or decreased	Normal or decreased	Decreased
Ocular exam				
External	Watery or purulent discharge	Watery discharge	Watery discharge	Watery discharge
Cornea	Usually normal, staining if keratitis	Staining	Normal or band keratopathy	Cloudy, enlarged
Anterior chamber	Normal	Normal	Cells, hypopyon, hyphema	Normal or shallow
Pupil	Normal	Normal	Small	Fixed
Intraocular pressure	Normal	Normal	Variable	Increased

TABLE 117-2   Differential Diagnosis of the "Red Eye"

Finally, conjunctivitis may be only one manifestation of a systemic disorder, such as measles and Kawasaki disease.

Complications

Conjunctivitis is generally self-limited, with the notable exceptions of herpes simplex and *N. gonorrhoeae.* The potential complications are corneal ulceration and scar formation leading to visual impairment.

Treatment

Bacterial and viral conjunctivitides are far and away the most common cause for the complaint of a red eye in childhood. Once the diagnosis of conjunctivitis is established on the basis of diffuse injection, purulent discharge, and normal vision, infectious and noninfectious causes are next separated. Allergic conjunctivitis is usually distinguished by chronicity, seasonality, pruritus, and associated symptoms of allergic rhinitis; if the physician is uncertain, a Gram stain should be done (Table 117-3).

	Allergic	Infectious
History		
Pruritus	Yes	No
Chronic	Yes	No
Recurrent	Yes	No
Seasonal	Yes	No
Sneezing, rhinorrhea	Yes	Variable
Exam		
Discharge	Watery	Watery or purulent
Chemosis	Present	Usually absent
Fluorescein	Negative	Negative, except keratitis
Lab		
Gram stain	Negative	White cells, bacteria

TABLE 117-3 Differential Diagnosis of Allergic and Infectious Conjunctivitis

In approaching infectious conjunctivitis (Fig. 117-1), the physician must decide whether the ocular disorder is one manifestation of a systemic illness such as measles or is occurring in relative isolation. Isolated conjunctivitis may be due to various viruses and bacteria, of which herpes simplex and N. gonorrhoeae are particularly severe, or to *C. trachomatis,* especially in the first 3 months of life.
FIG. 117-1. Approach to the child with an isolated, infectious conjunctivitis. *Abbreviations:* F/U, follow-up; GC, gonorrhea culture.

Fluorescein staining always should be performed in an effort to identify the dendritic corneal ulcerations characteristic of herpetic disease. If they are identified, treatment is with acyclovir or other antiviral agents under the supervision of an ophthalmologist. Because *N. gonorrhoeae* is usually acquired during passage through the birth canal, infants under 1 month of age must always be tested for this pathogen with a Gram stain and culture. If gram-negative intracellular diplococci are seen on smear, a single intramuscular injection of ceftriaxone (125 mg) is indicated. [1]

Infants beyond 1 month of age and older children with an obvious clinical diagnosis of conjunctivitis do not routinely require smears or cultures. In patients under 3 months of age, treatment is instituted with erythromycin (50 mg/kg/day) orally for *C. trachomatis* (Table 117-4). Older children require only topical antibiotic instillation into the conjunctival sac. A child who has unusually severe disease or who fails to respond to therapy within 48 h may benefit from a laboratory investigation. Appropriate studies in the infant under 1 month of age would include a Gram stain and bacterial culture and either a scraping or culture for *C. trachomatis*. Older children require only a Gram stain and bacterial culture. Diagnostic tests for herpes simplex are not usually rewarding in the absence of corneal ulceration; culture for adenoviruses may be helpful in persistent or severe hemorrhagic infections to avoid unnecessary additional testing, but there is no specific treatment. All children with conjunctivitis should be reevaluated within 48 h. Failure to improve warrants further investigation and continued, careful follow-up.

Viruses	
Herpes simplex	Trifluridine, vidarabine, or acyclovir, topically (neonates may also have systemic infection)
Other	Supportive
Chlamydia	
Chlamydia trachomatis	Erythromycin, 50 mg/kg per day orally, for 14 days
Bacteria	
Neisseria gonorrhoeae	Child: ceftriaxone 125 mg IM or IV Adult: ceftriaxone 250 mg IM or IV
Neisseria meningitidis	Child: penicillin, 50,000 units/kg/day, IV, for 7 days Adult: penicillin, 10 million units/day, IV, for 5 days
Hemophilus influenzae, Streptococcus pneumoniae, and others	Topical antibiotic ointments: sulfonamide, erythromycin, etc.

TABLE 117-4   Treatment of Conjunctivitis by Pathogen

IMPETIGO

Definition

Impetigo is a superficial bacterial infection of the skin confined to the epidermis. Deeper spread to the dermis leads to ecthyma. There are two varieties of impetigo: impetigo contagiosa and bullous impetigo.

Etiology

Traditionally, group A b-hemolytic streptococcus (GABHS) was considered the major pathogen in impetigo contagiosa. However, recent studies have suggested that *Staphylococcus aureus* often can be the primary infecting agent and that therapy which does not include coverage for this organism is significantly less effective. In particular, in bullous impetigo, the primary pathogen is *S. aureus.* [2]

Epidemiology

Impetigo is the most common skin infection seen in the emergency department. The prevalence is greatest in young children, particularly those under the age of 6 years. Impetigo may occur sporadically or, occasionally, in epidemics. Conditions favoring epidemic spread include warm weather, overcrowding, and poor hygiene. Bullous impetigo is less common than impetigo contagiosa.

Pathophysiology

The intact epidermis forms a relatively impervious barrier to bacteria. The development of impetigo follows a breach in the integument; this may be an obvious abrasion or an inconspicuous insect bite. Bacteria then invade the skin and elaborate toxins, such as streptolysins, which promote local spread.

Clinical Features

The chief complaint of children with impetigo is most often that of sores on the body. There are no associated systemic manifestations such as fever or malaise. Regional lymph nodes may be minimally enlarged.

The typical lesion of impetigo contagiosa begins as an erythematous papule. Small vesicles may follow transiently, but rapid progression to crusted lesions occurs. These crusts, which are initially honey-colored and fine in consistency, may appear on any area of the body; between the upper lip and the nose is a very characteristic site. The lesions enlarge over days to weeks, and the crusts become thicker. Erythema is mild. No induration is present.

In bullous impetigo, the characteristic skin lesions are superficial bullae filled with purulent material. The bullae range in size from 0.5 to 3 cm and have minimal, if any, surrounding erythema.

Diagnosis

The diagnosis of impetigo rests with the visual appearance of the lesions. Rarely are laboratory tests needed.

In cases where the diagnosis of impetigo is uncertain, Gram stain of the lesions is helpful, showing abundant polymorphonuclear leukocytes and gram-positive bacteria. Local culture may be obtained from patients whose disease does not respond to standard therapy. If performed, the peripheral white blood cell count is normal.

Differential Diagnosis

Several dermatologic disorders may resemble either impetigo contagiosa or bullous impetigo. These include tinea corporis, nummular eczema, small burns or abrasions, allergic contact dermatitis, eczema herpeticum (with underlying atopic dermatitis), and scalded skin syndrome.

Complications

Impetigo may spread locally or, in the case of streptococcal infections, lead to remote, nonsuppurative sequelae. Occasionally, impetigo may progress to cellulitis or lead to lymphadenitis in the regional nodes. The attack rate for acute poststreptococcal glomerulonephritis has been as high as 1 percent in certain epidemics; however, the disease is unusual following sporadic skin infections.

Treatment

The treatment of impetigo is oral antibiotic therapy or an appropriate topical antibiotic for limited eruptions. A first generation oral cephalosporin such as cephalexin (50 mg/kg/day) or erythromycin (50 mg/kg/day) provides effective oral therapy. Mupirocin is the only topical agent with proven efficacy. [3] Combination topical and systemic therapy is unnecessary. Vigorous scrubbing, in addition to topical or systemic antibiotic agents, offers no advantage; routine cleanliness is sufficient.

Antibiotic therapy hastens the resolution of impetigo and limits suppurative complications. Although the incidence of glomerulonephritis may be reduced, it has not been possible to demonstrate this effect with certainty in clinical studies due to the low incidence of this disease.

SINUSITIS

Definition

Sinusitis is an inflammation of the paranasal sinuses: maxillary, ethmoid, frontal, or sphenoid. This inflammation may be on the basis of infection or allergy; it may be acute, subacute, or chronic.

Etiology

The major pathogens in acute bacterial sinusitis in childhood are *Streptococcus pneumoniae, Moraxella catarrhalis,* and nontypable *Hemophilus influenzae.*[4] The incidence of *H. influenzae* sinusitis in children would be expected to decline with Hib vaccination. [5] Other potential etiologic agents found in a minority of infections include group A streptococcus, group C streptococcus, a-hemolytic streptococcus, and *Peptostreptococcus.* Similar clinical investigations in adults have been in general agreement, finding nontypable *H. influenzae* and *S. pneumoniae* in 60 to 70 percent of the cases. Although *S. aureus* and anaerobic organisms are isolated occasionally, they rarely play a role in acute infections in childhood. Severe sinusitis is not a common illness in children, but mild or subacute disease may occur more frequently.

Pathophysiology

The ethmoid and maxillary sinuses are present at birth, but the frontal and sphenoid sinuses do not become aerated until 6 or 7 years of age. The sinuses are lined primarily by ciliated columnar epithelium and connect with the nasopharynx via narrow ostia. Normally, the epithelium is coated by a double layer of mucus: a viscid gel layer superficially and a more fluid layer underneath. Resistance to infection depends on the patency of the ostia, the function of the ciliary mechanism, and the quality of the secretions.

Obstruction of the ostia results either from mucosal swelling or, less commonly, mechanical obstruction. By far the most frequent offenders are viral upper respiratory infection and allergic inflammation. Less common causes include cystic fibrosis, trauma, choanal atresia, deviated septum, polyps, foreign body, and tumor.

Factors that impair normal mucociliary function include viral infections, cold or dry air, certain chemicals or drugs, and, rarely, inborn errors of motility. Alterations of the mucus occur in asthma and cystic fibrosis.

The bacteria that cause sinusitis often colonize the nasopharynx of healthy children. Disruptions in one or more of the barriers described above allow these organisms to ascend through the ostia and multiply within the sinuses.

Clinical Features

The spectrum of sinusitis has not been completely defined as it relates to clinical manifestations. However, there are two major types of infection which can usually be distinguished on clinical grounds: acute, severe sinusitis, and mild, subacute sinusitis (Table 117-5).

	Acute, Severe Disease	Mild, Subacute Disease
Headache	+++	++
Fever	+++	+
Facial tenderness	++	—
Facial swelling	++	—
Nasal discharge	+++	++++

TABLE 117-5   Signs and Symptoms in Children with Sinusitis

Acute, severe infections of the sinuses are infrequent during childhood. Such patients often have a history of headache and an elevated temperature. Findings include fever, localized swelling and/or erythema, and facial tenderness. A mucopurulent discharge usually accompanies severe sinusitis but may also indicate a nasal foreign body when unilateral.

Mild, subacute sinusitis is encountered more commonly than the severe form during childhood. This type of infection usually manifests as a protracted "cold." Rather than improving in 3 to 7 days, these children persist with the symptoms of an upper respiratory infection beyond 2 weeks. They have a nasal discharge, which may be serous or mucopurulent. Fever is infrequent.

Bacterial infection of the sinuses must be contrasted with congestion of brief duration found in association with some viral upper respiratory infections. Such congestion per se does not constitute a purulent infection.

Diagnosis

The diagnosis of sinusitis is usually made on clinical grounds without any laboratory or radiographic studies. In older children and adolescents, transillumination of the maxillary or frontal sinuses may provide assistance.

Standard radiographs, including anteroposterior, lateral, and occipitomental views should be obtained in patients with an uncertain clinical diagnosis and in cases of severe sinusitis. The most diagnostic findings for purulence are an air-fluid level or complete opacification. Mucosal thickening greater than 4 mm is usually indicative of infection but may accompany viral upper respiratory disease, particularly in the first year of life. A normal radiograph suggests, but does not prove, that a sinus is free of disease.

Several studies have shown that ultrasonography may be useful for the diagnosis of sinusitis, but there is not sufficient experience to recommend this modality for routine use. The anatomy of the paranasal sinuses is superbly defined by computed tomography (CT). However, the cost of CT does not justify its substitution for plain radiography, except in cases where complications are suspected.

Ultimate confirmation of infection within the paranasal sinuses rests with demonstration of organisms by Gram stain and quantitative culture of aspirated secretions. Aspiration is not routinely indicated but can be performed in selected cases of maxillary sinusitis in the outpatient setting via the intranasal route. Appropriate circumstances for aspiration include (1) life-threatening complications, (2) immunosuppressive conditions, (3) clinical unresponsiveness, and (4) unusually severe disease. The presence of organisms on Gram stain and a count of at least 10^4 colony-forming units point to bacterial infection. [4]

Differential Diagnosis

Sinusitis may cause local swelling, facial pain, or nasal discharge. Other causes of swelling include superficial infection (cellulitis), trauma, cold injury, and allergic edema. Facial pain may be neurogenic, odontogenic, or related to the temporomandibular joint. Nasal discharge, particularly unilateral, should lead to a suspicion of a foreign body within the nares.

Complications

The proximity of the paranasal sinuses to the brain sets the scene for the occurrence of life-threatening complications from sinusitis; however, the use of antibiotics has reduced the incidence of such complications. Infection may spread from the sinuses to surrounding structures through the diploic veins, which have no valves, or by erosion through bone.

The most commonly encountered complications are periorbital cellulitis and orbital cellulitis/abscess. Periorbital infection causes swelling around the eye, while intraorbital accumulation of pus may be recognized on the basis of proptosis and decreased ocular motion. Infection may also produce osteomyelitis of the surrounding bone; in the frontal region this is referred to as Pott's puffy tumor. Less commonly, complications follow intracranial extension and may include epidural, subdural, or brain abscess; meningitis; and cavernous sinus thrombosis. Meningitis rarely follows sinusitis; it more commonly occurs after bacteremia. Focal intracranial involvement can be demonstrated by CT.

Treatment

In deciding on appropriate therapy, the first step is to differentiate bacterial sinusitis from nasal congestion accompanying viral upper respiratory tract disease. Although the latter resolves spontaneously or may be treated with decongestants, sinusitis requires therapy with antibiotics (Table 117-6). Mild, subacute infections respond well to oral therapy for 10 to 14 days; as for otitis media, amoxicillin (40 mg/kg/day) remains the first-choice antimicrobial (Fig. 117-2). Failure to improve with amoxicillin therapy suggests infection with pathogens that are often resistant to this drug, such as *M. catarrhalis* or *H. influenzae,* or perhaps with penicillin-resistant *S. pneumoniae.* A second course of treatment with erythromycin/sulfisoxazole, newer oral second and third generation cephalosporins such as cefprozil or cefpodoxime, or amoxicillin-clavulanic acid should then be instituted; aspiration for culture may be useful for those patients in whom the infection still persists after a second course of therapy.

	Acute, Severe Sinusitis	Mild, Subacute Sinusitis
Initial	Cefuroxime, 100 mg/kg/day IV *or* Ceftriaxone, 75 mg/kg/day IV *or* Ampicillin-sulbactam, 200 mg/kg of ampicillin/day IV	Amoxicillin, 40 mg/kg/day PO
Persistent	Antibiotics as above plus surgical drainage	Cefprozil, 30 mg/kg/day PO *or* Erythromycin-sulfisoxazole, 40 mg/kg/day of erythromycin PO
Penicillin allergic	Cefuroxime, 100 mg/kg/day IV	As for persistent cases

TABLE 117-6 Antibiotic Therapy for Sinusitis

FIG. 117-2. Approach to sinusitis in the immunocompetent child.

Acute, severe sinusitis may result in life-threatening complications and requires intravenous antibiotic therapy directed at *S. pneumoniae,* amoxicillin-resistant *H. influenzae,* and less commonly *S. aureus.* Cefuroxime (100 mg/kg/day) and ceftriaxone (75 mg/kg/day) represent single-drug regimens effective for this disease; ampicillin-sulbactam (200 mg/kg/day) is an alternative for the nonallergic patient. Failure of severe disease to respond promptly to antibiotic therapy or the occurrence of complications indicates the need for surgical consultation in regard to drainage procedures.

CELLULITIS

Definition

Cellulitis is an infection of the skin and subcutaneous tissues. It extends below the dermis, differentiating it from impetigo, but does not involve muscle (pyogenic myositis) or bone (osteomyelitis). Any region of the body may be involved, but two divisions are important in regard to predicting the most likely pathogens: (1) the trunk and extremities and (2) the face (buccal and periorbital cellulitis).

Etiology

The organisms that play an important role in the immunocompetent host under normal circumstances include *S. aureus, S. pyogenes* (group A b-hemolytic streptococcus), and *H. influenzae* (Table 117-7). In general, *S. aureus* is the most common and *H. influenzae* the least among the three major pathogens, particularly in children immunized against *H. influenzae* type B.[5] However, in certain anatomic locations, particularly for young or unimmunized children, *H. influenzae* remains an important consideration. Additionally, unusual organisms may cause cellulitis in immunocompromised hosts or following their introduction in special types of wounds (Table 117-7).

	Most Likely	Less Likely
IMMUNOCOMPETENT HOST		
Trunk/extremity	*S. aureus* *Streptococcus pyogenes*	*H. influenzae*
Face* (periorbital/buc- cal), unimmunized	*H. influenzae*	*S. aureus* *S. pneumoniae*
Face* (periorbital/buc- cal), immunized	*S. aureus* *S. pneumoniae*	*H. influenzae*
Any site/animal bite	*S. aureus*	*Pasteurella multocida*
Any site/human bite	Anaerobic organisms	*S. aureus*
IMMUNOCOMPROMISED HOST		
Any site	*S. aureus*, gram-nega- tive rods	Anaerobic organisms

* Definitive epidemiology awaits further studies since the advent of the wide-spread immunization against *H. influenzae* type B.

TABLE 117-7   Etiology of Cellulitis

Epidemiology

Cellulitis is a frequent infection, particularly in the warm weather. The precise incidence is unknown; however, in a study at an urban children's hospital, this infection accounted for 1 of every 500 visits. Children of any age may develop cellulitis, but, as noted above, disease due to *H. influenzae* has become rare, affecting mainly infants under the age of 6 months.

Pathophysiology

Cellulitis may occur either when a pathogen is directly inoculated into the subcutaneous tissue or following an episode of bacteremia. The majority of infections involve local invasion after a breach in the integument. The organisms responsible are usually *S. aureus* and *S. pyogenes.* In contradistinction, *H. influenzae* disseminates hematogenously.

Clinical Features

The child with cellulitis manifests a local inflammatory response at the site of the infection, including erythema, edema, warmth, and tenderness. There may be a history of a preceding wound or a complaint related to loss of function, such as limp with an infection of a lower extremity. Fever is unusual except in infections due to *H. influenzae* (Table 117-8).

Characteristic	*H. influenzae*	*S. aureus*
Age	<3 yrs	Any
Fever	Yes	No
Color of lesion	Violaceous	Erythematous
Location	Cheek, periorbital	Trunk, extremity
Preceding wound	No	Yes
WBC count	>15,000/μL	<15,000/μL
Bacteremia	Yes	No

TABLE 117-8   Usual Clinical and Laboratory Features of Children with Cellulitis

Inspection of the area of cellulitis usually shows intense erythema. A violaceous hue suggests *H. influenzae* but has been reported with other pathogens including *S. pneumoniae*. Red streaks may radiate proximally along the course of the lymphatic drainage, and the regional nodes may enlarge.

Diagnosis

The diagnosis of cellulitis is made by inspection. Laboratory studies including a WBC count, blood culture, and aspirate culture are obtained for specific indications: immunocompromise, fever, severe local infection, facial involvement, and failure to respond to therapy.

The WBC count is normal in most cases of infection due to *S. aureus* or *S. pyogenes,*, which are locally invasive. On the other hand, cellulitis due to *H. influenzae* results from bacteremia and is usually accompanied by a polymorphonuclear leukocytosis. In one study of children with cellulitis, the WBC count was over 15,000/μL in 3 of 4 children infected with *H. influenzae,* and 0 of 19 infected with *S. aureus* or *S. pyogenes.*[6] Among 194 patients with *H. influenzae* cellulitis reported in the literature as reviewed in 1983, the WBC count was greater than 15,000/μL in 84 percent, with a mean of 20,850/μL. [7]

The blood culture is usually negative in infections due to *S. aureus* and *S. pyogenes.* On the other hand, *H. influenzae* as a rule causes a bacteremic infection.

Aspirate cultures are best obtained close to the center of an infected lesion, as the periphery may consist primarily of edema fluid devoid of organisms. The needle should be sufficiently large to permit the evacuation of purulent material—22 gauge for the face and 19 gauge for the trunk and extremities. Using a 5- or 10-mL syringe prefilled with 1 mL of sterile, nonbacteriostatic saline, the needle is directed into the subcutaneous tissue to a depth of approximately 0.5 to 1.0 cm, and aspiration is attempted. If there is no return, the saline is injected and reaspirated. The material obtained is used for culture and Gram stain.

Differential Diagnosis

Cellulitis must be differentiated from other causes of erythema and edema, including trauma and allergic reaction. Allergic edema is not tender and usually only mildly erythematous. Traumatic lesions may be easily distinguished when there is a history of injury and absence of fever. Cold injury, especially on the cheeks ("popsicle panniculitis"), may be confused with cellulitis.

Complications

Cellulitis due to *S. aureus* and *S. pyogenes* may at times spread locally or involve the regional lymph nodes; distant foci occur only rarely. Bacteremic *H. influenzae* infections are more likely to spread hematogenously, involving the central nervous system, epiglottis, joints, or pericardium.

Treatment

The treatment of cellulitis is the administration of systemic antibiotic therapy. Although most patients respond rapidly to oral antistaphylococcal agents, the clinician must identify those individuals who require broad-spectrum or intravenously administered drugs (Fig. 117-3).

FIG. 117-3. Approach to the child with cellulitis.

Obviously, signs of sepsis are indicative of hematogenous dissemination and demand treatment as an inpatient. Additionally, children under 6 months of age and those with impaired immunity are unable to contain local bacterial infections and will benefit from intravenous therapy.

Among otherwise healthy children over 6 months of age, only those who are clinically ill-appearing, or in whom bacteremic disease is suspected, need to be admitted to the hospital. Prior to the advent of the *Hemophilus* vaccine, physicians could identify patients at risk for invasive *H. influenzae* disease fairly reliably on the basis of anatomic location, presence of fever, and a WBC count greater than 15,000/μL. Although the incidence of this disease has dropped considerably, it is important to remember that young infants are still at some risk of being infected with this organism.

The usual therapy for patients discharged from the emergency department is an antistaphylococcal antibiotic, such as dicloxacillin or cephalexin. Broad-spectrum therapy is recommended presumptively for patients who are immunocompromised or suspected to have bacteremia, pending a definitive isolate (Table 117-9).

TABLE 117-9   Initial Antibiotic Therapy for Cellulitis

PERIORBITAL/ORBITAL CELLULITIS

Definition

Cellulitis as previously defined may involve the tissues anterior to the orbital septum (periorbital cellulitis) or within the orbit (orbital cellulitis).

Etiology

S. aureus, S. pneumoniae, and *H. influenzae* are the principal etiologic agents. Orbital infections are most often caused by *S. aureus.*

Epidemiology

Children under the age of 3 years are more likely to become bacteremic than those who are older; thus, they experience the highest incidence of periorbital disease. Orbital cellulitis may occur at any age.

Pathophysiology

Organisms reach the periorbital area either hematogenously or by direct extension from the ethmoid sinus. In the case of orbital disease, contiguous spread is most common.

Clinical Features

Orbital and periorbital cellulitis cause the periorbital area to appear red and swollen. The periorbital edema is usually more prominent with preseptal infections. Proptosis or limitation of extraocular muscle function indicates orbital involvement. Fever is more common with periorbital cellulitis.

Diagnosis

Periorbital and orbital cellulitis are distinguished from noninfectious disorders on the basis of the clinical findings and the WBC count. Leukocytosis occurs frequently with cellulitis, more often with bacteremic preseptal infections. A blood culture is often positive.

CT is performed when orbital involvement is likely. An inflammatory mass is easily demonstrated when present using this modality.

Differential Diagnosis

As for cellulitis in other regions, allergic and traumatic causes for edema must be considered. Additionally, tumors and metabolic disease may cause swelling, discoloration, and/or proptosis. Thyrotoxicosis usually occurs in adolescents. The most likely tumor is metastatic neuroblastoma. Pseudotumor occurs rarely.

Complications

Periorbital cellulitis may serve as a focus for metastatic bacterial disease; of particular concern is the occurrence of meningitis. Orbital cellulitis may evolve into a subperiosteal abscess; this condition threatens the integrity of the eye and should be considered a surgical emergency. Intracranial extension may occur rarely.

Treatment

Admission and treatment with intravenous antibiotics is the rule. Blood cultures should always be done, and an aspirate culture is indicated for any ill child. In a child under 6 months of age, strong consideration of a lumbar puncture is indicated whenever infection with *H. influenzae* is suspected. Beyond 6 months of age, in the immunized child, although the possibility of meningitis remains, a decision regarding a lumbar puncture can be based on the clinical status and examination of the patient. Presumptive therapy of periorbital or orbital cellulitis is directed against *S. aureus* and *H. influenzae* (Table 117-9). Surgical drainage may be necessary with abscess formation or sinusitis.

Peter Mellis

For emergency physicians who frequently care for young children, the identification and treatment of potentially life-threatening systemic infectious disease represents a continuing challenge. Although most children have either self-limited viral or minor focal bacterial infection, a subset will have serious bacterial disease with potential for morbidity and mortality. This chapter provides an overview of the presentation and management of bacteremia, sepsis, and meningitis in pediatric patients in the ED. Although each is discussed separately, it must be kept in mind that these entities represent different points along a spectrum and may occur concurrently as a result of progression of disease.

BACTEREMIA AND SERIOUS BACTERIAL INFECTION

Pathophysiology

Children between the ages of birth and 3 years old are at relatively increased risk for bloodborne bacterial disease due to immaturity of the reticuloendothelial system. The term *bacteremia* refers to the presence of a positive blood culture without reference to specific clinical symptomatology. Bacteremia may resolve spontaneously, progress to *septicemia,* or be associated with focal *serious bacterial infection* (SBI), most often involving the meninges, lung, kidney, bowel, bone, or joint.

The risk of bacteremia decreases with age, with the highest incidence in the first 3 months of life (Table 118-1). Neonates with fever, defined as a rectal temperature of 38.0°C or higher, have a 5 percent risk for bacteremia and 15 percent incidence of SBI due to pathogens encountered at the time of birth. [1,2 and 3] Bacteremia in this age group either results in a fulminant septicemic process within hours to days of birth (*early-onset disease*) or a focal SBI developing weeks to months later (*late-onset disease*). Group B *Streptococcus* is by far the most common bacterial pathogen in this age group, followed by *Escherichia coli, Listeria monocytogenes,* and *Enterococcus* sp. Infants aged 30 to 90 days are at a progressively lesser risk for late-onset infection from these neonatally acquired pathogens but are increasingly susceptible to community-acquired pathogens. This age group thus represents a transition period from neonates and those infants aged 3 months and older.

Group	Risk	Pathogens
Neonates	High risk	Group B *Streptococcus* *Escherichia coli* *Listeria monocytogenes* *Enterococcus* sp.
Young infants 30–90 days	Intermediate risk	Neonatal pathogens (above) Community-acquired pathogens (below)
Older infants 3–36 months	Low risk	*Streptococcus pneumoniae* *Neisseria meningitidis* *Haemophilus influenzae* b (unimmunized) Group A *Streptococcus* *Escherichia coli* (pyelonephritis) *Salmonella* sp. (gastroenteritis) *Staphylococcus aureus* (osteomyelitis)

TABLE 118-1   Age-Related Risk Groups and Causes of Bacteremia in Children

Children aged 3 months and older are susceptible to infection from community-acquired pathogens and are at relatively less risk for bacteremia and SBI in comparison to younger infants. Bacteremia in this age group is either a result of SBI or may precede the development of focal serious infection. Focal SBI that may be associated with bacteremia includes meningitis, pneumonia, pyelonephritis, bacterial enteritis, facial cellulitis, septic arthritis, and osteomyelitis (Table 118-2). The reader is referred to subsequent chapters for description of the pathogenesis and microbiology of these infections in children. Pneumonia is most frequently viral in etiology in older infants and children, with less than 3 percent incidence of associated bacteremia, most often due to *Streptococcus pneumoniae.*[4] Urinary tract infection (UTI) is usually caused by *E. coli* ascending infection, with associated bacteremia most commonly noted in infants younger than 6 months of age. [5] Bacterial enteritis caused by *Salmonella* sp. as well as septic arthritis and osteomyelitis caused by *Staphylococcus aureus* and *Streptococcus pneumoniae* carry some risk of bacteremia in infancy. The development of generalized septicemia without a primary focus is quite rare in immunologically competent children, occurring primarily with *Neisseria meningitidis* infection.

Meningitis
Pneumonia
Pyelonephritis
Bacterial enteritis
Facial cellulitis
Septic arthritis
Osteomyelitis

TABLE 118-2   Serious Bacterial Infections Associated with Bacteremia

Bacteremia may also occur in the 3- to 36-month age group without clinically recognized septicemia or focal SBI. This "occult" bacteremia (OB) has been found to

have an incidence of 3 percent of children 3 to 36 months of age with rectal temperatures of 39°C or higher, a well clinical appearance, and no major focal bacterial infection.[6,7] The most common organism responsible is *Streptococcus pneumoniae*, which accounts for 90 percent of OB. *Streptococcus pneumoniae* OB most often resolves spontaneously but carries a 10 percent risk of complicating SBI, including a 3 percent risk of meningitis.[8] *Haemophilus influenzae* type b (HIB) has historically been reported to account for 10 percent of OB, with a 50 percent risk of progression to SBI, including a 25 percent risk of meningitis.[9] However, the impact of the HIB vaccine on the incidence of HIB-related bacteremic disease has been dramatic, virtually eliminating this organism as a potential pathogen in adequately immunized patients.[10] Other organisms, such as *Neisseria meningitidis* and *Salmonella* sp., contribute a minority of cases but with a high rate of subsequent focal SBI. Although uncommon, group A b-hemolytic streptococcus has been reported as a cause of bacteremia, often associated with primary varicella infection.[11] Initial studies reported that untreated OB, without reference to the specific etiology, carries a 10 percent risk of progression to complicating focal meningitis.[12] However, no studies have been performed since the universal introduction of the HIB vaccine, and the actual risk of progression from OB to complicating focal SBI in adequately immunized children is likely much lower.[8] Two developments will profoundly develop the future management of bacteremia and SBI due to *S. pneumoniae*. The widespread emergence of penicillin- and cephalosporin-resistant strains of *S. pneumoniae* has complicated the choice of optimal therapy for bacteremia, SBI and meningitis in particular. Antibiotic treatment within the prior month has been demonstrated to be a risk factor for infection due to a resistant strain.[13] Of potentially greatest importance to the emergency physician caring for a febrile child, a newly developed polyvalent pneumococcal vaccine has recently completed phase III clinical trials and was shown to reduce by 90 percent the incidence of all pneumococcal bacteremia and meningitis in immunized infants.[14]

Clinical Features

Historical risk factors for neonatally acquired bacterial infection in infants less than 3 months of age include premature delivery, ruptured amniotic membranes for more than 24 h prior to delivery, and maternal amnionitis prior to or following delivery. Specific symptoms suggestive of a focus of infection in this age group are rare. High fever is uncommon in this age group, and serious illness may be present in the setting of low-grade fever or normal temperature.[2] Infant temperatures should be obtained via the rectal route in the ED, as the axillary and auditory canal routes are less reliable in the identification of fever.[15] A history of fever measured by the parent via the rectal route carries the same significance as fever detected in the ED, although the perception of tactile fever at home in the setting of a normal temperature in the ED does not.[16] Of greatest utility to emergency physicians, *the symptoms and signs suggestive of bacteremia and SBI most frequently produce an overall ill appearance*. Parents may note poor feeding, decreased responsiveness, or irritability in response to attempts to console. Physical examination findings suggestive of an ill appearance include poor eye contact and muscle tone, including weak suck, poor head control, and indifferent response to stimuli. Signs of respiratory distress and poor perfusion parameters are suggestive of septicemia and should be specifically sought. Although uncommon, findings suggestive of a specific focus of infection, such as otitis media, skin, soft tissue, bone, or joint inflammation, place young infants in a higher-risk group for SBI. However, due to the nonspecific nature of the signs and symptoms of illness at this age, the history and physical examination alone are unreliable screening tools for bacteremia and SBI in neonates, with marginally improved predictive value in infants 30 to 90 days old.[17]

Children 3 months of age and older found to have bacteremia and SBI most often are noted to have fever with rectal temperatures of 39.0°C or higher,[18] although serious infection can uncommonly occur without the finding of fever.[19] As for younger infants, the most important historical and physical findings are related to overall appearance. *Parental report of persistent lethargy or irritability with associated fever raises significant concern for SBI with associated bacteremia*. Symptoms of respiratory, gastrointestinal, soft tissue, bone, or joint inflammation should be elicited. The reader is referred to subsequent chapters for a complete description of the symptoms suggestive of focal SBI in children. Historical risk factors of importance include immunization status, prior infections, and underlying conditions that impair immune response, such as sickle cell anemia and HIV. The physical examination is performed in two phases. The first is a global assessment of the child's appearance performed in order to categorize the child as "ill" versus "well," optimally after antipyretic therapy has been administered. This assessment should specifically include *mental status,* evaluated by observing response to parental physical and social stimulation, and *perfusion and hydration parameters. A well appearance* is evidenced by an awake, responsive infant or child with good eye contact, developmentally appropriate social interaction with family members, normal muscle tone, and vigorous cry. An *ill appearance* is evidenced by lethargy or irritability, failure to respond to or be consoled by family members, weak cry, poor muscle tone, or abnormal peripheral perfusion parameters. If the examination findings are equivocal, the child should be reassessed in a short period of time and, if unchanged, considered "ill-appearing." The performance of an overall assessment of appearance has been shown to improve the sensitivity of the history and physical examination in detecting SBI.[20] The second phase of physical examination is devoted to eliciting signs of specific SBI as well as minor focal infection. Signs of meningitis are reviewed later in this chapter. The finding of a minor focus of infection, such as upper respiratory infection, otitis media, pharyngitis, or gastroenteritis, does not exclude the possibility of bacteremia or SBI.

The clinical presentation of the patient at risk for OB includes age 3 to 36 months, rectal temperature of 39°C or higher, a well appearance, and either no other signs of infection or signs of minor focal infection only. However, only 3 percent of patients with these findings will have a positive blood culture. A well-appearing child with a rectal temperature less than 39°C is extremely unlikely to be bacteremic. By definition, it is impossible to distinguish children with OB from those without bacteremia by clinical features alone.[21]

Diagnosis

Because of the relatively greater risk for bacteremic illness and lack of sensitivity of the clinical examination, the febrile or ill-appearing neonate, regardless of temperature, should be comprehensively evaluated for SBI via a *sepsis workup*. This should include complete blood count, urinalysis, cerebrospinal fluid (CSF) cell count, Gram stain, evaluation of protein and glucose levels, and culture and sensitivities of the urine (suprapubic or catheterized), blood, and CSF. Respiratory symptoms or signs are indications for chest x-ray. The differential diagnosis for septic-appearing neonates includes congenital cardiac disease, metabolic disease, nonaccidental trauma, and bowel obstruction.

Infants 30 to 90 days of age are optimally evaluated via a *low-risk* versus *high-risk* stratification that combines both clinical and routine laboratory assessments[22] (Table 118-3). Low-risk infants are those who were born at full term, have no underlying medical problems, and have not previously been treated with antibiotics. On physical examination, these young infants must have a well appearance with no identified focus of possible bacterial infection to specifically include otitis media, skin, soft tissue, joint, or bone infection. To be considered low risk, these young infants must additionally have negative laboratory screening tests. These are defined as white blood count of 5000 to 15,000/μL with less than 1500 bands/μL, urinalysis revealing less than 10 white blood cells per high-power field (WBCs/hpf) and negative for leukocyte esterase and nitrite, and, when diarrhea is present, stool smear with less than 5 WBCs/hpf. Cultures of the blood and urine (suprapubic or catheterized) should be performed. Stool should be cultured if diarrhea is bloody or WBCs are present as above. A chest x-ray is indicated only if there are significant respiratory findings such as severe cough, tachypnea, grunting respirations, or rales.[23] Lumbar puncture should be performed routinely in febrile infants less than 60 days of age and strongly considered for those 60 to 90 days because of limited sensitivity of the clinical assessment at these ages for the detection of meningitis. Febrile infants aged 30 to 90 days who meet low-risk criteria have less than a 1 percent risk of bacteremia and less than a 2 percent risk of SBI. In contrast, young infants categorized as high risk are reported to have a 2 to 10 percent risk of bacteremia and 10 to 15 percent risk of SBI, with ill appearance weighing heavily toward the higher respective risks.[24] Infants 30 to 90 days of age considered high risk by either clinical or laboratory parameters should have a complete evaluation for sepsis as for neonates.

History
• Full term
• No underlying medical problems
• No prior antibiotics

Physical examination
• "Well appearance"
• No focus of infection (otitis, skin, soft tissue, bone, or joint)

Laboratory
• WBC 5000–10,000/μL with < 1500 bands/μL
• Urinalysis < 10 WBCs/hpf, negative for leukocyte esterase, nitrite
• Stool smear < 5 WBCs/hpf (if diarrhea present)
• Normal chest x-ray (if clinically indicated)

Follow-up
• Reliable parents
• Home telephone and transportation

TABLE 118-3 Low-Risk Criteria for Febrile Infants 30–90 Days of Age

The laboratory assessment of children 3 to 36 months of age and older should be individualized based on the overall appearance of the child, clues from the history and physical examination, and a knowledge of the incidence of bacteremia and SBI in this age group. Most importantly, *an ill-appearing febrile child, regardless of age, should be stabilized and comprehensively evaluated for sepsis* as just described. In contrast, *a well-appearing febrile infant should have laboratory evaluation based on clinically identified risk factors for SBI with bacteremia.* The reader is referred to subsequent chapters for a discussion of the laboratory evaluation for specific focal bacterial infections in children. Blood culture is of limited utility in the outpatient management of radiographically identified pneumonia but should be considered in those patients ill enough to warrant admission.[4] Similarly, blood cultures are indicated in febrile children aged 6 months or less who have UTI or those with clinical features of pyelonephritis indicating admission.[5] Blood cultures are also appropriate for febrile pediatric patients with presumed bacterial enteritis, facial cellulitis, septic arthritis, and osteomyelitis. All febrile patients who are immune-compromised, such as with sickle cell anemia and HIV, should also have blood cultures obtained (Table 118-4). The identification of a clearly recognizable viral syndrome such as bronchiolitis renders the yield of laboratory testing for bacteremic disease negligible.[25]

- Unexplained ill appearance, regardless of age or fever
- Febrile neonates
- "High-risk" febrile infants aged 30–90 days
- Meningitis
- Pneumonia (requiring admission)
- Pyelonephritis (age ≤ 6 months or febrile requiring admission)
- Bacterial enteritis (age < 2 years)
- Facial cellulitis
- Septic arthritis
- Osteomyelitis
- Underlying immune deficiency with fever

TABLE 118-4   Indications for Blood Cultures in Children

The complete blood count is a nonspecific test that may assist in the identification of bacteremia and SBI but is not diagnostic and must be interpreted in the clinical context. Although the incidence of bacteremia rises with white blood counts of 10,000/μL or more, there is no threshold value of the white blood count (WBC) that distinguishes between bacteremic and nonbacteremic patients or identifies patients with SBI with adequate sensitivity and specificity. A WBC of 5000/μL or less in ill-appearing infants is suggestive of overwhelming bacterial sepsis but in well-appearing infants suggests benign viral illness with transient bone marrow suppression. The choice of a threshold of WBC of 15,000/μL or more for obtaining a blood culture in the setting of a well-appearing child with temperature of 39°C or higher and no or minor focus of infection will identify only 65 percent of those with OB. Moreover, only 7.5 percent of such children who meet these clinical criteria will prove to be bacteremic. Decreasing the WBC threshold for obtaining a blood culture to improve sensitivity markedly decreases the specificity and predictive value of the test.[26] Other available screening tests, such as absolute band count, erythrocyte sedimentation rate, and C-reactive protein, have failed to provide significantly greater sensitivity or specificity. Although the blood culture is the "gold standard" for the identification of bacteremia, its result cannot be predicted by a screening test with any degree of confidence at the time of initial ED evaluation. *The pursuit of OB should not distract emergency physicians from carefully evaluating febrile infants for focal serious bacterial infections, including UTI, pneumonia, meningitis, and soft tissue, bone, or joint infection.*

Treatment

EMERGENCY   The treatment plan for febrile infants, like the diagnostic evaluation, must be stratified by patient age and directed toward the age-related and organ system–specific probable pathogens (Fig. 118-1 and Fig. 118-2 and Table 118-5). Febrile neonates, after being fully evaluated for sepsis as described above, should be stabilized with supportive care and treated with broad-spectrum intravenous antibiotics to cover group B *streptococcus, E. coli, Listeria monocytogenes,* and *Enterococcus* sp. pending culture results. Optimal therapy includes ampicillin 100 mg/kg and either cefotaxime or ceftriaxone 50 mg/kg IV, with initial doses given in the ED prior to admission. Young infants aged 30 to 90 days considered to be high risk for SBI based on the foregoing clinical or laboratory parameters should be similarly evaluated for sepsis and treated with ampicillin and either cefotaxime or ceftriaxone to cover both neonatal and community-acquired pathogens. Young infants aged 30 to 90 days considered low risk for SBI based on clinical and laboratory parameters may be reasonably managed as outpatients in two ways if follow-up is feasible based on physician judgment of parental reliability and availability of a home telephone and source of transportation. The more traditional and conservative approach is to perform a lumbar puncture on all such young infants to exclude bacterial and aseptic meningitis definitively and treat with ceftriaxone 50 mg/kg IM prior to discharge.[27] Alternatively, it has been shown that well-appearing infants in this age group considered low risk may be safely managed with selective lumbar puncture and without antibiotics, providing strict adherence to clinical, laboratory, and follow-up criteria is maintained.[28]
FIG. 118-1. Management scheme for febrile infants aged 0 to 90 days. *Abbreviations:* ED, emergency department.

FIG. 118-2. Management scheme for febrile infants aged 3 months or older. *Abbreviations:* ED, emergency department; HIB, *Haemophilus influenzae* type b.

Age Group	Bacteremia/Sepsis	Meningitis
Neonates	Ampicillin 100 mg/kg plus Cefotaxime 50 mg/kg or Ceftriaxone 50 mg/kg	Ampicillin 100 mg/kg plus Cefotaxime 50 mg/kg
Young infants 30–90 days	Ampicillin 100 mg/kg plus Cefotaxime 50 mg/kg or Ceftriaxone 50 mg/kg‡	Ampicillin 100 mg/kg plus Cefotaxime 100 mg/kg plus vancomycin 15 mg/kg† or Ceftriaxone 100 mg/kg plus vancomycin 15 mg/kg†
Older children	Cefotaxime 50 mg/kg or Ceftriaxone 50 mg/kg‡ plus consider Vancomycin 15 mg/kg†	Cefotaxime 100 mg/kg plus vancomycin 15 mg/kg† or Ceftriaxone 100 mg/kg plus vancomycin 15 mg/kg†

*All doses are IV unless specified otherwise.
†Vancomycin indicated only in suspected bacterial meningitis or sepsis with critical illness.
‡Preferred for outpatient treatment of occult bacteremia and serious bacterial disease due to long half-life; may be given IM.

TABLE 118-5   Antibiotic Dosages for Bacteremia and Meningitis*

The treatment of febrile infants 3 to 36 months of age remains a subject of considerable controversy. As for all infants, *an ill-appearing febrile child should be stabilized with supportive care and fully evaluated for sepsis, and broad-spectrum intravenous antibiotics such as cefotaxime or ceftriaxone should be administered in the ED*. Fortunately, most penicillin- and cephalosporin-resistant strains of *S. pneumoniae* demonstrate only intermediate resistance at this time and may be adequately treated with a third-generation cephalosporin. Treatment of focal SBI presumptively identified by diagnostic testing in the ED depends on the likely pathogens and is reviewed in subsequent chapters. Treatment of meningitis is reviewed later in this chapter. The optimal treatment for children at risk for OB has not been established. Published observational retrospective studies,[29,30] prospective randomized trials,[7,31] and meta-analyses of pertinent prior studies[12,33,34] have concluded that expectant antibiotic treatment of patients at risk for OB resulted in a shorter duration of fever and a lower rate of subsequent focal SBI. However, no study has shown that oral antibiotics alter the rate of subsequent development of meningitis.[8,12,30] Initial therapy for pediatric patients at risk for OB with ceftriaxone 50 mg/kg IM has been recommended because of a reported significant reduction in the incidence of subsequent culture-positive meningitis compared with oral antibiotics or observation without therapy.[7,12] However, critical reviews of these studies have revealed significant methodologic flaws that seriously undermine the conclusion that antibiotic therapy prevents subsequent SBI, in particular the failure to include partially treated meningitis as an adverse outcome. [33,34] At the present time, there is no standard of care for the treatment of well-appearing febrile children 3 to 36 months of age who are at risk for OB. [35] Reasonable approaches include (1) blood culture if WBC is 15,000 or greater, followed by ceftriaxone 50 mg/kg IM, and (2) no blood culture and antibiotic therapy only for clinically identified infection, e.g., otitis media, in either case with follow-up within 24 h. If antibiotic treatment for OB is chosen, *emergency physicians should be wary of both the efficacy of antibiotic treatment in preventing focal SBI and the potential for delayed diagnosis for partially treated infection with altered presentation*, e.g., UTI or meningitis.[36]

OUTPATIENT   Follow-up within 24 h and clear instructions regarding indications for early return are the cornerstones of management of well-appearing febrile infants 3 to 36 months of age. Young infants 30 to 90 days of age may be similarly managed as outpatients if all low-risk criteria have been met. Communication with a patient's primary physician to facilitate such follow-up represents optimal management. In the absence of a primary physician, consideration should be given to performing such follow-up in the ED. The parents should be educated regarding the effective use of antipyretics and instructed to return with the child to the ED immediately for symptoms of ill appearance suggestive of SBI. Patients who return to the ED with the report of a positive blood culture for *S. pneumoniae* who are afebrile and well appearing on follow-up may be managed as outpatients with repeat blood culture, oral antibiotic therapy, and follow-up in 24 h.

ADMISSION   All febrile neonates and ill-appearing infants should be admitted for observation and parenteral antibiotic treatment pending culture results. Young infants aged 30 to 90 days who fail to meet low-risk criteria should also be admitted and treated. Infants 3 months of age or older who return to the ED with either (1) a report of any gram-negative organism on blood culture or (2) persistent fever or ill appearance with a report of positive blood culture for *S. pneumoniae* should have a complete evaluation for sepsis, parenteral antibiotic therapy in the ED, and admission for continued treatment.

SEPSIS

Pathophysiology

Sepsis is a clinical syndrome defined by bacteremia with clinical evidence of invasive, systemic infection that can progress with variable rapidity to circulatory failure. Sepsis can occur in isolation or with focal bacterial disease such as meningitis. The pathophysiology of sepsis is related to (1) colonization with a bacterial pathogen, usually nasopharyngeal, (2) invasion of the blood by encapsulated organisms and release of inflammatory mediators, and (3) host defense-response failure. This process results in systemic manifestations that are clinically detectable. Circulatory consequences may include alteration in systemic vascular tone and decreased myocardial contractility. Neurologic effects include decreased cerebral perfusion pressure and abnormal temperature homeostasis. Sepsis may also result in a microvascular angiopathy and disseminated intravascular coagulopathy involving the kidneys, lungs, skin, and central nervous system.

Host defense risk factors for sepsis include impaired splenic function (e.g., congenital absence, surgical removal, or functional impairment in sickle hemoglobinopathy) and congenital metabolic disease (e.g., galactosemia), as well as the more rare primary or acquired humoral and cellular immunodeficiency states. The presence of an indwelling foreign body or obstruction to drainage of a body cavity represents additional risk factors.

The likely pathogens for sepsis demonstrate an age-related distribution. In the first month of life, group B *Streptococcus* and *E. coli* dominate and are capable of causing an explosive sepsis syndrome that may increasingly be recognized in the ED with the trend to early newborn discharge. The risk presented by these organisms falls dramatically by the third month of life. In infancy and early childhood, HIB and *N. meningitidis* predominate as pathogens for sepsis, although the incidence of HIB disease has fallen markedly since the introduction of the HIB vaccine. *Streptococcus pneumoniae* is more likely to cause focal disease but may also result in sepsis syndrome, particularly with sickle cell disease and other causes of asplenia. In school-age children, *N. meningitidis* predominates as the cause of sepsis, but group A b-hemolytic *Streptococcus* has increasingly been implicated. Rocky Mountain spotted fever, caused by *Rickettsia rickettsi* and acquired following tick bite in endemic areas of the United States, must not be overlooked as possible cause of sepsis in the summer and fall seasons.

Clinical Features

The sepsis syndrome may present with either a subtle or obvious, rapidly progressive clinical picture. Neurologic symptoms most frequently include altered mental status with irritability, confusion, or lethargy. Poor feeding, lack of spontaneous motor activity, and hypotonia are common findings. Hyperpyrexia, defined as a rectal temperature higher than 41.1°C, may occur, although this is not specific for sepsis. Hypothermia may occur, particularly in infants under 3 months of age, and is a grave finding. Tachypnea and retractions may reflect hypoxia or the development of metabolic acidosis. Early septic shock is accompanied by subtle findings of resting tachycardia, widened pulse pressure, warm distal extremities, and brisk capillary refill. Subsequently, classic signs of hemodynamic compensation occur, including weak distal pulses, delayed capillary refill, and cool extremities. Ultimately, these are followed by signs of decompensation with decreased sensorium and hypotension. Cutaneous findings may include petechiae, which may progress to coalescent purpura over hours to days.

Diagnosis

Sepsis represents a *clinical* diagnosis of exclusion in the ED, pending the results of cultures and treatment, because of the potential for rapid progression of disease. Obvious septic shock rarely presents a problem of diagnosis but rather of management. In more subtle cases, the combination of altered mental status and abnormal vital signs should suggest to the emergency physician the possibility of sepsis. Because of the characteristically nonspecific presentation, febrile or ill-appearing neonates should be considered septic until proven otherwise. No laboratory test is diagnostic, although a WBC greater than 20,000/μL is supportive of bacterial sepsis. However, the presence of a WBC in the "normal" range in the setting of an ill-appearing child is not reassuring. A WBC less than 5000/μL or platelet count less than 150,000/μL is a grave prognostic sign, particularly for disease due to *N. meningitidis*. Cultures of the blood, urine, CSF, and diarrheal stool, if present, should be obtained to identify a primary focus of infection and guide future therapy. Gram-stained smears made from CSF and petechial scrapings may provide immediate diagnostic information regarding the identity of the organism.

The differential diagnosis for a "septic-appearing" child includes infectious, cardiac, metabolic, and traumatic disease. Major focal bacterial infections, such as meningitis and pericarditis, and systemic viral disease may present with findings of fever, altered mental status, and cardiorespiratory compromise. Young infants with

congenital heart disease or viral myocarditis may present in cardiogenic shock with respiratory distress and signs of poor perfusion. Toxic ingestion and congenital metabolic disease may present with altered mental status as the major complaint. Finally, child abuse with head or abdominal injury may present with altered mental status, temperature instability, and signs of poor perfusion without historical or cutaneous evidence of trauma.

Treatment

EMERGENCY   Stabilization must take priority over completion of the diagnostic workup. Restoration of oxygenation and perfusion are the first priorities in the initial management of sepsis. An ill-appearing child should be provided high-flow oxygen and monitoring of heart rate, respirations, and blood pressure, and oxygen saturation should be initiated. Attention to airway patency should continue throughout the assessment, with particular emphasis during procedures such as lumbar puncture. Secure vascular access should be obtained early and, in the setting of signs of poor perfusion, fluid resuscitation performed with 20 mL/kg boluses of normal saline with serial reassessments. In such cases, an indwelling Foley catheter should be placed to ensure adequate response to fluid resuscitation by establishment of urine output of 1 to 2 mL/kg/h. In young infants in particular, hypoglycemia should be identified early by bedside testing and corrected with intravenous 25% dextrose (D25 or 25 gm/100 mL) 0.5-g/kg bolus(es). Endotracheal intubation and mechanical ventilation are indicated if a patient is judged to have advanced respiratory or circulatory failure and neurologic compromise with potential for loss of airway control. Intubation should also be considered for septic-appearing patients who require interhospital transport. If serial fluid bolus therapy does not restore evidence of adequate perfusion, inotropic support with dopamine in the setting of normal blood pressure or epinephrine in hypotensive states is indicated.

The diagnostic evaluation of septic-appearing infants in the ED should include cultures of the blood, urine, and CSF. Diarrheal stool should be stained for white blood cells and cultured, if present. A complete blood count, electrolyte panel, and determination of blood glucose level are routinely indicated. A chest x-ray and arterial blood-gas measurement are indicated for signs of respiratory distress or critical illness. Liver functions, coagulation studies, and fibrin split product analysis should be considered for critically ill children.

Antibiotic therapy should initiated in the ED as soon as possible and should not be withheld pending lumbar puncture if the patient is unstable. Antibiotic selection is made according to the likely age-related pathogens (Table 118-5). In the first 2 months of life, ampicillin 100 mg/kg and either cefotaxime or ceftriaxone 50 mg/kg IV are indicated. Adequate initial therapy for children 3 months and older is cefotaxime or ceftriaxone 50 mg/kg IV. Because of the widespread emergence of penicillin- and cephalosporin-resistant strains of *S. pneumoniae*, vancomycin 15 mg/kg IV should be considered as part of initial therapy for critically ill, septic children, particularly in the setting of an underlying immune deficiency state. [37] In endemic areas during the summer and early fall, chloramphenicol 25 mg/kg IV should be considered for children with possible Rocky Mountain spotted fever. Care must be taken to monitor patients following antibiotic administration for abrupt vascular collapse due to acute bacterial lysis with release of endotoxins.

ADMISSION   All children with suspicion for bacterial sepsis should be admitted for monitoring and treatment pending culture results. Disposition decision making for a possibly septic child must specifically include choice of the appropriate pediatric inpatient unit. A child with limited suspicion for sepsis who is alert and requires no cardiorespiratory stabilization in the ED may be admitted to a pediatric floor unit for antibiotic therapy pending culture results. A child with evidence of cardiorespiratory or neurologic compromise requiring stabilization in the ED should be admitted to a pediatric intensive care unit (PICU) because of the risk of progression of disease. If interhospital transfer to a PICU is necessary, a pediatric transport team should be utilized.

MENINGITIS

Pathophysiology

In most cases, meningitis occurs as a complication of a primary bacteremia. The inflammatory response to the products of bacterial multiplication may result in alteration of the permeability of the blood-brain barrier with extension of infection and inflammation to the brain itself. The resulting brain edema, increased intracranial pressure, decreased cerebral blood flow, and vascular thrombosis produce neuronal injury. Less commonly, meningitis occurs via the hematogenous route from a distant primary focal infection, direct extension from adjacent infection, or following head injury with cribriform plate fracture. The incidence of meningitis is highest between the ages of birth and 2 years, with age-related peak risks during the neonatal period and between 3 and 8 months. Host defense factors resulting in impaired splenic function or immunodeficiency are associated with increased risk for sepsis and meningitis.

The pathogenic organisms responsible for bacterial meningitis parallel those responsible for sepsis. In the neonatal period, group B *Streptococcus* and *E. coli* predominate. In older infants and children, *S. pneumoniae* and *N. meningitidis* are the likely pathogens. Although penicillin-resistant strains of *S. pneumoniae* are increasing in frequency, there is no evidence that these organisms are more virulent. [36] Infants and children who have not received the HIB vaccine continue to be at risk for HIB meningitis.

Clinical Features

Because the presenting symptoms are subtle and overlap with those of less serious infection, a high index of suspicion for meningitis is crucial. Two modes of presentation are seen. The most frequently encountered pattern is an insidious progression of a febrile illness over several days. Less commonly, a fulminant progression to septic shock and meningitis may occur over hours, most commonly caused by *N. meningitidis.*

Symptoms and signs of bacterial meningitis depend on patient age and duration of illness. No single complaint or physical finding is specific. However, the findings of *fever associated with altered mental status constitutes a reasonable basis for suspicion for meningitis.* Infants typically present with nonspecific symptoms including decreased responsiveness, poor feeding, and vomiting. Although common, fever is not universally present at the time of diagnosis. Signs of "paradoxical irritability" despite parental comforting attempts; decreased responsiveness to visual, verbal, and painful stimuli; hypotonia; bulging fontanelle; or respiratory distress may be seen. Older children will usually complain of headache, photophobia, nausea, and vomiting. As for infants, signs of lethargy and confusion are primary indicators for suspicion of meningitis, and fever may not be consistently present. Nuchal rigidity and the classic findings of the Kernig sign (neck pain elicited with passive knee extension) and Brudzinski sign (involuntary lower extremity flexion elicited with passive neck flexion) are helpful only if positive. Seizures occur early in the course of 25 percent of patients with bacterial meningitis and are typically initially generalized but may be focal. [38] Focal neurologic findings, focal or prolonged seizures, and presentation with obtundation or coma suggest an adverse outcome. Pretreatment with oral antibiotics is associated with an altered presentation characterized by less consistent findings of fever or altered level of consciousness and longer duration of symptoms before diagnosis. [36]

Diagnosis

On the basis of reasonable clinical suspicion, a lumbar puncture must be performed to make or exclude the diagnosis of meningitis. The WBC is not an adequate screen for meningitis. In the absence of fever, a computed tomography (CT) scan of the brain may be necessary to exclude intracranial mass lesion prior to lumbar puncture. If meningitis is strongly suspected, the CT scan should not delay antibiotic therapy. CSF should be obtained for culture and sensitivity, protein and glucose levels should be determined, and cell count and Gram stain should be rapidly performed. CSF leukocytosis with a predominance of polymorphonucleocytes, CSF protein level greater than 100 mg/mL, and CSF glucose level less than 50 percent of blood glucose level are considered positive screening test results for bacterial meningitis. The Gram stain has a 70 percent sensitivity for preliminary identification of the offending organism and should be reported to the emergency physician as soon as available. Because of the emergence of penicillin-resistant strains of *S. pneumoniae*, it is prudent to perform CSF latex agglutination for specific bacterial antigens on all patients with abnormal CSF to facilitate early identification of high-risk patients. If prior treatment with antibiotics has occurred, the emergency physician should have a lower threshold for performing a lumbar puncture, and rapid antigen techniques are routinely indicated as these are often essential to diagnosis.[39] A bedside blood glucose level, complete blood count, electrolyte panel, and cultures of blood and urine should be obtained before performing the lumbar puncture. Indications for deferring lumbar puncture in the ED include cardiorespiratory compromise or risk of increased intracranial pressure. In such cases, antibiotic therapy should be given in the ED and lumbar puncture performed as soon as possible in the inpatient setting.

The differential diagnosis for bacterial meningitis includes the same spectrum of systemic disease as described for sepsis. Aseptic meningitis refers to evidence of meningeal inflammation with negative CSF cultures and is far more common than bacterial meningitis. Most frequently, this is due to viral meningeal infection, but other causes such as tuberculosis or syphilis should be considered. Parameningeal infection or brain abscess may rarely mimic the presentation and laboratory features of meningitis. Central nervous system (CNS) mass lesion, nonaccidental head injury, and toxic drug ingestion should also be considered in afebrile patients.

Treatment

EMERGENCY   As for clinically septic children, treatment for meningitis begins with stabilization of oxygenation, ventilation, and perfusion parameters. Provision of supplemental oxygen and monitoring of heart rate and oxygen saturation during and following lumbar puncture are appropriate with careful attention to prevention of airway compromise.[40] Children with meningitis are often septic and may require vigorous initial isotonic fluid bolus therapy to restore systemic and CNS perfusion. However, subsequent fluid should be provided at a maintenance rate to minimize brain edema. Neurologic complications are frequent and must be treated aggressively to prevent secondary CNS injury. Seizures are treated with lorazepam 0.1 mg/kg IV and, if necessary, phenytoin 15 mg/kg or phenobarbital 10 mg/kg IV, along with correction of hypoglycemia or other underlying metabolic disorder. Severe respiratory distress and decreasing mental status with risk of loss of control of airway protective reflexes should prompt elective endotracheal intubation. Suspicion for increased intracranial pressure is a sufficient indication for hyperventilation and, if hemodynamic stability permits, mannitol 1 g/kg IV.

Empirical antibiotic therapy for the likely age-related pathogens should be initiated as soon as possible in the ED. Recommended antibiotic dosages are higher with meningitis because of poor drug penetration across the blood-brain barrier and concern for the possibility of antibiotic resistance. In the first 3 months of life, ampicillin 200 mg/kg and cefotaxime or ceftriaxone 100 mg/kg IV are indicated. Children 3 months of age and older should receive cefotaxime or ceftriaxone 100 mg/kg (maximum, 2 g) IV (see Table 118-5). Due to the widespread emergence of penicillin- and cephalosporin-resistant strains of S. pneumoniae, vancomycin 15 mg/kg IV should also be routinely administered as initial therapy to children older than 1 month who have presumed bacterial meningitis. [37,41]

Steroid therapy has been shown to decrease the incidence of neurologic complications significantly in bacterial meningitis due to HIB if given before or at the time of initial antibiotic therapy. However, this benefit has not been demonstrated for meningitis due to S. pneumoniae or N. meningitidis, and steroid therapy may actually worsen neurologic sequalae.[37] Current guidelines are to consider steroid therapy in cases of suspected bacterial meningitis, specifically administering dexamethasone 0.15 mg/kg IV either before or immediately after the initial antibiotic dose to children 1 month of age or older. [37]

Prophylaxis of contacts to eliminate carriage of organisms from the upper respiratory tract is indicated following identification of an index case of meningitis caused by organisms capable of causing epidemic disease. For HIB disease, a regimen of rifampin 20 mg/kg (maximum, 600 mg) once per day for 4 days is indicated for (1) household members if there is a home contact aged less than 4 years and (2) day-care center staff and enrollees resembling households, defined as children less than 2 years of age with contact of 25 h per week or more. For N. meningitidis disease, a regimen of rifampin 10 mg/kg (maximum, 600 mg) twice per day for 2 days is indicated for all household members, day-care center contacts, and medical personnel who have had direct physical exposure to the index case prior to antibiotic therapy. There is no indication or effective prophylaxis for S. pneumoniae disease.

ADMISSION   All pediatric patients with identified or presumed meningitis should be admitted for supportive care, monitoring for complications, and antibiotic therapy. As for sepsis, the disposition decision for children with meningitis must also include choice of the appropriate pediatric inpatient unit. Stable patients may be admitted to a monitored isolation bed on a pediatric floor unit for antibiotic therapy pending culture results. Children with evidence of cardiorespiratory or neurologic compromise should be admitted to a PICU because of the risk of progression of disease. If transfer of such a patient is necessary, a pediatric transport team should be utilized for referral to a tertiary care center.

119 VIRAL AND BACTERIAL PNEUMONIA IN CHILDREN

Kathleen Brown
Thomas E. Terndrup

EPIDEMIOLOGY

Pneumonia is defined pathologically as an inflammation of lower tract lung tissue. Clinically, pneumonia is defined by the presence of pulmonary infiltrates on a chest radiograph, usually associated with a combination of clinical signs, such as cough, fever, chest pain, tachypnea, and a variety of abnormal auscultatory findings. Most commonly, pneumonia is caused by an infectious agent, although aspiration of irritants and interstitial inflammation are also referred to as such.

Pneumonia develops more often in early childhood than at any other age. The incidence of pneumonia in children decreases as a function of age. In North America it has been estimated at 40 per 1000 in preschool children and approximately 9 per 1000 in 10-year-olds. [1,2] Infectious causes often display seasonal variation. Parainfluenza occurs predominantly in the fall, respiratory syncytial virus (RSV) in the winter, and influenza in the spring. Bacterial pneumonia is more common in the winter, when indoor crowding promotes respiratory transmission of microbes. Several risk factors increase the incidence or severity of pneumonia: prematurity, malnutrition, low socioeconomic status, passive exposure to smoke, and attendance at day-care centers. The mortality rate of childhood pneumonia is less than 1 percent in industrialized nations, but pneumonia accounts for up to 5 million deaths annually in children less than 5 years of age in developing countries. [3]

PATHOPHYSIOLOGY

The majority of pneumonias are acquired through aspiration of infective particles into the lower respiratory tract. There are a number of protective mechanisms preventing infection with aerosolized infective particles. Aerosolized particles are filtered in the nasal cavities or entrapped and cleared by the normal mucus and ciliated epithelium of the upper respiratory tract. Aspiration is further prevented by laryngeal reflexes and coughing. In the lower respiratory tract, alveolar macrophages and various immune mechanisms prevent further invasion by infectious agents. These defense mechanisms include the ingestion and killing of bacteria by macrophages, the activation of complement and antibodies that neutralize bacteria, and the transportation of particles from the lung by lymphatic drainage. Abnormalities in any of these protective mechanisms predispose patients to acquired pneumonia. Anatomic abnormalities of the respiratory tract, immune deficiencies, neuromuscular weakness, airway abnormalities that predispose the child to aspiration, and alterations in the quantity or quality of mucus secretion (e.g., cystic fibrosis). Passively acquired maternal antibodies may further prevent respiratory tract infection by pneumococcal and *Haemophilus influenzae* infections.

Suppression of the normal respiratory physiologic and anatomic defenses may occur secondary to a preceding viral infection of the upper respiratory tract. Coexistence of viral and bacterial pathogens in children has been demonstrated in 50 percent or more of cases. [4,5] Bacteria that cause pneumonia include many of the same organisms that colonize the child's upper airway. In addition, organisms that are transmitted person-to-person by airborne droplet spread may cause pneumonia. Less commonly, bacterial and certain viral (e.g., herpes simplex virus, varicella, rubella, rubeola, and Epstein-Barr virus) microbes may cause pneumonia through hematogenous or contiguous spread.

Parenchymal invasion by bacteria results in an acute inflammatory response that includes exudation of fluid; deposition of fibrin; and infiltration of the alveoli with fluids, polymorphonuclear leukocytes, and, soon, macrophages. Accumulation of excess alveolar fluid creates the characteristic consolidation seen on chest radiograms. Viral agents, mycoplasma, and chlamydia typically cause inflammation characterized by a predominately mononuclear infiltrate involving submucosal and interstitial tissues.

Etiology

The specific etiologic agent of pneumonia cannot be identified in up to 40 to 60 percent of patients. [4,5,6,7,8,9 and 10] The predominant pathogens that cause pneumonia in pediatric patients are a function of the patient's age, the presence of underlying disease, the vaccination status, and attendance in day care. Since clustering of cases of pneumonia due to a particular microbe are common, it is helpful to be aware of recent local outbreaks. When an etiologic agent is identified, the best predictor of the agent is age. The most common etiologic agents causing pneumonia according to age groups are illustrated in Table 119-1 and discussed below.

TABLE 119-1   Common Causes of Pneumonia

NEWBORNS: BIRTH TO 1 MONTH   The newborn age group is the only developmental period when bacterial infections are more common than viral agents as the leading cause of pneumonia. The majority of infections in this age group are caused by aspiration of the maternal genital organisms present during labor and delivery. The predominant pathogen is group B streptococcus, followed by *Escherichia coli, Klebsiella* species, and other gram-negative enteric bacilli from the Enterobacteriaceae family. Other, less commonly encountered organisms include nontypeable *H. influenzae,* other streptococci (group A and a-hemolytic species), enterococci, *Listeria monocytogenes,* Bordetella pertussis, and anaerobic bacteria. [11]

INFANTS: 1 TO 24 MONTHS   During the first 2 years of life, viruses are the most common etiologic agent of pneumonia. RSV, parainfluenzavirus, influenzavirus, and adenovirus account for most lower respiratory tract infections, including pneumonia, in this age group. [1,2,4,7] There are at least 14 other viral agents isolated in children with pneumonia, which include rhinoviruses, enteroviruses, coronavirus, measles, varicella, rubella, herpes simplex virus, and Epstein-Barr virus. [7,8,12] Bacterial pneumonia due to *Streptococcus pneumoniae, Streptococcus pyogenes, Staphylococcus aureus,* and *H. influenzae* should be considered in infants and toddlers who

are severely ill, have rapid onset and progression of symptoms, or have lobar or diffuse infiltrates, large effusions, or abscesses on radiograph. [13]

Very young infants (1 to 3 months) may present with what is often referred to as afebrile pneumonitis, or atypical pneumonia. This syndrome is typified by cough, tachypnea, and sometimes progressive respiratory distress in the absence of fever. Apneic episodes can occur with RSV, chlamydia, and pertussis. There is often radiographic evidence of bilateral diffuse pulmonic infiltrates with air trapping. The viruses listed above are the most common etiologic agents. [14] *Chlamydia trachomatis* is also often identified in this scenario. [10,14] *Ureaplasma urealyticum, Mycoplasma hominis, Pneumocystis carinii,* and *B. pertussis* have also been implicated in this syndrome, but the extent of their role is not as well defined. [10,15]

PRESCHOOL: 2 TO 5 YEARS   As age increases, the overall incidence of pneumonia decreases, but the relative frequency of bacterial pathogens, particularly *S. pneumoniae,* as etiologic agents increases. Despite this, respiratory viruses, particularly influenzavirus A and B and adenovirus, remain the most common cause of pneumonia in this age group. The most common bacterial pathogen encountered is *S. pneumoniae.* In the recent past, *H. influenzae* type B (HIB) was encountered nearly as frequently; however, since implementation of widespread immunization against this agent, its incidence as an agent of invasive disease is thought to be much less.[16,17] However, non-type-B *H. influenzae* (NTHI), which is not protected against by the vaccine, may be an increasingly common agent of bacterial pneumonia.[18] Other bacteria that are isolated less commonly include of *S. aureus,* group A streptococcus, and *Moraxella catarrhalis.*[1,4,7] *Mycoplasma pneumoniae* has been found more frequently in this age group in recent studies. [19,20]

SCHOOL AGE AND ADOLESCENCE   Once children reach school age, *M. pneumoniae* is the most frequent bacterial cause of pneumonia. [1,20,21] The peak incidence is between 10 and 15 years of age.[22] *Streptococcus pneumoniae* also remains a common pathogen in this age group.[1] *Chlamydia pneumoniae* is estimated to be the cause of up to 19 percent of pneumonias in school-aged and adolescent patients. [9,10,19,20] These infections are usually mild or asymptomatic. [20] *Staphylococcus aureus* pneumonia can occur at any age but tends to be most frequent in older children.[23] Respiratory viruses, especially adenovirus, can also cause pneumonia in this age group.

ALL AGES: SPECIAL CONSIDERATIONS   The most common etiologic agents causing severe pneumonia (requiring admission to an intensive care unit) in all age groups beyond the neonatal period include *S. pneumoniae, S. aureus,* group A streptococcus, HIB, adenovirus, and *M. pneumoniae. Staphylococcus aureus* is notorious for causing rapidly progressive disease, often with pulmonic abscesses. A resurgence of virulent group A streptococci has been associated with sporadic cases of invasive disease, including necrotizing fasciitis with pneumonia and empyema in children. [24] Increased severity of *M. pneumoniae* infections in children with sickle cell disease has been described.

Gram-negative bacilli, including *Pseudomonas,* should be considered in patients who have recently been hospitalized. Anaerobic infections should be considered in children with neurologic or anatomic defects that predispose them to aspiration. Unusual causes of bacterial pneumonia in children include *Mycobacterium tuberculosis, Legionella pneumophila, Chlamydia psittaci, Francisella tularensis,* and rickettsial infections. Children with progressive or unresponsive pneumonia should be evaluated for evidence of these microorganiams. An immunocompromised host is susceptible to all of the infections listed above as well as to opportunistic infections, such as *P. carinii,* cytomegalovirus, and fungal diseases.

CLINICAL FEATURES

Clinical findings in a child with pneumonia are highly variable and are dependent on the specific respiratory pathogen, age, the severity of the disease, and any underlying illnesses. Tachypnea is the most frequent sign of pneumonia in children and may be an otherwise isolated finding. The best physical examination finding for ruling out pneumonia in an infant or child is the absence of tachypnea. [25] However, tachypnea is a nonspecific symptom and may occur secondary to fever, anxiety, metabolic disease, cardiac disease, or other respiratory problems. Fever can increase an infant's respiratory rate by 10 breaths per minute for each degree centigrade of elevation.[26] Respiratory rates should be counted over 1 min. Several studies have shown that rates counted over less time tend to overestimate the rate. Generally accepted standards for tachypnea in an infant or child are shown in Table 119-2.[27]

Age, Months	Upper Limit of Normal Respiratory Rate, Breaths per Minute
<2	55
2–12	45
>12	35

TABLE 119-2   Standards for Tachypnea in Infants and Children

Auscultation of the lungs may reveal localized rales, wheezing, and decreased air entry in the affected area. However, auscultatory findings may not be reliable in children. When a group of pediatricians was asked to examine children with lower respiratory tract symptoms, there was only fair agreement about most auscultatory findings.[28] In younger children, decreased breath sounds, rather than rales, are often heard, since the involved areas tend to be ventilated poorly. Observable findings, such as respiratory rate and work of breathing, are more reliable. [25] Signs of increased work of breathing may include retractions, chest indrawing in infants, or paradoxical (seesaw) breathing. Grunting respirations are frequently present, particularly in infants with pneumonia. [29] Abdominal distention and pain may be present secondary to a paralytic ileus or diaphragmatic irritation in lower-lobe pneumonias. [30]

The clinical presentation may be suggestive of the etiologic agent. Two classic presentations have been described for pneumonia: typical pneumonia and atypical pneumonia. Typical pneumonia is characterized by abrupt onset of fever, chills, pleuritic chest pain, and productive cough. Associated physical examination findings include high-grade fever, localized findings on chest examination, and a toxic appearance. Atypical pneumonia is characterized by gradual onset (over days) of headache, malaise, nonproductive cough, and low-grade fever. Associated physical examination findings may include wheezing, prolonged expiration, rhinitis, conjunctivitis, pharyngitis, and rash. The typical pattern is generally thought to be associated with a bacterial pathogen, and the atypical pattern is thought to be more characteristic of a viral infection; however, significant overlap exists, and identification of a causal agent based on clinical presentation is not always reliable. [31]

Typical clinical presentations have been described for some specific pathogens. Pneumonia due to *S. aureus* is notorious for being particularly rapid in the progression of clinical findings. Patients with *B. pertussis* pneumonia typically develop prodromal symptoms, including mild cough, conjunctivitis, and coryza, that lasts 1 to 2 weeks. A severe, paroxysmal cough often associated with emesis and dehydration, because coughing prevents eating and drinking, is characteristic of the catarrhal phase of pertussis infections. The inspiratory whoop is generally present only in older children. A history of maternal pelvic or conjunctival chlamydial infection is present in up to 50 percent of cases in which the infant develops *C. trachomatis* pneumonia. An infant with a chlamydial infection is usually afebrile, has a distinct staccato cough (i.e., short, abrupt onset), and diffuse rales on auscultation. Such infants rarely appear systemically ill. Chlamydial pneumonia in adolescents is usually insidious in onset and often includes complaints of sore throat and dysphagia. Mycoplasmal infections generally present with the gradual onset of malaise, fever, and headache. A hacking, nonproductive cough usually begins 3 to 5 days after the onset of illness and is present in up to 98 percent of children. Mycoplasmal infection may produce pharyngitis, and rales are present in approximately 75 percent of patients. A variable rash, which may be papular, vesicular, urticarial, or erythema-multiforme-like, is present in about 10 percent of patients with *M. pneumoniae.*

The age of the patient may also affect the clinical presentation. Pneumonia often occurs in association with a sepsis syndrome in neonates. [11,22] Infants frequently lack the classic symptoms and present with a variety of nonspecific findings. Nonspecific symptoms and signs of pneumonia in infants include fever without a localizing source, apnea, poor feeding, abdominal pain, vomiting or diarrhea, hypothermia, grunting, bradycardia, lethargy, and shock. Sputum production is uncommon in

nontracheostomized children less than 8 years of age.

The severity of pneumonia may be judged by clinical features. More severe pneumonia is associated with deterioration of the patient's mental status, the use of accessory muscles, and the presence of retractions, nasal flaring, splinting, and cyanosis. Infants with poor feeding and lethargy may have more severe disease. A patient with a history of immunosuppressive therapy, a history of primary immune deficiencies, or a history suggestive of an immune deficiency may have more severe pneumonia, often caused by unusual pathogens. Children with underlying illnesses, such as congenital heart disease, chronic pulmonary disease, or sickle cell disease, are often more severely compromised by pneumonia.

DIAGNOSIS

Initially it is important to differentiate pneumonia from noninfectious pulmonary conditions, such as congestive heart failure, atelectasis, primary and metastatic tumors, and congenital abnormalities, such as pulmonary hypoplasia or congenital lobar emphysema. The wide variety of conditions that may simulate pneumonia include radiologic imaging problems (e.g., poor inspiration or a prominent thymus), recurrent or acute aspiration, atelectasis, tumors, collagen vascular disorders, allergic alveolitis, chronic pulmonary diseases (e.g., cystic fibrosis or asthma), and congenital abnormalities (e.g., pulmonary sequestration). A thorough history and physical examination usually help to exclude many of these conditions.

Radiographs

The chest radiograph is considered the pragmatic reference standard for making the diagnosis. [25] The finding of consolidation on radiograph is thought to be a reliable sign of pneumonia. [32]

Differentiating the various microbiologic causes of pneumonia is often more difficult. Typical patterns of clinical presentation and epidemiologic data on incidence have been described above but often overlap. Radiographically, viral pneumonias tend to appear as diffuse interstitial infiltrates, frequently with hyperinflation, peribronchial thickening, and areas of atelectasis. Bacterial pneumonias tend to have lobar or segmental consolidation. Pneumatocele formation and a combination of pneumothorax and empyema are highly suggestive of *S. aureus* infection. However, bacterial pneumonias with perihilar interstitial and nodular patterns on radiographs have been reported. [33,34] *Chlamydia trachomatis* infections usually lead to hyperexpansion and diffuse alveolar or perihilar interstitial infiltrates. Radiographic patterns in *M. pneumoniae* infections are variable. Lower-lobe streaky or patchy infiltrates are the most common, but many other patterns are possible, including lobar infiltrates in 10 to 25 percent of cases. Viral pneumonias can also cause lobar or segmental consolidations. [34] Several studies have looked at the accuracy of the chest radiograph in differentiating viral from bacterial disease. A recent review of these studies found sensitivities ranging from 42 to 80 percent and specificities of 42 to100 percent. [25]

Laboratory Studies

The white blood count is usually elevated with a left shift in bacterial pneumonia, especially early in the illness. [35] Typically, viral, chlamydial, and pertussis pneumonias produce lymphocytosis. However, it is not unusual for viral pneumonia to initially provoke a significant polymorphonuclear cell response. In patients with mycoplasmal pneumonia, the total white blood count and differential count are usually normal, but the erythrocyte sedimentation rate may be elevated. Chlamydial infections or parasitic infections often produce eosinophilia.

Blood culture results are rarely (5 to 10 percent) positive in children with pneumonia, even when it is proven to be bacterial. [4,8,22] Blood cultures should be obtained in infants who have high fever, appear ill, or require hospitalization. Sputum cultures may also help in identifying the causative organism but are difficult to obtain from nontracheostomized children, particularly those less than 8 years of age.

Cultures of the nasopharynx and throat for viral pathogens, chlamydia, pertussis, and mycoplasma often reveal the causative agent in patients with pneumonia caused by these organisms. Bacterial cultures of these regions have no diagnostic value. [6] Fluorescent antibody tests for *C. trachomatis* and *B. pertussis* are preferable to culture in some settings. Rapid viral antigen tests exist for a number of organisms, including RSV and influenza. Bacterial antigen testing is available in some centers but has a poor sensitivity and specificity in diagnosing the cause of pneumonia. [4,23] Serologic testing can be done for viruses, mycoplasma, parasites, and fungi in persistent or puzzling cases. Skin testing for tuberculosis should also be considered in patients not responding to traditional therapy or with apical, cavitary pneumonia. More invasive diagnostic procedures, such as obtaining endotracheal cultures, percutaneous lung aspiration, bronchoalveolar lavage, or open-lung biopsy, may be necessary in patients with severe disease that is unresponsive to empiric therapy. Results of tests for cold agglutinins are positive in 72 to 92 percent of patients with *M. pneumoniae* infection. Cold agglutinin test results may also be positive in viral infections and are less consistently positive in young children. To perform the bedside test for cold agglutinins, place several drops of blood in a blue-stopper coagulation profile tube, and place it in ice-water for 15 to 30 s. The presence of floccular agglutination is considered a positive result, and agglutination should disappear with rewarming.

TREATMENT

All patients with pneumonia should be assessed for hypoxia, and oxygen provided if indicated. Cyanosis is often not present in hypoxic children. [26] Oxygen saturation correlates well with clinical outcome and length of hospital stay. [36] Children with an oxygen saturation of 90 percent or less should receive supplemental oxygen. Additional respiratory support should be provided as dictated by the patient's clinical condition. Hydration status should be assessed and supplemental fluid administered if needed. In patients requiring hospital admission for suspected bacterial pneumonia, intravenous antibiotics should be administered in the emergency department. Empiric coverage should be guided by the age of the patient and the epidemiologic data discussed above. Table 119-3 contains suggested inpatient and outpatient antibiotic therapy. In newborns, ampicillin (150 to 300 mg/kg/day) in combination with either an aminoglycoside (gentamicin 2.5 mg/kg per dose) or a third-generation cephalosporin (cefotaxime 100 to 150 mg/kg/day) is preferred. The ampicillin provides coverage against *Listeria* and enterococcal species. For infants with pneumonitis syndrome or afebrile pneumonia (see above), erythromycin (40 mg/kg/day qid) is the drug of choice. In children 3 months to 5 years of age, ampicillin (150 mg/kg/day qid) or cefuroxime (150 mg/kg/day tid) alone is usually sufficient. In children who are unresponsive to this therapy or who have a suggestive clinical presentation, mycoplasma and chlamydial infections should be considered. Appropriate coverage for these infections include erythromycin (40 mg/kg/day qid) or clarithromycin (15 mg/kg/day bid). In children over 5 years of age, erythromycin or clarithromycin alone is usually sufficient. In severely ill hospitalized children in this age group, the addition of cefuroxime should be considered. In all age groups, if resistant *S. pneumoniae* is suspected, vancomycin should be added. [36]

Age Group	Inpatient Therapy	Outpatient Therapy
0–1 month	Ampicillin and gentamicin or ampicillin and cefotaxime	N/A
1–3 months	Pneumonitis syndrome: erythromycin or clarithromycin	N/A
	Other: cefuroxime	N/A
3 months to 5 years	Cefuroxime (consider adding erythromycin or clarithromycin)*	Amoxicillin, or erythromycin, or clarithromycin
6–18 years	Erythromycin or clarithromycin (consider adding cefuroxime)*	Erythromycin or clarithromycin, or azithromycin
All ages	Add vancomycin if resistant *S. pneumoniae* is suspected	

*Add additional coverage in severely ill patients.

TABLE 119-3   Antibiotic Therapy for Children with Pneumonia

Children with fulminant viral pneumonia, such as an immunocompromised patient with varicella, may require treatment with acyclovir. In RSV pneumonia, ribavirin therapy should be considered for selected high-risk children, such as those with significant underlying cardiopulmonary or oncologic diseases and those with severe RSV pneumonia. Lymphocytic interstitial pneumonia in HIV-positive children should include a combination of prednisone and zidovudine. Bone marrow and solid organ transplant patients with cytomegalovirus pneumonia may require ganciclovir and gammaglobulin. In a recent study, ceftazidime or ceftriaxone eradicated nosocomial pneumonia in 90 percent of cases, but ceftazidime had improved efficacy against *Pseudomonas aeruginosa.* Children with cystic fibrosis often develop

acute infectious exacerbations secondary to *Pseudomonas* and *S. aureus,* often with reduced antimicrobial resistance to standard antibiotics.

Most children with uncomplicated pneumonia can be treated as outpatients. If a bacterial cause is suspected, the patient should be placed on an appropriate antibiotic. The choice of oral antibiotic should be based on the considerations discussed above regarding the most likely etiologic organisms based on the age and clinical presentation of the patient. For outpatient treatment, amoxicillin (40 mg/kg/day tid) is preferred for children between 3 months and 5 years. [36] Alternatively, daily intramuscular ceftriaxone may be used.[36,38] After 5 years of age and in penicillin-allergic children, erythromycin (40 mg/kg/day qid) or tetracycline (in children >9 years of age) are the preferred initial agents. Recent data indicate similar cure rates, fewer side effects, and reduced termination of therapy with clarithromycin compared to erythromycin.[39,40] Azithromycin has also been shown to have a cure rate equal to that of erythromycin in children with community-acquired pneumonia. [41] It should be noted that both of these drugs are significantly more expensive than erythromycin or tetracycline.

If viral pneumonia is suspected, no specific antibiotic therapy is warranted. Symptomatic treatment should include fever control and hydration. Patients with viral pneumonia often have a mixture of airway and air-space disease. If the patient has prominent airway disease (bronchiolitis-like) symptoms, bronchodilator therapy should be considered.

All patients discharged with a diagnosis of pneumonia should have routine follow-up with a primary care provider within 1 to 2 days. The duration of therapy varies with the clinical response, predisposing host factors, and suppurative complications. Ten days of antimicrobial treatment should suffice for most uncomplicated cases.

DISPOSITION

Admission Criteria

Suggested criteria for admission of children with pneumonia include hypoxia (oxygen saturation £90 percent), respiratory distress, a history of apneic episodes or cyanosis, toxic appearance, dehydration, age less than 3 months, impaired immune function, and infections unresponsive to oral therapy. The presence of underlying disease and the ability of the care givers should also be considered. The finding of a pleural effusion or pneumatocele or findings suggestive of a bacterial infection in a child less than 1 year of age suggest a pathogen other than *S. pneumoniae* (particularly HIB or *S. aureus*). Since such infections can progress rapidly and are not well tolerated, hospitalization is generally required. Infants with suspected *B. pertussis* or *M. tuberculosis* should be admitted. Children with moderate or severe complications from pneumonia should be hospitalized. Indications for admitting patients with RSV pneumonia are the same as for RSV bronchiolitis.

Complications

Most viral pneumonias will resolve spontaneously without specific therapy. Complications are similar to those for bronchiolitis and include dehydration, bronchiolitis obliterans, and apnea. Apnea is commonly seen in very young infants with RSV, chlamydial, or pertussis infections. Pleural effusions can occur with viral pneumonias but are not common.

Uncomplicated bacterial pneumonia usually responds rapidly to antibiotic therapy. A delay in improvement or a worsening condition after therapy has begun should prompt an evaluation for possible complications. Complications of bacterial pneumonia include pleural effusions, empyemas, pneumothorax, pneumatoceles, dehydration, and development of additional infectious foci. Pneumococcal pneumonias are accompanied by pleural effusions in about 10 percent of cases. Pneumonia due to HIB is complicated by pleural effusions in from 25 to 75 percent of cases. Other foci of infection are frequently seen with HIB and can include meningitis, septic arthritis, epiglottitis, soft tissue infections, and otitis media. Pneumonias secondary to *S. aureus* have a high rate of complications, including empyemas (80 percent) and pneumatoceles (40 percent). Mycoplasmal pneumonia is only rarely complicated by pleural effusions, meningitis, encephalitis, arthritis, and hemolytic anemia. Whenever pneumonia is complicated or prolonged, roentgenographic follow-up is recommended to assure complete resolution, which may take 4 to 6 weeks or longer.

Discharge Instructions

All children released to go home from the emergency department with a diagnosis of pneumonia should receive specific advice on the dosage and scheduling of medications and the signs of worsening respiratory distress. Children who become unable to ingest adequate amounts of fluid or prescribed antibiotics should be instructed to return for further care. All children discharged with the diagnosis of pneumonia should have follow-up scheduled with the primary care provider within 24 to 48 h.

120 PEDIATRIC ASTHMA AND BRONCHIOLITIS

Maybelle Kou
Thom Mayer

ASTHMA

Asthma is a chronic disease of the tracheobronchial tree characterized by airway obstruction, inflammation, and hyperresponsiveness. Triggers for cytokine-mediated inflammation and hyperresponsiveness are well known and can be as innocuous as changes in barometric pressure. The cascade of events leading to mucous plugging, airway edema, and obstruction is generally reversible with appropriate, aggressive therapy. Symptoms of asthma can vary from overt wheezing to paroxysmal dyspnea to cough. In the absence of audible wheezing, the child may frequently go undiagnosed, which may lead to high morbidity as the disease goes untreated. The need for parents, caretakers, and physicians to correctly assess the severity of the disease and provide adequate and timely treatment is paramount to the care of children with asthma.

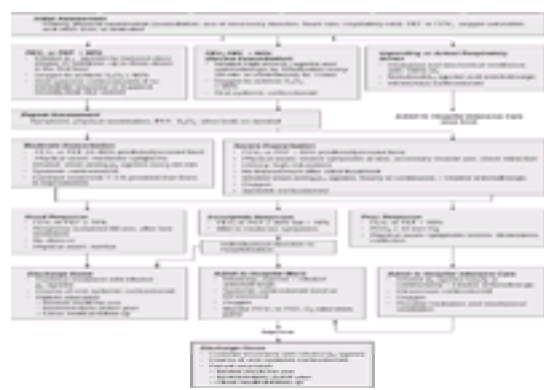
The National Institutes of Health (NIH) 1997 Expert Panel Report 2 (EPR-2), *Guidelines for the Diagnosis and Management of Asthma*,[1] is a publication with which all physicians should be familiar. It provides treatment algorithms for use in the acute-care setting and clear guidelines to outpatient management (Fig. 120-1). However, most institutions will need to tailor these protocols to meet regional, local, and individual hospital needs.


FIG. 120-1. Management of asthma exacerbations: emergency department and hospital-based care. (From the National Institutes of Health, National Heart, Lung, and Blood Institute.)

Epidemiology

Asthma affects 14 million Americans, 4.8 million below 18 years of age.[2] The prevalence of asthma has increased in all age groups by 40 percent in the last decade. In 1995, there were more than 1.8 million emergency department (ED) visits for asthma, 570,000 of which were patients from 0 to 14 years of age.[3] The estimated number of admissions in this same age group approached 70 per 10,000. An investigation of over 113,000 pediatric asthma admissions from 1986 to 1993 revealed that although the number of discharges paralleled the general increase in population, the percentage of patients with adverse outcomes [mainly intubation, but also need for cardiopulmonary resuscitation (CPR)] as well as death almost tripled.[4] Between 1993 and 1995 there were 170 deaths due to asthma in the age group from 0 to 14.[5] Some authors interpret these data as a sign that the emphasis upon outpatient management of asthma may be leading to increased morbidity and mortality.

Specific risk factors associated with the development of asthma in children include low birth weight, family history of asthma, urban household, low-income household, and race (children of African-American, Asian, and Hispanic descent).[6,7] These factors also have an influence on when hospitalization might be required during exacerbation. Most children presenting with asthma do so before the age of 8, with male predominance in the prepubertal age group. During adolescence, this ratio equalizes.

Risk factors that contribute to the deaths of children with asthma include socioeconomic background, limited access to health care, improper medication administration, and unrecognized severe disease. Extreme lability of disease, nocturnal asthma, and history of respiratory failure with previous intubation have also contributed to these deaths.[8]

Pathophysiology

Bronchial hyperreactivity appears to have a genetic basis; however, the difficulty in distinguishing atopy from asthma has resulted in limited studies of this area. Nonetheless asthma is classified as extrinsic (IgE-mediated), intrinsic (infection-induced), and mixed (both IgE- and infection-induced). Since environmental factors are strongly implicated in the initiation of bronchial hyperreactivity, it should come as no surprise that 66 to 75 percent of asthmatic children are "allergic," [9] many with serum IgE elevation. Concurrent sinusitis and bronchospasm secondary to chronic postnasal drip may be present. Whereas allergens and irritants are the most common and preventable triggers of asthma in children above 2 years of age, viral respiratory infections are felt to be predisposing in those below age 2. Respiratory syncytial virus is one of many viruses that can cause wheezing; this is discussed below, under "Bronchiolitis" (Table 120-1).

TABLE 120-1   Asthma Triggers

AIRWAY INFLAMMATION   Bronchial smooth muscle cells are regulated by the autonomic nervous system. Sympathetic b_2 receptors cause bronchodilation, whereas parasympathetics govern bronchoconstriction. While the exact neurogenic mechanism for hyperreactivity is unknown, IgE-mediated inflammation is well characterized as a contributor in the pathogenesis of an asthma attack. Mast cells release histamine, leading to the formation of arachidonic acid metabolites and the inflammatory cytokine cascade. Asthma is a two-stage process: (1) bronchoconstriction due to histamine and leukotriene release (early stage) and (2) airway mucosal edema with mucous plugging (late phase). Since resolution depends largely on the degree of mucosal inflammation, an asthma attack may persist from days to weeks.

AIR TRAPPING, $\dot{V}/\dot{Q}$ MISMATCH, AND HYPOXEMIA   Bronchospasm, mucosal edema, and mucous plugging cause variable and reversible airflow obstruction with subsequent air-trapping and impaired oxygen exchange. While increased lung volumes and pulmonary overdistention may help maintain airway patency, the resultant tidal volume approaches the volume of the pulmonary dead space and results in alveolar hypoventilation. Concurrently, $\dot{V}/\dot{Q}$ mismatch in areas of atelectasis contributes to hypoxia.

CARBON DIOXIDE RETENTION AND RESPIRATORY FAILURE   In the early stages of a severe exacerbation, symptoms of CO_2 retention may not be clinically obvious due to effective alveolar capillary diffusion. Indeed, compensatory hyperventilation may cause a fall in Pa_{CO_2} and even a respiratory alkalosis. More severe obstruction and inadequate alveolar ventilation ultimately result in marked CO_2 retention, respiratory acidosis, and respiratory failure.[11] *Pseudonormalization* of Pa_{CO_2} is therefore ominous: the apparently "normal" Pa_{CO_2} of 40 mmHg coupled with altered mental status is a clear sign of respiratory failure. The acidosis that results from hypoxia and hypercapnea leads to pulmonary vasoconstriction, pulmonary hypertension, and right heart strain.

PEDIATRIC ANATOMIC DIFFERENCES   The untreated pediatric asthma patient is ultimately at higher risk of respiratory failure due to these anatomic differences:

- Increased compliance of the infant rib cage and immature diaphragm result in paradoxical respiration: inward displacement of the ribs during inspiration contributes to increased work of breathing and respiratory muscle fatigue.
- Young lung tissue lacks elastic recoil and is more prone to atelectasis. This then contributes to $\dot{V}/\dot{Q}$ mismatch.
- Airway walls are thicker and result in greater narrowing with bronchoconstriction.

Thus if expiration is hampered by obstruction, complete collapse of alveoli and lung segments may occur.[12]

Postmortem specimens of pediatric asthma patients show the lungs to be pale and hyperinflated. Microscopy reveals smooth-muscle hyperplasia of bronchial and bronchiolar walls, thickened basement membrane, and mucosal edema. Submucosal eosinophilic infiltration is the hallmark of asthma. The leukocyte-laden mucous plugs occluding the airway contain eosinophils, polymorphonuclear cells, lymphocytes, and shed epithelial cells; there is an absence of mast cells.

Evaluation

To avoid delays in treatment, a brief physical examination should be performed before a detailed history is obtained. Treatment with inhaled b_2 agonists should not be withheld while the initial evaluation is in progress, even if the patient is in the triage area owing to lack of availability of a treatment room. Examination of vital signs should include respiratory rate, pulse, blood pressure, temperature, and pulse oximetry (Sa_{O_2}). Pulse oximetry, "the fifth pediatric vital sign," is an excellent noninvasive device for detecting severe airway obstruction. A room-air oxygen saturation of less than 91 percent in an infant may predict the need for hospitalization. *Oxygen supplementation should never be delayed for any child in apparent respiratory distress for the sake of obtaining a pulseox*. Oximetry may also be inaccurate in states of poor perfusion and fails to reflect a decrease in Pa_{CO_2} until the value of 80 mmHg is reached.

After initial stabilization, the health care provider must perform a complete exam, trying not to upset the child further. Children who are nonverbal and in respiratory distress may cry and be excessively clingy. The patient's chest must be visible for complete examination. Inspection and auscultation should be performed to assess alertness, accessory muscle use, and work of breathing. The severity of disease may be underestimated in the silent or "quiet wheezer," in whom the expiratory phase is usually prolonged and wheezing is absent due to extreme air trapping.

The "tripod position" is a significant indicator of distress: the child sits forward, hands over knees, on the edge of the bed. The nostrils should be inspected for presence or absence of nasal flaring, foreign bodies, and concurrent sinusitis. Hallmark "musical" polyphonic inspiratory and expiratory wheezes may not always be present on lung exam and are not prognostic of severity of disease. Extremities should be inspected to assess cyanosis and clubbing. Insensible fluid losses may result in delayed capillary refill and poor skin turgor. Pulsus paradoxus in severe exacerbation is usually 20 to 40 mmHg and may be reflected by significant jugular venous distention, which is otherwise difficult to appreciate in the pediatric examination.

Parents should be asked specifically if the child has previously had spells of wheezing (asthma attacks) and of what severity (Table 120-2). A history of asthma may be denied because pediatricians who are reluctant to give the diagnosis of asthma use *reactive airway disease* as alternative nomenclature. History of previous hospitalizations, intubation, and tracheostomy should be actively sought, including old records when the parent is unable to give information owing to a language barrier or ignorance of the situation. History of prematurity, bronchopulmonary dysplasia (BPD), and oxygen requirement is especially significant. Specific questions should be asked of information that the parent may not automatically volunteer—for example, regarding a stay in the neonatal intensive care unit (NICU) (see Table 120-2). In the adolescent, specific questions regarding, for example, use of inhalants, tobacco, or drugs (especially amphetamine and cocaine) should be asked, as well as over-the-counter purchases of bronchodilators that their parents may not be aware they have been using. History of aspiration or choking, as well as possible ingestion should be included for all ages. Family history of asthma and allergy can also give a sense of whether or not the parent or caretaker will be able to continue treatment once the ED visit terminates.

TABLE 120-2   Pertinent Questions to Ask about Asthma History

CLINICAL SCORING SYSTEMS IN ASTHMA   The Wood-Downes-Lecks[13] clinical scoring system had been used in the past but is now replaced by the Expert Panel Report of the NIH (Table 120-3). The authors feel that scoring systems are not helpful in predicting outcome, since asthma is a dynamic and not static illness; they recommend that scoring systems be used only as a guide for progression of treatment.

TABLE 120-3   Classifying Severity of Asthma Exacerbations*

MEASUREMENT DEVICES FOR PEAK EXPIRATORY FLOW RATE (PEFR)   The 1997 EPR-2 advocates use of the PEFR (or peak flow) meters in the ongoing assessment and management of asthma. The newer hand-held spirometers are designed for personal use and portability and are readily available in the ED. Forced expiratory volume in 1 s (FEV_1) is estimated by measuring PEFR and correlates with the degree of airway obstruction; PEFR is already decreased by 25 percent once wheezing is detected by stethoscope (see Table 120-4). PEFR values in liters per minute are based on the child's height. A PEFR of less than 50 percent indicates severe obstruction, less than 25 percent indicates possible hypercarbia. In the ED, PEFR is an excellent tool to evaluate mild asthma or for reevaluating patients after treatment, especially those who know their "personal best" score. Pre- and posttreatment values should be obtained when possible.

TABLE 120-4   Classification of Asthma Severity: Clinical Features before Treatment

Use in children below age 5 is limited by patient cooperation. In older children, the ability to perform deep inspiration and forced expiration may not be feasible during an acute exacerbation (Table 120-5).

Source: From Polger G, Promedhat V: *Pulmonary Function Testing in Children: Techniques and Standards.* Philadelphia: Saunders, 1971, with permission.

TABLE 120-5   Predicted Average Peak Expiratory Flow for Normal Children and Adolescents, Male and Female

Arterial blood gas analysis should be obtained to determine Pa$_{CO_2}$ in children with impending respiratory failure, if the patient is hypoventilating, if PEFR is less than 30 percent of predicted, or if the patient is not responding as expected to treatment. It may also be helpful in determining which children should potentially be admitted to an intensive care unit versus a regular floor.

Complete blood count and chemistries are usually unnecessary unless there is a concurrent febrile illness or coexisting disease. Chronic steroid use can cause leukocytosis and elevated band count. Chronic use of albuterol can cause significant hypokalemia. If the child is on theophylline, a level should be obtained.

Chest x-ray is not routinely recommended but should be performed in new-onset asthma or to rule out pneumonia, pneumothorax, foreign body, or pneumomediastinum. A chest x-ray should also be obtained when a patient is admitted to the hospital. Findings typical of asthma are hyperinflation, flattened diaphragm, increased AP diameter, peribronchial cuffing, and atelectasis.

Differential Diagnosis

NEW-ONSET ASTHMA   In the new-onset "wheezer," upper and lower respiratory and nonrespiratory causes must be differentiated (Table 120-6).

TABLE 120-6 Differential Diagnosis of Asthma

INFECTION   Fever and focal wheezing implicate infectious etiologies such as pneumonia or bronchiolitis. Nocturnal wheezing, nocturnal cough, and poor exercise tolerance may be clues of more chronic illness. Sinusitis can exacerbate asthma symptoms; a history of nasal congestion and nocturnal cough or snoring should be treated with at least a 2-week course of antibiotics and nasal steroids. Recurrent attacks, failure to thrive, and a history of sinusitis and chronic ear infections should raise suspicion of cystic fibrosis as an etiology.

CARDIAC LESIONS: CONGENITAL AND ACQUIRED   Infants with history of BPD may present with mild illness with rapid deterioration. Prolonged mechanical ventilation in the neonatal period causes smooth muscle hypertrophy and pulmonary hypertension, leading to cardiac disease. It may be necessary to distinguish pulmonary edema as a cause of wheezing; usually a history of diuretic use will aid in diagnosis. Congenital heart lesions causing congestive heart failure will also present with wheezing that may have been mistaken for asthma, exacerbated by concurrent viral infection. Other clues—such as feeding difficulties, failure to thrive, hepatosplenomegaly, genetic syndromes, and radiographs revealing abnormal cardiac silhouettes—point to a cardiac etiology. Workup to exclude viral myocarditis should be considered in the previously well child.

UPPER AIRWAY OBSTRUCTION   A monophonic fixed inspiratory wheeze at the level of the vocal cords suggests upper airway obstruction such as that secondary to croup, which may be more prominent on expiration (the seal-like cough). Careful history can indicate tracheomalacia, either congenital or secondary to prolonged intubation. A toxic child in tripod position with inspiratory stridor, absent cough, and inability to tolerate secretions is more likely to have retropharyngeal abcess or epiglottitis. Lateral and AP neck radiographs will aid in differentiation; if epiglottitis is suspected, the patient should never be left unattended. Vocal cord dysfunction can be voluntary, producing an inspiratory wheeze, shortness of breath, and parental anxiety. The wheeze is usually extinguishable with a b_2 agonist and behavioral modification (removal of stressor).

FOREIGN-BODY ASPIRATION   Sudden onset of unilateral wheezing in the previously healthy child suggests foreign-body aspiration, most commonly in the right mainstem bronchus. If chest x-ray fails to reveal a radiopaque density, an expiratory film may show hyperinflation on the side of the obstruction due to air-trapping (ball-valve mechanism). A lateral decubitus film is more helpful in the small child who cannot follow commands. The dependent lung, usually deflated due to external compression from the x-ray table, will appear normal or hyperinflated if a foreign body is present. Infection and abcess must be suspected if fever is present.

GASTROESOPHAGEAL REFLUX DISEASE (GERD)   A history of postprandial wheezing or coughing is indicative of GERD with microaspiration of liquid into the tracheobronchial tree. Severe GERD has been implicated in apnea and sudden infant death syndrome. Recurrent microaspiration can result in fever and pneumonia. Most children with reflux can be managed conservatively; however, a history of cyanotic spells after feeding warrants admission for barium swallow and upper gastrointestinal (GI) series. Tracheoesophageal fistula should be suspected in the newborn who experiences choking and cyanosis after feeding, although most cases should be diagnosed in the nursery: these can be missed due to shorter hospitalizations following delivery.

Treatment

b_2-RECEPTOR AGONISTS **Albuterol** (salbutamol) is the treatment of choice. Dosage is as follows: unit dose (0.5 percent solution) by nebulizer, O_2 flow at 6 to 7 L/min up to 2.5 mg/20 min or three unit doses by continuous nebulizer over 1 h. This may be repeated to a total of six unit doses. Continuous cardiac monitoring is required.

b_2 receptors are widely distributed on bronchial smooth muscle and airway epithelial cells. b_2-receptor agonists activate adenylate cyclase, increase cyclic adenosine monophosphate (cAMP) levels, cause bronchial smooth muscle relaxation due to increased binding of intracellular calcium to the endoplasmic reticulum, and decrease myoplasmic calcium. The development of specific b_2-receptor agonists such as albuterol (salbutamol in Canada, not to be confused with the long-acting Salmeterol) has revolutionized treatment of asthma, reducing the b_1 side effects of tachycardia and dysrhythmias seen with isoproterenol, which is now rarely used. Tachycardia and "jitteriness" are common side effects (more so with oral medication than inhaled), and, rarely, dysrhythmias have been reported. During an acute attack, use of a b_2-receptor agonist may cause transient drops in PO_2 due to pulmonary vasodilatation and ventilation-perfusion mismatch. Anecdotally, nebulized terbutaline (0.25 mL) has no advantage over albuterol and may be useful in patients who respond. Salmeterol (Serevent), a long-acting b_2 agonist that has been shown to reduce the need for "as needed" albuterol dosing, is not indicated for use in acute exacerbations.

Tachyphylaxis has been documented with chronic and improper use of b_2 agonists[17] and appears to be related to saturation of b_2 receptors from frequent dosing intervals and/or decreased downregulation of the number of b_2 receptors on leukocytes of asthmatic patients. In this setting, increasing doses of b_2 agonists prove to be ineffective. Efficacy is preserved as long as the medication is used as needed and not on a scheduled basis. Overuse of such medications as aerosolized epinephrine (available over the counter as Primatene Mist) has also been implicated in the deaths of asthmatics due to tachyphylaxis and cardiac dysrhythmias. Furthermore, most physicians do not recommend the use of such products for even mild bronchial asthma. Physicians and pharmacists should educate patients to use medications only under a doctor's supervision.

METERED-DOSE INHALER (MDI)   Continuous aerosolized therapy with albuterol is a safe,[14] fast, and effective way to deliver medication directly to the lung capillary beds and may be associated with a reduction in hospital admission.[15] Although the literature has stated that MDI therapy is just as effective as nebulizer treatment in children above 6 years of age,[16] patient compliance may be the rate-limiting factor in administering MDI in the emergency setting. Failure to improve with home MDI use occurs in children due to tachypnea, inability to take a breath and hold it, and inability to form a seal around the chamber mouthpiece, at which point nebulized medication becomes a necessity.

SUBCUTANEOUS EPINEPHRINE   If a patient is unresponsive to the above therapy or respiratory distress increases, subcutaneous epinephrine should be administered while line placement is attempted. Give 0.01 mL/kg aqueous epinephrine 1:1000 to a maximum of 0.3 mL. This may be repeated every 20-30 minutes for a total of 3 doses.

TERBUTALINE   More b_2-specific than epinephrine, terbutaline can be given subcutaneously in place of epinephrine as 0.01 mL/kg of 1-mg/mL solution up to 0.25 mL.

Terbutaline is the only intravenous b_2 agonist available in the United States (intravenous albuterol is available in Europe and Canada). Its use should be considered in children who have not responded to conventional therapy who are admitted to a monitored unit. Side effects will be seen more frequently with intravenous than aerosolized administration. The use of terbutaline in exacerbations of pediatric asthma is limited in older children, where myocardial ischemia has occurred secondarily to tachyarrhythmias caused by the drug. Intravenously, terbutaline is given as 0.05 to 0.1 µg/kg per minute. Continuous cardiac monitoring is recommended.

CORTICOSTEROIDS   Glucocorticoids are well known to inhibit the secretion of inflammatory leukotrienes and prostaglandins and to prevent and reverse the increase in vascular permeability that leads to airway edema. In vitro studies have shown that glucocorticoids cause an increase in density of b_2 receptors on

leukocyte cell membranes and reverse tolerance to b$_2$ agonists.[18,19] Early administration during the course of an acute exacerbation is recommended for all patients unless the PEF is >50 percent and there is an immediate response to the first treatment (Fig. 120-1) and except when exercise-induced attacks occur in a previously well child. If the parent has already administered a dose at home, the dose can be repeated in the ED. Orally, prednisone or prednisolone is administered as 2 mg/kg. Prednisolone formulations are as follows: Pediapred 5 mg/5 mL and Prelone 15 mg/5 mL. Intravenous methylprednisolone is available as Solumedrol, single 2 mg/kg.

The current literature states that there is no advantage in giving intravenous versus oral glucocorticoids in the acute setting. [20] If a child has vomited oral medicines or is already intubated, then intravenous administration is preferred. Intramuscular administration is also an option.

It is well known that outpatient maintenance glucocorticoid therapy reduces the severity of attacks and thus reduces the need for hospitalization. A few controlled studies in pediatric patients have compared early ED administration of steroids versus placebo and have found that hospitalizations were less frequent in the treatment group than in those who did not receive treatment,[21,22] albeit the samples studied were small. Conversely, studies have shown no significant difference in the hospitalization rate when glucocorticoid treatment is begun in the ED. [23,24 and 25] While these data may be somewhat conflicting, the authors' position is that steroids treat inflammation, reduce relapse attacks, and therefore should be administered as early as possible in the acute attack to prevent prolonged hospitalization.

Inhaled glucocorticoids are increasingly recognized as the mainstay of asthma prevention in the population with mild to severe asthma, but they play a lesser role in treatment of the acute attack. There is still underuse[26] of inhaled glucocorticoids despite their well-documented efficacy in long-term control, prevention of "rescue" utilization of medication, and role in airway remodeling. [27] Side effects are less serious than with chronic oral glucocorticoids, although a few cases of adrenal suppression have been reported in the literature. Oral candidiasis can be prevented by diligent lingual hygiene (tongue brushing) and rinsing of the oral cavity after use. On an anecdotal basis, usage of nebulized dexamethasone is not recommended, as the molecule is too big to be absorbed at the alveolar-capillary level. Initial Canadian studies of nebulized budesonide, however, do suggest a benefit in treatment of asthma. [28,29]

Emergency physicians treating new-onset asthmatics may occasionally encounter parents who are skeptical about the use of glucocorticoids. The parents may often be fearful of the side effects and/or may confuse these with anabolic formulations. The parents should be educated about the reasons that warrant glucocorticoid therapy and reassured that short-term treatment is not usually associated with long-term sequelae.

INTRAVENOUS FLUIDS   Most children presenting in status asthmaticus will be dehydrated because of increased insensible losses. It is worthwhile to administer a bolus of fluid (20 mL/kg of normal saline) to aid in thinning secretions and repleting lost volume, especially in those patients for whom admission seems inevitable.

ANTICHOLINERGIC THERAPY   Studies in children suggests that use of nebulized ipratropium bromide (Atrovent) potentiates the effects of albuterol [30,31] and has the added advantage of compatibility when mixed with albuterol solution for combined administration via nebulizer. The anticholinergic action of such treatment is thought to prevent bronchoconstriction induced by cyclic guanosine monophosphate. Continued debate has led to many studies in adults that reveal no significant differences in efficacy from the use of ipratropium bromide with albuterol, although anecdotally the response is variable. It is a safe drug with few side effects and may be given to patients of all ages. It is available in liquid and MDI form. An MDI in combination with albuterol (Combivent) is at this time indicated for adult use only. The dosage of ipratroprium bromide is 250 µg in 2 mL of NaCl. It may be mixed with albuterol solution and administered as 250 µg every 6 h, or it may be added to first continuous nebulizer treatment.

MAGNESIUM SULFATE   Intravenous magnesium sulfate has been used for the treatment of acute asthma exacerbations for many years; it may be administered to patients who are slow responders to conventional therapy and to intubated asthmatic patients. The exact mechanism of action is unknown but may resemble the tocolytic effects of magnesium sulfate on uterine smooth muscle. Several small studies have shown that patients who receive intravenous magnesium show improvement in short-term pulmonary function without adverse effects, such as low blood pressure. [32,33] Magnesium sulfate may be given as 25 to 50 mg/kg IV over 20 min; this may be repeated once to a serum magnesium level of 4 mg/dL. The maximum dose for children is 2 g.

HELIOX   Heliox is generally available as 80:20 or 60:40 mixtures of helium and oxygen. If available, it may be initiated in the ED. It is recommended for the asthmatic who does not improve with conventional treatment but in whom intubation is not imminent. [34] The lower density and high diffusivity of the gas allows easier passage through turbulent obstructed airways. The peak flow rate increases while airway resistance and work of breathing decrease. It is possible to continue to administer b$_2$ agonists during Heliox treatment.

OTHER THERAPIES   Theophylline is a competitive phosphodiesterase inhibitor that was thought to aid bronchodilation by increasing cAMP. While it is mentioned here for completeness, the authors do not recommend its routine use in the ED. Routine addition of theophylline to conventional therapy shows no benefits in the treatment for acute bronchospasm. It has an extremely narrow therapeutic-to-toxic ratio as well as side effects such as central nervous system (CNS) irritability and tachycardia. Drug interactions with P-450 metabolites also make its use undesirable. It is reserved for patients who clearly respond to it or for those who remain refractory to other modes of treatment. Aminophylline 6 mg/kg (85% theophylline) is given in 25 to 50 mL of NaCl over 20 min IV. If the patient is already on theophylline, a loading dose is given [(mg) = (desired level – measured level)/2 × kg].

Inhaled anesthetics such as halothane have also been used as inpatient treatment. Selected patients have been placed on cyclosporine, gold, hydroxychloroquine, and other immunomodulators. Health care professionals should be aware of the recent popularization of herbal remedies and inquire about their use: as of yet, no clinical studies have been performed on these medicines.

Chest physical therapy is of no proven benefit in the setting of acute asthma. Mucolytics may exacerbate symptoms by causing worsening of airway obstruction by loose particles. Sedation, unless in the setting of intubation, should be avoided to help protect airway reflexes.

Agents for Adjunct Ambulatory Treatment

Cromolyn sodium has long been used to inhibit mast-cell degranulation and histamine release. It is not recommended in the acute attack.

Nedocromil (Tilade) works similarly; however, it may be effective only if strict compliance is maintained. A primary feature is that it reduces the cough component of asthma; it is also considered to be "steroid sparing."

Leukotriene receptor inhibitors (LTRIs) are increasingly popular agents for use in the outpatient prophylactic management of asthma. These medications do not supersede steroid use in the acute attack. They are classified as 5-lipoxygenase inhibitors or 5-lipoxygenase–activating protein inhibitors, of which montelukast is approved for pediatric use; zafirlukast may be used in children of age 12 and above. Currently only limited data are available, but the initial response is encouraging and suggests less need for medication and chronic steroid use. A trial comparison to inhaled steroids will provide more information. Although initial studies have revealed a relatively good safety profile, zafirlukast has been linked to several adult cases of Churg-Strauss syndrome [36] (granulomatous necrotizing vasculitis). Interleukin 4–receptor medications are not currently approved for pediatric use.

Most *hand-held aerochamber devices* have a one-way valve and mouthpiece for children over age 4. A slow 3- to 5-s inhalation is required for each MDI actuation. For children below age 4, a mask attached to the end of the chamber is fitted over the nose and mouth. The appropriate size should be given. The MDI is attached to the other end of the chamber and medication is delivered. The mask is held to the child's face for five inhalations. Teaching should be performed before the child is discharged.

Complications of Moderate and Severe Asthma Exacerbation

Respiratory failure may occur even if treatment is in progress, mainly from muscle fatigue. Atelectasis is common and may be responsible for the overdiagnosis of pneumonia in pediatric asthmatic patients. While pneumomediastinum is rare, children may present with vague chest pains for which a radiograph can reveal the diagnosis. Most can be managed on an outpatient basis provided that there is good follow-up. Generally, mediastinal air will resorb over 2 to 3 days. A large pneumomediastinum and/or pneumothorax requiring chest tube thoracostomy will require admission for close monitoring and observation.

Reassessment and Disposition

Treatment algorithms greatly simplify the decision of whether or not a child should be admitted. Disposition can be made after 2 to 4 h of therapy for patients who remain stable (Table 120-7). A child who does not respond after 2 h of continuous treatment whose Pa_{CO_2} is greater than 40 mmHg should be admitted to an intensive care unit (ICU) for continuous therapy. Children with oxygen requirements, refractory asthma, and/or dyspnea on exertion may be admitted to the floor. If parents of children with newly diagnosed asthma do not feel comfortable taking care of their children even with adequate teaching, admission may be warranted (this also applies to patients with mild attacks requiring nebulization but with limited resources and inability to obtain nebulizers on weekends and at night).

Respiratory failure requiring intubation

Status asthmaticus:
   Persistent retractions, tachypnea
   O₂ requirement after 2 h of therapy

Return ED visit within 24 h

Limited home resources

Pneumothorax

Complete lobar atelectasis

Large pneumomediastinum

Underlying cardiopulmonary disease

TABLE 120-7 Admission Criteria

An intubated patient or patient requiring continuous nebulization should be transported to a facility with pediatric intensivist capability by advanced life support providers with pediatric airway experience.

Discharge Instructions and Ambulatory Treatment

Children responding well to conventional therapy may be discharged after 2 to 4 h of treatment. A short ED observation period is recommended for patients with an incomplete response but acceptable PEFR. Detailed discharge instructions should outline medication administration, inhaler use, and follow-up (Table 120-8). No child should be discharged without an MDI and spacer (Fig. 120-2), and prescriptions for oral glucocorticoids are generally recommended unless the attack was extremely mild (resolved with minimal treatment) or exercise-induced. Studies suggest that a tapered dose is not generally needed for "burst dose" (3- to 10-day) therapy,[35] since the side effect of adrenal suppression with prolonged use is unlikely to occur. Of the two most common forms of methylprednisolone, Pediapred is reported to taste better than Prelone; however, its lower concentration requires that three times the volume of Prelone be given for the same dose.

TABLE 120-8   Discharge Treatment Dosage Guidelines
FIG. 120-2. Steps for using your inhaler. (From the Expert Panel Report 2: Guidelines for the Diagnosis and Management of Asthma. National Asthma Education and Prevention Program, National Heart, Lung, and Blood Institute, 1997.)

A courtesy call to the private pediatrician of the child who has been treated for asthma in the ED should be made, as it facilitates continuity of care for the child and ensures follow-up. All children should be referred to their pediatrician for follow-up within 24 h.

BRONCHIOLITIS

Bronchiolitis, or inflammation of the bronchioles, is the term applied to the clinical syndrome of wheezing, chest retractions, and tachypnea in children below age 2; it causes more significant illness in infants less than 6 months of age.

Epidemiology

Peak prevalence is from late October to May. Over 90,000 children are hospitalized at an average cost of $70,000 per child, with 4500 deaths annually from RSV infection. The peak age of incidence in urban populations is 2 months and results in hospitalizations lasting 5 to 7 days. Disease in older children is usually milder. Bronchiolitis has also been shown to be a cause of severe pneumonitis in elderly populations.

This highly infectious virus is transmitted by direct contact with large droplets of secretions and self-inoculation by contaminated hands via the eyes and nose (no significant transmission occurs by small-particle aerosol). RSV-infected secretions remain infectious on countertops for more than 6 h. Strict attention to hand washing and use of masks and gloves can prevent transmission. RSV is shed from the respiratory tract of symptomatic and asymptomatic patients for up to 9 days. Immunocompromised patients may continue to shed for up to 6 weeks.

Pathophysiology

Respiratory syncytial virus (RSV) causes 50 to 70 percent of clinically significant bronchiolitis. [37] First isolated in the 1950s, it is a significant cause of infant morbidity and is one of the major causes of hospital admission in infants below 1 year of age. Symptoms can vary from minimal rhinorrhea to bronchiolitis or pneumonia. Of the two antigenic subtypes of RSV, A and B, the former is generally more severe but less common. Two surface proteins, G (attachment) and F (fusion), are necessary for RSV to cause infection. Research is concentrating on F protein antibodies, which show less antigenic diversity than G proteins and neutralize both RSV subtypes. Immunity to the virus is variable owing to antigenic diversity; therefore reinfection does occur. No vaccine has yet been identified.

Non-RSV bronchiolitis is caused by influenza virus, parinfluenza virus, echovirus, and rhinovirus. *Mycoplasma pneumoniae* and *Chlamydia trachomatis* also produce symptoms. Adenovirus causes a particularly destructive form, bronchiolitis obliterans, observed in Native Canadian Eskimo populations.

Mucous plugging results from necrosis of the respiratory epithelium and destruction of ciliated epithelial cells. This and submucosal edema lead to peripheral airway narrowing and variable obstruction, with areas of patchy atelectasis or overdistention in lung segments. Progressive disease causes severe pneumonia, with extensive destruction of respiratory epithelium, parenchymal necrosis, and formation of hyaline membranes. Bronchiolar regeneration occurs within 3 to 4 days; however, cilia may take as long as 15 days to regenerate.

Increased airway resistance and decreased compliance result in increased work of breathing. Like the infant with lower airway obstruction, the infant with bronchiolitis breathes at higher lung volumes due to uneven resistance within the lung. Alteration of gas exchange results from the patchy atelectasis and airway obstruction. $\dot{V}/\dot{Q}$ mismatch is variable and severe hypoxemia may result.

Clinical Features

Infection begins with nasal discharge, pharyngitis, and cough. Fever accompanies the first few days of illness, with temperatures as high as 40°C (104°F). The parent brings the child to the ED because of increased respiratory symptoms, nasal congestion, and difficulty feeding.

Symptoms reach a peak at 3 to 5 days, generally resolving in 2 weeks with normalization of pulmonary function. It must be noted that resultant wheezing can persist for weeks to months. Respiratory isolation precautions should be entertained owing to the severity of illness that can occur in children with a history of prematurity, cystic fibrosis, congenital heart disease, or immunocompromise. These latter children are more at risk for apnea also.

Physical findings include tachypnea greater than 50 to 60 breaths per minute, tachycardia, mild conjunctivitis, chest retractions, prolonged expiration with hyperresonant chest, wheezes throughout, and hypoxemia. The most reliable clinical finding that correlates with hypoxemia is tachypnea, which signifies serious impairment of gas exchange. The hypoxemic child with bronchiolitis may not show cyanosis. The severity of wheezing or intercostal retractions will also not correlate with the severity of hypoxemia. Respiratory rate must be followed, but this may be difficult, as variation occurs with fever and crying. Pulse oximetry is the single best objective predictor of severe disease, and most children with saturations of less than 91 percent will probably need admission. If respiratory rate cannot be determined in the very small or dehydrated child, an arterial oxygen saturation should be obtained.

YOUNG INFANTS AND APNEA   The mechanism inducing RSV-related apnea in young infants is not completely understood but may be related to hypoxemia and upper airway obstruction. [51] Infants at highest risk are less than 6 weeks old, have a history of prematurity, apnea of prematurity, and low O_2 saturation on admission. [51] It is difficult to predict apneic events. The severity of wheezing and retractions does not correlate with frequency of apnea, and most infants less than 1 month of age will have atypical disease, where they may present without wheezing and retractions. Apneic infants generally require intubation during the course of the illness, sometimes requiring mechanical ventilation for up to a week or more. Postextubation, these infants are not at higher risk of apnea and may be discharged without apnea monitors.

Children with underlying diseases such as bronchopulmonary dysplasia, cystic fibrosis, immunodeficiency, or congenital heart defects are at increased risk of severe RSV. Care must be taken in treating infants with a history of BPD, as many will have a tendency toward chronic CO_2 retention. Since hypoxemia remains the major respiratory stimulus in this population, supplemental oxygen may cause further CO_2 retention, therefore saturations of 94 to 95 percent are acceptable.

Numerous retrospective analyses and observations note that children with bronchiolitis as infants frequently develop asthma later on. [52]

Diagnosis

The diagnosis of bronchiolitis is suggested by clinical presentation, patient age, and history of RSV exposure or community epidemic. Immunofluorescence assays currently available are extremely sensitive but not necessary for all patients. Since the prevalence of RSV during an epidemic is so high, routine testing is costly and is best reserved for children with predisposing medical conditions or complicated courses of disease.

Complete blood counts (CBCs) and chemistries may not be helpful in diagnosis. The white blood cell count can be normal or elevated with a left shift. An elevated band count may be present. Chemistries should be obtained if there is poor feeding or evidence of dehydration. Salicylate ingestion may present with respiratory distress, and mixed metabolic acidoses and respiratory alkalosis and b-blocker ingestions can exacerbate wheezing, so the history should include questioning about possible injestion. Chest x-ray may reveal patchy atelectasis, segmental atelectasis, hyperinflation, and peribronchial thickening.

Emergency Department Management

Most cases of bronchiolitis are treated on an outpatient basis, for which close follow-up with a private pediatrician is essential. During RSV epidemics, the emergency physician will be exposed to a broad spectrum of patients at varying stages of disease and must be able to identify those who need admission and who are at risk for apnea. Infants in respiratory failure will require emergent intubation and admission to the ICU. Treatment is mainly supportive and consists of oxygen, fluid replacement, fever management, and optimal bronchodilators. The most important therapy is supplemental humidified oxygen. At concentrations of 28 to 40 percent, arterial hypoxemia is improved in most infants.

Increased insensible fluid loss occurs from increased work of breathing and can cause significant dehydration that warrants a 20 mL/kg bolus. Patients with poor fluid intake due to congestion may also require intravenous hydration and admission (especially if parents are unable to feed the child owing to uncontrollable secretions). Beyond initial resuscitation, fluid replacement should not exceed maintenance due to the potential for the development of pulmonary edema in some of these children.

Fever should be controlled with acetaminophen or ibuprofen. Children with concurrent otitis media should receive the appropriate course of oral antibiotics. Those who appear toxic with temperature above 38.5°C should have a CBC drawn to rule out other intercurrent infections. A 9-year prospective study of 565 children with documented RSV showed the risk of secondary bacterial infection was low; subsequent secondary bacterial infections were seen more frequently in the group treated with antibiotics. [38]

BRONCHODILATORS   A trial of bronchodilator therapy is optional and reasonable in the treatment of bronchiolitis and can be aborted if the child fails to show a response. Much research points to the fact that unless there is a history of asthma, there is a limited role for bronchodilator therapy in treatment of bronchiolitis. Many studies of oral and nebulized albuterol alone show that it fails to improve oxygen saturation or to reduce the length of hospitalizations, [39,40 and 41] leading some authors to question the cost/benefit of such therapy. Ipatropium also does not affect the natural course of the disease, [42] although anecdotes suggest it may have a role in drying up secretions.

Racemic epinephrine has been compared with albuterol and found to reduce hospitalizations in children with bronchiolitis. [43] It can improve symptom scores of respiratory rate, wheezing, and retractions at 15 min compared with nebulized saline. [44] It can be used safely in hospitalized children up to every 2 h. If used in the ED, the authors recommend an observation period of 4 h before a disposition decision is made.

HELIOX   Heliox can be considered for children with severe obstructive symptoms and works for the same reasons as in asthma. A recent study [45] showed that its use

increased Sa$_2$ in children when compared with oxygen alone. At this juncture, its use can provide a useful bridge in reducing the need for intubation in certain populations of infected children.

GLUCOCORTICOIDS   Controlled studies have failed to demonstrate any proven benefit in the use of glucocorticoids, including studies on oral prednisolone and dexamethasone.[46] The authors recommend the use of glucocorticoids only if there is a history of asthma; these drugs have been helpful in infants with a history of BPD. Initial reports on budesonide, a smaller molecule that has been widely studied in Europe and Australia, suggest a benefit. In a Finnish study [47] of 100 patients, budesonide was seen to reduce the number of hospital admissions and subsequent wheezing episodes as compared with controls. A more recent study on nebulized budesonide[48] stated that its effects in preventing postbronchiolitic wheezing were unremarkable. It is currently being introduced in the United States in a MDI form and more studies need to be performed.

RIBAVIRIN   Ribavirin is a guanosine-resembling synthetic nucleoside analogue generally used as inpatient therapy. When delivered as a small-particle aerosol, it has produced improvement in oxygenation. It is thought to work by decreasing viral protein synthesis. Candidates for such treatment are those with immunodeficiency, cystic fibrosis, congenital heart disease, and severe illnesses of infancy. Since the introduction of intravenous immunoglobin, the use of ribavirin appears to be less frequent.

RESPIGAM RSV IMMUNE GLOBULIN INTRAVENOUS (HUMAN)   RespiGam has been in use for the past few years as outpatient passive immunization for infants at risk for severe RSV disease. The treatment involves monthly intravenous infusion of immunoglobulin during RSV season. It is recommended for infants with documented BPD and for those with a gestational age of less than 35 weeks (at the discretion of the physician). The PREVENT [49] study demonstrated a reduction of the incidence and duration of RSV hospitalization and severity of illness.

PALIVIZUMAB (SYNAGIS)   The FDA approved Synagis in mid-1998 for prevention of RSV in pediatric patients. It is the first monoclonal antibody that can be given by intramuscular injection to provide protection against infection [50] (protein binding neutralizes the virus). Like RespiGam, it is administered monthly to those patients at highest risk and is desirable for those children in whom vascular access is a challenge. The Impact-RSV trial [50] showed a 55 percent reduction in hospitalization in a group of 1500 patients, with few adverse effects. These results and the ease of administration are encouraging in reducing the morbidity of the disease.

OTHER MODALITIES   The anecdotal theory that mist helps to dilute secretions has not been proven; in fact, very little water reaches the lower airways to begin with. Infants with high temperatures and documented RSV are unlikely to require workup for occult bacteremia unless they appear septic. Studies have failed to show any utility in obtaining blood cultures in children with fever attributable to RSV. Antibiotics should be reserved for concurrent otitis media or other identifiable bacterial infections.

Disposition

Infants with visible moderate to severe respiratory distress, apneic spells, or dehydration should be admitted to the ICU. Infants without wheezing but sustained tachypnea (RR > 60) should also be admitted, preferably to a step-down unit. Hospitalization should be considered in all infants with a history of BPD, congenital heart disease, and immunocompromise.

Those with mild disease who are taking fluids well and whose parents are capable of taking care of them may be released with good follow-up instructions. Home health visits and nebulizers may be instituted if deemed necessary. Albuterol in syrup form can also be initiated for children who respond. Parents should be instructed on how to perform aggressive nasal suctioning and evaluate respiratory distress. Use of vapor solutions available over the counter should be discouraged, and parents who smoke cigarettes should be cautioned that tobacco smoke can worsen the illness. Decongestants and antihistamines are of questionable benefit; their use in infants less than 6 months of age is not recommended.

121 SEIZURES AND STATUS EPILEPTICUS IN CHILDREN

Michael A. Nigro

Approximately 2 percent of the United States population have some form of epilepsy. Many more experience seizures in association with febrile illnesses or other acute problems. In children aged 0 to 9 years, the prevalence is 4.4 cases per 1000, and in those 10 to 19 years, the prevalence is 6.6 cases per 1000. Simple febrile convulsions constitute a separate category, with an incidence of 3 to 4 percent in children.

These numbers alone do not reveal the most important features of the seizure phenomenon—the increased morbidity and mortality rates that are a direct result of seizures, their cause, or their treatment. Epidemiologic studies indicate an overall mortality rate two to three times higher in epileptic patients than in nonepileptics. The earlier the onset of seizures and the more deprived the social environment, the higher the morbidity and mortality rates.

Typically, a patient with seizures arrives at the emergency department with one of the following:

1. The initial or a recurrent seizure
2. Status epilepticus
3. Complications of medication
4. A history of seizures with an acute, underlying disease—e.g., sickle cell anemia, metabolic disease, or febrile illness—that needs treatment

Emergency care should include (1) safely stopping the seizure, (2) identifying and correcting immediately treatable or reversible causes, and (3) initiating appropriate diagnostic studies and arranging follow-up. If management is difficult, the patient should be admitted. There are significant enough differences in the treatment of children that unless the physician is experienced in pediatric management or able to readily obtain pediatric consultation, the child should be transferred to a pediatric facility. Treatment and diagnostic studies may be complex, and time is important in reducing morbidity.

DEFINITION

A *seizure* is an episodic alteration in motor activity, behavior, sensation, or autonomic function. It represents an abrupt change in brain function. The term *epilepsy* indicates recurring seizures without a simple discernible and reversible cause. Physiologically, a seizure is an abnormal, sudden, and excessive electric discharge of neurons (gray matter) that propagates down the neuronal processes (white matter) to affect end organs in a clinically measurable fashion. The International Classification of Epileptic Seizures is accepted as the contemporary standard (Table 121-1).

TABLE 121-1   International Classification of Epileptic Seizures

EEG

Electroencephalographic (EEG) recording on an emergent basis is becoming more commonplace as the phenomenon of nonconvulsive status epilepticus (NCSE) is appreciated. In this condition, the patient seems to be seizure free but unresponsive and the EEG indicates a condition of subclinical status epilepticus and warrants more aggressive treatment to improve the EEG abnormality, if this is possible. In a child who unexpectedly remains comatose or in a neonate where clinical seizures

may be difficult to detect, immediate and continuous EEG monitoring may more reliably direct aggressive antiepileptic drug (AED) treatment.

NEUROIMAGING IN EPILEPSY

The choice of central nervous system (CNS) imaging depends in part on the circumstances and the age of the patient:

1. Cerebral ultrasound is most advantageous in the evaluation of neonates and young infants as a quick and relatively reliable method to identify intraventricular and parenchymal hemorrhage, periventricular leukomalacia, major malformations, cerebral edema, and hydrocephalus. It is not as useful in identifying more discrete cerebral migrational defects.
2. Computed tomography (CT) has its best application in evaluating seizures associated with head trauma.
3. Magnetic resonance imaging (MRI) is the preferred imaging technique in evaluating causes of epilepsy including migrational defects, mesial temporal sclerosis, acute parainfectious disseminated encephalomyelitis, stroke, and neoplasm.
4. Magnetic resonance angiography (MRA) is of value in defining vascular abnormalities of stroke and stroke-like events.
5. Transcranial doppler can be helpful in determining impending cerebrovascular occlusive disease of sickle cell anemia.

NEWER ANTIEPILEPTIC DRUGS (AEDs)

Newer AEDs are indicated in the management of seizures as add-on drugs, although there are currently numerous studies determining their application as initial and monotherapy.

Gabapentin

Gabapentin (Neurontin) was released in 1994 as adjunctive therapy for partial seizures. It is a novel AED with ill-defined mechanism of action, although it was initially designed as a GABAergic agent, i.e., increasing the effect of g-aminobutyric acid (GABA), the major cerebral inhibitor. It has no drug interactions, is not metabolized, and is not protein bound. Normal renal function is desirable, since it is excreted solely via the renal system. A short half-life of 5 to 6 h, and limited intestinal absorption capability necessitates frequent dosing of 3 to 4 times a day. Dosage is 20 to 60 mg/kg/day, and maximal dosage can be reached in several days. Side effects are mild, self-limiting, and usually consist of vertigo, light-headedness and, infrequently, behavioral changes. Rarely, myoclonic seizures have been provoked soon after initiating the drug. AED levels are not useful in determining therapeutic and toxic effects. It is available in 100-, 300-, and 400-mg capsules.

Lamotrigine

Lamotrigine (Lamictal) probably acts on voltage-sensitive sodium channels and excitatory amino acid neurotransmitters. Two very important features of lamotrigine include its predilection to produce a significant rash, which could progress to Stevens-Johnson syndrome, and the effects of comedication. The half-life of lamotrigine is reduced by 50 percent when administered with enzyme inducers such as phenytoin, carbamazepine, and phenobarbital and doubled when used in conjunction with valproate. The combination with valproate has been associated with most of the adverse reactions. In children, it should be started very slowly and increased very gradually. It is indicated in the treatment of partial and generalized epilepsy, including absence, drop, and myoclonic seizures. When administered with enzyme inducers, the dose begins at 2 mg/kg/day and is increased over 6 to 8 weeks to a maximum of 15 mg/kg/day. When used with valproate (Depakote), it should be started at 0.2 mg/kg every other day, increased by 0.2 mg/kg/day to 1 mg/kg/day, and then, over the next 6 weeks, increased to a maximum of 5 mg/kg/day. When changes are made in reducing or introducing comedication, the lamotrigine dose will have to be modified in most instances. Given as monotherapy, the half-life is 25 to 30 h. It has minimal protein binding. Blood levels do not reflect toxic or therapeutic effects. There is no reported significant hepatic or hematologic side effect.

Topiramate

Topiramate (Topamax) became available in 1997. Its mechanism of action is uncertain, but it appears to be effective in preventing propagation of the seizure from its focus. The half-life is 19 to 23 h, and 85 percent of the drug is eliminated unchanged through the renal system. The remaining 15 percent is metabolized by P-450 hepatic metabolism. With the relatively long half-life, the drug is given in a twice-daily dosage. It is indicated in the treatment of partial seizures and is being evaluated as monotherapy. In children, the drug is begun slowly at 1 mg/kg/day and over 8 to 12 weeks is gradually increased to a maximum of 10 mg/kg/day or 400 mg/day if necessary. The major side effect limiting dosage and rate of incrementing dosage is the effect on memory and name recall.

Tiagabine

Tiagabine (Gabitril) is a GABA reuptake inhibitor resulting in higher levels of cerebral GABA available for inhibition of the epileptic excitatory activity. With a relatively short half-life of 5 to 8 h ultimate dosage should be administered tid. Absorption is slower and the drug more easily tolerated when given with meals. Metabolism is via the P-450 mechanism and, as a result, the half-life is significantly reduced by coadministration with enzyme inducers such as carbamazepine, phenytoin, and phenobarbital. The maximum effective dose in children at this time is estimated to be 1 mg/kg/day. This dose should be started at 0.1 mg/kg/day and gradually increased over the next 6 to 10 weeks. Because of high protein binding, free levels of coadministered AEDs should be monitored (phenytoin, carbamazepine, and valproate). Most common side effects are sedation and behavioral. Activation of myoclonic seizures can also occur.

Vigabatrin

Vigabatrin (Sabril) is an enzyme-induced irreversible inhibitor of GABA aminotransferase resulting in increased cerebral GABA levels. It is rapidly absorbed, unaffected by food consumption. It is not protein-bound and is excreted unmetabolized by the renal system. It has no significant drug interactions. Blood levels are not useful in determining therapeutic effect or toxicity. Abnormalities of cerebral myelin have not been substantiated in humans; however, recently investigators identified visual changes in adults using vigabatrin. Dosage is initated at 30 mg/kg/day and gradually increased over 4 weeks to a maximum of 100 mg/kg/day (bid dosage) if necessary for improved seizure control. European studies initially found it very effective in the treatment of infantile spasms associated with tuberous sclerosis. More common side effects include dizziness, ataxia, and behavioral changes in children. As with all AEDs, seizure activation has been reported but cannot be predicted with any reliability.

Oxcarbazepine

Oxcarbazepine (Trileptal) is a 10-keto analogue of carbamazepine but is not oxidatively metabolized. As a result, there is little, if any, induction of hepatic enzymes and no autoinduction of metabolism, allowing for a more rapid titration to maximum dosage. Its active metabolite is a monohydroxy derivative (MHD) that has a half-life of 10 h, allowing for a bid dosing. It is begun at 20 mg/kg/day and increased to a maximum of 60 mg/kg/day or to tolerance and seizure control. It will probably be approved for use as adjunctive treatment of partial epilepsies. It can be used in combination with any of the existing AEDs, including carbamazepine. Unlike carbamazepine, it has no epoxide metabolites and is not affected by erythromycin.

Depacon

Depacon is the intravenous preparation of valproate, and recent experience indicates it is well tolerated by children. It is usually administered IV when the oral maintenance dose cannot be tolerated and can also be used at a higher induction dose when rapid levels are desired and the patient is naive to the drug. Dosage is the usual maintenance dose administered IV over 15 min. Loading dose for naive patients is 10 to 30 mg/kg IV over 15 min.

Extended Release Agents

Carbatrol and Tegretol XR are extended-release forms of carbamazepine that permit bid or 12-h dosing.

Fosphenytoin

Fosphenytoin (Cerebyx) is a prodrug of phenytoin that contains a disodium phosphate ester that is cleaved during hydrolysis, yielding a molecule of phenytoin. Phosphatases are ubiquitous and present in newborns, so fosphenytoin can be used at any age. It is water soluble and can be given IV and intramuscularly (IM)

without the side effect of infusion-related complications attributed to phenytoin extravasation. A 1 mg phenytoin equivalent (PE) is the therapeutic equivalent of 1 mg of phenytoin. Fosphenytoin can be infused at 3 mg PE/kg/min with therapeutic free phenytoin levels achieved by 7 to 8 min following infusion and 30 min following IM use. Rapid infusion in alert patients may produce perineal pruritis.

ADDITIONAL ADVANCES IN EPILEPSY TREATMENT THAT WARRANT CONSIDERATION

Increasingly, children with intractable epilepsy are undergoing implantation of the Cyberonics vagus nerve stimulator (Neurocybernetic Prosthesis System). This devise is programmed to deliver a stimulus at a specific intensity and frequency for a specific interval (e.g., 15 s every 3 min). Although the mechanism of action is uncertain, electrical stimulus of the left vagus nerve can significantly reduce seizure frequency. Common side effects include hoarseness and difficulty swallowing during stimulation. Problems with instrumentation are unlikely to warrant an emergency department visit. A malfunctioning stimulator can be temporarily turned off by taping a magnet over the subcutaneous pacemaker.

The ketogenic diet has been used with increasing frequency in the management of childhood epilepsy. Ketones are an alternative energy source for cerebral metabolism. By severely restricting glucose and increasing fat intake, ketosis can be maintained and seizure control improved. There are several concerns about an emergency department visit that warrant mention. It is necessary to maintain ketosis and, as a result, glucose infusions should be avoided if possible, and prescriptions given should have no measurable carbohydrate content. This is most easily managed by consultation with the prescribing neurologist, associated dietician, and pharmacist. Hematuria and flank pain may be due to renal calculi. Pancreatitis is an uncommon occurrence in children on the ketogenic diet.

THE FIRST SEIZURE

The first seizure in a child usually causes some degree of panic in the parents, and an accurate description of the seizure and preseizure events may not be obtainable. If it lasts seconds to minutes, and if others in the family have experienced seizures, an emergency visit may not be made. Unless the child is in status epilepticus, or seizures recur in the emergency department (Table 121-2), the physician can defer immediate anticonvulsant treatment and concentrate on defining the cause and the risk of recurrence (Fig. 121-1).

TABLE 121-2   Critical Pathway: New-Onset Seizure with Neurological Compromise

FIG. 121-1. New onset seizure. General treatment plan.

Hauser and coworkers[2] categorized seizure recurrence for all ages according to the presumed cause. Of their patients, 73 percent were categorized as having idiopathic seizures and 27 percent as having remote symptomatic seizures. Idiopathic seizures recurred in 17 percent of the patients by 20 months after the initial seizure and in 26 percent of the patients by 36 months after the first seizure, but the recurrence rate was greater in patients with generalized spike-wave EEGs and in patients with siblings who had had seizures. In patients with prior neurologic insult (cerebrovascular accident, meningitis, etc.), the recurrence rate was 34 percent by 20 months after the initial seizure.

Immediate diagnostic evaluation (Table 121-3) is initiated in the emergency situation. If the seizure was brief and appears to be idiopathic, the decision to initiate anticonvulsant therapy can be deferred until the appropriate neurologic assessment is completed. The causes of a first seizure vary, but idiopathic seizures account for 26.3 to 47 percent of children seen with seizures, depending on the study cited. Secondary seizures occur for a wide variety of reasons (e.g., inflammatory, structural, metabolic, or secondary to general illness).

TABLE 121-3   Diagnostic Studies in Seizure Patients

In any group of seizure patients, there is a subgroup in which the seizure is a symptom of an underlying disorder and is not due to idiopathic epilepsy. In such cases, correction of the primary problem makes seizure recurrence unlikely. Thus, the primary goal must be to uncover disorders that are readily identifiable and reversible. Symptomatic seizures of hypoglycemia, hypocalcemia, and electrolyte imbalance can be treated immediately. There is little risk of recurrence and no need for anticonvulsant use. Seizures occurring as a result of intracranial infections and craniocerebral trauma may require only immediate or short-term anticonvulsant use. Symptomatic seizures of systemic lupus erythematosus (SLE), sickle cell anemia, leukemia, arteriovenous malformations, and neoplasms may be the heralding

symptoms of a complex, yet treatable, underlying disease. Seizures have been reported in children after topical application of *N, N*-diethyl-*m*-toluamide (DEET) and lindane (Kwell). Ingestion of rare and common agents has been associated with new-onset seizures, including camphor, theophylline, isoniazid, tricyclic antidepressants, oral and parenteral meperidine, cyclosporine, stimulants such as methylphenidate, and lead and mercury exposure. These seizures may be brief and self-limiting or may progress to status epilepticus and result in permanent neurologic sequelae and epilepsy. Identification and specific treatment of the underlying problem are most important to achieve full recovery. Aseptic and bacterial meningitis, viral encephalitis, brain abscess, and more uncommon problems such as cat-scratch fever and mycoplasma-related encephalopathy may present with seizures. In a child with a ventriculoperitoneal shunt, seizures are more likely to arise from associated cerebral abnormalities (epilepsy) rather than shunt malfunction.

If the initial seizure is prolonged or emerges into status epilepticus, appropriate therapy and diagnostic workup must be initiated (Table 121-3, Table 121-4 and Table 121-5). If seizures are acutely repetitive or occur in the presence of associated or preexisting neurologic deficit and the patient is at a higher risk for recurrence of seizures, then anticonvulsant management can be initiated immediately (Table 121-4). For partial seizures, carbamazepine, phenytoin, and phenobarbital are most commonly used and equally efficacious whereas, in primary generalized seizures, valproate is most commonly used. However, the other AEDs are also effective and may need to be used because of intolerance or ineffectiveness. For the most part, these AEDs can be used interchangeably.

TABLE 121-4   Initial and Maintenance Doses in the First Seizure (Nonstatus Partial and Tonic, Clonic, and Tonic-Clonic Seizures of Childhood)

TABLE 121-5   Doses for Status Epilepticus in Children

Side-effect profile, physician preference, and parental experience and comfort usually dictate which AED will be used initially. Phenytoin and carbamazepine have a similar mechanism of action and effectiveness; therefore, their side-effect profiles will determine which to initiate. Phenobarbital is quite effective and, though a sedative, in some may create more problems of irritability and limit its effectiveness. Nonetheless, it can be well tolerated in the majority of infants and children and has a wide spectrum of effectiveness. See Table 121-2 for the clinical pathway in management of new-onset seizures.

Absence seizures (petit mal) rarely require emergency care, and an EEG should be obtained for confirmation before one starts AEDs, since absence seizures could mimic partial status and an AED such as ethosuximide will be ineffective. Valproate, ethosuximide and, more recently, lamotrigine are the appropriate AEDs for absence epilepsy chronic management, with the benzodiazepines effective in the acute management of status absence epilepticus.

FEBRILE SEIZURE

Febrile seizure is a unique and common form of seizure in childhood. Although various types occur (tonic, tonic-clonic, and clonic), the characteristics of a simple febrile seizure separate it from other symptomatic and idiopathic seizure disorders. The National Institutes of Health (NIH) Consensus Development Conference of Febrile Seizure defined it as an event in infancy or childhood usually occurring between 3 months and 5 years of age, associated with fever but without evidence of intracranial infection or defined cause. [3] Typically, these seizures are generalized and last less than 10 min, and there is no postictal focal neurologic deficit. The EEG usually does not reveal paroxysmal (epileptic) activity, and there often is a family history of similar seizures. Typically, a rapid rise in temperature, usually above 38.8°C (101.8°F), occurs at the onset of the illness and, on occasion, recurs several times in the course of the illness. Three to four percent of young children experience febrile seizures and, of these, 30 to 40 percent have recurrences, especially when the first seizure occurs when a child is younger than 1 year of age. The mortality from simple febrile seizures is extremely low.

Evaluation

The first febrile seizure warrants the most concern, because the benign nature of the illness has not yet been established. More concern regarding intracranial infection is justified with the first febrile seizure before the propensity for recurring simple febrile convulsions has been established. The initial evaluation concentrates on serious causes, such as meningitis, encephalitis, and bacterial sepsis. Lumbar puncture is warranted whenever intracranial infection appears likely. If a cause is not found and the child is ill, admission, workup, and therapy are warranted. Underlying diseases should be diagnosed. Toxic encephalopathy with fever as a symptom should be identified and treated. An EEG can be done electively and, when indicated by family history or atypical presentation, may be helpful in determining whether AED treatment is warranted.

Treatment

Therapy for the cause of the fever is the main goal. A simple febrile seizure does not warrant treatment with AEDs. Information from the NIH collaborative study pointed out the lack of benefit of chronic AED use, the greater likelihood of AED-related side effects, and the good prognosis in untreated patients. If a child exhibits repetitive seizures with this or prior febrile seizures, then phenobarbital can be administered and maintained until the child improves. Chronic AED prophylaxis with phenobarbital or valproate is limited to children with (1) complex febrile seizures (prolonged or focal), (2) a preexisting neurologic deficit, e.g., cerebral palsy, (3) onset under 6 months of age, (4) repeated seizures in the same illness, (5) prior nonfebrile seizures, and (6) more than three febrile seizures in 6 months.

Rectally or orally administered diazepam has been used successfully to prevent seizures when given at the onset of a febrile illness. Usual dosage is 0.2 to 0.5 mg/kg as a single dose.

If acute treatment is warranted, the following protocol is recommended:

1. Interrupt the fever gradually with tepid baths (no alcohol) and acetaminophen or ibuprofen administration.
2. Identify the source of infection and perform a lumbar puncture if meningitis or encephalitis is suspected.

3. If indicated, administer a loading dose of phenobarbital 15 mg/kg IV, followed by 4 to 6 mg/kg/day to attain therapeutic levels of 15 to 40 µg/mL.
4. Arrange for follow-up studies with the child's family physician.
5. Admit the ill child without an easily treatable problem or one in whom recurrent seizures have occurred within several hours or 1 day.
6. Obtain an EEG when appropriate. An EEG may be helpful (if abnormal) as an indication of a convulsive disorder.

An alternative AED regime has been the administration of oral or rectal diazepam at the onset of a febrile illness prior to the onset of seizures. The Tufts University study by Rosman and colleagues[4] proved diazepam efficacy in seizure prevention when oral diazepam 0.33 mg/kg was administered every 8 h during all febrile illnesses in at-risk children. Importantly, 39 percent experienced side effects such as lethargy, ataxia, and irritability.

NEONATAL SEIZURES

Seizures in neonates are difficult to identify and often require aggressive therapy. All neonates experiencing seizures should be considered to be at serious risk from the underlying disorder and the effect of unremitting seizures and also to be at increased risk for epilepsy. Electroconvulsive activity should be of as much concern as the outward clinical signs of seizure. Prompt, effective anticonvulsant therapy and other specific therapies lessen the impact of short-term detrimental effect on long-term neurologic functioning. In many instances, the seizure itself is less important for its immediate effects than it is as an indicator of significant underlying disease (e.g., infection, metabolic disorder, or CNS malformation) that will ultimately have more effect on the morbidity and mortality rates.

The difference in seizure presentation is due to the lack of arborization of the immature brain, which prevents rapid propagation of electrical epileptic activity, and to the particular illnesses to which newborns are subject (hypoxic ischemic encephalopathy, and metabolic and dysplastic conditions). Multifocal or fragmentary seizures occur more commonly at this age, and clonic or tonic movements independently affect the limbs simultaneously or fleetingly.

Progressive migratory partial seizures (Jacksonian) are rarely seen at this age. Autonomic seizures manifest as variable changes in respiration (tachypnea, depression, or apnea), temperature, and color (cyanosis), and also as cardiac dysrhythmias and pupillary changes. Myoclonic seizures usually have hypoxic or metabolic causes and indicate a poor prognosis unless the cause is easily identifiable and readily reversible (e.g., hypocalcemia or hypoglycemia). Myoclonic seizures can, however, be refractory in metabolic disorders such as urea cycle defects and nonketotic hyperglycinemia. Unilateral (partial or focal) seizures may be associated with structural lesions, and permanent neurologic deficit may be associated with them. The causes of neonatal seizures are diverse, but the majority of the seizures are attributable to a few well-defined causes.

Evaluation

Common neurologic nonepileptic problems encountered in newborns are hyperexcitability in tremulous infants, nonepileptic cerebral manifestations of sepsis, cardiac disease, hypoxia, apnea of prematurity, and benign myoclonus. A rare condition seen in neonates is hyperekplexia. It is usually autosomally dominantly inherited and presents with exaggerated startle reactions to tactile stimuli over the face and trunk, resulting in tonic extension of the limbs, flexion of the head, and apnea. It is responsive to clonazepam.

The workup includes early assessment for treatable causes. Sepsis and metabolic derangements are frequent causes of neonatal seizures. The highest incidence of neonatal seizures is in infants with hypoxia/ischemia, sepsis, or hypoglycemia. Hereditary neonatal seizures ("fifth day fits") are autosomal dominant, variably expressed, and usually require chronic AEDs, often with a good outcome.

Complex hereditary metabolic disorders—e.g., urea cycle defects with hyperammonemia, maple syrup urine disease, and methylmalonic acidemia—usually become evident days or weeks after feedings with protein are initiated. Others may appear symptomatic in utero or soon after delivery—e.g., nonketotic hyperglycinemia, in which the mother reports fetal hiccoughs—and soon after birth the infant is flaccid, exhibiting myoclonic seizures. Seizures in these metabolic disorders are a signal of possibly significant CNS impairment.

Some of these disorders may be completely controlled or the effects may be reversed with appropriate dietary management (galactosemia and urea cycle defects) or coenzyme replacement (pyridoxine dependency, biotinidase deficiency, subtypes of folate, and vitamin B_{12} responsive methylmalonic acidemia).

In evaluating an infant, the cause of the seizures may be readily apparent. Dysmorphic newborns could have a chromosomal defect (trisomy or deletion) or be identifiable only by the combination of unusual features (Cornelia de Lange syndrome). Neurocutaneous diseases infrequently cause seizures in newborns but are readily identifiable by certain signs, e.g., encephalotrigeminal hemangiomatosis in Sturge-Weber syndrome, or achromic patches in tuberous sclerosis. Cutaneous herpes with seizures is an indication that herpes simplex encephalitis is present. Chorioretinitis is a clear sign of intrauterine infection that could cause seizures (e.g., herpes, toxoplasmosis, cytomegalovirus, or rubella). Cerebral imaging is warranted in neonates to help define cerebral hemorrhage and structural abnormalities. Ultrasound may be sufficient for diagnosis in some cases, but MRI is the best study for migrational defects of the CNS (e.g., lissencephaly, heterotopia, and agenesis of the corpus callosum).

Treatment

Several factors influence treatment in neonates: (1) variations in the metabolic half-lives of drugs, (2) associated etiologic conditions (e.g., hypoxia prolongs the half-life of many drugs and may affect the renal or gastrointestinal clearance rate), and (3) greater difficulty in identifying the end point of seizure control in neonates.

Effective seizure control is obtained by rapidly achieving therapeutic blood levels of the anticonvulsant chosen. Newborns have different rates of metabolism and excretion of anticonvulsants from older infants and children. In infants younger than 7 days of age, the half-life of phenobarbital, the drug of first choice, is 100 h and, after 28 days of continuous therapy, the half-life of the drug is reduced to 60 to 70 h.

In the presence of hypoxia with tissue acidosis and associated renal and hepatic dysfunction, anticonvulsant half-lives may be increased, with therapeutic and toxic levels achieved more readily, and requiring lower dose and less frequent administration of AEDs.

Blood levels of phenobarbital of 16 to 40 µg/mL are necessary to achieve seizure control in the majority of cases. Levels of 40 to 80 µg/mL have been maintained in resistant cases with inconsistent benefit. Dosages of phenobarbital of 3 to 4 mg/kg/day maintain mid to high therapeutic levels and prevent toxicity.

Phenytoin is the second drug of choice in treating neonatal seizures. Fosphenytoin is well tolerated in neonates and can be used for induction and maintenance therapy without the problems associated with phenytoin administration. Loading doses of fosphenytoin are 15 to 20 mg PE/kg at 3 mg PE/kg/min with IV maintenance of 4 to 8 mg PE/kg/day. When converting to oral dosage of phenytoin, 8 to 12 mg/kg/day is typically required. Free phenytoin levels up to 2.2 µg/mL may be necessary for adequate seizure control.

Pyridoxine (vitamin B_6) 100 mg/day is empirically used when no reasonable cause for seizures has been identified and the seizures remain uncontrolled. Seizure reduction rather than EEG improvement is the best indication of B_6 response, Biotin 10 mg/day is the long-term replacement therapy for biotinidase deficiency.

In status epilepticus of neonates, diazepam or lorazepam must be used with caution, since its half-life may be prolonged, and respiratory depression superimposed on an immature and possibly compromised respiratory apparatus should be anticipated. Diazepam may exaggerate hyperbilirubinemia by uncoupling the bilirubin-albumin complex and should be used with caution in jaundiced babies.

Treatment principles in the management of neonatal seizures are as follows:

1. Identify and correct treatable causes (hypocalcemia, hypoglycemia, and electrolyte imbalance).
2. Identify and treat associated problems such as sepsis, hyperbilirubinemia, and acidosis.
3. Initiate anticonvulsant therapy with appropriate loading doses, and carefully observe blood levels to adjust the maintenance dosage (Table 121-6).

TABLE 121-6   Drug Regimen for Neonatal Seizures

INFANTILE SPASMS

Infantile spasms are a unique form of seizures. The onset is typically between 3 and 9 months of age but may begin as late as 18 months. Concurrently, the child exhibits regression in development. The spasms are very brief, lasting a split second, often with flexion or extension of the head and trunk. They occur singly or repeatedly in bursts of 5 to 20 spasms at a time, usually several times per day and more often upon arousal from sleep or with sudden auditory or physical stimulation. The EEG is abnormal in virtually every case (hypsarrhythmic in 50 percent). Mental retardation in patients with this disorder is as high as 85 percent. Parents are often frustrated because medical professionals fail to recognize these spasms as seizures.

There are many causes of infantile spasm (secondary type), including migrational defects, prior CNS trauma, hypoxia, neurocutaneous disorders, and infectious and metabolic disorders. The idiopathic type is the most alarming because it affects children with no prior neurologic disorder and no etiology is identified. Differential diagnosis includes benign myoclonus, dyskinesia due to gastroesophageal reflux, and tics.

Treatment

Early diagnosis and aggressive management may minimize the neurologic deficit associated with infantile spasms. Although adrenocorticotropic hormone (ACTH) remains the treatment of choice because of favorable outcome, the frequency and severity of complications warrant consideration of alternative AEDs. Clonazepam and valproate have been effective in limited cases and warrant consideration in refractory cases or when the potential side-effect risk is too great with ACTH (e.g., active cytomegalovirus infection). Vigabatrin has particular effectiveness in infantile spasms associated with tuberous sclerosis.

Once infantile spasms are recognized, prompt neurologic referral is recommended. It is necessary to initiate a basic assessment including electrolytes, calcium, glucose, complete blood count, creatinine and lumbar puncture (LP). The LP is warranted to identify the rare syndrome of glucose transporter defect, which is a potentially treatable cause of infantile spasms. If the cerebrospinal fluid (CSF) glucose is less than 60 percent of blood glucose, this disorder should be highly suspected. The best course of treatment is the ketogenic diet. More complex metabolic testing is not necessary in the emergency department situation. MRI is the preferred neuroimaging study and can be done electively.

HEAD TRAUMA AND SEIZURES

Head trauma can result in seizures of three types: immediate seizures, early posttraumatic seizures, and late posttraumatic seizures. Immediate seizures result from impact and presumably are due to traumatic depolarization of neurons. The risk of recurring seizures in these patients is minimal unless there are more serious prognostic factors such as prolonged coma and penetrating head injury.[5] Anticonvulsants are sometimes used because of the unknown potential for immediate recurring seizures. In a patient who recovers rapidly, chronic anticonvulsant use is usually not indicated. An exception would be a patient with a prior seizure history or a family history of epilepsy.

Early posttraumatic seizures occur within the first week after trauma, and epilepsy results in 20 to 25 percent of these patients. These early seizures are presumed to result from the focal effects of contusions or lacerations and the associated hypoperfusion, which causes ischemia and related metabolic changes.

Treatment of immediate and early posttraumatic seizures requires the correction of neurologic problems, e.g., depressed fracture or hematoma, the reduction of cerebral edema, proper oxygenation (airway maintenance and correction of shock), and the careful administration of anticonvulsants. With immediate and early posttraumatic seizures when impaired consciousness already prevails, it is helpful to avoid the use of significantly sedative medication (barbiturates or diazepam), if possible. Phenytoin may be used successfully with relative safety (Table 121-4). The dosage is determined by the clinical presentation. Rapid loading is warranted to obtain immediate therapeutic levels in patients in whom repeated seizures are occurring or likely to recur, especially when a seizure may further aggravate associated medical or surgical conditions.

Immediate posttraumatic seizures warrant anticonvulsant therapy for initial control, whereas long-term management of immediate seizures remains controversial.

Late posttraumatic seizures occur after 1 week and may be seen as late as 10 years after the trauma. Structural changes such as atrophy with gliosis and permanent local vascular changes, altered dendrite branching, and presumably modified neurotransmitter function account for the development and permanence of these seizures. Of these seizures, 40 percent are focal or partial seizures and 50 percent are temporal lobe seizures, indicating the predilection for traumatic injury and known epileptogenic properties of this structure. The risk of recurring seizures in this group is reported to be as high as 70 percent.

Early and late posttraumatic seizures warrant long-term anticonvulsant therapy in view of the risk of immediate and later recurrence. Late-onset posttraumatic seizures are most likely to recur, and long-term anticonvulsant therapy is necessary. Patients at greater risk for chronic posttraumatic seizures include those with depressed skull fractures, posttraumatic amnesia more than 24 h after the trauma, dural penetration, acute intracranial hemorrhage, early posttraumatic epilepsy, and a foreign body in a cerebral wound. The more severe the seizure and the later the onset, the less likely remission will occur.

Emergency management of seizures related to trauma should emphasize neurosurgical assessment; the rapid, careful administration of nonsedative anticonvulsants; the interruption of the seizures; and the stabilization of the general medical condition.

BREAKTHROUGH SEIZURES IN KNOWN EPILEPTICS

When seizures recur in known epileptics, something has occurred to alter the balance of the excitation-inhibition complex, causing the seizure threshold to be lowered. Complete seizure control is not always possible. A child with mental retardation, cerebral palsy, and complex partial seizures with or without secondary generalization is most likely to have recurring seizures. Tonic-clonic (grand mal) seizures are the most dramatic and often lead to emergency treatment. The usual causes of seizure breakthrough can be summarized as follows: lowered anticonvulsant blood levels, change in habits, complicating factors of epilepsy management, and progression of the underlying cause. Superimposed head trauma may also precipitate seizures. And, finally, an unprovoked episode of seizures may occur in a well child with adequate levels of anticonvulsants.

Lowered Anticonvulsant Blood Levels

1. Due to noncompliance. This is a common cause, most often in a preteen or teen who has been given the responsibility for self-medication, more often seen with tid and qid dosing.
2. Related to intercurrent infection. Anticonvulsant levels fall during acute infections (viral or bacterial) with or without fever. Quite often, a child's seizure recurrence is an indication of the infection before the acute problem is evident, e.g., varicella or otitis media.
3. The interaction of different drugs. An example is the reduction of the phenytoin level by the induction of parahydroxylation when barbiturates are used

concomitantly (see the section on "Problems of Anticonvulsant Use").

Change in Habits

1. Altered sleep patterns because of trips, holidays, or parties.
2. A job, exams, or an emotional stress may lead to seizures in active teens. If a pattern develops, knowledge of the pattern is quite helpful in defining treatment.
3. Alcohol use can lower the seizure threshold and can also increase noncompliance.
4. The use of illicit drugs or prescription drugs that lower the threshold. Examples are neuroleptic agents, lindane (Kwell), theophylline, phencyclidene (PCP), LSD, cyclosporine, isoniazid, meperidine, tricyclic antidepressants, stimulants, and certain anesthetic agents (e.g., ethrane).

Complicating Factors of Epilepsy Management.

1. Toxic levels of drugs. An example is phenytoin intoxication, which can increase seizure frequency. Carbamazepine and other AEDs in therapeutic dosage have been found to infrequently increase seizures. Tiagabine and gabapentin may increase myoclonic seizures.
2. The use of phenytoin in some myoclonic epilepsies.
3. Anticonvulsant-induced osteomalacia with hypocalcemia (rickets). This uncommon problem may increase the seizure frequency and typically occurs after 5 to 7 years' use.
4. Downregulation of benzodiazepine receptor sites with decreasing antiepileptic response (e.g., clonazepam and nitrazepam).
5. Carbamazepine-induced hyponatremia.

Progression of the Underlying Cause

. Examples are subacute focal (Rasmussen) encephalitis, neoplasm, arteriovenous malformation, and degenerative disease (ceroid lipofuscinosis—Huttenlocher-Alpers). Blume and coworkers[6] reported that 16 of 38 children undergoing cerebral resection for intractable seizures were found unexpectedly to have a cerebral tumor.

Treatment

When a child known to have epilepsy presents with recurring seizures, several steps may minimize the treatment time and disclose the reason for the breakthrough. The physician should first assess the obvious factors: the airway and the vital signs. Next, if the patient is having seizures at the time, the physician should test for the levels of anticonvulsants, electrolytes, calcium, and glucose and should obtain a complete blood cell count with differential. An IV catheter should be inserted if the child is not alert, so that medication can be administered as necessary. If the patient is febrile, a source of infection should be sought.

Once these procedures have been completed, anticonvulsant management is initiated. Assume the anticonvulsant levels are low and give a partial loading dose. If the patient is compliant, give the daily dose of phenobarbital or phenytoin orally if the patient is able to swallow, or intravenously if not. If the patient is known to be noncompliant or if the levels of the anticonvulsant are found to be significantly below the therapeutic range, give double the daily dose (e.g., in a child on 60 mg of phenobarbital, give 120 mg initially and repeat the dose if the seizures recur despite levels in the low therapeutic range).

If the anticonvulsant levels are within a high therapeutic range and the child is well without an obvious source of infection or other cause of breakthrough, then one can decide whether another anticonvulsant is necessary. One may decide to wait and see whether there is a trend toward increased seizure frequency, warranting additional medication, or whether this is a solitary episode, warranting observation, monitoring of drug levels, and follow-up. If the levels are within the high therapeutic range and seizures recur, additional anticonvulsants are warranted in appropriate loading doses (Table 121-4).

Recurring or frequent tonic, tonic-clonic, or clonic seizures warrant loading doses that produce therapeutic levels safely and rapidly. Phenobarbital or fosphenytoin can be administered IM and IV while Depacon (valproate) can be given IV to achieve this effect. Rectal administration of liquid preparations of valproate, phenobarbital, phenytoin, primidone, and carbamazepine can result in therapeutic levels within 4 h. Using large enough doses of primidone, carbamazepine, topiramate, and tiagabine will most likely result in significant CNS toxicity and a greater likelihood of sedation, ataxia, and confusion. Because of the greater risk of serious rash, lamotrigine should not be given in an emergency situation for immediate seizure control.

Seizures that begin with focal features, partial or complex partial (temporal lobe, psychomotor), may appear less dramatic and typically warrant a slower modification of drug therapy unless the seizures are prolonged or postictal Todd paralysis occurs. If a patient requires additional drugs, phenobarbital, phenytoin, and valproate can be used interchangeably without producing uncomfortable side effects. Patients with petit mal (generalized absence) epilepsy rarely are brought to the emergency department, since the seizures are not alarming to the parents. If some injury occurs because of the absence spells, or if the parent is unusually concerned and brings the child for emergency treatment, determining the blood levels of anticonvulsants is most useful. Addition of another anticonvulsant can be initiated, e.g., lamotrigine (Lamictal), ethosuximide (Zarontin), valproate (Depakote), clonazepam (Klonopin), or acetazolamide (Diamox).

Most often, epileptic patients with breakthrough seizure can be sent home, and modification of the drug regimen can be carried out by the attending physician. Following the initial evaluation, modification of drug therapy, and treatment for any superimposed problems, the emergency physician should (1) arrange for follow-up evaluation by the attending physician, (2) emphasize the need for compliance, and (3) provide continued treatment for infections.

STATUS EPILEPTICUS

Status epilepticus (SE) represents a state of "epileptic seizure that is so frequently repeated or so prolonged as to create a fixed and lasting epileptic condition."[7] This definition applies to continuous seizures lasting at least 30 min. As a practical measure, seizures are usually treated as SE if they persist more than 10 min. Classification of status seizures is listed in (Table 121-7).

Primary generalized convulsive status grand mal (continuous and noncontinuous)
    Tonic-clonic status
    Myoclonic status
    Clonic-tonic status

Secondary generalized convulsive status (continuous and noncontinuous)
    Tonic-clonic status with partial onset
    Tonic status

Simple partial status
    Partial motor status including epilepsia partialis continua
    Partial sensory status
    Partial status with vegetative or autonomic symptoms
    Partial status with cognitive symptoms
    Partial status with affective symptoms

Complex partial status

Absence (petit mal) status

Source: Modified from Delgado-Escueta and Bajorek[13] with permission.

TABLE 121-7 Classification of Status Seizures

About 5 to 10 percent of children with epilepsy and 60,000 to 100,000 total epileptics experience one bout of status grand mal (SGM). This condition is a neurologic emergency that could be fatal. The longer the SGM persists, the greater the morbidity and the mortality rates and the more difficult it is to control the seizures. In patients with no neurologic sequelae, the mean duration of SGM is $1\frac{1}{2}$ h. Neurologic sequelae result when SGM lasts an average of 10 h. The mean duration of SGM in patients who die is 13 h.

Effects of Status Grand Mal

Experimental models in animals provide evidence of the neurologic effects of SGM. Selective permanent cell damage in the hippocampus, amygdala, cerebellum, thalamus, and middle cerebral cortical layers develops after 60 min of seizure activity. Even with artificial ventilation and correction of existing metabolic derangements, most changes still occur. This cell death results from the increased metabolic demands and the exhaustion of the continuously firing neurons. In addition, there are secondary effects that probably exaggerate the adverse effects of SGM. After unremitting SGM, the cerebral P $_{O_2}$ and amounts of cytochrome A and cytochrome A3 reductase decrease, enhancing the risk of cell damage. Increases in calcium, arachidonic acid, arachidonic diglycerol, prostaglandin, and leukotriene levels in the neurons exaggerate or cause cerebral edema or cell death. Increased levels of cyclic AMP and increased release of prolactin, growth hormone, ACTH, cortisol, insulin, glycogen, epinephrine, and norepinephrine may contribute to the progression of cell damage with the loss of physiologic responsiveness.

Late secondary effects include lactic acidosis, elevated CSF pressure, hyperglycemia followed later by hypoglycemia, dysautonomia with hyperthermia, diaphoresis, dehydration, hypertension followed by hypotension, and eventually shock. In addition, excessive muscle activity leads to myolysis, myoglobinuria, and renal failure. Neuropathologic studies indicate nucleovacuolation and ischemic nerve cell damage leading to neuronal dissolution.

Treatment

Treatment is best initiated when the type of seizure is identified. To obtain the most effective and rapid cessation of SE, the following evaluation and therapeutic goals must be reached:

1. Specific delineation of the type and subtype of SE so that appropriate treatment can be chosen. For example, tonic-clonic generalized SE is very responsive to diazepam or phenytoin; noncontinuous clonic or tonic-clonic seizures may be refractory to diazepam.
2. Identification and treatment of the reversible precipitating cause of SE, e.g., cerebral infection, trauma, electrolyte disturbance, brain abscess, hypoglycemia, or sickle cell crisis.
3. Rapid cessation of SE to prevent secondary effects that both prolong the seizures and cause irreversible neuronal damage.
4. Full support of medical systems to prevent unwarranted complications of the seizures or the treatment, e.g., respiratory depression, dysrhythmia, aspiration pneumonia, shock, and myoglobulinuria.

In treating patients with SE, the end point of therapy is cessation of the clinical seizures, with return of normal function. When a patient fails to arouse, the possibility of nonconvulsive status must be entertained and then the end point is improvement in the EEG abnormality. The amount of benzodiazepines (BZDs) necessary to stop the seizures has been derived from studies that confirm an essential point, i.e., complications of BZDs occur in markedly ill patients with complex disorders or with prior use of high doses of other hypnotic drugs.

Rapid-acting BZDs remain the drug of choice in SGM. BZDs are effective in SE via several mechanisms: (1) agonist binding at the BZD receptor causes an increase in GABA for its receptor and GABA acts as a receptor for a longer period, and (2) BZDs block sustained high-frequency discharges of epileptic neurons. BZDs are effective because they have high lipophilicity, rapid brain penetration, and brain receptor binding. Multiple studies have compared the safety and effectiveness of lorazepam, diazepam and, more recently, midazolam. Each has its own merit in terms of onset and duration of action. Treiman and colleagues [9] recently reported on a comparison of three therapies in the treatment of SE. They found lorazepam superior to phenytoin and equal to phenobarbital alone and phenytoin in combination with diazepam. The ease of IV lorazepam use made it the recommended initial treatment in SE.

Currently, lorazepam is used as the initial treatment because of its pharmacokinetic properties, exhibiting a slightly slower onset of action (latency) but a longer duration, allowing for a more prolonged seizure-free interval following initial infusion. Lorazepam is begun at 0.1 mg/kg given over 2 min and repeated for a maximum of 8 mg. To maintain the seizure-free state, a long-term AED is started simultaneously with phenobarbital 20 mg/kg at 1 mg/kg/min. Alternatively, fosphenytoin 20 mg PE/kg at 3 mg/kg/min can be used.

In an open study by Lacey and coworkers, [10] lorazepam was administered to 31 children with SE. The initial dose was 0.05 mg/kg, with 20 patients requiring two injections and one patient requiring three injections. The median dose was 0.05 mg/kg, with a total median cumulative dose of 2.0 mg. The median latency was 10 min; control lasted at least 3 to 6 h in 83 percent of the patients and 24 h in nearly 50 percent of the patients. In a double-blind randomized trial by Leppik and coworkers, [11] 78 adult patients were treated with either lorazepam (4 mg) or diazepam (10 mg). Latency (2 to 3 min), efficacy (76 to 89 percent), and adverse effects (12 to 13 percent) did not differ significantly in both groups.

Diazepam was the BZD used initially in the modern era of epilepsy management and can be used in addition to or instead of lorazepam. A starting diazepam dose of 0.2 to 0.5 mg/kg, given at a rate of 1 mg/min and repeated as needed to a maximum of 2.6 mg/kg, is recommended to stop continuous tonic-clonic and clonic seizures. This higher dose is rarely used, since most patients stop seizing at lower doses and additional drugs such as phenytoin may be employed.

The safety of diazepam at the maximum dose of 2.6 mg/kg over the course of treatment has been substantiated. Smith and Masotti [12] described an effective dose of diazepam as 0.08 to 2.72 mg/kg in infants and young children, with an average effective dose of 0.68 mg/kg. Many authors recommend initial doses of 1 mg per year of age, with a maximum total dose of 5 mg in infants and 10 mg in children. Eckert [13] reported maximum doses in adolescents as 35 mg in brief periods and 100 mg in 24 h.

Midazolam (MDZ) is a more rapid-acting BZD and has the advantage of relatively rapid IM absorption. It has been used via IV, IM, nasal, and rectal routes in the treatment of SE. We are currently completing a study on its effectiveness and safety in childhood SE in comparison to lorazepam. MDZ is water soluble at physiologic ph (open ring) and becomes lipid soluble (ring closure) after injection. It has a distribution half-life of 1.5 to 3.5 h. The initial dosage is a 0.2-mg/kg bolus, which can be repeated in 15 min. Because of its short half-life, it has been used as a continuous infusion at 0.05 to 0.4 (mg/kg)/h to treat continuous unresponsive seizures, but this has not been extensively tested. When given IM, seizure control occurred within 2 to 3 min of injection. In a study by Chamberlain and colleagues, [14] more rapid cessation of seizures occurred with MDZ (7.8–4.1 vs 11.2–3.6 min) in comparison to IV diazepam. This was attributed to the ease of administration of the IM MDZ as compared with the time needed for IV site acquisition with the diazepam.

The following steps should be followed when treating continuous SGM (tonic-clonic SE) (Table 121-5):

1. Assess basic functions immediately and maintain blood pressure, airway, and pulse.
2. Obtain blood to be tested for levels of anticonvulsants, electrolytes, blood urea nitrogen, calcium, and glucose, and for a complete blood count with differential while inserting an IV catheter for fluid administration.
3. Administer a bolus of 25 percent glucose, 2 mL/kg.
4. Administer IV lorazepam, 0.1 mg/kg, and repeat up to a total dose of 8 mg or early signs of respiratory depression. Alternatively, administer IV diazepam, 0.2 mg/kg over 2 min, repeating in 15 min and 30 min, if necessary, to a total dose of 2.6 mg/kg.
5. Administer IV phenobarbital, 20 mg/kg at 1 mg/kg/min, as BZD is being infused.
6. Administer IV fosphenytoin, 20 mg PE/kg at 3 mg/kg/min, if phenobarbital is ineffective. When a patient reaches this level, transfer to the intensive care unit is warranted.
7. If seizures persist, give additional 10 mg/kg of phenobarbital to reach levels of 60 µg/mL.
8. Administer paraldehyde rectally, 0.3 mL/kg, mixed with an equal amount of mineral oil, if available and the above are ineffective.
9. Under intensive care monitoring, administer pentobarbital, 2 mg/kg bolus, followed by maintenance of 1 to 2 mg/kg/h, to effect 3 to 6 s of EEG burst suppression.
10. In noncontinuous SGM, administer continuous MDZ at a dose of 0.04 to 0.05 mg/kg/h.

Noncontinuous SE can be more difficult to treat since the end point is more elusive. Rapidly acting drugs such as diazepam and lorazepam are less effective, and a more sustained effect is necessary. Often noncontinuous SE is not responsive to appropriate therapeutic levels of phenytoin and phenobarbital. MDZ can be given as a continuous infusion of 0.04 to 0.05 mg/kg/h. Alternatively, large doses (0.2 to 0.6 mg/kg) of clonazepam via nasogastric tube may be used to produce the desired effect of cessation of noncontinuous seizures and the anticonvulsant effect can be maintained by additional drugs (phenytoin or phenobarbital) and clonazepam (0.1 to 0.3 mg/kg/day).

Paraldehyde rectally administered can be very effective in treating SE and acute repetitive seizures. Paraldehyde should be administered only with glass syringes and rubber tubing in view of its degradation to toxic by-products in the presence of certain plastics.

In absence SE, the BZDs are highly effective. The child usually appears dazed and may exhibit repetitive eye blinking.

Epilepsia partialis continua is a serious neurologic condition, although it does not appear life threatening at first. The patient exhibits repeated continuous or minimally interrupted clonic jerking of one side of the body and usually one part of an extremity for days, weeks, or months. It is typically due to encephalitis or cerebrovascular accident or associated with heterotopias and indicates a relatively poor prognosis. Initial management is similar to that of SE.

The use of propofol has been advocated in adults with refractory SE,[15] but its prolonged use in children with refractory SE was associated with progressive severe metabolic acidosis and rhabdomyolysis, which the authors concluded was due to propofol.[16]

DIFFERENTIAL DIAGNOSIS OF SEIZURES

It is necessary to identify nonepileptic paroxysmal disorders to prevent confusion with epilepsy. The differential diagnosis of seizures must take into account many disorders that can produce loss of consciousness, unusual movements, impaired awareness, or bizarre behavior. Many of these disorders are age-specific.

In newborns, the problems partly reflect the intrauterine experience. Jitteriness or hyperexcitability appears as high-amplitude tremulousness easily brought out by passive movement of the extremities or jarring of the crib. Drug-withdrawn infants are irritable and tremulous and may have diaphoresis, vomiting, and diarrhea. In addition, seizures may occur. Sepsis, hypoglycemia, and hypocalcemia may produce nonepileptic paroxysmal activity in addition to seizures. Hyperekplexia, or startle disease, mimics tonic and clonic seizures. Near-miss sudden infant death syndrome (SIDS) remains a multifactorial condition in which seizures are part of the differential diagnosis and might be considered part of the cause.

In older infants, it is more common to see cyanotic and pallid breath-holding spells, which typically occur following an abrupt trauma (a fall or a minor spanking) or a verbal reprimand. The infant gives a sudden cry followed by prolonged inhalation or exhalation, resulting in no air exchange, and a Valsalva maneuver, often with bradycardia. A brief tonic nonepileptic seizure often occurs. Drug intoxication manifested by hyperkinesis, impaired awareness, or altered behavior (hallucinations) is usually accidental at this age. In adolescence, PCP intoxication mimics complex partial seizures and may result in seizures with more severe overdoses.

Congenital heart disease can produce paroxysmal events at all ages. Abrupt mental status changes may occur in patients with pulmonary hypertension, aortic stenosis, tetralogy of Fallot, single ventricle, cardiac rhabdomyomas, etc. Acquired cardiomyopathy may result in decreased cardiac output (Adams-Stokes disease) or cerebrovascular accident. The prolonged QT syndrome and neurocardiogenic syncope may cause nonepileptic seizures or syncopal episodes. They should be evaluated for when epilepsy is unsubstantiated or the more obvious problems of diaphoresis, light-headedness, and skin color/temperature changes precede or accompany unconsciousness. In adolescents, syncope due to stretching and yawning or following hair combing (vasovagal) is more common. Many children experience syncope when standing in church.

Hyperkinetic movement disorders can be difficult to differentiate from complex partial seizures. Sydenham's chorea is infrequently seen today, and drug-induced chorea (ethosuximide, carbamazepine, or diphenhydramine hydrochloride) and lupus-induced chorea are likewise very uncommon. Tourette syndrome is more frequently seen, but rarely does the child appear acutely ill. Kinesogenic chorea is a movement disorder brought on by action and mimics simple motor partial seizures.

Immediate posttraumatic migraine may recur after relatively minor injury and cause confusional states mimicking concussion or complex partial seizures.

Pseudoseizures represent a particular problem for the treating physician because the "seizures" appear to represent a significant threat to the patient's safety, and vigorous anticonvulsant therapy is often initiated. Unfortunately, pseudoseizures often occur in patients with documented epilepsy. Secondary gain should become evident in these cases. The "seizures" are atypical in that the patient may waken fully in the interictal phase and require repeated large doses of anticonvulsants even to the point of protracted drug-induced depression. Another form of pseudoseizures consists of those described by the parent and never observed by other witnesses (Münchausen by proxy).

To distinguish pseudoseizures from the true epileptic spells, a bedside technique may be dramatic and diagnostic, and prevent over-treatment. One method is to insert a nasopharyngeal tube and observe the patient's response. A pseudoseizure patient will become responsive immediately. Experience dictates referral, or even hospitalization, for patients with a diagnosis of pseudoseizure, to prevent recurrences, provide family education, and lessen the likelihood of inappropriate treatment.

Simple sleep myoclonus and night terrors are of concern to parents but are easily distinguished from nocturnal seizures. REM sleep disorder may mimic seizures.

Preventing misdiagnosis and mistreatment is an essential part of the emergency management of seizures and related disorders.

PROBLEMS OF ANTICONVULSANT USE

Unwanted features of anticonvulsants may be seen soon after the drug is initiated or may develop weeks, months, or years later. These problems may turn up during evaluation for other illnesses (e.g., macrocytic anemia) or be the basis for emergency treatment.

Immediate side effects often subside in time. Lethargy is usually dose related and subsides with chronic use and can occur with the oldest AED (phenobarbital) as well as the newest AEDs (topiramate and tiagabine). Irritability and changes in cognition can persist and be significant but are unrelated to drug levels (valproate). Rashes may occur within days or weeks of initiation of therapy but must be differentiated from concurrent viral exanthem. Pruritic and/or morbilliform rashes usually require cessation of medication. Stevens-Johnson syndrome, with bullous skin lesions affecting mucous membranes, is a serious potential reaction. There is a risk of serious sequelae—blindness, esophageal stenosis, or loss of life.

With valproic acid use, hepatic failure may occur within days or up to 2 years after first use. The drug reaction results in behavior alteration, increasing lethargy, and vomiting. Levels of liver enzymes may be minimally to markedly elevated, and hyperammonemia with or without symptoms of hepatic failure may be found. Immediate cessation of valproate, hospitalization, and observation are necessary if symptomatic hepatic reaction is evident. In asymptomatic patients with enzyme level elevations, a reduction of the dosage and careful observation are warranted. Gastrointestinal side effects are common with initial use of valproic acid and may be so severe that more serious hepatic problems are considered. These side effects can be avoided by taking the drug with meals, by avoiding carbonated beverages and citric juices, and by using the enteric-coated form or sprinkles. Pancreatitis secondary to valproate use may occur with initial and chronic use.

Toxicity due to overdosage at any time can produce some readily identifiable symptoms and signs. Phenytoin toxicity occurs when serum levels exceed 25 µg/mL in most patients (above 20 µg/mL in some). Nausea, dysarthria, diplopia, and ataxia are seen early, with progression to impaired levels of consciousness and decerebrate posturing. Virtually all anticonvulsants produce ataxia and lethargy with significant overdosage. Cardiopulmonary monitoring during high-dose drug use in SE should be employed, since cardiac dysrhythmia, hypotension, or respiratory depression can occur. The use of fosphenytoin has eliminated the problem of venous and subcutaneous extravasation-related phenytoin side effects. Chronic phenytoin use can result in folate deficiency with macrocytic anemia, acquired osteomalacia (increased vitamin D turnover), neutropenia (often transient), peripheral neuropathy, lupus-like syndromes, and myasthenic weakness.

Valproate-induced thrombocytopenia is a significant side effect warranting lowering or discontinuation of the drug if platelet levels are significantly lowered or bleeding is evident. Lower carnitine levels due to valproate metabolism may be a contributing factor of valproate hepatotoxicity.

Drug interactions may be quite dramatic. Valproate and aspirin use can result in a bleeding diathesis. Antihistamines used in conjunction with barbiturates can be very sedating, warranting smaller doses of the antihistamine. When erythromycin is used, particular care must be exercised, since the carbamazepine levels may rise to toxic levels rapidly. Toxicity is greater when carbamazepine and lithium are used together, and blood levels may be in the therapeutic range. Total phenytoin levels are typically reduced when valproic acid and tiagabine are also used, but free phenytoin usually remains therapeutic and it is essential to measure free phenytoin. When barbiturates are used concomitantly with phenytoin, increased parahydroxylation can cause enhanced metabolism of phenytoin so that therapeutic levels fall, resulting in seizure breakthrough. Hyperbilirubinemia and hypoalbuminemia can affect anticonvulsant binding and blood levels.

Movement disorder (e.g., chorea) can result after several weeks' or months' use of ethosuximide and carbamazepine. The movements may be profound and usually

respond to the reduction or discontinuation of the drug and, if necessary, the use of diphenhydramine (Benadryl), 12.5 to 25 mg IV. Clonazepam and diazepam can cause acute bladder dysfunction with urinary retention.

Many problems of dose-related toxicity can be avoided by maintaing therapeutic blood levels. Blood level determinations should be done randomly to determine compliance at times of increased seizure frequency or when signs of toxicity develop. In some patients, side effects develop at therapeutic levels. Idiosyncratic effects cannot be predicted, but families must be made aware that significant side effects can develop with little warning, and evaluation by a physician is recommended before a drug is dismissed. Obtaining the patient's history, consulting with the primary physician or consultant, and reviewing readily available drug information in the package insert or *Physicians' Desk Reference* make emergency evaluation and treatment of anticonvulsant drug reactions simpler.

ERRORS IN EMERGENCY MANAGEMENT OF SEIZURES

After a patient arrives for treatment, the initial assessment may be incomplete, resulting in inappropriate or inadequte therapy. Not identifying treatable infections, electrolyte imbalance, child abuse, and accidental trauma can lead to rapidly progressive deterioration and demise, or may make seizure control difficult. By not ascertaining anticonvulsant levels in a patient with epilepsy, the physician loses an opportunity to determine whether the anticonvulsant is ineffective or simply at too low a level.

If the emergency physician communicates with the primary physician, unnecessary studies and drugs that either were ineffective or produced some side effects can be avoided. Additionally, it is important to consult with the patient's physician when prescribing nonanticonvulsants that might interfere with anticonvulsants or produce unwanted side effects.

In the aggressive treatment of seizures (SE and recurring breakthrough seizures), inadequate loading doses or improper drug selection may prolong the seizure and worsen the prognosis. Excessive dosage can result in respiratory depression or hypotension and, in rare instances, can exacerbate the seizures. If nonepileptic paroxysmal disorders are not recognized, the patient is put at the additional risk of unnecessary medication and inadequate treatment of the real disorder.

Emergency physicians cannot deal with all the problems facing patients with epilepsy. Follow-up care by the primary physicians or appropriate consultants ensures better compliance and, hopefully, lessens emergency situations in the future.

122 VOMITING AND DIARRHEA IN CHILDREN

Christopher M. Holmes
Ronald D. Holmes

Vomiting is the forceful ejection of stomach contents through the mouth and is always a cause for concern. Associated symptoms, the age of the child, the pattern of vomiting, and the duration of symptoms help to determine the etiology. The causes of acute vomiting are listed in Table 122-1.

TABLE 122-1 Differential Diagnosis of Vomiting

Most infants and children who come to the emergency department because of vomiting have a self-limited viral disorder. Only a small percentage of these patients will require assessment beyond obtaining a careful medical history and performing a physical exam, and a smaller number will require specific treatment. For most children, the only treatment will be the recommendation to provide additional fluids and to continue age-appropriate feedings. It is important to remember that vomiting need not resolve before a rehydrated or well-hydrated child may be discharged from the emergency department.

Diarrhea is defined as an excessive loss of water in the stool. Most cases of diarrhea result from self-limited enteric infections. Infectious diarrhea may be either inflammatory (dysentery) or noninflammatory. Inflammatory infectious diarrhea is commonly due to bacterial or parasitic infections/infestations. These organisms tend to localize in the colon or distal small bowel and result in dysentery, which is characterized by frequent bowel movements containing blood, mucus, or pus. Noninflammatory infectious diarrhea is caused by viruses and parasites that localize to the proximal small bowel, or by toxin-producing bacteria. In these cases, the diarrhea is profuse, watery, and commonly associated with nausea and vomiting. Fever is less likely. The term *gastroenteritis* is applied to this group of infections, although the stomach is rarely involved.

Other causes of acute diarrhea are uncommon but must be considered. In agricultural areas, poisoning with anticholinesterase insecticides, organophosphates, and carbamates must be considered, especially if diarrhea is accompanied by profuse sweating, lacrimation, hypersalivation, and abdominal cramps. Vomiting and diarrhea may also be a nonspecific presentation for other infectious diseases, such as otitis media, urinary tract infection, or other more serious conditions, including intussusception, malrotation, increased intracranial pressure, and metabolic acidosis.

EPIDEMIOLOGY

In the United States, children younger than 3 years of age have 1.3 to 2.3 episodes of diarrhea each year. The prevalence is higher in children attending day-care centers. Up to one-fifth of all acute-care outpatient visits to hospitals are by families with infants or children affected by acute gastroenteritis, and 9 percent of all hospitalizations of children younger than 5 years of age are for diarrhea.[1] Most enteric infections are self-limited, but excessive loss of water and electrolytes, resulting in clinical dehydration, may occur in 10 percent and is life threatening in 1 percent.[2]

Pathogenic viruses, bacteria, or parasites may be isolated from nearly 50 percent of children with diarrhea. Viral infection is the most common cause of acute diarrhea. Bacterial pathogens may be isolated in 1 to 4 percent of cases. While infants and children who attend day-care centers are most likely to acquire viral gastroenteritis, they are at increased risk of acquiring a variety of enteric infections/infestations by *Shigella*, *Campylobacter*, *Clostridium difficile, Salmonella*, *Cryptosporidium*, and *Giardia lamblia*. The attack rate during outbreaks may range from 30 to 100 percent, and shigellosis is particularly contagious.[3]

Enteric infections causing diarrhea are spread by the fecal-oral route by contaminated food, water, and fomites. Rotaviruses, Norwalk viruses, the enteric adenoviruses, calicivirus, and astroviruses are the most recognized viral pathogens that affect children. Of these, rotavirus is the most common, typically occurring in the cooler months of the year in North America (October to April), and infecting every child in the United States by age 4 years. This virus causes potentially lethal dehydration in 0.75 percent of children younger than 2 years of age.[4] Older children and adults have acquired immunity against the rotaviruses and are less likely to develop the severe dehydrating syndrome. Symptomatic enteric adenovirus (EAd) infection with serotypes 40 and 41 causes diarrhea that is associated with concurrent respiratory symptoms. Infections, with no clear peaks, occur throughout the year and may be responsible for 5 to 20 percent of hospitalizations for childhood diarrhea.[5] Outbreaks of EAd infection occur second only to rotavirus infection in prevalence. Norwalk virus infection is also implicated in causing epidemic gastroenteritis. In addition to developing nausea, vomiting, diarrhea, and abdominal cramps, affected children and adults may have headache, fever, chills, and myalgias. Vomiting is more prevalent in children, whereas diarrhea is more common in adults.

The major bacterial enteropathogens in the United States are *Campylobacter jejuni*, *Shigella* species, *Salmonella* species, *Yersinia enterocolitica, Clostridium difficile*, *Aeromonas hydrophila,* and *Escherichia coli*. *Escherichia coli* is the most common bacterial organism causing diarrhea in children around the world but is less common in the United States. Diarrhea due to *E. coli* may be watery and caused by enterotoxigenic *E. coli* (ETEC) or enteropathogenic *E. coli* (EPEC), or present as a dysentery-like disease due to infection with enterohemorrhagic *E. coli* (EHEC).

Giardia lamblia is a common cause of diarrhea in infants and young children in day-care centers. As many as 50 percent of infected children may be asymptomatic. *Cryptosporidium* infestations occur in a similar epidemiologic pattern. Although *Cryptosporidium* was first recognized as an opportunistic pathogen in immunocompromised children, it is now recognized as a cause of protracted watery diarrhea in otherwise healthy children. *Entamoeba histolytica* causes diarrhea, proctitis, dysentery, or hematochezia. Symptomatic infection in children results from exposure by travel to a geographic locale endemic for the organism or in

adolescents through sexual transmissions.

PATHOPHYSIOLOGY

Viral pathogens cause acute gastroenteritis by tissue invasion and a directly cytopathic effect to small intestinal villous cells. As a consequence, there is villous damage and decreased intestinal absorption of nutrients, electrolytes, and water, resulting in watery diarrhea. Villous injury also results in reduced disaccharidase levels and diminished total mucosal glucose-coupled sodium transport. The end result is a decrease in intestinal water absorption. The volume of fluid delivered from the lumen of the damaged small intestine exceeds the colon's limited ability for fluid absorption, and the net result is watery diarrhea.

Bacteria cause diarrhea by a variety of mechanisms, including production of enterotoxins and cytotoxins and invasion of the mucosal absorptive surface. Enteric infections with *E. coli* are prototypic for understanding several of these pathogenic processes. ETEC and EPEC adhere to the mucosa and produce enterotoxins or damage the microvilli, respectively. Certain strains of EHEC invade the colonic mucosa, resulting in inflammation and an illness similar to shigellosis. EHEC serotype O157:H7 typically produces a hemorrhagic colitis with little inflammation and may produce verotoxins that have been implicated in causing hemolytic-uremic syndrome (HUS).[6] Antibiotic-associated diarrhea and colitis due to cytotoxigenic *Clostridium difficile* may result in a similar pattern of diarrhea.

Bacterial toxins may also be ingested directly in food. The most common are heat-stable toxins produced by *Staphylococcus aureus* present in improperly stored or prepared meats, poultry, and dairy products. *Bacillus cereus* also produces a heat-stable toxin typically ingested with boiled or fried rice. Although *Shigella* is considered a prototype organism causing dysentery, it can also produce a toxin that causes watery diarrhea, encephalopathy, or seizures. Parasitic infestations may cause diarrhea by a variety of mechanisms similar to those discussed for viral gastroenteritis.

CLINICAL FEATURES

Evaluation of a child's state of hydration is most important. If possible, it is best to determine the degree of fluid loss by comparing the child's current weight to a recent previous weight. When objective measurements are not available, the state of hydration can be assessed by physical examination. Combinations of physical signs, including ill general appearance, capillary refill of longer than 3 s, dry mucous membranes, and absent tears, are good predictors. The presence of two or more signs predicts 5 percent or greater dehydration, whereas three or more signs predict 10 percent or greater dehydration. [7] Severe dehydration accompanied by lethargy, hypotension, and delayed capillary refill requires immediate administration of parenteral fluids. Although capillary refill may be affected by conditions other than dehydration, it should be considered a sign of significant dehydration until proven otherwise. [8] Guidelines for assessing dehydration are listed in Table 122-2.

Variable	Mild, 3%–5%	Moderate, 6%–9%	Severe, >9%
Blood pressure	Normal	Normal	Normal to reduced
Quality of pulses	Normal	Normal or slightly decreased	Moderately decreased
Heart rate	Normal	Increased	Increased
Skin turgor	Normal	Decreased	Decreased
Fontanelle	Normal	Sunken	Sunken
Mucous membranes	Slightly dry	Dry	Dry
Eyes	Normal	Sunken orbits	Deeply sunken orbits
Extremities	Warm, normal capillary refill	Delayed capillary refill	Cool, mottled
Mental status	Normal	Normal to listless	Normal to lethargic or comatose
Urine output	Slightly decreased	<1 mL/kg/h	<1 mL/kg/h
Thirst	Slightly increased	Moderately increased	Very thirsty or too lethargic to indicate

TABLE 122-2   Assessment of Dehydration

Bacteria that invade the mucosa of the terminal ileum and colon can cause dysentery, which is characterized by frequent bowel movements that contain blood, mucus, or pus. The diarrhea is often accompanied by fever, tenesmus, and painful defecation. Infants and children who have bloody or mucousy diarrhea after having received antibiotics may have antibiotic-associated pseudomembranous colitis due to infection with cytotoxigenic *C. difficile*. Infestations with *Entamoeba histolytica* may also cause dysentery. Table 122-3 lists the enteric infections that cause children to have bloody diarrhea.

Trichuris trichiura

TABLE 122-3   Enteric Pathogens That Cause Dysentery

DIAGNOSIS

The approach to diagnosis and successful treatment involves obtaining a medical history carefully, and selective laboratory testing. Most hospital laboratories provide various cultures and immunoassays of stool for the presence of the enteric pathogens. Routine stool culture for bacterial pathogens now includes *Campylobacter jejuni*, *Y. enterocolitica*, and *Aeromonas* in addition to *Salmonella* and *Shigella*. Subculturing for *E. coli* serotypes or stool assays for *Clostridium difficile* toxin activity are available. Enzyme immunoassays also are available to test stool for the presence of rotavirus, enteric adenovirus, and astrovirus.

Most children have a nonspecific gastroenteritis and not dysentery. Clinicians must assess the likelihood of defining a treatable etiology and, as a consequence, the indication for performing a stool culture. The presence of fecal leukocytes or positive guaiac testing has been used as a screening tool to identify children at increased risk for invasive bacterial enteric infection, but fecal leukocytes have poor sensitivity and guaiac testing has poor specificity. [9] Therefore, it is best to combine these tests with the clinical findings to determine the need for stool cultures. If a child is febrile and has abrupt onset of diarrhea occurring more than four times per day or blood in the stool, the illness is more likely to have been caused by a bacterial pathogen and stool cultures are indicated. [10] The likelihood of identifying bacterial pathogens is increased if the patient's stool or accompanying exudate contains polymorphonuclear leukocytes. [11]

Anaerobic stool cultures and assay of stool for *Clostridium difficile* toxin activity should be obtained for children who have been receiving antibiotics and develop bloody diarrhea. A history of hiking or camping should prompt examination for ova and parasites. In addition, a swab of mucus or bloody exudate from the stool should be placed in transport medium and sent to the laboratory for culture of *Shigella* species. *Shigella* is a fastidious pathogen and is more likely to be recovered from a swab than from a fresh stool specimen. In cases of persistent or recurrent diarrhea, especially with weight loss or day-care center exposure or in immunocompromised children, stool samples should be collected in fixative and examined for *G. lamblia, Entamoeba histolytica,* and *Cryptosporidium*. Depending on geographic location or travel history, serologic testing for confirming *E. histolytica* infection may be indicated.

Dehydration caused by diarrhea is usually isotonic, and measurement of serum electrolytes is not necessary. It is most important, however, to be aware of the

physical findings of hypernatremic dehydration (hyperirritability, sunken eyeballs and fontanel, parched mucous membranes, and thickened, doughy skin) and the special requirements for rehydrating these infants following initial fluid resuscitation. In children receiving intravenous (IV) therapy, electrolytes may be measured initially and during therapy.

Protracted vomiting and/or diarrhea occurring in infants and toddlers, in combination with fasting, may increase the risk of hypoglycemia. Measurement of blood glucose may be helpful in managing these patients.

SPECIFIC ISSUES THAT IMPACT DIAGNOSIS, EVALUATION, AND TREATMENT

Age

Infants under 1 year of age pose a more difficult problem because of the risk of rapid dehydration and hypoglycemia. Signs of sepsis in this age group may be nonspecific, but any infant who fails to make eye contact or to respond to a parent's voice or face may be toxic and will likely be admitted to the hospital. Although bilious vomiting may develop in older infants and children who acquire viral gastroenteritis, bilious vomiting in an infant under 2 years of age is a sign of intestinal obstruction until proven otherwise.

Comorbid Medical Conditions

Infants and children who appear to be malnourished are at significant risk of complications of diarrhea and dehydration and should be admitted to the hospital. In addition, high-risk social situations should be identified and consideration given to admitting such children. These situations include the single, often teenage, parent who is without an intact support system, or parents/caregivers who are homeless or unable to provide appropriate fluids to the child. Special consideration must also be given to chronically ill infants who develop acute diarrhea or severely handicapped, developmentally delayed children in whom it is difficult to provide oral fluids.

EMERGENCY TREATMENT

Gastroenteritis

Treatment of diarrhea changed in the mid-1960s with the introduction of oral rehydration solution (ORS) as an alternative to administration of IV fluids. Although ORS is still not universally used in the United States, it has been proven to be effective and to result in fewer complications than IV therapy. ORS successfully rehydrates 90 percent of children in whom it is used.[11]

The majority of children with diarrhea and vomiting who become dehydrated may be treated with ORS (Fig. 122-1). This treatment capitalizes on the fact that glucose-coupled sodium and water absorption remains sufficiently intact during most infections. Glucose-electrolyte solutions, like Pedialyte, are commonly available in the United States. The glucose concentration of these solutions does not exceed the sodium concentration in millimolar units by more than 2:1. In addition, the osmolality of commercial hydration solution is relatively low and about 310 mosm/L. In contrast, other clear fluids, such as soft drinks, juices, and Jell-O water, are largely carbohydrate based, are typically deficient in Na $^+$ and Cl$^+$, and have osmolalities ranging from 510 to 1225. The routine use of such highly osmolar sugar-based solutions to treat acute diarrhea will predictably amplify net small intestinal fluid secretion and increase diarrhea.

FIG. 122-1. Evaluation and treatment of diarrhea in children.

Vomiting is not a contraindication to administering ORS. The key in the treatment of vomiting children is to give small volumes of glucose-electrolyte solution, often starting with 5 mL at a time given every couple of minutes. ORS may also be given in the form of a popsicle. Giving ORS in this manner is labor intensive, though, and, if parents or staff are not available, then IV therapy may be necessary. For IV rehydration, between 20 and 40 mL/kg of Ringer's lactate or normal saline may be given over 1 to 3 h. Following parenteral rehydration, many children may be discharged home for regular feedings and supplemental ORS solution, provided follow-up is available, they do not appear toxic, and the caregiver is reliable. The daily volume of ORS should not exceed 150 mL/kg/day. [12] Breast milk or infant formula should be used if additional fluid is needed to satisfy thirst.

Children who have mild diarrhea and no dehydration may continue age-appropriate feedings and supplemental fluids as needed to replace ongoing stool loss (10 mL/kg/stool). ORS may be used to replace stool loss: although the solution is salty and may be refused, children who are dehydrated rarely refuse ORS. Mild dehydration (3 to 5 percent) may be treated by giving 50 mL/kg ORS plus replacement of ongoing losses over a 4-h period. Moderate dehydration (6 to 9 percent) is treated with 100 mL/kg plus replacement of ongoing losses over 4 h. Age-appropriate feedings should be reintroduced after a child is rehydrated. Severe dehydration (more than 10 percent) is a medical emergency, and the child should be given bolus IV fluids (20 mL/kg) using normal saline. The bolus may be repeated as needed to restore circulating volume and the child admitted to the hospital.

In general, reinstatement of food should begin after the 4-h rehydration phase is completed and never delayed more than 24 h. Recent studies have shown that the introduction of full-strength formula or unrestricted diet immediately following rehydration is associated with decreased duration of diarrhea, positive nitrogen balance, and increased weight gain. Breast-feeding should be routinely continued for infants with acute gastroenteritis. Infants who have been receiving formula feedings and who are not dehydrated may rapidly return to their feeding. There is no need to give dilute formula. Some practitioners have recommended the BRAT diet (bananas, rice, applesauce, and toast), but this diet does not provide adequate energy, fat, or protein. Instead, complex carbohydrates, lean meats, yogurt, fruits, and vegetables should be encouraged. Fatty foods and foods high in simple sugars like juices and soft drinks should be avoided. Some ethnic groups may prefer to use traditional home remedies like herbal teas or rice water. Since the osmolality of these solutions is variable, they may worsen the diarrhea. Finally, there is little evidence to support a lactose-free diet. Over 80 percent of children with acute diarrhea can tolerate full-strength milk safely. [13]

Vomiting

The use of antiemetics is controversial. The consensus opinion of a panel convened by the American Academy of Pediatrics and published in 1996 is that antiemetic drugs are not needed. If vomiting persists despite efforts to give ORS, then IV hydration is indicated. Physicians who prescribe antiemetics should be aware of the potential adverse effects of these drugs.[14]

Dysentery

Antibiotic therapy does not affect the clinical course in most cases of acute diarrhea. Patients with uncomplicated *Salmonella* gastroenteritis should not be given antibiotics unless they appear septic or are bacteremic, have a hemoglobinopathy, or have an underlying chronic gastrointestinal disorder. However, infants younger than 6 months of age are generally treated with antibiotics because of their overall risk of bacteremia or suppurative disease. If a child has had diarrhea lasting longer than 10 to 14 days and has a significant fever, systemic complaints, and inflammatory cells or blood in the stool, then empiric antimicrobial treatment may be indicated

after sending a stool sample for bacterial culture. Therapy should provide coverage for the usual dysenteric agents (*Shigella, Salmonella,* and *Campylobacter*), and either ampicillin or trimethoprim-sulfamethoxazole are reasonable choices. Debilitated patients, children with underlying gastrointestinal disorders, immunocompromised children, and children with severe bloody diarrhea should be treated with oral antibiotics [15] (Table 122-4).

TABLE 122-4   Clinical Features, Diagnostic Aids, and Treatment of Diarrheas

Children who have been receiving antibiotics and develop bloody diarrhea may have antibiotic-associated colitis. Most cases of antibiotic-associated colitis caused by *Clostridium difficile* resolve spontaneously when antibiotics are discontinued. Infants and children with protracted diarrhea that has not improved after discontinuing antibiotics may benefit from receiving cholestyramine [2 (g/kg)/day divided into three equal doses]. Cholestyramine is an anion-exchange resin that adsorbs *C. difficile* cytotoxin.

Several antidiarrheal drugs are available to alter intestinal motility, decrease secretions, and adsorb toxins or fluids to reduce diarrhea. Few published data are available, though, to support the use of these agents for treating acute diarrhea in children. Antimotility agents should not be used to treat acute diarrhea in children. [16]

DISPOSITION

Indications for Hospital Admission

All infants who appear toxic should be admitted. Patients with 10 percent dehydration, intractable vomiting, or altered consciousness should be given an infusion of normal saline or Ringer's lactate, regardless of the serum osmolality, and admitted. Infants who are less ill, but whose families may not be able to follow the guidelines for administering ORS, should also be admitted.

Infants who are malnourished and have acute diarrhea require special attention. They more often need to be admitted to the hospital and may require consultation. Malnourished infants are likely to develop metabolic acidosis accompanied by an increase in the anion gap and renal dysfunction. The increased anion gap is due to the accumulation of unmeasured anions, lactate, and phosphate and is accompanied by normochloremia. This is in contrast to most well-nourished infants, who develop hyperchloremic acidosis due to fecal loses of bicarbonate. The latter group of infants can be expected to improve with oral therapy.

Infants and children with bloody diarrhea may have a gastrointestinal infection due to *Escherichia coli* O157:H7 and are at risk of developing HUS. The source most frequently identified in outbreaks has been exposure to undercooked ground meat, undercooked poultry, eggs, or unpasteurized milk. Person-to-person transmission, especially in child day-care centers, is also a well-recognized risk factor for childhood HUS. The risk is highest for children under 5 years of age who are infected with *E. coli* O157:H7 and may approach 13 percent.[6] Any child who presents with acute bloody diarrhea and laboratory evidence of hemolytic anemia, thrombocytopenia, and/or elevated serum creatinine should be admitted.

Most cases of acute gastroenteritis do not require consultation. In cases of suspected intestinal obstruction, appendicitis, or intussusception, surgical consultation is indicated. Many surgeons prefer consultation prior to radiologic confirmation of intussusception. Ingestions of toxins often require consultation with a poison control center or toxicologist. In cases where abuse or neglect is suspected, social service and the primary care physician should be involved. Chronic diarrhea or chronic vomiting should be discussed with the child's primary care provider to determine whether consultation is indicated.

DISCHARGE INSTRUCTIONS

Infants and children who are not dehydrated or who have responded well to oral or IV hydration may be discharged with instructions to take ORS solutions and age-appropriate feedings. The family should be instructed to return to the emergency department or to their own physician if the child becomes unable or unwilling to drink the ORS solution, begins to vomit, has increased emesis, develops bilious emesis, or shows signs of dehydration, such as decreasing urine output or decreased tearing, or if there is a decrease in the child's level of activity or state of alertness. Infants and small children should be reevaluated within 24 h especially if they continue to have diarrhea. The family should be instructed to telephone their primary care provider and he or she should decide if a visit is necessary. If the family does not have a primary care physician, then the family should contact the emergency department.

123 PEDIATRIC ABDOMINAL EMERGENCIES

Robert W. Schafermeyer

Evaluation of abdominal emergencies in childhood presents a diagnostic challenge. Some diseases are common to both adults and children and others are age specific, such as congenital anomalies, volvulus, and Hirschsprung disease. One must understand the differential diagnoses of the presenting symptoms, recognize the clinical manifestations of the more common and life-threatening diseases, and be sensitive in approaching infants and children.

One can classify abdominal disease processes in several ways. Is the child febrile or afebrile? Does the disease appear to be obstructive or nonobstructive, abdominal or extraabdominal in nature? Is it due to a local process, or is it systemic? Does the child appear healthy and happy or sick and septic?

The child's age influences the presenting signs and symptoms significantly. The spectrum of pathologic gastrointestinal (GI) conditions of a 2-day-old infant is vastly different from that of a 2-week-old, and both are quite different from that of a 2-year-old.

HISTORY

An infant or young child cannot give a complete history, but if the child is verbal, one should try to get historical information from him or her and then obtain and listen carefully to what the parent or caregiver says. Find out the accurate chronology of events, whether fever has been a part of the illness, the quality and location of pain, feeding and bowel habits, and the quality and quantity of vomiting and bowel losses. Inquire whether bleeding has been present in vomitus or stools. Ask about weight changes. A history of prematurity, necrotizing enterocolitis, congenital anomalies, inborn errors of metabolism, cystic fibrosis, intussusception, or sickle cell anemia are all associated with abdominal complications.

Unfortunately, because some children either are too young or too frightened to speak for themselves or have not been under continuous observation, trauma as a factor in the development of a GI emergency may be missed in battered or abused children. A parent or caregiver may mislead and confuse a physician by evasion and lies. Trauma must always be considered by physicians evaluating pediatric patients presenting with what appears to be an abdominal emergency.

EVALUATION

Children vary greatly in their ability to cooperate with a physical examination. One should take a few moments to gain the confidence of the child before any painful examination or procedures occur. Allowing the child to rest or be on the caregiver's lap may help. Remove clothing to avoid missing an incarcerated hernia, petechiae, visible masses, or peristalsis. Look first and then feel. Consider some nontouch maneuvers and observations such as the child's responses during coughing, walking, climbing onto the table, or jumping up and down.

The child can be invited to self-palpate or palpate with the physician. Start in the least painful areas. Also evaluate extraabdominal areas such as the pharynx, mucous membranes, neck, lung fields, inguinal regions, femoral triangles, testes, and scrotum. Failure to do so may result in delayed or missed diagnoses. Never omit the rectal examination and guaiac test. The diagnosis of Hirschsprung disease, volvulus, or intussusception will be missed without them.

The most important studies include a urinalysis, a complete blood count and differential, and a test of the stool for occult blood. Other tests, ultrasound, and x-ray evaluation should be guided by history, physical examination, how ill the child appears, and the differential diagnoses. Electrolyte and amylase studies, a pregnancy test, and chest and abdominal x-rays may be useful in certain cases. Computed tomography and ultrasonography are also helpful in the evaluation of stable patients with acute pain.[1]

Once the history, physical examination, and laboratory studies are completed, one should have a list of differential diagnoses. If a child is critically ill, resuscitation and evaluation must be simultaneous. Early consultation must be part of the child's care. If the child is ill but stable and the findings are equivocal, then the patient should be admitted for observation and reassessment.

KEY SYMPTOMS

The important GI signs and symptoms are pain, vomiting, diarrhea, constipation, bleeding, jaundice, and masses.

Pain

Abdominal pain can be a manifestation of a variety of disease states not necessarily related to the intestinal tract.[2,3] The origin of the pain may be extraabdominal, such as one might see in a 3- to 6-year old with tonsillitis or pneumonia. Therefore, a careful general physical examination is necessary. One should distinguish between two types of pain—peritonitic and obstructive:

1. Peritonitic pain tends to be exacerbated by motion and thus keeps patients relatively immobile, as, for example, in appendicitis.
2. Obstructive pain is usually spasmodic and associated with restlessness and motion, as, for example, with intussusception.

In the very young (up to 2 years of age), pain is usually described by the caregiver in general terms, such as fussiness, irritability, and inconsolableness. With severe peritonitic pain, the caregiver may state that the child is very irritable or lethargic or seems to be grunting as if in pain. Peritonitis or pain from intussusception may present as lethargy or an altered level of consciousness. Between 2 and 6 years of age, pain of GI origin is usually referred to the periumbilical region, and diagnosis requires correlation of the patient's observations and the physician's visual and tactile evaluation. Youngsters with pain of peritonitic origin walk with obvious discomfort and prefer to lie still. In contrast, youngsters with obstructive pain may be unable to remain immobile on the examining table. The etiologies of pain vary significantly with age (Table 123-1). Every emergency physician must be familiar with and recognize the life-threatening causes of pain (Table 123-2). The clinician must provide appropriate supportive therapy while completing the diagnostic evaluation and/or consultation.

TABLE 123-1   Etiology of Pain

Appendicitis	Metabolic acidosis
Congenital anomalies	Peptic ulcer disease: complications
Diabetic ketoacidosis	Pneumonia
Ectopic pregnancy	Sepsis
Hemolytic-uremic syndrome	Toxins
Incarcerated hernia	Trauma
Intussusception	Volvulus

TABLE 123-2   Life-Threatening Causes of Pain

Vomiting

Vomiting is a common childhood problem and may be a specific or nonspecific manifestation of a benign process or a serious, life-threatening illness or injury. Vomiting or regurgitation may be a manifestation of a relatively minor problem (e.g., a nervous parent, poor feeding habits, or gastroesophageal reflux) or it may be a sign of a more serious illness. Bilious vomiting is always a serious manifestation in an infant or a child. Vomiting may be a sign of obstructive or nonobstructive GI diseases, or of infections or metabolic disorders (Table 123-3).

TABLE 123-3   Causes of Vomiting

Vomiting (bilious or not) is a classic symptom of mechanical intestinal obstruction in children. In the early phases of illness, before a child has developed electrolyte abnormalities (e.g., in a child with pyloric stenosis) or before a child has reached the stage of harboring gangrenous bowel (e.g., internal volvulus), the child's general condition may appear to be good. The child may be hungry immediately after vomiting and even eat vigorously. One must not ignore the possibility of a serious underlying intraabdominal pathologic condition merely because a vomiting child appears to be systemically well.

The emergency physician must evaluate the child's circulatory and volume status and administer boluses of normal saline at 20 mL/kg for any child in shock or dehydrated. A one-time dose of an antiemetic can be given safely to children over 6 months of age. Children with shock or severe dehydration will need consultation. For children who appear systemically well after about 2 h, 30 mL of clear liquids or infant rehydration solution can be provided at 15- to 30-min intervals.

Diarrhea

Diarrhea is an increased number of watery stools over a defined period of time. An infant may have a formed or semiformed stool after each feeding and this could be normal. Several mechanisms can cause diarrhea in the child, including osmotic, secretory, and transit disorders. Viral and bacterial pathogens cause the majority of episodes of diarrhea. Some tumors, such as neuroblastomas, secrete hormones that can increase stool water content.

When the presenting symptom is diarrhea, one must quantitate the number and volume of stools, consistency, and the presence of blood. Ascertain the norm for the child, since there is great individual variability in frequency and type of stools. Associated symptoms or the presence of diarrheal illness in other members of the family helps in establishing the diagnosis. Dehydration and electrolyte imbalance should be assessed and treated. Diarrhea may represent fluid expelled around an anatomic obstructive mass, such as an impaction, or functional obstruction, as in Hirschsprung disease (absence of parasympathetic ganglia cells in the muscle layers of the colon). Bloody diarrhea may be infectious or a manifestation of a systemic disease (e.g., hemolytic-uremic syndrome; Table 123-4).

Anatomic: Hirschsprung disease

Dietary: allergy, malabsorption, overfeeding

Infectious: bacterial, parasitic, toxic, viral

Inflammatory: Crohn's disease, hemolytic-uremic syndrome, ulcerative colitis

Malabsorption: cystic fibrosis, enzyme deficiencies, celiac disease

Systemic: endocrinopathy, immunodeficiencies

Obstructive: fecal impaction

TABLE 123-4   Causes of Diarrhea

Treatment of diarrhea will vary depending on cause. A suspicion of Hirschsprung or Crohn's disease warrants surgical consultation. Malabsorption, hemolytic-uremic syndrome, cystic fibrosis, or persistent diarrhea with weight loss and failure to thrive warrants pediatric consultation. Other causes may only require 24 h of rehydration solution and avoiding fatty or high-carbohydrate-containing foods for 2 or 3 days. Stool cultures are warranted in children with bloody diarrhea, diarrhea for more than 5 days, or toxic appearance or to track an epidemic form of illness.

Constipation

Constipation is infrequent, dry, hard stools that may result from defects in filling or emptying the rectum.

Constipation may be a sign of a pathologic or functional process. Eventually, watery stool works its way around the impaction and causes diarrhea. Thus, rectal examination is very important in the evaluation of both constipation and diarrhea.

Causes of constipation are quite different in infants and older children. In infancy, one must consider causes such as maternal drugs, congenital GI anomalies, cystic fibrosis, Hirschsprung disease, poor intake, and anal fissure. One should note abdominal shape and girth, and the presence of bowel sounds and masses, and check the anal area. Check rectal tone and stool for occult blood. If a bowel obstruction is suspected, surgical consultation is necessary. If no systemic cause or serious illness is suspected, dark thick molasses or corn syrup can be added to the diet. Finally, if the child is listless or hypotonic, one should consider infantile botulism (see Table 123-5).

TABLE 123-5   Acute and Chronic Constipation

In older children, one should not automatically think that the cause is functional. Constipation is seen in children who are anorexic or who have cerebral palsy, neuromuscular disease, dehydration, hypercalcemia, hypokalemia, hypothyroidism, or depression or who have ingested drugs such as diuretics, antihistamines, anticholinergics, or narcotics. A thorough history and physical examination, including rectal, are necessary. An empty rectal vault does not rule out constipation. If there are signs of bowel obstruction, tumor, or serious illness, one should consult an appropriate specialist.

Acute constipation is treated by increased oral fluids and possibly a stool softener or milk of magnesia. Chronic constipation is treated in three separate steps, and follow-up with a primary care specialist is important. The steps are cleanout, maintenance, and behavior modification.

Bleeding

Bleeding may be a sign of GI inflammation, duplication, foreign-body infection, or systemic illness, or it may be nothing more than an anal fissure or milk allergy. GI bleeding in the newborn, either vomited or per rectum, may be the result of swallowed maternal blood. The laboratory can differentiate between maternal and fetal blood by the Kleihauer-Betke test or hemoglobin electrophoresis. Rarely, hemorrhagic states cause GI bleeding in the newborn. Small amounts of blood in the stool of an infant, if fresh, may be a manifestation of anal fissures, which are easily identified. In children 2 to 10 years of age, painless bleeding of small to moderate amounts of fresh blood usually mixed through the stool might be an indication of benign GI polyps, or bloody diarrhea may indicate a bacterial infection or inflammatory bowel disease.[4]

The presence of small to moderate amounts of blood in the stool of an infant (particularly associated with vomiting) must lead the physician to consider malrotation of the midgut. This is a life-threatening condition that requires immediate investigation and surgical consultation because volvulus of the midgut can lead to midgut gangrene if the problem is not identified and corrected early in its course.

Major painless upper GI bleeding in infants or children is most commonly the result of bleeding varices secondary to portal hypertension. Major painless lower GI bleeding in infants or children is frequently ascribable to a Meckel's diverticulum.

Frequently, the cause of minimal to moderate amounts of blood in the stool of an infant or a child may never be identified. Repeated episodes of bleeding require GI studies, endoscopic evaluation, and Meckel isotope scanning (Table 123-6).

TABLE 123-6   Causes of Gastrointestinal (GI) Bleeding

Jaundice

Jaundice is an ominous sign, since it represents hepatic dysfunction. It might represent sepsis, congenital infection (TORCHS), or postnatal viral hepatitis. It might represent a minor ABO incompatibility or a major ABO or Rh factor incompatibility, with the possibility of kernicterus or death. It may represent the first signs of cystic fibrosis, galactosemia, or other hepatic enzyme deficiencies, or it could be the harbinger of an anatomic problem such as biliary atresia, a choledochal cyst, or even pyloric stenosis. All jaundiced patients must be evaluated promptly and consultation obtained (Table 123-7).

Unconjugated	Conjugated
ABO or Rh incompatibility	Anatomic defect: biliary, hepatic
Autoimmune hemolytic anemia	Hemolytic-uremic syndrome
Hepatic: Crigler-Najjar syndrome,	Hepatic abscess
Gilbert's disease	Hepatitis: congenital, acquired
Hypothyroidism	Hepatitis: TORCHS
Sepsis	Inflammatory bowel disease
Sickle cell anemia	Metabolic: cystic fibrosis, galacto-
G6PD deficiency	semia, etc.
	Sepsis
	Sickle cell anemia
	Toxins
	Urinary tract infections
	Wilson's disease

TABLE 123-7   Causes of Bilirubin Abnormalities

Masses

The presence of a mass could be the first sign of a congenital anomaly or a tumor (e.g., Wilms's tumor or neuroblastoma). It could be a pyloric "olive" or the intussusception mass if associated with vomiting or a guaiac-positive stool. If a child has an acute surgical or obstructive abdomen, resuscitation and prompt surgical consultation are necessary. Otherwise, emergency evaluation should be followed by pediatric consultation and admission (Table 123-8).

DIAGNOSIS AND MANAGEMENT OF SELECTED EMERGENCIES

Gastrointestinal Emergencies in Infants in the First Year of Life

MALROTATION WITH AND WITHOUT VOLVULUS   Volvulus is a major life-threatening complication of malrotation. [5] The complications of malrotation occur most commonly in the first year of life, although malrotation can give rise to symptoms at any time in a person's life. It is the most urgent of GI emergencies in infants and children because of consequent gangrene of the total midgut. The time interval from the first symptom to the development of total midgut gangrene may be only a few hours.

Pathophysiology   During gestation, at approximately 6 weeks of age, the elongating intestines prolapse into the yolk sac. Upon reentry at 10 weeks, the midgut undergoes a 270° counterclockwise turn around the superior mesenteric artery. Usually, the duodenum and the cecum become fixed by peritoneal bands, and the small intestine has a broad mesenteric attachment along its base. Abnormal rotation and inadequate fixation can occur during gestation. Incomplete rotation or malrotation can leave the cecum high in the abdomen, with its peritoneal attachments crossing the duodenum in an obstructing manner. The mesentery fails to fan out, and the midgut is suspended and its entire vascular supply travels along a narrow pedicle.

Clinical Features   The presenting symptoms are usually vomiting (ultimately becoming bilious), with or without abdominal distention, and streaks of blood in the stool. Infants with symptoms of obstruction or bilious vomiting must receive prompt surgical consultation and active resuscitation. The most dramatic presentation in newborns is the sudden onset of an acute abdomen and shock, with a rigid and discolored abdomen associated with bilious or bloody vomiting and bloody stools, indicating the presence of gangrenous bowel. On physical examination, such infants may appear pale and have grunting respirations, and approximately one-third of the infants will appear jaundiced. The vast majority of cases present within the first month of life. In older children, the pain is usually constant, not colicky. This symptom complex usually occurs in previously healthy children. However, there may have been minor episodes in the past of vomiting or abdominal discomfort. A child suspected of harboring a malrotation with possible midgut volvulus should have flat and upright abdominal x-rays. The presence of a loop of bowel overriding the liver is suggestive of the diagnosis. Occasionally, an upper GI examination may reveal an abnormal location of the ligament of Treitz.

Intussusception, duodenal stenosis, or atresia can produce a clinical picture similar to midgut volvulus.

Treatment   An infant with systoms of obstruction or bilious vomiting must receive prompt surgical consultation, active resuscitation, and hospital admission. Intravenous fluid should be started immediately, and a nasogastric tube placed. Blood should be typed and crossmatched. A white blood cell count may identify early gut necrosis. Electrolytes and venous blood gases may identify sodium or potassium abnormalities or ongoing acidosis. Any child with vomiting or bloody stools who is identified as having an incompletely rotated bowel requires urgent laparotomy to prevent the development of midgut volvulus and total midgut gangrene.

INCARCERATED HERNIA   **Clinical Features**   An incarcerated hernia will not be detected unless the infant or child is totally undressed at the time of examination. The symptoms include irritability, poor feeding, vomiting, and an inguinal or scrotal mass. The differential diagnosis of an inguinal or scrotal mass most frequently includes hydrocele of the cord or the scrotum, undescended testicle, torsion of the testicle, torsion of the appendix testis, inguinal lymphadenopathy, inguinal node abscess, orchitis, and inguinal or scrotal trauma. The incidence of incarceration of inguinal hernias is highest in the first year of life. In both boys and girls, the incarcerated sac may contain small or large bowel. In girls, an ovary may be present in the sac.

Treatment   In most instances, provided the child is examined gently and his or her confidence obtained, it is possible to achieve manual reduction of the incarcerated hernia (if it has been present for only a short period of time) without the use of sedation. When this maneuver is unsuccessful, most cases can be successfully reduced following the administration of intramuscular meperidine (up to 2 mg/kg of body weight in the first year of life). Quite often, as a result of the relaxation induced by the meperidine, the hernia spontaneously reduces. In the absence of spontaneous reduction, one should attempt to reduce the hernia. The few patients who do not respond to these maneuvers must undergo surgical reduction.

Once the hernia is reduced, the patient should be referred for surgical repair on an elective basis. Provisions are generally made for pediatric surgical consultation the next day. If it was a difficult reduction, the child should be admitted or observed for 6 to 12 h, and the pediatric surgeon consulted.

INTESTINAL OBSTRUCTION   **Clinical Features**   Intestinal obstruction presents in infants and young children in the classic manner, with symptoms of pain (manifested by irritability); vomiting; abdominal distention; and, later, absence or diminution of bowel movements. The differential diagnosis of intestinal obstruction in newborns and infants includes intestinal atresia or stenosis, meconium ileus (newborns only), incarcerated inguinal hernia, intussusception, malrotation, malrotation with volvulus, volvulus around a congenital intraabdominal band, duplication cysts of the intestinal tract, imperforate anus, and Hirschsprung disease.

Diagnosis and Treatment   Flat and upright films of the abdomen show dilated loops of bowel with air-fluid levels (Fig. 123-1). Such an appearance on the plain

x-ray film warrants a barium enema examination with a Hirschsprung catheter, which helps to differentiate between Hirschsprung disease, malrotation, and colonic stenosis and also separates lower large bowel obstruction from upper small bowel obstruction.

FIG. 123-1. Mechanical intestinal obstruction. *A.* Upright film. *B.* Flat film.

Once intestinal obstruction has been diagnosed, the patient should be prepared for surgical intervention by having an intravenous line and a nasogastric tube placed and should be admitted.

PYLORIC STENOSIS   The infant with a history of nonbilious projectile vomiting must be considered to have pyloric stenosis. The disorder affects approximately 1 in 150 male and 1 in 750 female patients. It occurs more frequently in firstborn males, and a familial incidence is noted in approximately 50 percent of patients. It is caused by diffuse hypertrophy and hypoplasia of the smooth muscle that narrows the antrum of the stomach to a small channel that can be easily obstructed.

Clinical Features   Onset is rare before the age of 1 week, and the disorder usually begins in the second or third week of life. It seldom develops after the third month of life. Initially, the infant may only regurgitate small amounts of milk, making it difficult to distinguish the cause of vomiting from simple regurgitation, gastric reflux, or milk intolerance. Vomiting usually becomes projectile within a week of onset of symptoms, and the vomitus is never bile stained although it may occasionally have streaks of blood. Vomiting occurs just after or near the end of feeding, and afterward the infant will refeed hungrily unless the child has become malnourished or dehydrated.

Vomiting eventually becomes projectile. Constipation usually is noted because the infant is not retaining enough formula and becomes dehydrated.

Physical examination usually demonstrates a hungry infant who has failed to gain weight over the past several weeks or has lost weight. Jaundice occurs in 1 to 2 percent of cases. If one undresses and then feeds the infant, peristaltic waves can sometimes be seen passing from left to right across the upper abdomen, just prior to an episode of vomiting. Palpation of a pyloric tumor—the "olive"—is pathognomonic. If it is present, one can be sure of the diagnosis. The olive is usually felt near the lateral margin of the right rectus muscle just below the liver edge. Palpation of the olive is very dependent on the amount of hypertrophy of the pylorus and the skill of the clinician.

In advanced cases, the physical examination will reveal dehydration and lethargy. The child may appear moribund, with sunken eyes, decreased elasticity of the skin and loss of subcutaneous tissue.

Diagnosis   If the olive is palpated, further studies are not necessary. If no olive is palpated, abdominal ultrasonography is recommended. Accuracy depends on the use of a high-resolution machine and an experienced sonographer. Although false positives are rare, false negatives can occur in up to 20 percent of cases, often due to bowel gas interference. If the diagnosis is highly suspected and the findings on ultrasonography are normal, an upper GI series can be performed. This usually demonstrates delayed gastric emptying and indentation of the antrum by the pyloric olive. The pyloric channel is narrowed and appears like a "string." If pyloric stenosis is not noted, the radiographer can evaluate the infant for gastroesophageal reflux. The major risk from the upper GI series is the potential for aspiration. The barium should be removed after the x-ray to prevent aspiration.

Treatment   Once the diagnosis of pyloric stenosis has been confirmed or is highly suspected, surgical consultation should be obtained. Surgery is the treatment of choice, and the procedure is very safe.

Oral intake should be restricted and an intravenous line started. Dehydration and electrolyte abnormalities must be corrected before surgery. Much of the reduced morbidity and mortality from surgery for this disease can be attributed to improved preoperative status. Extensive and protracted vomiting in pyloric stenosis may lead to hypokalemia and hyponatremia. More striking decreases occur in chloride concentration and an increase in pH and carbon dioxide content. This constitutes the characteristic changes of hypochloremic alkalosis. Initial administration of 5% dextrose in normal saline or normal saline to which potassium chloride is added gradually and successfully replaces the calculated deficits of potassium chloride and sodium.

INTUSSUSCEPTION   Intussusception occurs when a portion of the alimentary tract is telescoped into another segment. It is the most common cause of intestinal obstruction between 3 months and 6 years of age and is rare under 3 months of age. The male/female ratio is 4:1.

Pathophysiology   The causes of most intussusceptions are unknown. There is a seasonal incidence that seems to follow peak viral illness seasons. In some patients, recognizable causes for intussusception are found, such as Meckel's diverticulum, intestinal polyp, duplication, lymphosarcoma, or as a complication of Henoch-Schönlein purpura, but are rarely found in infants under 2 years of age. Rarely, tumors or foreign bodies may cause intussusception. Ileocolic intussusceptions are the most common. The upper portion of the bowel invaginates into the lower portion, bringing the mesentery with it. Constriction of the mesentery obstructs venous return with engorgement of the intussusceptum. With edema and bleeding, there may be bloody stools, with mucus giving rise to the characteristic "currant jelly" stool.

Clinical Features   The classic patient is a robust, 6- to 18-month-old infant without prior difficulty. Suddenly, the child appears to be in pain. The youngster may be playing quietly in the playpen and suddenly stop playing, begin to cry, and even roll around in discomfort. Just as suddenly, the pain ceases, and the child appears to be as happy and content as before the onset of pain. Episodes may recur at more frequent intervals, with the duration of the painful attacks increasing. Some children become very still, listless, and pale, and appear to be in a shocklike state due to the visceral pain. Vomiting is rare in the first few hours but usually develops after 6 to 12 h. The classic "currant jelly" stool associated with intussusception is a late manifestation of the disease complex and is present in only 50 percent of cases. [6] Its absence should not delay evaluation for intussusception in the patient. However, a positive stool guaiac test is present in almost every case. Fever can occur and even rise to 41°C (106°F). Respirations may be shallow and grunting in nature.

Apathy or lethargy may be the only presenting sign of intussusception in up to 10 percent of cases. Because of this, some infants will receive a lumbar puncture and other diagnostic studies, thus delaying the diagnosis and management of the child's illness. [7,8]

Examination between attacks may reveal the often-described sausage-shaped tumor mass of intussuscepted bowel in the right side of the abdomen. If this mass is felt in the epigastrium, the long axis is usually horizontal. At least one-third of patients do not have a palpable mass, but the absence of a mass must not delay further investigation. An ileoileal intussusception may have a less typical presentation, with symptoms and signs suggestive of intestinal obstruction.

Diagnosis and Management   The presumptive diagnosis of intussusception is made on the basis of the history and may be seriously considered as a result of a telephone description of a child's problem by the caregiver. The apparent well-being of a child in the absence of clinical findings should not mislead the physician. An x-ray examination of the abdomen may show a mass or filling defect in the right upper quadrant of the abdomen (Fig. 123-2A). Even in the presence of normal plain x-ray films (which can be 30 percent of cases), the history described demands a barium enema examination, which demonstrates the classic "coiled spring" (Fig. 123-2B). The barium enema examination is not only a diagnostic tool in the management of this disease, but is frequently curative. [7] If it is obtained in the first 12 to 24 h of the developing intussusception, up to 80 percent of cases can be corrected by barium enema alone. When barium enema does not resolve the intussusception,

surgical intervention is indicated. If the barium enema reduces the intussusception, the parents should be warned of a 5 to 10 percent recurrence rate, usually within the first 24 to 48 h following barium enema reduction.

FIG. 123-2. Intussusception. *A.* Plain film with loss of bowel pattern in the right upper quadrant. *B.* With barium enema, showing a "coiled spring" in the ascending colon.

Recently, air insufflation is being used by radiologists more frequently than barium to diagnose and manage intussusception. This is a safer method particularly if there is a possibility of perforation, since the peritoneum would not be contaminated by barium. It may be as effective as barium and enables better control over colonic pressure used for the reduction. [9] In most hospitals, protocol calls for notification of the pediatric surgeon prior to radiologic reduction of intussusception.

Once reduction occurs, the child should be observed to watch for any recurrence of symptoms or for complications from the reduction. Reliability of the parents or caretaker and other pediatric social concerns may affect length of observation.

A barium enema reduction is contraindicated if there is free peritoneal air on plain films or if the infant has signs of peritonitis or sepsis. The surgeon and emergency physician should provide intravenous fluid replacement for hypovolemia (due to vomiting, poor intake, and third spacing of fluids) and provision of antibiotics is essential in such a patient.

The recurrence rate after barium enema reduction ranges from 5 to 10 percent and usually occurs within the first 24 to 48 h following reduction. A second attempt at barium reduction can be considered and is usually successful. If another episode of intussusception occurs, then an exploratory laparotomy is necessary.

Gastrointestinal Emergencies in Children 2 Years and Older

APPENDICITIS   **Clinical Features**   Although appendicitis can occur in children younger than age 2, the presentation is usually one of peritonitis or sepsis because of the delay in diagnosis. [10] Over age 2, appendicitis becomes a more important part of the differential diagnoses of abdominal pain. The classic progression of symptoms associated with appendicitis applies equally to children and adults. The events involve early anorexia followed by the development of mild to moderate periumbilical pain and then vomiting and the movement of the pain to the right lower quadrant of the abdomen. The youngster should be observed walking into the examining room; in most instances, the child appears to be in discomfort as he or she moves along. This discomfort associated with motion can be exacerbated by asking the youngster to jump up and down before he or she lies down on the examining table. On inspection of the patient, the physician may find limited motion of the lower abdomen due to inflammation of the peritoneum and, depending on the duration of the symptoms, there may be abdominal distention. Palpation may reveal the presence of tenderness in the right lower abdominal quadrant. The position of the appendix may vary greatly, and thus tenderness on examination may vary. Guarding and rebound tenderness may or may not be present in this area. The longer the duration of the symptoms, the greater is the possibility of finding a right lower quadrant mass representing localized perforation with the development of an appendiceal abscess. A rectal examination should be performed to detect the presence of a low-lying, intrapelvic, acutely inflamed appendix or to palpate a mass. The child may have a mild fever and an elevated white blood cell count in the range of 11,000 to 20,000. When there is doubt in the overall symptom complex, an x-ray may reveal the presence of an appendicolith (Fig. 123-3).

FIG. 123-3. Appendicitis; appendicolith in the right lower quandrant.

Diagnosis   Symptoms consistent with appendicitis together with the presence of an appendicolith warrant the clinical diagnosis of appendicitis and laparotomy. Intravenous fluids should be given and surgical consultation obtained. The following signs and symptoms make the diagnosis of acute appendicitis difficult:

1. The temperature may be normal.
2. The white blood cell count may be normal.
3. The child may not be anorexic and may actually request food.
4. A heavily built child may manifest minimal right lower quadrant tenderness and minimal tenderness on rectal examination.
5. Gastroenteritis is not infrequently associated with appendicitis. Thus, a child presenting with a several-day history of vomiting and diarrhea, perhaps even with siblings suffering from the same problem, should not have the diagnosis of appendicitis discounted on this basis. Intensification of pain in the presence of a history of gastroenteritis should suggest an acutely inflamed appendix secondary to gastroenteritis. [11]
6. Appendicitis has been identified in children younger than 1 year of age and is not uncommon in the second year. The incidence of perforation in this age group is much higher because of the difficulty of making the diagnosis and the confusion with gastroenteritis.

Recently, ultrasonography has been a subject of interest in identifying patients with appendicitis. It is, however, operator dependent and has missed not only inflamed appendices but also ruptured appendices. Overall, it has good sensitivity and specificity. It is not yet a gold standard. [12]

Treatment   Once the diagnosis of appendicitis is strongly considered or confirmed, surgical consultation should be obtained and the child should be admitted to the hospital. The child should receive any appropriate supportive therapy. If the child is febrile, rectal acetaminophen may be given. The child should not receive any oral fluids or food. Start an intravenous line and administer fluid boluses if the child shows signs of sepsis or shock. Closely monitor the child's vital signs and give pain medication parenterally after consultation with the surgeon.

If the diagnosis is possible but not probable, surgical consultation should be considered and the child reexamined until either resolution of the illness or need for

laparotomy is determined.

If a perforated appendix is suspected or the child appears septic, ensure that the patient is adequately oxygenated and ventilated, and hypovolemia is corrected. Ensure adequate circulation and urinary output. Start broad-spectrum antibiotics. Ampicillin, gentamicin, and clindamicin are possible regimens.

MECKEL'S DIVERTICULUM   A Meckel's diverticulum can cause a variety of signs and symptoms, such as bleeding, peritonitis, intussusception, and intestinal obstruction. The presence of gastric mucosa in the diverticulum may give rise to an ulcer in the adjacent ileum, which may cause symptoms such as painless rectal bleeding. Bleeding is brisk and usually bright red. The ulcer may perforate and cause peritonitis. Isotope scanning reveals the presence of a Meckel's diverticulum containing gastric mucosa in up to 50 percent of the cases. A scan with normal findings does not eliminate the diagnosis.

Acute inflammation in a Meckel's diverticulum may simulate acute appendicitis or may initiate intussusception. Finally, the vitellointestinal remnant attaching the apex of a Meckel's diverticulum to the intraabdominal umbilical region may be the focus around which volvulus of the small bowel or an internal hernia develops, each of these giving rise to intestinal obstruction. Surgical consultation is necessary.

BLEEDING   There are several systemic processes that can result in GI bleeding. Upper GI bleeding is usually the result of peptic ulcer disease, varices, or gastritis. Lower GI bleeding can be due to not only the previously mentioned diseases, but also due to infectious colitis, coagulopathies, ulcerative colitis, and Crohn's disease. Two other illnesses can cause abdominal pain and bleeding: Henoch-Schönlein purpura (HSP) and hemolytic-uremic syndrome (HUS)

In HSP, some children may present with joint pain, abdominal pain, or seizure. Usually, there is a petechial or purpuric rash on the buttocks and lower extremities. Many children have guaiac-positive stools but rarely present with bleeding unless there is associated intussusception. Treatment is usually symptomatic and on an outpatient basis unless the child appears ill or has a complication of the disease.

In HUS, there is usually a history of a gastroenteritis with or without bloody diarrhea up to 2 weeks before onset of illness. Toxigenic strains of *Escherichia coli* have been implicated as a possible link to HUS. Low-grade fever, pallor, hematuria, and hematochezia occur. The central nervous system can be involved. Hypertension occurs in up to 50 percent and seizures in up to 40 percent of cases. Acute bowel perforation, toxic megacolon, intussusception, renal failure, and pancreatitis can occur. These children should be managed by appropriate pediatric specialists or intensivists.

COLON POLYPS   Single polyps or multiple or classic familial polyposis may give rise to painless hematochezia. Single polyps are usually benign (juvenile), with no propensity for malignant degeneration. Frequently, the parent describes what is obviously a prolapsed polyp, easily palpated on rectal examination. It is rare for bleeding originating from a polyp to be life threatening. Familial polyposis is rare and is a premalignant syndrome. The child should be referred to a pediatric surgeon.

OTHER CAUSES OF GASTROINTESTINAL BLEEDING   Blood represents local irritation or erosion in the majority of children. What appears to be a small amount of blood on the stool or diaper of a healthy child is probably due to an anal fissure or could be related to food substances that have a red or melanotic coloration. A stool test for occult blood and a gentle rectal examination may be all that is needed in a healthy child.

On the other hand, if the child is sick- or ill-appearing or shocklike or has petechiae, one must consider vascular malformation, Meckel's diverticulum, intestinal duplication, or sepsis. In adolescents, one must consider stress ulceration, peptic ulcer disease, and inflammatory bowel disease. Sepsis, severe gastroenteritis, HSP, and HUS should also be part of the differential diagnoses.

In infants, a coagulation survey should be included in the evaluation if the child is ill or shocklike or has a family history of a clotting disorder. Also remember that GI bleeding could be the presentation of intussusception or volvulus. In neonates the differential diagnosis consists of many severe disorders, and consultation may be necessary to exclude them (Table 123-6).

Pancreatitis

Pancreatitis is not common in childhood. The most common cause is abdominal trauma. It can also occur as an idiopathic or postviral process (mumps, influenza, coxsackie, etc.) or be due to drugs or toxins. Systemic diseases such as cystic fibrosis, systemic lupus erythematous and a $_1$-antitrypsin deficiency can cause pancreatitis.[13]

Clinical findings include central abdominal pain, vomiting and, sometimes, fever. The abdomen may be distended and is tender to palpation. Patients should receive fluids to correct dehydration and any hypovolemia and receive appropriate pain management. Most of the children will need to be admitted for intravenous hydration, pain management, and diagnostic studies.

Intraabdominal Masses

Every child should have a careful abdominal examination because intraabdominal masses grow silently at first until they cause obstruction, bleeding, or hemorrhage into the tumor or until a parent sees a mass protruding in the abdomen. The child should be supine with his or her head turned toward the parent, and one should carefully palpate all quadrants of the abdomen. If a mass is palpated, the child should be referred to a pediatric surgeon and diagnostic imaging studies obtained. A careful rectal examination, especially if the child has constipation or a gait abnormality, must be done to check for a presacral teratoma and for ovarian masses; both of these tumors can show calcifications on plain film x-rays in approximately 50 percent of cases.

Neuroblastomas can arise from adrenal glands or along the sympathetic chain. They often cross to the midline, and the best cure rate is obtained in children under 1 year of age. Computed tomography is the best way to evaluate this tumor. Wilms's tumor is an intrarenal tumor initially and should be considered in children with hematuria. Ultrasound and computed tomography help define this tumor. Bone scan is also needed. Rhabdomyosarcoma occurs in the pelvis or anywhere there is striated muscle, and it is highly malignant.

In girls over the age of menarche, one must consider pregnancy, and if there is lower quadrant pain, one must consider ectopic pregnancy. One should obtain a serum pregnancy test and consider the use of ultrasonography.

Foreign Bodies in the Gastrointestinal Tract

It is safe to generalize that anything that reaches the stomach will eventually traverse the GI tract and be spontaneously evacuated through the rectum. Nails, open safety pins, pieces of glass, and coins are examples of objects that have traveled the intestinal tract completely. It may take weeks for a coin, for example, to complete the trip to the anus. Any foreign body caught in the esophagus must be removed by esophagoscopy (see Chap. 75). Very rarely is surgical removal of a foreign body in the stomach or distal to the stomach warranted. Occasionally, a long, thin foreign body may not traverse the duodenum and may need to be removed surgically. Round objects almost always pass spontaneously.

Portal Hypertension

Portal hypertension is rare in children in the United States, but is one of the common causes of major upper GI hemorrhage. Extrahepatic portal thrombosis, parenchymal liver disease associated with fibrocystic disease, and biliary cirrhosis in youngsters with congenital biliary atresia surviving as a result of portal enterostomy are examples of conditions that can result in portal hypertension and esophagogastric varices. In two-thirds of cases, no specific cause is found.

Massive hematemesis is the usual initial manifestation, along with hematochezia in children, whereas ascites is more common as the presenting sign in infants. Usually, the bleeding is self-limited. A nasogastric tube can be placed to empty the stomach and to monitor for continued bleeding and blood transfusions given as indicated. Correct any coagulation abnormalities. Emergency consultation with a surgeon, pediatric surgeon, or a pediatric gastroenterologist is necessary.

124 THE DIABETIC CHILD AND DIABETIC KETOACIDOSIS

Maribel Rodriguez
Thom A. Mayer

EPIDEMIOLOGY

Diabetes mellitus is classified in two types. Type I, or insulin-dependent diabetes mellitus (IDDM), is seen mostly in children and adolescents. Insulin deficiency characterizes IDDM, and patients need exogenous insulin for survival. Type II, or non-insulin-dependent diabetes mellitus (NIDDM), is the type seen most commonly in older people or those with obesity and is rarely seen in childhood and adolescence. NIDDM is not discussed in this chapter. IDDM is the most common endocrine disorder of childhood and adolescence, affecting at least 1 in 400 children in the United States. [1] Incidence increases with age and peaks in early to mid-puberty. A seasonal distribution of new cases has been reported, with more cases during the cooler months for unknown reasons. [2] Female and male incidence rates are approximately equal.

PATHOPHYSIOLOGY

IDDM is a disease caused by autoimmune destruction of insulin-producing b cells of the pancreatic islets of Langerhans. [3] There is no single diabetes gene, but a genetic predisposition for acquiring IDDM exists. Certain genetic alterations raise or lower the risk of b-cell damage. In white populations, inheritance of the human leukocyte antigen HLA-DR3 or HLA- DR4 is present in 90 percent of type I diabetes, and 1 in 50 persons with both antigens will have the disease. [1] This and other genetic markers help to explain the worldwide differences in prevalence and incidence of type I diabetes. [4]

DIAGNOSIS

The diagnosis of IDDM in the pediatric population is usually straightforward. While the triad of polyuria, polydipsia, and polyphagia is the classic presentation, other symptoms include failure to gain weight, weight loss, enuresis, anorexia, and changes in vision, behavior, and school performance. Hyperglycemia in association with glucosuria with or without ketonuria establishes the diagnosis. [5] In rare instances, hyperglycemia in children can be found in association with hyperthyroidism, lead intoxication, Cushing disease, brain tumors, pheochromocytoma, and therapy with corticosteroids. [1]

DIABETIC KETOACIDOSIS

Diabetic ketoacidosis (DKA) is a common complication among children with IDDM, accounting for 14 to 31 percent of all diabetes-related hospital admissions. [6,7] It is the single most common cause of death in diabetic patients under 24 years of age. [7] DKA is considered to be present when there is hyperglycemia (i.e., blood glucose level >250 mg/dL), ketonemia (i.e., ketones >1:2 dilution of serum), and metabolic acidosis (i.e., pH <7.2 and plasma bicarbonate £15 meq/L) [5] accompanied by glucosuria and ketonuria. The majority of patients are also moderately to severely dehydrated. Precipitating factors for the initial presentation or for DKA include stress such as trauma, infection, vomiting, and psychological disturbances. [5]

The basic cause of DKA is absolute or relative insulin deficiency (Fig. 124-1). There also are elevated levels of counterregulatory hormones (glucagon, cortisol, growth hormone, epinephrine, and norepinephrine), which antagonize insulin. [2] These hormonal abnormalities result in increased glucose production (promoting glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis) and decreased utilization. With progressive insulin deficiency, glucosuria accompanies the hyperglycemia. The resultant osmotic diuresis produces polyuria, which can result in a profound loss of fluids and electrolytes, dehydration, and compensatory polydipsia. Hyperosmolality is commonly encountered as a result of progressive hyperglycemia, which contributes to the symptoms, especially cerebral obtundation, in DKA. Serum osmolality can be estimated with the following formula:

FIG. 124-1. Pathophysiology of diabetic ketoacidosis.

$$\text{Serum osmolality (mosm/kg)} = (2 \times \text{serum Na}^+ \text{[meq/L]}) + \frac{\text{glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8}$$

The hormonal interplay of insulin deficiency and glucagon excess shunts free fatty acids into ketone body formation. The rate of formation of these bodies, principally b-hydroxybutyrate and acetoacetate, exceeds the capacity for peripheral utilization and for renal excretion. The combination of ketoacid formation and dehydration results in metabolic acidosis, and, for compensatory alkalosis, rapid deep breathing (Kussmaul respirations) may be manifested at advanced stages. Dehydration with decreased perfusion to the tissues leads to lactic acidosis, which contributes to more profound acidosis. Once patients are sufficiently ketotic and acidotic, they manifest the classic fruity breath odor of ketosis. The state of consciousness may vary from alertness to drowsiness or coma, depending on the severity of DKA. Other findings on physical examination include fever, vomiting, and exquisite abdominal pain with guarding and rigidity, which can mimic an acute abdomen. The clinical findings of acute abdomen usually resolve with the treatment of DKA, but if not, an underlying cause must be sought. DKA should be considered in children who are vomiting and appear dehydrated but continue to urinate excessively.

In known diabetic patients, DKA may be precipitated by acute infections or other stresses but is usually caused by omission of insulin. A thorough search for sources of infection is essential. It is important to note that the degree of hyperglycemia does not correlate with the degree of acidosis, and patients who are only minimally

hyperglycemic may be severely acidotic. The early recognition and treatment of DKA should be well known to every emergency physician so that the morbidity and mortality rates associated with this complication of IDDM can be reduced.

TREATMENT OF DIABETIC KETOACIDOSIS

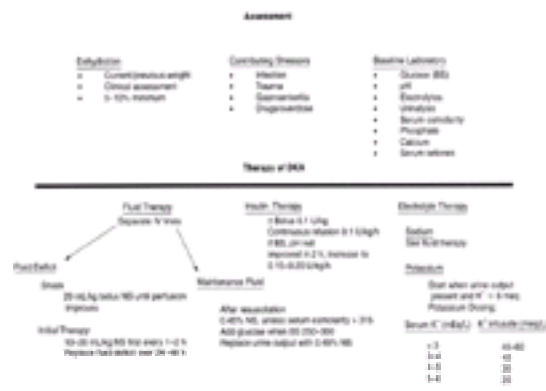
The basic components of DKA treatment are appropriately aggressive fluid and electrolyte replacement (with special attention to potassium) and initiation of insulin therapy, which is essential to arrest further metabolic decompensation (Fig. 124-2). Once the diagnosis is confirmed, determinations of the glucose level, venous pH, and electrolyte levels should be made and checked hourly, with further therapy adjusted accordingly. An electrocardiogram is useful for potential evidence of hyperkalemia. If sepsis is suspected as the precipitating factor, blood and urine cultures, lumbar puncture, and chest x-ray should be performed, and antibiotics should be started if indicated.


FIG. 124-2. Treatment of DKA.

Fluid Resuscitation

Appropriate fluid replacement should be instituted promptly. Water and electrolyte losses occur secondary to polyuria caused by the osmotic diuresis produced by glycosuria, hyperventilation, vomiting, and diarrhea. Dry mucous membranes, poor skin turgor, and orthostatic hypotension in the older child are the most accurate clinical indications of dehydration. Virtually all patients with DKA are at least 5 to 10 percent dehydrated and require both maintenance and replacement fluid therapy. However, fluid resuscitation that is too aggressive can result in cerebral edema, the most lethal complication of DKA. For initial rehydration, 10 to 20 mL/kg/h of 0.9% NS solution should be given for the first 1 to 2 h of resuscitation to establish adequate vascular volume and improve tissue perfusion. If signs of shock are present, a 20 mL/kg bolus of 0.9% normal saline solution should be given and may need to be repeated if dehydration and shock are severe. However, for the majority of patients, the initial volume resuscitation of 10 to 20 mL/kg/h for the first 1 to 2 h is adequate to restore perfusion. Once this is accomplished, the remaining fluid deficit can be replaced over the next 24 to 48 h. If possible, the fluid deficit should be calculated by comparing the patient's weight on presentation with a recent, healthy weight. If such an estimate is not possible, it can be assumed that the fluid deficit is 10 percent of the body weight (100 mL/kg) in children in DKA unless the patient is in shock.

Maintenance Fluids

After the initial reexpansion, 0.45% NS is used. In children whose serum osmolality is high, 0.9% NS should be continued until it has decreased toward normal (<315 mosm/L).[2] After the initial resuscitation is completed, the calculated remaining deficit should be replaced over the next 36 to 48 h depending on the calculated or measured osmolality (>320 mosm/L or >340 mosm/L, respectively).[8] Once the serum glucose level is between 250 and 300 mg/dL,[2,5] intravenous fluids should be changed to 5% dextrose solution (D5) and 0.45% NS. Administration of glucose limits the decline of serum osmolality and reduces the risk of cerebral edema. Insulin should be continued even after dextrose infusion has been started because blood glucose levels are corrected more rapidly than ketoacidosis. As long as acidosis persists, insulin infusion should be maintained at the same rate. Blood glucose levels should be maintained at approximately [5] 250 to 300 mg/dL,[2,5] and urine output should be replaced hourly with 0.45% NS. Oral hydration may be started as soon as nausea and vomiting subside. Fluid resuscitation and correction of metabolic abnormalities should not be undertaken too rapidly in order that such complications as cerebral edema, hypoglycemia, and hypokalemia may be avoided.

Electrolyte Management

Monitoring and correction of electrolyte imbalances are paramount to the treatment of DKA. Despite the common findings of lowered serum sodium and potassium levels on initial presentation, the body stores of these two electrolytes are depleted even more than is obvious, secondary to the osmotic diuresis and renal excretion of anionic ketoacids. In addition, the hyperglycemia and hyperlipidemia of DKA cause spuriously low serum sodium measurements that do not adequately reflect the degree of sodium deficit. While maintenance sodium levels are 3 meq/kg/day, children with DKA have a sodium deficit estimated at 6 meq/kg. Fluid replacement is best accomplished through two intravenous lines: one replacing the fluid deficit as 0.9% NS and a second providing maintenance fluid therapy as 0.45% NS. Decline of the serum sodium level during resuscitation is a potential marker for the development of cerebral edema, and fluid therapy should be adjusted accordingly. Serum sodium levels should be monitored at least every 3 to 4 h during the initial resuscitation phase.

Virtually all patients with DKA also have potassium depletion, regardless of their serum potassium level on presentation. Administration of potassium should be started early, even when serum potassium concentration is normal. If the potassium level is high (>6 meq/L), replacement should be withheld until urine output is established and the serum potassium level begins to fall, in order to avoid iatrogenic hyperkalemia and cardiac dysrhythmias. Although potassium moves from intracellular to extracellular sites during acidosis, the reverse occurs during correction of acidosis. This shift of potassium back to the intracellular compartment may result in life-threatening hypokalemia. Therefore, potassium is added to the fluid resuscitation after boluses of NS once the patient's urine output is adequate. Often, twice-daily maintenance therapy of potassium (3 to 4 meq/kg/day) is needed to replenish potassium stores and achieve acceptable serum levels. An electrocardiogram provides a rapid assessment of serum potassium concentration. T waves are peaked in hyperkalemia and low and associated with U waves in hypokalemia. Because both hypokalemia and hyperkalemia are potential causes of death due to cardiac instability, the serum potassium level should be monitored every 1 to 2 h.[2]

Potassium chloride is the most common form used to replenish potassium deficits, and excess chloride may aggravate acidosis. The extent of acidosis can be reduced by substitution of potassium phosphate, which is also depleted in diabetic ketoacidosis. [5] Potassium replacement may be accomplished with one-half the dose as potassium chloride and phosphate. By contributing to the formation of 2,3-diphosphoglycerate, exogenous phosphate shifts the oxygen dissociation curve to the right, facilitating release of oxygen to tissues and aiding in correction of acidosis. Furthermore, resistance to insulin action is associated with hypophosphatemia. [9] Therefore, the use of phosphate is recommended by most endocrinologists, but its efficacy is debated by others, who recommend phosphate therapy only if the serum level is 2 meq/L or less. Because the excessive use of phosphate may result in hypocalcemia, serum calcium should be monitored periodically.

Insulin Therapy

Continuous low-dose short-acting (regular) insulin by intravenous infusion is the method of choice for treating DKA. Continuous intravenous insulin eliminates the problem of poor absorption from other routes. A priming dose of 0.1 U/kg of regular insulin is followed by a constant infusion of 0.1 U/kg/h. Some authorities debate the necessity or efficacy of the initial intravenous bolus and begin with the infusion. If acidosis has not improved in 2 h, the inravenous insulin rate should be increased to 0.15 to 0.2 U/kg/h.[2] Concern that the insulin may adhere to the glass and tubing has proven to be unfounded, and effective delivery of insulin can be provided without the addition of albumin or gelatin to the infusate. [5] When acidosis is corrected, the continuous infusion may be discontinued.

Ketonemia and ketonuria may persist despite clinical improvement. Nitroprusside, which is routinely used to measure ketones, reacts with acetoacetate and weakly with acetone, but not with b-hydroxybutyrate. With the correction of acidosis, b-hydroxybutyrate dissociates to acetoacetate, which is identified by the nitroprusside

reaction. Therefore, the persistence of ketonuria may not reliably reflect the clinical improvement.

Bicarbonate therapy remains highly controversial. With provision of fluids, electrolytes, glucose, and insulin, metabolic acidosis is usually corrected through the interruption of ketogenesis and the generation of bicarbonate by the distal tubule. [5] Concerns that the therapeutic administration of bicarbonate may result in paradoxical central nervous system acidosis and possible cerebral depression, shift of the oxygen dissociation curve to the left (diminishing the release of oxygen to tissues), worsening hypokalemia, and alkalosis underlie the recommendation to avoid bicarbonate therapy unless severe acidosis (pH < 6.9) threatens to cause cardiac dysrhythmias or decreases cardiac contractility. [9] In general, the majority of patients with DKA, even those with severe acidosis, can be adequately resuscitated without bicarbonate therapy, which carries substantial side effects.

Cerebral Edema

Cerebral edema is unpredictable. It usually becomes apparent several hours after the child appears to be improving. A previously alert patient may become lethargic; complain of headache; have abnormal neurologic findings, including papilledema; progress to coma; and have respiratory arrest, with herniation of the brainstem. Recovery may occur with prompt recognition and treatment with intravenous mannitol. Although clinically apparent cerebral edema is often fatal, subclinical cerebral edema is present in many patients during therapy for ketoacidosis. [10] Although the precise pathophysiology of cerebral edema in DKA is unknown, factors associated with increased incidence include excessive fluid administration, precipitous correction of the blood glucose level, failure of the serum sodium level to rise with treatment, and bicarbonate therapy.

Treatment of clinical cerebral edema includes control of intracranial pressure with mannitol therapy, intracranial pressure monitoring, ventriculostomy fluid drainage, fluid restriction, and other therapies to control intracranial pressure, including barbiturate therapy when indicated.

DISPOSITION

The vast majority of patients who present with DKA are sufficiently ill to require admission to the hospital for correction of fluid and electrolyte imbalances over a 24- to 72-h period. A very small and select group of patients can be considered for outpatient management of DKA, provided there is appropriate follow-up and supervision by the patient's parents and the treating physician. Patients with stable vital signs who can easily tolerate oral fluids and have minimal dehydration and electrolyte imbalances can be considered for discharge. Such patients still require 3 to 6 h of emergency department treatment to ensure clear documentation that clinical findings and laboratory values are improving. Most important, discharge instructions and follow-up should be carefully and cautiously coordinated between the caregivers and the patient's primary care physician.

However, the majority of patients with a past history of DKA need to be admitted to the hospital for ongoing therapy, treatment of underlying diseases that may have precipitated the DKA, and normalization of fluid and electrolyte levels. Patients with altered mental status, severe acidosis, or profound fluid and electrolyte deficits should be considered for management in the pediatric intensive care unit. Many hospitals have developed clinical treatment guidelines for patients with DKA, including criteria for admission to the intensive care unit.

125 HYPOGLYCEMIA

Randolph Cordle

Emergency physicians must be able to recognize the sometimes subtle and other times stunning effects that hypoglycemia may cause, as prompt diagnosis and treatment may spare an otherwise normal child severe brain damage or even death.[1] This is especially true in the first year of life when the diagnosis is difficult to make based on clinical findings alone (Table 125-1).

TABLE 125-1   Cause of Hypoglycemia in Children

DEMOGRAPHICS

The definition of hypoglycemia is somewhat controversial. In the past, many believed neonates would tolerate lower levels of glucose than older children. Most agree that, in all pediatric age groups, a blood glucose <40 mg/dL should be considered abnormal. Normally the whole blood concentration of glucose is 10 to 15% less than that found in the serum or plasma. This is due to a dilutional effect caused by the red blood cells in whole blood that contain little glucose. Therefore, acceptable serum or plasma glucose levels would be greater than 45 mg/dL. Values slightly above this may still be concerning in symptomatic patients.

Pediatric hypoglycemia may be considered a relatively rare disorder if one excludes diabetics and the neonatal population. Hypoglycemia was reported in only 6.54/100,000 children presenting to a pediatric emergency department (ED).[2] Of these, 58 percent had a diagnosis of idiopathic ketotic hypoglycemia. Outside of the neonatal period, idiopathic ketotic hypoglycemia was by far the most common cause of hypoglycemia presenting to the ED. Surprisingly, only 10 percent of the presenting hypoglycemic patients were found to be diabetics having an insulin reaction, possibly because prehospital treatment alone is sufficient for most cases. Outside of the neonatal period, if all children are considered, the highest prevalence of hypoglycemic events is almost certainly in the insulin dependent diabetic population.

PATHOPHYSIOLOGY

Normally a highly sophisticated regulatory system maintains glucose concentrations within a very narrow range. This is truly a steady state system and not an equilibrium. The rate of production does not equal the rate of utilization at any given moment. Both production and utilization change on a minute-to-minute basis. Relative to body weight, glucose production and utilization are much higher in children than in adults. This is due to the higher basal metabolic rate of children, utilization of glucose for growth and development, and greater activity. The quantity of glucose produced and utilized per kilogram of body weight is known as *glucose flux*. This is discussed further below.

All tissues can use glucose for energy metabolism. Tissues such as the heart, other muscles, and the kidneys can use other substrates quite efficiently; however, the brain, red blood cells, lymphocytes, and platelets are nearly totally dependent upon glucose for their metabolism. Pagliara demonstrated that, in the fasted adult model, up to 80 percent of the glucose produced by glycogenolysis and gluconeogenesis is used for brain metabolism.[3] Nearly all the rest is used by the formed elements of blood. An adequate quantity of glucose for the brain's metabolism depends on its degree of utilization and the plasma glucose level.

Relatively speaking, the brain is a much larger organ in children than in adults. Therefore more than 80 percent of the glucose utilization in the fasted child is by this one organ. In fact, studies have demonstrated that glucose utilization correlates better with brain weight than with body weight. In the postabsorptive state, the glucose requirement of small children is up to $2\frac{1}{2}$ times that of the adult, or about 5 to 7 mg/kg per minute. After fasting, this drops to 4 mg/kg per minute, a value still much higher than that in the fasted adult. The majority of brain development has occurred by the end of the second year of life. During the fasting state, nearly all the endogenously produced glucose in children below 2 years of age is required and utilized by the brain. When inadequate quantities of glucose are available, development and growth will stop, so that all sources of endogenous energy can be used strictly for the maintenance of brain metabolism. Therefore normal growth and brain development will not occur if inadequate quantities of glucose are supplied.

During periods of inadequate glucose supply to the brain, alternative sources of energy such as ketones and Krebs cycle intermediates will be utilized. Adult studies have demonstrated that, in the short term, up to two-thirds of the brain's energy requirements can be supplied using these substances. Ketones should not, however, be relied upon to save the brain from injury or death even in the short term. Not surprisingly, many causes of childhood hypoglycemia are associated with the lack of ketone production. Even in normal patients with hypoglycemia, ketone production is a slow process occurring over a period of hours. Ketones are not immediately available when acute changes in blood glucose occur. Neonates and children with free fatty acid utilization abnormalities, carnitine deficiency, and ketone-production-limiting hyperinsulinemias are at particular risk for devastating neuroglycopenia because they lack the ability to effectively produce or utilize ketones as an alternative energy source.

Carrier mediated transport is responsible not only for shuttling glucose through the blood-brain barrier but also moving it from the cerebrospinal fluid (CSF) into the extracellular space, where it can be utilized by the individual cells of the brain. A limiting factor in the movement of glucose from the plasma to the brain is the turnover rate of this carrier system. When the plasma glucose concentration and brain glucose utilization are normal, this carrier-mediated system maintains a three-fold surplus of glucose in the brain. This buffer allows for normal fluctuations of plasma glucose over time. The CSF glucose concentration is maintained at about 65% of that found in the blood while that of the brain's extracellular fluid is maintained at about one-third the CSF glucose concentration. In general, CSF and brain extracellular glucose concentrations remain near constant. When the plasma glucose level drops to about 30 mg/dL, the supply to the brain cells becomes dangerously low. If not rapidly corrected, the extracellular glucose concentration may approach zero and neuronal metabolism will fail. Fortunately, acute changes in the plasma glucose concentration do not immediately affect that of the CSF and brain. Changes here lag behind those in the plasma by a few hours. As the plasma glucose concentration decreases, systemic changes occur, hopefully leading to a resupply of exogenous or endogenously produced glucose. If not, neuroglycopenia will arise. Conversely, when neuroglycopenic patients are given exogenous glucose, it often takes a few hours for their mental status to return to normal even if there are no permanent sequelae. In patients presenting with stroke-like symptoms, it is not uncommon for paresis to last a few hours. Peak CSF glucose levels do not occur until 2 h after intravenous dextrose is given. Equilibrium of glucose between the CSF, brain extracellular space and plasma is typically not achieved for about 4

h. Assuming ongoing carbohydrate provision, plasma equilibrium occurs more quickly.

Although these alternative fuel sources can temporarily maintain cerebral metabolism, rapid return of glucose is necessary for multiple additional reasons. Glucose is utilized exclusively for brain growth and development. It is also required for the development of membrane lipids and structural proteins. Infant brain myelination is dependent on adequate substrate supply, including glucose. Cerebral hypoperfusion has also been linked to episodes of hypoglycemia. Hypoglycemia associated with anoxia or poor cerebral perfusion is more likely to cause permanent brain damage than if associated with normal cerebral perfusion and oxygenation. Prolonged or repetitive episodes of hypoglycemia may cause permanent neurologic sequelae, including mental retardation and death. At the time of presentation, it is not possible to determine clinically which patient's signs and symptoms will be permanent. Some patients develop cerebral edema secondary to prolonged neuroglycopenic seizures. More commonly, cerebral damage from hypoglycemia alone is thought to be due to the release of excitotoxins, which lead to neuronal necrosis. True infarction is relatively rarely seen. This neuronal necrosis selectively affects some parts of the brain while leaving others, such as the brainstem and cerebellum, relatively intact.

With the ingestion of a meal, macromolecules are enzymatically broken down into their component parts. Once absorbed, the elevated glucose concentration causes the release of insulin. Simultaneously, glucagon secretion is suppressed. Depending upon the amount and type of food ingested as well as the degree of glucose utilization, the patient may have ample glucose immediately available for the next few hours. In addition to its effect on glucagon, insulin in concert with an elevated glucose level suppresses glucocorticoid release. The elevated insulin levels also lead to the suppression of ketogenesis, gluconeogenesis, lipolysis, and glycogenolysis. Simultaneously, they induce glycogen production in the liver and muscle from glucose, protein production from amino acids, and fat production from lipids. Fats are also produced from endogenous lipids formed from surplus amino acids and glucose in the liver. Fat is the body's major energy storage form.

In the early fasting state, the remaining free glucose is rapidly utilized for energy. After this, insulin levels drop as glucagon and epinephrine levels increase, inducing glycogenolysis. Assuming that normal glycogen stores are present, children may be able to maintain a normal plasma glucose concentration for 4 to 6 h, only half the time seen in adults. This is primarily due to two factors. Children, as discussed above, have a much higher relative glucose flux than do adults. They also have relatively smaller glycogen stores.

In the late fasting state, children become dependent on gluconeogenesis and, to a lesser extent, alternative fuels. Gluconeogenesis uses amino acids and glycerol as substrates. These substrates are derived primarily from muscle protein and fat. Elevated glucagon, cortisol, and growth hormone in the milieu of a low insulin level stimulate gluconeogenesis. Low levels of insulin and elevated levels of growth hormone, epinephrine, and glucagon stimulate lipolysis to provide glycerol for gluconeogenesis and free fatty acids for ketogenesis. Mitochondrial beta-oxidation of free fatty acids leads to the production of acetyl-CoA and NADH + H $^+$, substrate inducers of gluconeogenesis. During the late fasted state, free fatty acids are converted to acetyl-CoA faster than the liver can use it to produce ketones. Accumulating acetyl-CoA allosterically stimulates one of the rate-limiting enzymes of gluconeogenesis—namely, pyruvate carboxylase. The NADH + H $^+$ is then used to reduce newly formed oxaloacetate to malate, which is carried to the cytoplasm, where the rest of gluconeogenesis occurs. Without this reducing substance, oxaloacetate would just build up in the mitochondria and gluconeogenesis would not occur. An additional important precursor for gluconeogenesis is lactate. It is primarily generated from pyruvate. Although almost exclusively occurring in the liver during prolonged fasts, a minor degree of gluconeogenesis may occur in the kidneys as well.

As discussed above, ketogenesis may play a vital role in providing glucose to the brain during the fasted state. Although its direct role is relatively minor, its indirect one may be great. By providing for the energy needs of the heart, kidneys, muscles, and other tissues, it allows a higher percent of endogenously produced glucose to be utilized by the brain. Like gluconeogenesis, the production of ketones is also dependent upon the release of triglycerides from adipose tissue. Once released into the milieu of low insulin and glucose, these triglycerides are degraded to form glycerol and free fatty acids. The glycerol enters the liver and is used for gluconeogenesis and/or glycolysis. The free fatty acids diffuse into hepatocytes, where they are converted to fatty acyl-CoA by thiokinase (fatty acyl-CoA synthetase). Fatty acyl-CoA is then carried through the inner mitochondrial membrane by carnitine. Without this carrier, these polar molecules could not pass through the membrane.

Once in the mitochondria, beta-oxidation occurs. In addition to acetyl-CoA's role in gluconeogenesis, it is also converted in the liver to acetoacetate and beta hydroxybutyrate, the primary ketones utilized for fuel. Therefore, defects in medium or, less commonly, long and short chain acyl-CoA dehydrogenase enzymes may lead to nonketotic hypoglycemia. Nonfunctional lipases, nonfunctional carnitine transferase, and low levels of carnitine may lead to a similar clinical syndrome. Abnormal metabolites of fatty acids may accumulate in the liver. In the past, treatment for these disorders was preventing the occurrence of the late fasting state. This was accomplished with frequent feedings. More recently, carnitine deficiency may be treated with the addition of supranormal levels of carnitine to the diet. Although rare in this country, Jamaican vomiting illness may also present with a nonketotic hypoglycemia. The toxin hypoglycin, found in the unripe akee fruit, prevents proper beta-oxidation of fatty acids. Therefore, acetyl-CoA is not produced, gluconeogenesis is not induced, and ketones are not formed normally.

The complexity of this homeostatic system should be apparent from the above discussion. As the glucose approaches 70 mg/dL, glucagon and epinephrine levels begin to rise. By the time the glucose level reaches 55 mg/dL, an intense counterregulatory chemical response is apparent. In children with insulin-dependent diabetes or chronic hyperinsulinemia, the epinephrine response may be diminished. In these children, activation of this response may not occur until the glucose concentration is about 35 mg/dL. Under conditions of even normal glucose utilization, there may not be time for endogenous mechanisms to prevent severe hypoglycemia. Patients on b blockers are also at particularly high risk. These agents often blunt the counterregulatory catecholamine response leading not only to worsening hypoglycemia but also to a paucity of classic signs often used to make the diagnosis. These patients may present with only neuroglycopenic symptoms and signs, such as seizure, "stroke," or coma. Glucagon's release is normally stimulated by hypoglycemia as well as elevated levels of growth hormone, epinephrine, and cortisol. However, calcium-channel blockers, b agonists, and anticholinergic drugs suppress its release. Therefore, these drugs may predispose individuals to hypoglycemia (Table 125-2). In the fed state, insulin levels may be in the range of 50 to 100 μU/mL. During periods of hypoglycemia, insulin levels are normally suppressed to 5 to 10 μU/mL maximum.

Ethanol	Sulfonylureas	Salicylates
Insulin	Phenformin/	Sulfisoxazole
β-blockers	metformin	Ethylenediaminetetraacetic
Bishydroxycoumarin/	Oxytetracycline	acid
warfarin	Phenylbutazone	Manganese
Propoxyphene	Chlorpromazine	Diphenhydramine
Indomethacin	Para-aminobenzoic	Haloperidol
	acid	

TABLE 125-2   Drugs Related to Hypoglycemia

CLINICAL FEATURES

Classically, hypoglycemic patients present with either neuroglycopenic or excessive adrenergic signs and symptoms (Table 125-3). Postprandial hypoglycemia is more likely to present with signs of adrenergic excess whereas fasting hypoglycemia commonly presents with neuroglycopenic symptoms. In general, the more rapid the decrease in glucose concentration, the more adrenergic-type symptoms will be noted. Variability and crossover in symptoms is the rule, however, and not the exception. Neonates and young children may present with poor feeding, jitteriness, emesis, ravenous hunger, lethargy, altered personality, repetitive colic-like symptoms, hypotonia, or hypothermia. In other cases they unfortunately present after an apparent life-threatening event, seizure, or cardiac arrest. As children grow older they begin to present more like adults, with signs of adrenergic excess and then neuroglycopenia. If treatment is not forthcoming, the adrenergic symptoms may abate, leaving only the neuroglycopenic ones. In some cases, as with type I glycogen storage disease, patients may have no obvious symptoms despite an incredibly low blood glucose concentration. Children with unexplained catastrophic presentations such as coma, severe hypothermia, and arrest should have bedside glucose testing performed immediately and, if clinically indicated, a specimen should be sent for formal laboratory evaluation as well. Empirically treating patients after cardiac arrest with glucose may worsen neurologic outcomes, as hyperglycemia is detrimental in cases of cerebral edema and anoxia. Therefore, whenever possible, bedside testing and historical data surrounding the event should guide therapy in this population. Hypoglycemia should be suspected in all moderately to severely injured or ill

children. The underlying disease process will often mask the symptoms of hypoglycemia. Children with increased physiologic stress require periodic reevaluation for hypoglycemia, as they are often unable to maintain sufficient glucose influx to meet their increased needs. This is especially true in patients whose illness, injury, or treatment prevents them from being able to express their needs.

Adrenergic Excess	Neuroglycopenia
Anxiety	Confusion
Tachycardia	Ataxia
Perspiration	Headache
Nausea	Depressed consciousness
Tremors	Blurred vision
Pallor	Lightheadedness
Chest pain	Focal neurologic deficits
Weakness	Seizures
Abdominal pain	Strabismus
Hunger	Staring
Irritability	Paresthesias

TABLE 125-3 Clinical Signs of Hypoglycemia

The most common cause of hypoglycemia in non-insulin-dependent children over the age of 1 year is idiopathic ketotic hypoglycemia. It is more a physiologic aberration than a true pathologic syndrome.[2,4] It usually presents in children less than 18 months of age after a period of fasting. Often this is seen on holidays and weekends, when parents sleep late, inadvertently extending the child's usual nighttime fasting period. It is also more common during illnesses preventing normal food intake. These children return to normal after a glucose load and have no suspicious findings in either their history or physical exams.[2,5] Classically, this problem was thought to arise because these children were small for age, but that idea has been called into question by more recent findings.[2,4] Currently, alanine, by far the most important amino acid in gluconeogenesis, is thought to play a major role in this disorder.[3,6] Haymond et al.[5] demonstrated lower serum alanine concentrations in these patients as compared with age-matched control groups during fasting. Giving gluconeogenic precursors to these patients during periods of fasting prevents hypoglycemia, lending further support to the theory outlined above. Children with idiopathic ketotic hypoglycemia present with normal ketonemia and ketonuria. If not tested for early, the ketones may be missed because they dissipate rapidly with treatment of the hypoglycemia. If tested, insulin will be normally suppressed and cortisol as well as growth hormone will be normally elevated during the hypoglycemic period. Treatment is primarily to avoid prolonged fasting. Provision of frequent high-carbohydrate and high-protein meals also helps to prevent recurrence. Some have used feedings of raw cornstarch at bedtime, as described under "Treatment" at the end of this chapter. Monitoring of urine ketones during periods of decreased oral intake, such as illness, is recommended.[4] Should ketones be detected, the patient should be given additional carbohydrate and protein containing foods and/or be brought to medical attention at once.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hypoglycemia differs in different age groups. Some disorders are only transiently seen in neonates, while others may start in the neonatal period but extend throughout childhood. Still others are not usually seen until after the neonatal period. For example, some inborn errors of metabolism always present in early infancy while others may not be clinically apparent until the child is a few years old. Table 125-1 lists some causes of hypoglycemia in childhood. A full discussion of each of these is beyond the scope of this chapter. Diagnostic suspicion of many of these should prompt a discussion with and referral to an expert in metabolic diseases.

Many drugs (Table 125-2) may predispose children to hypoglycemia. Some have more supporting evidence and occur more frequently than others. Besides insulin and possibly sulfonylurea type medications, ethanol is by far the most common cause of drug-induced hypoglycemia in children. Ethanol inhibits gluconeogenesis. Hypoglycemia after the ingestion of alcohol may occur in adults but is far more likely in children due to their higher relative glucose utilization and much lower relative quantities of glycogen. As mentioned above, children become more quickly dependent on gluconeogenesis than do adults. This effect on liver metabolism is often seen at alcohol levels too low to cause clinical intoxication. Therefore, any child with a history of alcohol ingestion should be closely monitored for hypoglycemia and given glucose either orally or parenterally. In nonintoxicated patients, this may be accomplished by feeding. Intoxicated-appearing patients should always be evaluated for hypoglycemia at presentation and every few hours thereafter if unable to eat. In young children who will not be able to eat for more than 4 h, maintenance fluids containing dextrose should be given.

Testing for blood glucose has evolved over the recent past. Rapid bedside test strips and colorimetric readers should be available in all EDs. These are most accurate when the glucose concentration is in the normal range. Their specificity decreases at both ends of the concentration spectrum, so they should only be used as a screening tool. All patients with symptoms of hypoglycemia should have a specimen sent to the laboratory for chemical analysis. Bedside test strips occasionally give falsely elevated results. Residual isopropyl alcohol on the skin may lead to false positive low glucose values. The definitive diagnosis and workup should be based on the chemical analysis and not just the screening reagent-strip test. In symptomatic patients, treatment should begin based on the bedside test result. Treatment can be altered, if necessary, upon return of the chemical analysis.

EVALUATION

This is quite complex in some cases and controversial in others. In all cases, a detailed history should be obtained and a meticulous physical exam performed. Inquiry regarding prior episodes of hypoglycemia should occur. Detailed data regarding family, birth, development, and past medical history are needed. History of childhood death from unknown causes in a first- or second-degree relative should be sought. Potential access to insulin, sulfonylureas, b blockers, salicylates, and other toxins should be determined. Physical exam should include a head-to-toe survey for signs of other serious illness as well as findings more specifically related to hypoglycemia. Hypopituitarism may be associated with midline defects such as abnormal incisors, palatal defects, cleft-lip defects, midface abnormalities, or abnormal palpebral fissures. Hyperpigmentation, undescended testes, severe dehydration, and micropenis may be associated with abnormalities arising from the adrenal or pituitary glands. Children with short stature or less than expected recent growth should be evaluated for growth hormone abnormalities.[2,4] Height, weight, and head circumference should be plotted on a standardized growth chart. Tanner stage should be determined. The fundi should be evaluated for signs of optic nerve hypoplasia associated with hypopituitarism. Each patient should have a thorough examination of the abdomen specifically in an attempt to identify large masses such as those from neuroblastoma and, more importantly, hepatomegaly associated with most hypoglycemia causing glycogen storage, fatty acid oxidation, and other metabolic abnormalities.

Emergency physicians should make the diagnosis of hypoglycemia and any other clinically important associated disease processes. They should then institute appropriate therapy. Concurrently, they must differentiate between ketotic and nonketotic hypoglycemia and, based on this information, make decisions regarding the potential need for further studies. In questionable cases, it is practical to collect an extra set of blood tubes and an additional urine specimen for later use if deemed necessary. Many potentially required additional study results are valuable only if they are based on samples obtained when the child is hypoglycemic. This being said, children should not be allowed to remain hypoglycemic for any significant period of time before treatment. Overzealous or time-consuming attempts at laboratory collection should be avoided.

Prehospital protocols for hypoglycemic children should include the collection of appropriate blood specimens prior to treatment whenever possible. Prehospital laboratory specimens should not be discarded except at the discretion of the consultant or admitting physician.

The majority of children who present to the ED, however, probably do not need extensive laboratory evaluation. Infants and especially neonates should be evaluated thoroughly on first presentation unless the cause of hypoglycemia is clear. Developmentally normal children over 1 year of age who have normal head circumference and growth, who make a complete recovery after receiving glucose, have normal electrolytes, and present with findings consistent with idiopathic ketotic hypoglycemia do not usually need a detailed investigation. Patients with hepatomegaly, other signs of illness, significant acidemia, hyperpigmentation, or other clinically significant physical findings require a complete evaluation at presentation. In patients where a full workup is deferred, appropriate tubes of blood and a urine specimen may be collected and held by the lab. Close follow-up should be arranged and the patient's primary care physician made aware of the child's visit and findings. Should hypoglycemia recur or the child's clinical situation change, the held specimens may be extremely valuable. See Fig. 125-1 for a general approach to

the laboratory evaluation of these patients. Variance from this is not only acceptable but expected based on the specifics of the individual clinical situation.

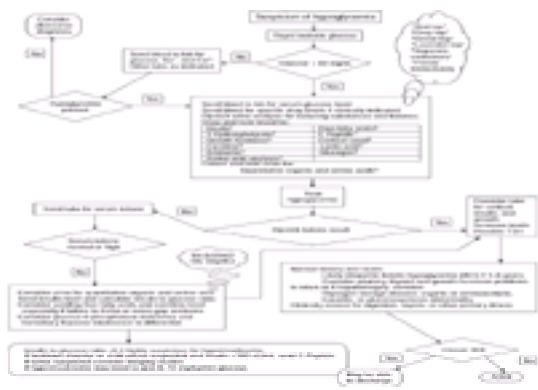

FIG. 125-1. General approach to the lab evaluation of hypoglycemia.

SPECIAL ISSUES AFFECTING DIAGNOSIS

1. Mentally challenged children can be especially difficult to evaluate. Often they have dysautonomia as well as feeding difficulties. A low threshold for blood glucose evaluation is appropriate in these patients, especially if the caretakers note a change in baseline behavior or mental status.
2. Most children who present with self-harming thoughts, suicidal threats, or true suicide attempts should have their glucose checked as part of their medical clearance. This is especially true of diabetic children and those with access to a relative's oral hypoglycemic agents. Inpatient monitoring of glucose may be necessary if overdose of an oral hypoglycemic agent is suspected. Most cases, however, will demonstrate hypoglycemia within 6 to 8 h. Management of such overdoses is often complex and is beyond the scope of this chapter.
3. In patients thought to have a factitiously depressed glucose associated with an elevated insulin level, the C-peptide level should be determined. [7,8] Typically the insulin level in these cases will be very high. If exogenous insulin is the cause, the C-peptide level will be inappropriately suppressed. [7] Normally C-peptide is produced in equimolar quantities during the processing of proinsulin to insulin; therefore, its levels should follow those of insulin itself. In cases of insulinoma, for example, both the insulin and C-peptide levels will be high.
4. Patients found to have hypoglycemia and non-glucose-reducing substances in their urine should have galactosemia ruled out. The dipstick urine test will be negative for glucose, but the laboratory evaluation for reducing substances will be positive in this case. This disease usually presents during infancy with failure to thrive, vomiting, hepatomegaly, and jaundice.

TREATMENT

Whenever possible, if the clinical condition allows, children should be treated with oral glucose loading. Clearly this should not occur in children unable to protect their airways. Common methods include orange juice with 2 tsp of sugar added per glass, maple syrup, honey (in older children), and, in mild cases, nondiet soda. Sucrose and fructose should not be given to any child suspected of having hereditary fructose intolerance. Lactose should not be given to children suspected of having galactosemia. Once the glucose concentration is back to the normal range, these children should be given a meal containing complex carbohydrates, proteins, and fats. This is presuming that inborn errors of metabolism have been ruled out.

When oral treatment is not an option, the intravenous route should be used (Table 125-4). Boluses of 0.25 to 0.5 g/kg are most commonly used. This is equivalent to 2.5 to 5 mL/kg 10% D/W, 1 to 2 mL/kg 25% D/W, or 0.5 to l mL/kg 50% D/W. If no response is seen within 5 min, this should be repeated and a bedside glucose checked. If the glucose remains <50 mg/dL and three boluses have been given, the clinician should consider using one of the alternative agents listed below. The proper choice should be based upon the clinical and historical findings.

TABLE 125-4 Treatment of Hypoglycemia

Boluses in neonates should be given with 10% D/W. Infants should receive 10% D/W whenever possible, although 25% D/W is acceptable as well. In older children, 25% D/W may be used. 25% D/W and especially 50% D/W are very hyperosmolar and may cause phlebitis or tissue necrosis, if they extravasate. Even without extravasation, patients commonly complain of pain at the injection site for 1 to 2 weeks. The risk of extravasation is increased when smaller veins, such as those found in infants, are used. In addition to this, hyperosmolar loading in premature neonates is associated with an increased risk of intracranial germinal matrix hemorrhage and subsequent periventricular leukomalacia. The use of 25% D/W and 50% D/W may also lead to an increased incidence of rebound hypoglycemia due to endogenous insulin release. When time allows, diluting 50% D/W or 25% D/W to 10% D/W with normal saline or half normal saline will decrease the risk of pain, phlebitis, and necrosis at the injection site by decreasing the osmolarity. This practice also prevents the administration of large volumes of free water when multiple boluses are required, as would occur if sterile water were used as the diluent. This volume would be equivalent to a fluid bolus of 2.5 to l5 mL/kg. Since many of these patients are also dehydrated, this amount of electrolyte-containing solution is certainly not excessive and probably somewhat therapeutic.

Once the patient's glucose is brought into the normal range, maintenance fluids should be started. The amount of glucose required for maintenance of euglycemia varies with age, underlying glucose utilization and the patient's insulin level. Neonates commonly require 6 to 8mg/kg per minute or 4 mL/kg/ per hour of a 10% dextrose containing electrolyte solution. In general, children will require 4 to 6 mg/kg per minute or about 3 mL/kg per hour of a 10% dextrose containing electrolyte solution. Plain 10% dextrose should never be used for multiple boluses or maintenance fluids. This practice causes water intoxication, hyponatremia, intractable seizures, and possibly death. Typically, 10% D/0.9% NS or 10% D/0.45% NS (77 mmol/L Na^+ will be appropriate. Alterations may occur once the serum sodium is known. Likewise, potassium may be added once urine output is established and the current serum concentration is known. This is especially important in patients with potential mineralocorticoid deficiency. Patients who are hyperinsulinemic often require maintenance rates of 10 to 12 mg/kg per minute. In some cases, 25 mg/kg per minute will be needed. The clinician will need to use more concentrated glucose-containing electrolyte solutions in these cases. A central line should be considered if a concentration greater than 12.5% dextrose is required.

Glucagon works only if the patient has intact glycogen stores. [4,9] Its use should be considered, especially in the prehospital arena, when an intravenous line cannot be placed. In some children, hypoglycemia is due to depleted, abnormally produced, or unmobilizable glycogen stores. [4] An intraosseous line should be considered in these cases, if an intravenous line is unobtainable so as to allow glucose loading, especially if symptoms of neuroglycopenia are present. Controversy surrounds the use of glucagon in cases of sulfonylurea overdose and hyperinsulinemia. Glucagon stimulates insulin release; therefore, at least theoretically, giving it to these patients could lead to worsening hypoglycemia. The glycemic response to insulin is increased in these patients. At present, there are no prospective controlled studies in this patient group to guide the clinician. Typical dosing is 1 mg glucagon in adults, 30 μg/kg in children, and 50 μg/kg in infants. The maximum single dose

is 1 mg for hypoglycemia, although higher doses are used for other indications. It may be given subcutaneously, intramuscularly, or intravenously. Studies have demonstrated effectiveness even when glucagon is given intranasally, although this is not the standard of care at this time. [10], [11] and [12] If no intravenous line is available, the intramuscular route is probably best. One exception to this is in small neonates who may not have adequate muscle mass. The diluent that is packaged with glucagon contains phenol. When glucagon is given to children, it should be diluted with saline or sterile water. Phenol especially should not be used if glucagon will be given intravenously. If a 50% rise in serum glucose concentration is not seen within 30 min, the clinician should suspect either previous depletion of glycogen stores, an abnormality in fatty acid oxidation, or type I glycogen storage disease. Less commonly, glycogen storage disease types III, VI and IX can present in this fashion as well.

In refractory cases, especially those associated with adrenal insufficiency, steroids may be useful. Hydrocortisone succinate is a good choice owing to its effective glucocorticoid and additional mineralocorticoid effects. The majority of adrenally suppressed patients will have associated mineralocorticoid depression as well. In these cases a steroid such as hydrocortisone must be used instead of one such as dexamethasone, which has almost no mineralocorticoid activity. The dose of hydrocortisone succinate is 1 to 2 mg/kg IV every 6 h. The minimum dose is 25 mg and the maximum dose is 100 mg.

Hyperinsulinemic patients may also be given diazoxide to inhibit insulin release and activity. [6] More recent literature has suggested that octreotide may be a better choice; it is not associated with the rare hypotensive effects of diazoxide. Octreotide dosing for this potential indication is controversial and not yet established. Diazoxide is given intravenously at 3 to 5 mg/kg for neonates and 1 to 3 mg/kg for children every 8 h. Diazoxide should be given over at least 30 min to prevent severe hypotension. In children who are able to eat, feedings every 3 to 4 h will often suffice as well. If given only simple carbohydrates, these children will develop postprandial hyperglycemia with subsequent rebound hypoglycemia secondary to stimulation of insulin secretion. Therefore, their diet should consist of complex carbohydrates, proteins, and fats as well. Feedings of raw cornstarch at night usually maintain safe glucose levels for a number of hours and are not typically associated with the rebound phenomenon discussed above. [13] Starches are absorbed slowly, leading to a lower but more continuous supply of glucose. Children with endogenous hyperinsulinemia due to insulinomas often require near total pancreatectomy. 126 ALTERED MENTAL STATUS IN CHILDREN

Nancy Pook
Natalie Cullen
Jonathan I. Singer

Altered mental status (AMS) in a child is the failure to respond to the external environment in a manner appropriate to the child's developmental level, despite verbal or physical stimulation.[1] Alteration in mental status consists of impairment of awareness and arousal, the two components of consciousness. Patients with AMS require simultaneous stabilization, diagnosis, and treatment. The objectives of treatment are to sustain life and prevent irreversible central nervous system damage. Once the patient is resuscitated, the next objective is to establish the cause of AMS and stop disease progression.

PATHOPHYSIOLOGY

There is a spectrum of alterations of mental status, ranging from confusion or delirium (disorders in perception) to lethargy, stupor, and coma (states of decreased awareness). A lethargic pediatric patient has decreased awareness of self and the environment. In an emergency setting, this translates to decreased eye contact with family members, nursing, and physician personnel.[2] A stuporous pediatric patient has decreased eye contact, decreased motor activity, and unintelligible vocalization. Stuporous patients can be aroused with vigorous noxious stimulation. Comatose patients are unresponsive and cannot be aroused by verbal or physical stimulation, such as phlebotomy, arterial catheterization, or lumbar puncture.[3,4 and 5]

Irrespective of the cause, AMS is indicative of either depression of the cerebral cortex or localized abnormalities of the ascending reticular activating system. Both cerebral cortices must be affected in order to cause AMS. Classic causes of bilateral cortical impairment are toxic and metabolic states that deprive the brain of normal substrates. Altered mental status can also be produced through dysfunction of the reticular activating system that is housed in the brainstem and midbrain. This system connects cranial nerve nuclei and extends from the brainstem to the thalamus. It governs respirations, cardiovascular functions, and many aspects of homeostasis, as well as daily wake-sleep cycles. Any abrupt interruption or selective destruction of the reticular activating system may result in AMS.[1,3]

The pathologic conditions that effect awareness and arousal can be described using three broad pathologic categories: supratentorial mass lesion, subtentorial mass lesion, and metabolic encephalopathy.[3,6]

Supratentorial mass lesions cause AMS by compressing the brainstem and/or diencephalon. Signs and symptoms of this type of lesion include focal motor abnormalities that are often present from the onset of the altered level of consciousness. The progression of neurologic dysfunction is from rostral to caudal with sequential failure of midbrain, pontine, and medullary function. Compromise by supratentorial lesions causes slow nystagmus toward and fast nystagmus from a cold stimulus during caloric testing.

Subtentorial mass lesions lead to reticular activating system dysfunction, in which prompt loss of consciousness is generally the rule. There is a discrete level of dysfunction. Cranial nerve abnormalities are frequently found due to the highly packed neurologically eloquent anatomy. Abnormal respiratory patterns such as Cheyne-Stokes respiration, neurogenic hyperventilation, and ataxic breathing are common. With brainstem injury, asymmetric and/or fixed pupils are found. No eye movements occur despite cold stimuli to both auditory canals.

Metabolic encephalopathy usually causes depressed consciousness before depressed motor signs, which, when present, are typically symmetric.[3,7] Respiratory function is involved relatively early, and abnormalities are often secondary to acid-base imbalance. Pupillary reflexes are generally preserved. Pupils may be sluggish, but the movement is intact and symmetric. Exceptions occur with profound anoxia and the influence of cholinergics, anticholinergics, opiates, and barbiturates.

CLINICAL FEATURES

Two individuals are needed to manage a pediatric patient with AMS. One individual should act as historian to perform a methodical and comprehensive interview. The key questions that must be explored concern prodromal events leading to the change in consciousness, recent illnesses, the likelihood of an infectious exposure or exposure to intoxicants, and the likelihood of trauma, including abuse.[1,4] The historian should make inquiries regarding antecedent fever, headache, head tilt, abdominal pain, vomiting, diarrhea, gait disturbance, seizures, drug ingestion, palpitations, weakness, hematuria, weight loss, and rash. For infants and young children with AMS, developmental milestones should be pursued. The past medical history, immunization history, and family history are important in children of all ages. The clinician should be alert for any inappropriate responses or inconsistencies and delays in seeking care that may arouse the suspicion of child abuse. Although it may be possible to obtain a history quickly, in order to be thorough and pay attention to detail, one physician must be dedicated to obtaining the history while the second physician manages the resuscitation.

One should proceed with a general examination only after cardiac and cerebral resuscitation. The objectives of the examination are to identify occult infection, trauma, toxicity, or metabolic disease.[4,6] The neurologic examination should document the child's response to sensory input, motor activity, pupillary reactivity, oculovestibular reflexes, and respiratory pattern. Although several coma scales have been published,[8,9] the most simplified and functional in an emergency setting is the AVPU scale. This is a descriptive tool in which *A* means "alert," *V* means "responsive to verbal stimuli," *P* means "responsive to painful stimuli," and *U* means "unresponsive."

Following a targeted history and a focused examination, the treating physician should anticipate and observe changes in the patient's status that may indicate improvement or deterioration. An additional task of the physician who attends the patient is to make an operational, if not specific, diagnosis of AMS.

DIAGNOSIS

The differential diagnosis for AMS in children is diverse and differs slightly from that for adult patients. [1,4] The familiar mnemonic AEIOU TIPS remains a useful tool for organizing the diagnostic possibilities (Table 126-1).

TABLE 126-1   AEIOU TIPS: A Mnemonic for Pediatric Altered Mental Status

Alcohol

In younger pediatric patients, alcohol ingestion is typically accidental; intentional ingestion is more likely in adolescents. AMS may occur with serum levels less than 100 mg/dL. Hypoglycemia may occur concurrently.

Acid Base and Metabolic Disorders

Children with diabetes may present in ketoacidosis. The classic presentation includes weight loss, polyuria, polydypsia, polyphagia, weakness, vomiting, abdominal discomfort, Kussmaul respirations, a fruity acetone breath, and AMS. Patients with diabetic ketoacidosis, as well as many other pediatric disease states associated with a loss of circulating volume, may develop inadequate perfusion. Patients with hypotonic or hypertonic dehydration may develop AMS with and without seizures. Poorly perfused patients or patients with inadequate air exchange have insufficient oxygen delivery to the brain and exhibit insomnia, somnolence, and confusion. Patients who develop hypercapnia as a result of primary lung disease or neurologic dysfunction may also present with AMS. Those with hepatic failure present with nausea, fatigue, and behavioral alterations and may rapidly become obtunded. Patients with inborn errors of metabolism typically present early in life with poor feeding, recurrent vomiting, seizures, metabolic acidosis, lethargy, stupor, and coma.

Dysrhythmia and Other Cardiogenic Causes

Ventricular fibrillation causes unconsciousness by diminished oxygen delivery to the brain. In a Stokes-Adams attack, heart block leads to loss of consciousness. Critical aortic stenosis leads to unconsciousness through decreased cardiac output.

Encephalopathy

Hypertensive encephalopathy may occur in pediatric patients at diastolic pressures of 100 to 110 mmHg. Reye syndrome follows a viral illness, such as influenza or varicella. Patients are afebrile and anicteric, and develop pernicious vomiting. Confusion and delirium may lead to increasing obtundation. Hemorrhagic shock and encephalopathy syndrome is a symptom complex of unknown cause that affects previously healthy infants. The common features include a mild prodromal, nonspecific illness of several days' duration followed by the onset of profuse, watery diarrhea that becomes bloody, and seizures. Patients present poorly perfused, with profound metabolic acidosis and evidence of disseminated intravascular coagulation. Laboratory evidence of hepatic, renal, pancreatic, and myocardial dysfunction is common.

Endocrinopathy

AMS is a rare presentation of these disorders. Patients with Addison disease present with nausea, vomiting, abdominal pain, weakness, malaise, hypotension, and mental status changes, including psychosis. Presumptive evidence is provided by finding hyperpigmentation, depressed sodium and blood sugar levels, an elevated potassium level, and a variably increased calcium level. Infants with congenital adrenal hyperplasia may present in an acute salt-losing, volume-depleted hypotensive crisis or with virilization, characterized by ambiguous genitalia and cortisol insufficiency also manifested as hypoglycemia. Thyrotoxic infants may present with ventricular dysrhythmia. Patients may also exhibit symptoms similar to those of adults, including goiter, irritability, exophthalmos, hyperthermia, high-output congestive heart failure, mania, delirium, psychosis, and, later, apathy and decreasing levels of consciousness. Patients with pheochromocytoma may present with hypertensive encephalopathy.

Electrolytes

Hyponatremic children become symptomatic with plasma levels around 120 meq/L. Manifestations include anorexia, headache, nausea, vomiting, irritability, weakness, cramps, disorientation, seizures, and AMS. Hypernatremic individuals develop muscle weakness, irritability, seizures, and AMS. Disorders of calcium, magnesium, and phosphorus present with neuromuscular signs, including weakness, tetany, seizures, and apathy.

Insulin

Hypoglycemia may be an end product of an endocrinopathy (e.g., adrenal insufficiency, hyperthyroidism, or hypopituitarism) or the result of an exogenous substance, such as ethanol, salicylate, oral hypoglycemics, and insulin. Hypoglycemia may result from a common stress pathway of decreased gluconeogenesis, as seen during sepsis or Reye syndrome. Adrenergic signs of palpitations, hunger, and sweating are seen at levels less than 60 mg/dL. Irritability, confusion, seizures, and coma occur at levels of 40 mg/dL or less. Infants and children are prone to develop ketotic hypoglycemia with fasting, especially with infections in early infancy. AMS from hyperglycemia is rare in children. The most common cause of hyperosmolar central nervous system dysfunction is diabetic ketoacidosis.

Intussusception

Intussusception is readily diagnosed in the small percentage of younger children who present with a classic constellation of abdominal pain, vomiting, abdominal mass, and rectal bleeding. AMS may be the initial symptom and dominant concern of the physician and the parent caring for a child with intussusception. AMS remains until the bowel obstruction is reduced. [10]

Opiates

Children who have ingested opiates may present with miosis, absent bowel sounds, and lethargy. Common opiates that may be present in the household include dextromethorphan, diphenoxylate and atropine (Lomotil), and loperamide (Imodium). Ingestion of clonidine, an a agonist, may also cause signs and symptoms similar to opiate intoxication. Abuse and neglect should always be suspected in children with opiate intoxication.

Uremia

In children with chronic renal failure, neurologic dysfunction may develop secondary to stroke, hypertension, or metabolic derangements. Encephalopathy occurs in over one-third of patients with chronic renal failure and is manifested by headache, irritability, cognitive derangement, and seizures. Hemolytic uremic syndrome is a

pediatric disorder characterized by microangiopathic hemolytic anemia and uremia. It follows a prodrome of abdominal pain and diarrhea and is manifested by pallor, thrombocytopenia with purpura, red blood cell fragmentation, and oliguria.

Trauma

Trauma may occur on the cellular or global level. In the context of multisystem trauma, a hypovolemic state may create insufficient cerebral perfusion. Such hypovolemic states may be created by other "traumatic" insults, such as primary peritonitis or ruptured appendicitis with hypovolemia. Children may have transient loss of consciousness after closed head injury. Occasionally, a seizure may occur immediately after closed head injury, resulting in AMS from the postictal state. The signs and symptoms of acute epidural hematoma are typically posttraumatic loss of consciousness followed by a lucid interval and then rapid AMS. Acute epidural hematoma can also present with a gradual loss of consciousness associated with ipsilateral pupillary dilatation. As in adults, subdural hematomas may be acute, subacute, or chronic. Most children with subdural hematomas have external signs of trauma. The exceptions are abused infants, typically less than 6 months of age, who may present without external signs of injury. Abused children who are shaken typically present with a history of vomiting, seizures, and changes in respiratory pattern associated with AMS. Retinal hemorrhages or a tense fontanel may suggest the diagnosis. Children with blunt head trauma are more inclined than adults to develop diffuse cerebral swelling, increased intracranial pressure, and AMS without extracerebral or intracerebral collections of blood. While uncommon in childhood, cerebrovascular accidents, including bleeding from arteriovenous malformations, may cause focal neurologic deficits followed by status epilepticus and coma.

Tumor

Primary brain tumor or metastatic or meningeal leukemic infiltration may alter the metabolism of the brain. Intracerebral tumors commonly produce focal neurologic dysfunction, whereas posterior fossa tumors typically block the ventricular system and create signs and symptoms suggestive of hydrocephalus. Both supratentorial and infratentorial tumors may present abruptly with AMS, fever, or meningismus after an intratumor hemorrhage.

Thermal

Extremes of body temperature may also lead to central nervous system dysfunction. Progressive hypothermia leads to insidious AMS. Patients who develop body-core temperatures greater than 41°C (105.8°F) develop headache, weakness, and dizziness followed by confusion, euphoria, combativeness, and AMS. Posturing, seizures, hemiparesis, and pupillary changes may be present.

Infection

Infection is more common as a cause of AMS in children than in adults. The incidence of bacterial meningitis and septicemia is highest in early infancy and considerably higher throughout childhood than in adulthood. Bacterial meningitis should be high on the differential diagnostic list in a pediatric patient with AMS. Unless there are contraindications to lumbar puncture, examination of cerebrospinal fluid (CSF) should be considered in lethargic, febrile pediatric patients (Table 126-2). Similarly, pediatric patients may become encephalopathic due to direct invasion of the brain by multiple pathogens. Patients with encephalitis have fever, headache, and, may have signs of meningeal irritation or neurologic deficits. Herpes viruses, arbovirus, rotavirus, and Epstein-Barr virus are among the most common viral agents associated with encephalitis. Encephalitis may occur in the course of mycoplasmal illness, shigellosis, Lyme disease, or cat-scratch disease. Visceral larva migrans may produce encephalopathy in the young. A brain abscess may create signs and symptoms suggestive of encephalitis. Patients with a brain abscess present with fever and headache that precede changes in presentation and consciousness. Affected patients may also present with generalized or focal seizure activity. Patients at risk for brain abscess include those with sinusitis, cyanotic congenital heart disease, immunodeficiency, and intravenous drug abuse. Any systemic infection associated with vasculitis, or vasodepressor toxins, with shock may lead to AMS secondary to cerebral hypoperfusion.

TABLE 126-2   Procedure: Lumbar Puncture

Intracerebral Vascular Disorders

Subarachnoid hemorrhage may occur following trauma or spontaneous rupture of a berry aneurysm or arteriovenous malformation. Nuchal rigidity is an inconstant finding. Venous thrombosis may follow severe dehydration or a pyogenic infection of the paranasal sinuses, mastoid, or middle ear. Periorbital edema with cranial nerve abnormalities is a clue. Arterial thrombosis is uncommon in children, except in those with homocystinuria. Children with homocystinuria have a marfanoid appearance, dislocated lenses, and mental retardation. Intracerebral and intraventricular hemorrhages may follow birth asphyxia or trauma in neonates, but in older children they may signify a congenital or acquired coagulopathy. Signs of subacute bacterial endocarditis include splinter hemorrhages, splenomegaly, microscopic hematuria, and AMS caused by cerebral emboli. Acute infantile hemiplegia presents with an acute seizure followed by hemiparesis and coma. Acute confusional migraine may be associated with profound alterations in consciousness.

Poisoning

Drugs may be transferred to a fetus transplacentally. Infants and children may receive drugs through neglect, abuse, or accident. Drugs may be utilized as a suicide gesture in adolescents. AMS may be caused by exogenous intoxicants, such as ethanol, ethylene glycol, methyl alcohol, paraldehyde, salicylates, anticholinergics, including antihistamines, cholinergics, opiates, tricyclic antidepressants, carbamazepine, clonidine, sedative-hypnotics, amphetamines, cocaine, cannabis, nicotine, carbon monoxide, hydrocarbons, and phenothiazines. Household and beauty products may also cause AMS.

Psychogenic

Psychogenic unresponsiveness is a rarity in pediatric patients. It is characterized by decreased responsiveness but otherwise normal findings on neurologic examination, including normal oculovestibular reflexes. Psychogenic unresponsiveness may occur as a conversion reaction, an adjustment reaction, a panic state, or a manifestation of malingering.

Seizure

Generalized tonic-clonic major motor seizures are associated with prolonged unresponsiveness in pediatric patients. Seizure in a young febrile patient suggests intracranial infection.

DIAGNOSTIC ADJUNCTS

Ancillary procedures for diagnosis of AMS include analysis of blood, gastric fluid, urine, and CSF; electrocardiography; roentgenography; ultrasonography; and computed tomography (CT) scanning.[1,3,5] Diagnostic tests should be guided by the clinical situation. Rapid estimation of the blood glucose level with a glucose

oxidase strip is a universally accepted evaluation in pediatric patients with AMS. Confirmation by laboratory analysis of venous blood is recommended. Electrolyte determinations, liver function studies, and renal function studies may provide additional information regarding the state of hydration, suspected endocrine and metabolic derangements, and liver and kidney function. If the history is consistent with a toxic ingestion or a toxidrome is identified, toxicology screening is in order. The white blood cell count and differential blood count as independent evaluations are rarely helpful, except perhaps in management decisions regarding highly febrile children less than 2 years of age. A blood culture should be obtained whenever sepsis is suspected.

An arterial blood gas or capillary blood gas analysis with pulse oximetric analysis may provide useful information in cases of trauma, respiratory distress, or suspected acid-base imbalance.

It is not inappropriate to place an indwelling urinary catheter in an ill pediatric patient. The initial urine specimen can be analyzed and a portion sent for toxicologic screening.

Lumbar puncture with CSF examination should not be delayed if AMS is thought to be secondary to meningitis or encephalitis. [11] The lumbar puncture should not be performed and CT should be performed first if AMS is thought to be secondary to trauma, suspected increased intracranial pressure, subdural or epidural fluid collection, cavernous sinus thrombosis, lateral sinus thrombosis, cerebral hemorrhage, brain tumor, cord tumor, or brain abscess. Shock or hypotension and hypoxia should be corrected before lumbar puncture, and empiric antibiotics should be given if meningitis is suspected.

A 12-lead electrocardiogram should be obtained if there are pathologic auscultatory findings or a rhythm disturbance is evidenced while monitoring the patient. An electrocardiogram may further guide therapy in cases of tricyclic antidepressant overdose.

Radiologic evaluation should be directed by the clinical scenario. Portable cervical spine radiography is mandatory prior to mobilization of the neck in a traumatized patient. A chest x-ray may be used to confirm or clarify examination findings and to document endotracheal tube placement. Abdominal films are indicated for the acute ingestion of radiopaque material if suspected, or if the patient exhibits signs and symptoms of an acute abdomen, including possible intussusception. Abdominal ultrasound studies may useful to screen cases of intussusception with an atypical presentation. [12] Skull films are reserved for traumatized patients in whom a depressed fracture is suspected. A CT scan of the head may be obtained for suspected increased intracranial pressure, vascular disorder, or mass lesion. [13]

Miscellaneous adjuncts that may be of assistance in specific instances are blood ammonia, serum osmolality, blood alcohol level, thyroid function tests, and a blood lead level. Skeletal survey may be of significance in a potentially abused young child. Barium or air enema may be both diagnostic or therapeutic in patients with intussusception and AMS. A portable EEG may prove to be diagnostic in a case of non-motor status epilepticus.

TREATMENT

The first priorities in AMS are stabilization and reversal of acutely life-threatening conditions before specific diagnostic maneuvers, such as lumbar puncture, are undertaken. [1,4,6] Airway, breathing, and circulation must be assured. For suspected cervical injury, spinal immobilization is mandatory, and the airway is opened with the jaw-thrust maneuver.

Hypoxia must be corrected, and continuous pulse oximetric monitoring should be established. There is no contraindication to providing oxygen to pediatric patients. Oxygen is obviously indicated for patients with signs of hypoxemia or hypoperfusion, but hypercapnia must be avoided. Bag-valve-mask ventilation may reverse hypercapnia, but endotracheal intubation is necessary to protect the patient from aspiration.

Fluid resuscitation is necessary in hypotensive comatose patients, since cerebral perfusion is dependent on adequate mean arterial pressure. A fluid bolus of 20 mL/kg of isotonic crystalloid should be given quickly. Poorly perfused patients should be reassessed and boluses repeated up to a total of 60 mL/kg as necessary. Thereafter, pressors should be utilized. In hemodynamically stable patients with suspected head injury, encephalitis, or meningitis, the intravenous fluids should be reduced to an hourly rate that provides two-thirds of the calculated maintenance volume. Empiric therapy may be initiated with 2 mL/kg of a solution of 25% dextrose in water intravenously if hypoglycemia is strongly suspected. [14] Alternatively, the blood glucose level may be rapidly estimated by means of a glucose oxidase stick, and glucose-containing fluids may be indicated by absolute or borderline levels. [15]

If there is clinical suspicion of opiate or clonidine overdose, a narcotic antagonist may be administered. The recommended dose for naloxone is 2 mg/kg as a starting dose. [16] Any dose, if successful, may be repeated as necessary to maintain narcotic reversal. Flumazenil (Mazicon ®), a benzodiazepine antagonist, may be used for pure benzodiazepine ingestion in an otherwise healthy child. It is dosed at 0.01 mg/kg intravenously with cardiac monitoring established. [17]

Seizures should be aborted if present. Benzodiazepines are typically first-line drugs. The longer-acting anticonvulsants, such as phenytoin or phenobarbital, may additionally be needed.

The treating physician must restore acid-base balance, primarily by ensuring adequate hydration and compensatory ventilation. Sodium bicarbonate should be utilized sparingly and only in circumstances where the pH is 7.0 or less.

The clinician should control core body temperature. Maintaining euthermia is critical to minimizing metabolic demands. A child's increased body surface area hastens radiant heat loss. Heat loss may be minimized with the use of a heating lamp during resuscitative procedures.

Septic-appearing patients and those suspected of having intracranial infection should receive empiric intravenous antibiotics in a timely fashion. [2,11]

DISPOSITION

All patients with AMS should receive continuing care in an area that can provide physiologic monitoring and repeated physical examinations from caretakers. In general, this requires admission to an intensive care unit or transfer to a tertiary care center with pediatric intensive care capabilities. Only those patients with transient, reversible causes of AMS may be treated, monitored in the emergency department, and discharged following observation. Patients who are discharged (e.g., those with a closed head injury or simple febrile seizure) should receive disease-specific discharge instructions. Patients who are evaluated for AMS and discharged home should have a repeat evaluation within 24 h of discharge.

127 SYNCOPE AND SUDDEN DEATH

William E. Hauda II
Thom Mayer

Although syncope is usually benign, it may be a symptom of serious cardiac disease and can predispose individuals to sudden death. The sudden death of a child may be due to cardiac, neurologic, or respiratory illnesses, or trauma. This chapter discusses syncope and sudden death due to cardiovascular causes, although the other causes of sudden death are mentioned briefly.

EPIDEMIOLOGY

Syncope

Syncope is very common in adolescence and less common in younger children. Between 20 and 50 percent of adolescents experience at least one episode of syncope.[1,2] Syncope is a presenting symptom of 0.05 percent of pediatric visits[3] and 6 percent of hospital admissions.[2] Approximately 25 percent of patients referred to a cardiology or neurology specialty clinic for the evaluation of syncope are eventually diagnosed with a serious illness.[4] However, most causes of syncope are benign, the most common cause being neurally mediated syncope.[3] Prior syncopal events are not always associated with an increased risk of future sudden death.[5]

Sudden Death

A distinction must be made between sudden unexpected death and sudden cardiac death, as the first includes many causes, such as a seizure, asthma, or toxic ingestion. Sudden cardiac death includes just those causes that directly relate to cardiovascular dysfunction. The rate of sudden unexpected death in children is 2.3 percent of all deaths or 1.3 cases per 100,000 patient years.[6] Sudden cardiac death encompasses approximately one-third of these deaths, or about 600 deaths per year in the United States. Excluding trauma, sudden cardiac death is the most common cause of sports-related death in young athletes.[7] The sports most frequently associated with sudden death are basketball, football, and track events.[8] The greatest risk for sudden cardiac death is among patients with congenital or acquired structural cardiac disease, including postoperative congenital heart disease. The most frequent causes of sudden cardiac death in children are acute myocarditis, cardiomyopathy, cyanotic and noncyanotic congenital heart disease, valvular heart disease, congenital complete heart block, Wolff-Parkinson-White syndrome (WPW), long QT syndrome (LQTS), Marfan syndrome, coronary artery disease, and anomalous coronary arteries.[9,10] Hypertrophic cardiomyopathy is the most common cause of sudden cardiac death in adolescents without known cardiac disease.[9]

PATHOPHYSIOLOGY

Syncope is the temporary loss of consciousness from reversible disruption of cerebral functioning (Table 127-1) and usually refers to inadequate cardiac output and cerebral hypoperfusion, resulting in a temporary loss of consciousness.

TABLE 127-1   Causes of Syncope in Children and Adolescents

Vascular syncope occurs when a stimulus causes venous pooling in the legs, leading to a decrease in ventricular preload with a compensatory increase in heart rate and myocardial contractility. After fainting, return of consciousness occurs while lying on the floor because gravity no longer contributes to venous pooling of blood. Neurally mediated syncope (NMS) or reflex syncope occurs when receptors in the atria, ventricles, and pulmonary arteries sense a decrease in venous return, and an efferent brainstem response via the vagal nerve causes bradycardia, hypotension, or both. Because the pathophysiology of NMS is related to abnormal circulatory control, this form of syncope is often grouped with other forms of vascular syncope, such as orthostasis and hypovolemia.

Cardiac syncope occurs when there is an interruption of cardiac output from an intrinsic cardiac problem. These causes are divided into tachydysrhythmias, bradydysrhythmias, outflow obstruction, and myocardial dysfunction (Table 127-1).

Any event that causes sufficient cerebral hypoperfusion can lead to sudden death. The most common causes are seizures, cardiac diseases, and metabolic diseases. Little is known regarding the most common dysrhythmias that cause sudden death in children, because such cardiopulmonary arrests are unwitnessed. In children, bradycardic or asystolic arrests are thought to be most common, especially in children younger than 1 year of age, but in older children ventricular fibrillation is also seen.[11] Overall in children, however, the incidence of ventricular fibrillation as the presenting cardiac dysrhythmia is much lower than that in adults. [8,11,12]

CLINICAL FEATURES

Syncope is characterized by a sudden onset of falling with a brief episode of loss of consciousness. Other associated symptoms or signs are usually related to the etiology for the syncopal event. Two-thirds of children experience a prodrome of light-headedness or dizziness prior to the event, [4] but vertigo is much less common. Involuntary motor movements occur with all types of syncopal events but are somewhat more common with seizures.[4] Factors related to more serious causes of syncope are outlined in Table 127-2. Events that may mimic syncope in children are listed in Table 127-3.

Exertion preceding the event

History of cardiac disease in the patient

Family history of sudden death, deafness, or cardiac disease

Recurrent episodes

Recumbent episode

Prolonged loss of consciousness

Associated chest pain or palpitations

Medications that can alter cardiac conduction

TABLE 127-2   Risk Factors for a Serious Cause of Syncope

Condition	Distinguishing Characteristics
Basilar migraine	Headache, rare loss of consciousness, other neurologic symptoms
Seizure	Loss of consciousness simultaneous with motor event, prolonged postictal phase
Vertigo	Rotation or spinning sensation, no loss of consciousness
Hyperventilation	Inciting event, paresthesias or carpopedal spasm, tachypnea
Hysteria	No loss of consciousness, indifference to event
Hypoglycemia	Confusion progressing to loss of consciousness, requires glucose administration to terminate.
Breath-holding spell	Crying prior to event, child 6–18 months old

Adapted from Braden and Gaynora,[17] with permission.

TABLE 127-3   Events Easily Mistaken for Syncope

Sudden cardiac death is usually an unexpected, unwitnessed, terminal event. In patients who have a witnessed arrest and resuscitation is rapidly started, the likelihood of survival is much greater, approaching 25 percent. [8] Witnesses may be able to describe prodromal symptoms to aid in determining the cause of the event.[13]

DIAGNOSIS

No clinical or historical features reliably distinguish between vasovagal syncope and other causes. [4] However, certain historical features and a careful history and physical exam should increase an emergency physician's suspicion of a potentially serious cause (Table 127-2). Particular attention should be directed to the cardiovascular exam, including palpation of the cardiac impulse, auscultation of the heart, and evaluation of the peripheral pulses. Orthostatic measurements will identify volume depletion or autonomic dysfunction. An electrocardiogram (ECG) should be obtained for nearly all children but will usually be normal. [4] Other laboratory studies are directed by the nature of the history and physical exam.

Many of the diseases that cause syncope also cause sudden death in children. A syncopal event can be the presenting symptom of these more serious illnesses. Up to 25 percent of children who suffer a sudden death have a history of at least one prior syncopal event. [6] Because syncope is a very common event, however, a syncopal event by itself is not associated with an increased risk of sudden death unless certain features are present. [5] The two most common causes of sudden cardiac death among children who do not have known cardiac disease are hypertrophic cardiomyopathy and myocarditis. [6] Primary rhythm disturbances undoubtedly are underrepresented due to the inherent difficulty in identifying these causes after death.

Among athletes who have died suddenly, however, only 10 percent had previously experienced at least one episode of syncope. [13] Even with a standard sports screening evaluation, fewer than 5 percent of athletes who subsequently die are suspected of having cardiac disease. [13] The two most common cardiac lesions associated with sudden death among athletes are hypertrophic cardiomyopathy and aberrant coronary arteries. [15] Other coronary artery abnormalities, Marfan syndrome (ruptured aortic aneurysm), valvular heart disease, myocarditis, and dilated cardiomyopathy are less common.

History

The most crucial step in evaluating a child with a syncopal or near death event is a careful medical history. Interview any family members, friends, or witnesses who were with the child just prior to the event. The events leading up to the incident should be described in detail, as should any apparent change in the child's behavior or symptoms. Pay particular attention to details such as the intake of medications, drugs, fluids, and food. Note the position the child was in when syncope occurred, because recumbent positioning is less consistent with NMS or other forms of vascular syncope. A history of syncope during exertion or exercise increases the likelihood of the more serious etiologies. The prodromal symptoms will often aide in identifying the cause of the event. The sequence and timing of motor movements, level of consciousness, and postural positioning will help to differentiate primary seizures from NMS or other true causes of syncope. A history of previous syncopal events should be sought. Any known medical problems should be considered, especially known cardiac diseases, diabetes, seizures, medication or drug use, or psychiatric or psychological problems. Ask about a family history of structural cardiac disease, dysrhythmias, sudden death, migraines, or seizures. Statements by the witnesses that the patient appeared dead and required cardiopulmonary resuscitation (CPR) must be evaluated carefully. The duration of pulselessness and the degree of intervention required should be carefully recounted by the witnesses. Anytime that CPR has been performed, even if by an inexperienced layperson, the event should be considered a resuscitated sudden death and evaluated comprehensively.

Physical Examination

Complete cardiovascular, neurologic, and pulmonary examinations are crucial, but the findings are normal in the vast majority of children with syncope, regardless of the seriousness of the etiology. The cardiovascular examination includes assessment of blood pressure, resting heart rate, oxygen saturation, and respiratory rate. Blood pressure and heart rate should also be measured during positional changes (orthostatic vital signs). Auscultation should be performed to identify any murmurs, abnormalities in rhythm, and variations or abnormalities in heart sounds. Any abnormalities in the cardiovascular assessment require an in-depth cardiac evaluation. [14]

Laboratory Assessment

An ECG is recommended for every patient, as it is a relatively inexpensive test that can identify some very serious causes of syncope. [15] Abnormalities found on the ECG may not correlate with the syncopal event, however, and some patients with an arrhythmic cause of syncope will have normal ECGs. [4] Other laboratory tests should be guided by clinical suspicion (for example, a hemoglobin measurement for a patient with possible anemia or a glucose measurement for a patient with

diabetes). Routine laboratory studies are not needed in a child with a clear episode of vasovagal syncope. However, patients with an atypical presentation or worrisome associated symptoms should have a serum chemistry panel, hematocrit, thyroid function tests, chest radiograph, and ECG in the emergency department. Hyperthyroidism predisposes patients to supraventricular tachycardias (SVTs), so thyroid function tests must be obtained with any child where an SVT is considered. In adolescents, a serum alcohol level and urine drug screen should be considered due to the possibility of illicit drug use (most commonly cocaine and amphetamines).

An echocardiogram should be obtained for patients with known or suspected cardiac disease. A patient with abnormal heart sounds, cardiac murmurs, evidence of cardiac chamber enlargement or repolarization abnormalities on ECG, or other features that suggest myocardial dysfunction requires a prompt echocardiogram. If an echocardiogram cannot be obtained in the emergency department, then an inpatient evaluation must be performed.

The clinical utility of other tests, such as stress tests, tilt-table tests, electrophysiologic studies, and cardiac catheterization, are usually directed by the pediatric cardiologist and are beyond the scope of this chapter.

Patients resuscitated from sudden death must have a complete evaluation unless a clear cause for the arrest is apparent. The diagnostic possibilities are extensive, so laboratory and radiographic studies should be directed by clinical and historical information. All such patients should have a serum chemistry panel, CPK-MB, complete blood count, serum alcohol level evaluation, urine drug screen, thyroid function tests, chest radiograph, and ECG in the emergency department. Look for complications resulting from the arrest, such as hypothermia, acidosis, rhabdomyolysis, and cerebral edema or hypoxia. The inpatient evaluation can include an echocardiogram, cardiac catheterization, stress test, and electrophysiologic testing.

SPECIFIC CONDITIONS

Neurally Mediated Syncope

This category encompasses the terms vasovagal syncope, vasodepressor syncope, neurocardiogenic syncope, reflex syncope, and simple faint. NMS is the most common cause of syncope in children[3] and usually is preceded by a sensation of warmth, nausea, light-headedness, and a visual grayout or tunneling of vision. [15] This type of syncope frequently lasts less than 1 min. [4] Common precipitating factors include prolonged recumbence just prior to standing or prolonged standing, sight of blood or disfiguring injury (for example, fractures or soft tissue injuries), emotional upset, mild physical trauma or pain, physical exertion, and hot or crowded conditions. Other contributing factors that are less common include hypovolemia, anemia, dehydration, and pregnancy. NMS can also occur with swallowing, urination, defecation, and coughing; breath-holding spells are a variant of this form of syncope. Medications that alter vascular tone or heart rate may contribute to the development of syncope, including b blockers, calcium-channel blockers, and diuretics. Surreptitious use of diuretics is common among athletes, such as wrestlers, who must maintain weight restrictions.

Identifying NMS as the cause of syncope can be difficult in an emergency department. Because NMS is physiologically based on inadequate compensatory mechanisms to maintain blood pressure and cardiac output in a wide range of clinical states, the distinction between syncope from NMS and other causes of orthostatic syncope is often blurred. However, NMS and other orthostatic causes of syncope are generally considered to be benign illnesses.

Three clinical patterns of NMS occur: vasodepressor syncope, cardioinhibitory syncope, and mixed syncope. Any disorder that causes vasodilatation, vagal stimulation, or both can result in syncope.

ORTHOSTATIC SYNCOPE   Patients will typically complain of light-headedness and weakness after standing for a period of time ranging from seconds to minutes. Factors that predispose children to orthostatic syncope include anemia, dehydration, and medications, especially calcium-channel blockers and angiotensin-converting enzyme inhibitors. [3] A drop of greater than 20 mmHg in blood pressure with an increase in heart rate of more than 20 beats per minute while checking vital signs with the child in the supine to standing position is often considered diagnostic of orthostatic hypotension.

SITUATIONAL SYNCOPE   Urination, defecation, coughing, and swallowing have all been described as causing syncope. The pathophysiology is thought to be related to an exaggerated Valsalva response causing cardioinhibitory syncope. Stretching, neck extension, external neck pressure, and hair grooming have also been described as causing syncope, presumably due to carotid sinus hypersensitivity or abnormal Valsalva responses. [14]

FAMILIAL DYSAUTONOMIA   Abnormalities in heart rate and blood pressure control can be inherited as a primary disorder, such as the Riley-Day syndrome. This disorder results from abnormal development of the sensory and autonomic ganglia, perhaps due to a lack of nerve growth factor during embryogenesis. Manifestations include failure to thrive, developmental delay, temperature instability, abnormal sweating, absent lacrimation, breath-holding spells, and seizures. [14]

Cardiac Dysrhythmias

Outpatient continuous portable ECG monitoring (Holter monitoring) only identifies the cause of syncope in 3 percent of pediatric patients. [4] A cardiac dysrhythmia should be suspected if the syncope is associated with an intense sympathetic stimulus such as fright, anger, surprise, or physical exertion. [16] The event will usually start and end abruptly, contrary to nonarrhythmogenic causes such as hypoglycemia or seizures, which are more gradual. Associated symptoms may include palpitations or irregularities of heartbeat.

LONG QT SYNDROME   This disorder may be inherited or acquired and is characterized by a prolonged QT interval on the surface ECG. Although the incidence of inherited LQTS is rare (1:5000 births), it is associated with hypertrophic cardiomyopathy and thus accounts for up to half of the cases of sudden cardiac death. [17] Classically, a patient with LQTS should have a corrected QT interval that is longer than 0.44 s on the surface ECG. [16] Other abnormalities on the ECG associated with LQTS include torsade de pointes, T-wave alternans, notched T waves in three leads, and prominent U waves. [14] Patients with a LQTS may have a normal ECG in the emergency department.[4] These patients may be diagnosed by a history of LQTS in a family member (familial LQTS), stress testing (exertional LQTS), or Holter monitoring (intermittent LQTS). The history should also include any recent use of medications that can prolong the QT interval (Table 127-4). The 10-year mortality can be reduced from 70 to 4 percent by appropriate treatment.[17] Genetic studies to date have identified four genetic loci associated with LQTS, all of which encode proteins involved in sodium and potassium transport. Two clinical syndromes not associated with structural heart disease are also recognized: Romano-Ward syndrome is an autosomal dominant condition not associated with deafness, whereas Jervell-Lange-Nielsen syndrome is an autosomal recessive disease associated with deafness.

TABLE 127-4   Medications That Prolong the QT Interval

WOLFF-PARKINSON-WHITE SYNDROME   WPW is characterized by antegrade conduction through an accessory pathway causing a reentrant SVT. Symptoms are manifested when conduction down the accessory pathway occurs at very rapid rates leading to a reentrant SVT. An ECG may show the characteristic delta wave, but it can also be normal. Although WPW occurs in only 0.1 percent of the population, it is more common in patients with Ebstein malformation, corrected transposition of

the great arteries (levo-TGA), and hypertrophic cardiomyopathy. [14] The risk of sudden death and syncope are highest in patients who have atrial dysrhythmias such as atrial fibrillation and atrial flutter. Patients at greatest risk for death are those who conduct antegrade over the accessory pathway, allowing 1:1 conduction of an atrial dysrhythmia. Atrial fibrillation and atrial flutter are rare prior to adolescence.

ATRIOVENTRICULAR BLOCK   This condition is most common in children with congenital heart disease but also occurs as a rare congenital disorder. Atrioventricular (AV) block is most common after heart surgery but also occurs with acquired heart disease, such as hypertrophic cardiomyopathy and myocarditis, and muscular dystrophy. [14] Carditis associated with Lyme disease has an 87 percent incidence of AV block. [18] Congenital AV block was first described by Morquio in 1901, and although the risk of death is highest in infants, asymptomatic children may also die in adolescence. [19] Congenital AV block is also associated with mothers who have connective tissue disease. [14] Syncope from a high-degree AV block not related to positional changes or exertion is called a Stokes-Adams attack. Prophylactic pacemaker insertion is routinely performed in children with either acquired or congenital AV block.

SICK SINUS SYNDROME   Sick sinus syndrome is also known as tachycardia-bradycardia syndrome. Isolated sinus node dysfunction rarely causes syncope; a syncopal event is more likely to be due to a reentrant atrial tachycardia. [14] Most commonly, these dysrhythmias are associated with prior heart surgery, especially the Mustard or Senning operation for transposition of the great vessels and the Fontan operation. [14,20] Syncope and sudden death can occur following pacemaker placement, since the pacemaker will prevent bradycardia but not tachycardia.

SUPRAVENTRICULAR TACHYCARDIA   Any cause of SVT can lead to syncope while recumbent if the heart rate is high enough to inhibit cardiac filling or if coincident vasomotor abnormalities occur. [21] WPW and atrial fibrillation are the most common causes, but primary SVT can also occur. Episodes of SVT are associated with congenital heart disease, including Ebstein anomaly and l-TGA.

PACEMAKER MALFUNCTION   Although pacemakers are not common in childhood, any child with a pacemaker who has syncope or presyncope should be presumed to have a pacemaker malfunction. Syncope can be caused in several ways: lack of pacemaker output (low battery, broken lead, or malfunction), noncapture of myocardium (exit block or lead fracture), retrograde AV conduction (reflex vasodilatation from enhanced jugular venous pulsations with a ventricular pacemaker), and pacemaker-mediated tachycardia (sensed atrial tachycardia or retrograde P waves with atrial sensing pacemaker).

Structural Cardiac Disease

HYPERTROPHIC CARDIOMYOPATHY   Also known as idiopathic hypertrophic subaortic stenosis, this disease is both a dynamic and a fixed subvalvular obstruction. Exertional syncope is a common presentation, but infants may present with congestive heart failure and cyanosis. Any child with exertional related syncope must have this diagnosis considered. Onset of symptoms in early childhood is associated with a greater risk of mortality; the 10-year mortality is 50 percent for children diagnosed by 14 years of age. [22] Syncopal events appear to be related to myocardial ischemia and/or ventricular tachycardia, probably as a LQTS. An echocardiogram is necessary to exclude or confirm this diagnosis and should be done in the emergency department or on the inpatient ward. Most authors recommend implantable cardiac defibrillators in children with hypertrophic cardiomyopathy.

DILATED CARDIOMYOPATHY   This disorder is unusual in children but can occur by three general mechanisms: idiopathic, with congenital heart disease, or after myocarditis. Syncope and death are thought to be caused by ventricular dysrhythmias or severe myocardial dysfunction.

ARRHYTHMOGENIC RIGHT VENTRICULAR DYSPLASIA   This disorder is rare in the United States but is a common cause of adolescent death in Italy. Presentation is more common in older adolescents or adults. [14] Patients usually present with congestive heart failure, cardiomegaly, and syncope or sudden death from an dysrhythmia. ECG abnormalities include left bundle branch block and T-wave inversion, but some patients may have a normal ECG. [14]

CONGENITAL CYANOTIC AND NONCYANOTIC HEART DISEASE   Hypercyanotic spells may progress to syncope in tetralogy of Fallot, tricuspid atresia, TGA, and Eisenmenger syndrome. Children with structural heart disease are also prone to ventricular dysrhythmias and AV block.

VALVULAR DISEASES   Several valvular lesions are associated with syncope and sudden death. In general, the degree of valve dysfunction correlates with the risk of sudden death. *Aortic stenosis* is usually due to a congenital defect, often associated with a bicuspid valve, although unicommissural or severely dysplastic valves also occur. Other associated cardiac anomalies, particularly coarctation of the aorta, also occur. [23] Most patients are identified by the presence of a murmur. Exertional syncope is due to reduced cerebral blood flow and is commonly associated with chest pain, dyspnea on exertion, and poor exercise tolerance. [23] Mitral valve prolapse (MVP) is probably not by itself associated with an increased risk of sudden death. [24] A child with MVP and syncope requires a more intensive diagnostic workup. Adults with MVP and significant mitral regurgitation have more frequent dysrhythmias, but this has not been shown in children. Ebstein malformation of the tricuspid valve is an uncommon disorder. Sudden death is thought to be due to the development of supraventricular or ventricular dysrhythmias. [25]

PULMONARY HYPERTENSION   Primary pulmonary hypertension (without structural heart disease) is uncommon but can present in adolescence. It is often associated with dyspnea on exertion, shortness of breath, exercise intolerance, and syncope. Eisenmenger syndrome is acquired pulmonary hypertension due to a cardiac shunt. High blood flow to the pulmonary circulation from a left-to-right shunt leads to a reactive increase in pulmonary resistance. After months to years, the development of pulmonary hypertension causes the shunt to reverse to a right-to-left shunt and cyanosis becomes apparent. One-half of patients with pulmonary hypertension develop syncope. [14] Physical findings include an increased ventricular impulse, a loud second heart sound, and cyanosis, which is particularly prominent in patients with Eisenmenger syndrome. Syncope and sudden death in these patients are usually related to an dysrhythmia.

CORONARY ARTERY ABNORMALITIES   Many of these patients present with sudden death often during exercise or with a prior history of exercise-induced syncope. [26] Abnormalities of coronary artery origin include the left main artery arising from the right sinus of Valsalva or, less frequently, the right artery arising from the left sinus. In both cases, the aberrant artery often passes between the aorta and pulmonary artery, thus placing it at risk for extrinsic compression, especially during physical exertion. Other abnormalities include myocardial overbridging, coronary artery fistulae, coronary artery spasm, and coronary artery aneurysms and stenosis from Kawasaki disease.

Noncardiovascular Causes

SEIZURES   Although not truly syncope, a seizure may appear to be a syncopal event even to the medical professional. Seizures often have little or no prodrome and are associated with a loss of consciousness. Seizures usually have a prolonged recovery phase (postictal phase), which most syncopal events lack. Other findings commonly associated with a seizure include onset while supine, convulsions immediately with loss of consciousness, and a warm, flushed, or cyanotic skin color. [14] Many patients who are diagnosed with a syncopal event in the emergency department are later found to have a seizure disorder. [3] Adding to the confusion, up to 71 percent of syncopal events may have associated behavior that could be called a seizure. [27]

BREATH HOLDING   Breath-holding spells are thought to be related to NMS. Typically, the children are 6 to 18 months old and have an intense emotional trigger that causes crying and then a breath hold during expiration. [28] The children then become cyanotic or pale and lose consciousness from the progressive cerebral hypoperfusion. Myoclonic activity or seizures may occur. The episode is usually short, requires no specific intervention, and rapidly resolves with gasping respirations and progressive loss of cyanosis or pallor. Up to 20 percent of children with breath-holding spells develop NMS in later life. [28]

ATYPICAL MIGRAINE   Basilar artery migraines may be associated with syncope due to poor cerebral circulation during vasospasm. Most patients with this disorder will also have headache, a family history of migraines, symptoms referable to the posterior cerebral circulation (visual changes, dysarthria, tinnitus, vertigo, or ataxia), and a normal heart rate and blood pressure during the event. [29,30]

HYPERVENTILATION   Severe hypocapnia can cause syncope by intense cerebral vasospasm that leads to cerebral hypoperfusion. Typically, there is also a history of dyspnea, chest tightness, light-headedness, tunnel vision, carpopedal spasm, or paresthesias.

HYSTERIA   Hysterical syncope is an event that occurs without neurologic or cardiovascular changes but otherwise has the visual appearance of syncope. Often these events occur in front of an audience, are independent of posture, and rarely result in injury. The patient may even describe the event, often in an indifferent or unconcerned manner, clearly indicating that consciousness was not lost.

HYPOGLYCEMIA   Syncope due to hypoglycemia is more commonly of a gradual onset and is associated with diaphoresis, tachycardia, hunger, and generalized weakness. Unconsciousness resolves with glucose administration but does not usually resolve with the supine position. A history of disorders of glucose production (enzyme or storage deficiencies) or glucose utilization (diabetes) is usually present.

TREATMENT

Syncope

Most children with syncope will be fully recovered by the time they arrive at the emergency department. [3,4] Continued altered level of consciousness should prompt an evaluation for causes other than syncope. Treatment should be tailored to current symptoms. Signs of compromised oxygenation, ventilation, or circulation should be addressed immediately. A cardiac monitor should be applied to the patient while gathering the history and physical findings to document any transient dysrhythmias. Vascular access and blood for laboratory studies should be obtained for all children except those in which a simple vasovagal event explains the symptoms.

Treatment is targeted to specific identified etiologies for the syncopal event. Ongoing cardiac dysrhythmias or seizures should be managed as appropriate. Most patients, however, will have no treatable dysrhythmias in the emergency department.

Sudden Death

A child who survives an out-of-hospital cardiac arrest must be rapidly stabilized, and any identified conditions must be quickly treated. In general the principles of pediatric advanced life support are followed (see Chap. 10, "Pediatric Cardiopulmonary Resuscitation"). Unstable ventricular or supraventricular rhythms should be immediately cardioverted with direct-current countershocks in either a synchronized or unsynchronized fashion. Wide QRS-complex tachydysrhythmias should not be treated with class 1A agents such as procainamide and quinidine if LQTS is suspected, because these medications act by also prolonging the QT interval. Class IB drugs such as phenytoin or intravenous amiodarone should be used instead.

Treatment in the emergency department is directed at identifying the probable cause for the arrest so that future events can be prevented. The possible etiologies are extensive, so laboratory and radiographic studies are directed by clinical and historical information. All patients should have a serum chemistry panel, complete blood count, serum alcohol level, urine drug screen, thyroid function tests, chest radiograph, and ECG in the emergency department. The inpatient evaluation can include an echocardiogram, cardiac catheterization, stress test, and electrophysiologic testing.

DISPOSITION

Syncope

A child who had a syncopal event can present a challenging disposition decision. When the cause of syncope is not readily apparent from the emergency department evaluation, multiple additional tests are frequently performed but rarely provide further diagnostic information. [31] Unfortunately, few studies have examined the most effective evaluation in the emergency department and the hospital.

Obviously, any child with a dysrhythmia documented by prehospital providers or on the ECG in the emergency department must be admitted. Children who have any of the risk factors in Table 127-2 should also be admitted in consultation with a pediatric cardiologist. Patients with a normal ECG but a history suspicious for an dysrhythmia are candidates for outpatient ambulatory cardiac monitoring. [14] Identified causes of syncope should be treated as appropriate in the emergency department and admission to the hospital should be directed by the need for further evaluation or therapy. All children admitted for a syncope evaluation should be placed on a cardiorespiratory monitor in the hospital.

If, after an appropriately thorough history, physical, and laboratory evaluation, a clear precipitating cause for the syncope cannot be identified in the emergency department, the child may be discharged to home with close follow-up by the child's primary physician or a cardiologist. Because NMS accounts for up to 50 percent of the cases of syncope in children, most pediatric patients without cardiac risk factors or exercise-induced symptoms may be safely evaluated as outpatients. [14,31,32] Many of these children will have addition tests as outpatients, including portable rhythm monitoring, tilt-table testing, and stress testing, although the cost effectiveness of this approach remains in doubt. [31]

Sudden Death

After stabilization, children who have suffered a sudden cardiac arrest should be transferred to a pediatric intensive care unit that is capable of managing cardiac disorders. These children must be transferred with a crew capable of treating cardiac arrest from any dysrhythmia. In general, this should be done with a dedicated pediatric critical care transport team and consultation with the receiving pediatric intensivist.

128 FLUID AND ELECTROLYTE THERAPY

William Ahrens

INTRODUCTION

Fluid and electrolyte abnormalities are among the most common problems confronting physicians who care for children. This is primarily due to the high incidence of gastroenteritis in the pediatric population, and the vulnerability of children to the loss of water and solutes. In poor countries, diarrheal diseases are common causes of infant death. In the United States, they often result in prolonged emergency department stays and hospitalization. Electrolyte abnormalities are most commonly secondary to fluid imbalances.

FLUID REQUIREMENTS

The key to managing fluids in infants and children is the realization that there are vast differences in the maintenance requirement of water in first 2 years versus the rest of life. There is a direct correlation between caloric requirements and the need for free water, and rapidly growing infants require an enormous amount of calories relative to their body weight. They therefore require a correspondingly enormous amount of water. The daily turnover of free water in infants is up to 3 to 4 times that of adults. This includes increased insensible losses from the skin and respiratory tract, which are usually electrolyte free. Urine accounts for approximately 50 percent of daily fluid requirements and is the predominant cause of sensible losses; because infants have a decreased ability to concentrate urine, they must lose a relatively large amount of free water to excrete waste products. In addition, a relatively large percentage of young infants' total body water is contained in the extravascular space in comparison with older children and adults. This puts them at greater risk for cardiovascular compromise when confronted with sudden fluid losses.

Caloric expenditure and therefore fluid requirements can be estimated from body surface area, which is huge in infants when compared with adults. However, weight is a sufficiently accurate and more easily obtained method of calculating fluid requirements. The fundamental formula is

For the first 10 kg: 100 mL/kg/24 h
For the second 10 kg: 50 mL/kg/24 h
For more than 20 kg: 20 mL/kg/24 h

For example,

1. A 10-kg baby requires 100 mL × 10 kg, or a total of 1000 mL/24 h.
2. A 20-kg baby requires 100 mL × 10 kg = 1000 mL + (50 mL × 10 kg) = 500 mL, for a total of 1500 mL/24 h.
3. A 40-kg baby requires 100 mL × 10 kg = 1000 mL + (50 mL × 10 kg) = 500 mL + (20 mL × 20 kg) = 400 mL, for a total of 1900 mL/24 h.

Note that despite a fourfold increase in body weight, the water requirement does not even double; this reflects the relatively small increase in body surface area that accompanies the increase in mass in growing babies. Hypermetabolic states increase the requirement for free water. The most common of these are fever (which increases the free water requirement by approximately 12 percent per degree of elevation in temperature centigrade) and increased sweating.

Electrolyte requirements remain constant throughout childhood and can be estimated by body weight. All infant formulas contain sufficient electrolytes to satisfy these, as do Ricelyte and Pedialyte. The requirement for sodium is 2 to 3 meq/kg/24 h and for potassium is 2 meq/kg/24 h (Table 128-1).[1]

Body weight	1-10 kg	10 to 20 kg	>20 kg
Total water volume	100 mL/kg	1000 mL + 50 mL/kg for each kg > 10 kg	1500 mL + 20 mL/kg for each kg > 20 kg
Sodium	3 meq/kg	3 meq/kg	3 meq/kg
Potassium	2 meq/kg	2 meq/kg	2 meq/kg
Chloride	5 meq/kg	5 meq/kg	5 meq/kg

TABLE 128-1   Maintenance Requirements for Fluid and Electrolytes, Based on Body Weight

ISOTONIC DEHYDRATION

Isotonic dehydration occurs when there is a proportionately equal loss of sodium and water; the serum sodium thus remains within normal range of 130 to 145 meq/L. It most often results from diarrheal illness and is the most common fluid and electrolyte problem encountered in pediatrics. Fluid is initially lost from the extracellular space. Intracellular fluid then shifts into the vascular tree, which protects circulating blood volume at the expense of intracellular dehydration.

The clinical manifestations of isotonic dehydration depend on the absolute volume deficit, the rate at which fluid is lost, and the age of the patient. When fluid is lost over a relatively long period, a large deficit may be well tolerated and clinical manifestations can be rather subtle, even though up to 40 percent of intracellular fluid may be lost. This most commonly occurs in patients with protracted diarrheal illnesses. In contrast, sudden massive loss of fluid such as occurs in cholera-associated or rotavirus diarrhea can be fatal if not treated aggressively, because most of the volume is lost from the extracellular space and there is insufficient time for intracellular fluid to shift into the vascular tree. This is especially true in young infants, because a relatively large percentage of their total body water is contained in

the extracellular space. Rapid fluid loss can result in cardiovascular collapse, whereas older children will remain well compensated.

EVALUATION

The most accurate way to estimate the degree of dehydration is calculating weight loss, which in acute situations amounts to free water deficit. However, this information is rarely available. In practice, estimating the degree of dehydration depends on integrating multiple factors. Patients usually have a history of vomiting and diarrhea. It is useful to quantitate the approximate number of stools and to determine whether the patient is able to tolerate any oral feedings without vomiting. Parents are asked what liquids the child has been given, since excess free water can cause hyponatremia, and "homemade" remedies may contain excess sodium. A history of decreased urine output implies significant fluid loss.

Physical examination has been demonstrated to provide a reliable estimation of the degree of dehydration [2] (Table 128-2). Hypotension indicates hypovolemic shock. The patient's mental status is important: normal mental status usually implies mild dehydration, whereas irritability signifies at least moderate fluid loss. Lethargy implies severe volume loss and/or an electrolyte abnormality, especially hypernatremia. Decreased skin turgor and sunken eyes and fontanelle imply moderate to severe fluid loss and usually occur when intracellular fluid has had time to diffuse into the intravascular space. In these patients, vital signs may be only slightly abnormal and not indicative of the degree of dehydration.

TABLE 128-2   Estimation of Dehydration

It is important to realize that assessing the degree of dehydration in very young infants is notoriously difficult, and fluid losses are often underestimated.

LABORATORY FINDINGS

In isotonic dehydration, the sodium level is within normal range. The potassium level is usually normal or slightly decreased. The serum bicarbonate level is often decreased: in mild dehydration it is usually in the range of 15 to 20 meq/L, whereas in more severe cases it falls below 10 meq/L. A low serum bicarbonate level reflects stool losses, the presence of ketones from "starvation," and in severe dehydration lactic acidosis. The blood urea nitrogen level usually rises with increasingly severe fluid losses. Urine specific gravity also rises in significant dehydration and may reach 1.030. In young infants, a decreased ability to concentrate urine may result in a falsely low specific gravity. It is not necessary to check the electrolyte level of patients who are mildly dehydrated. [3]

MANAGEMENT

The management of dehydrated children depends on the degree of fluid loss, as well as a patient's ability to tolerate oral liquids. Mildly dehydrated patients (<5 percent) who tolerate Pedialyte can usually be discharged home on clear liquids, with close follow-up. Moderately dehydrated patients generally require intravenous therapy, although oral rehydration (discussed below) is an option.

Severely dehydrated patients require aggressive resuscitation. Boluses of 20 mL/kg of 0.9 normal saline (NS) are given until improved mental status, vital signs, and peripheral perfusion indicate stable intravascular volume. [4] In extreme situations, an intraosseous line may be necessary. Fluid replacement then consists of replacing 50 percent of the estimated volume deficit in the first 8 h, and the remainder of the deficit in the next 16 h. If diarrhea continues, the ongoing losses must also be replaced. Maintenance fluids are added to the deficit replacement. [5]

For example, a 12-kg infant is estimated to be 10 percent dehydrated. After a 20 mL/kg bolus of 0.9 NS, she is alert and perfusion is adequate. Fluid orders can then consist of

1. Maintenance is 100 mL/kg × 10 kg/24 h = 1000 mL + (50 mL/kg × 2 kg/24 h) = 100 mL, for a total of 1100 mL/24 h or 46 mL/h.
2. Deficit = 10 percent of body weight (1.2 kg) = 1200 mL; replace 600 mL over the first 8 h or 75 mL/h; replace 600 mL over the next 16 h or 38 mL/h.

Thus, for the first 8 h, maintenance + deficit = 121 mL/h; for the next 16 h, maintenance + deficit = 84 mL/h.

Appropriate rehydrating solutions in infants are 5% D/0.2NS or 5% D/0.45NS. In infants, 5% D in 0.2NS is isotonic for maintainance rehydration in isotonic dehydration. In children, 5% D/0.45NS can be used for maintainance rehydration in isotonic dehydration. Glucose is added to the solution to minimize further catabolism. Remember that 0.9NS is used for bolus rehydration. After the patient has urinated, potassium can be added at a maximum concentration of 40 meq/L. Most patients will begin to tolerate oral feeding with clear liquids within 24 h. All severely dehydrated patients are admitted to the hospital.

Patients who are moderately dehydrated can be managed in a number of ways. Oral rehydration is an effective modality, but is labor intensive and time-consuming. Some patients can be aggressively rehydrated with normal saline over a period of 2 to 4 h in the emergency department and safely discharged. [4,6] The success of rapid rehydration may be correlated with an initial serum bicarbonate level of greater than 13 meq/L, but further study is needed to clarify this. Extreme caution should be exercised in using rapid rehydration in neonates and young infants, since the underlying gastroenteritis is likely to continue and these patients are at relatively great risk of cardiovascular compromise. If they are discharged, follow-up must be expedient and absolutely certain. Patients with persistent profuse diarrhea and those with intractable vomiting are candidates for admission. Fluid management is then the same as for severely dehydrated patients, with 50 percent of the deficit replaced in the first 8 h and the remaining 50 percent replaced over the next 16 h.

HYPERNATREMIC DEHYDRATION

Hypernatremic dehydration occurs when there is a relatively greater loss of free water than sodium. It often occurs when patients with gastroenteritis are treated with salt-rich solutions. The predominant clinical problems related to hypernatremic dehydration result from the increase in serum osmolarity. As sodium rises and osmolarity increases, fluid is drawn from the interstitial and intracellular spaces into the vascular tree. This protects circulating blood volume and peripheral perfusion and can result in deceptively normal vital signs, despite severe dehydration. Loss of intracellular fluid causes doughy, tenting skin. Faced with osmotic disequilibrium, brain cells create charged molecules (*idiogenic osmols*) in an effort to preserve intracellular volume and electrical neutrality. Despite this, mental status changes are common, including irritability, lethargy, and seizures.

The most essential aspect of managing hypernatremic dehydration involves replacing lost free water in such a way that the serum sodium falls no more than 10 to 15 meq/L/24 h. A more rapid decrease in serum osmolarity can result in the influx of water into brain cells, resulting in cerebral edema. In patients in whom perfusion is inadequate, a 10- to 20-mL/kg bolus of 0.9 NS is administered. There is no universal agreement on the optimal subsequent hydrating solution to be used, but 5% D/0.45 NS will be adequate in the majority of cases and is probably less risky than the more hypotonic 5% D/0.2 NS. It is most important that rehydration be spread out over 48 to 72 h, rather than the 24 h used for isotonic dehydration. In cases of severe hypernatremia (Na $^+$ > 165 meq/L), it is reasonable to consult a pediatric

intensivist or nephrologist after the patient is stabilized. Even with optimal management, patients with severe hypernatremia are at risk for neurologic sequelae.

DIABETES INSIPIDIS

Diabetes insipidis, which is most commonly caused by a deficiency of the antidiuretic hormone (ADH) arginine vasopressin, usually occurs secondary to damage to the neurohypophyseal unit and commonly occurs after severe head trauma, central nervous system infections, and suprasellar tumors, especially craniopharygiomas. An extremely rare form of diabetes insipidis is characterized by a failure to respond to vasopressin and is referred to as *nephrogenic.*

Clinically, the syndrome is characterized by polyuria, which can be massive. Most patients also manifest polydipsia. The excessive loss of free water can result in hypernatremia. The patient's urine is usually extremely dilute, with a specific gravity of less than 1.005 and an osmolality of 50 to 200 mosm/L. Diagnosis can be made by water deprivation testing or by serum assay of vasopressin.

Diabetes insipidis is treated with desmopressin (DDAVP), an analogue of vasopressin. The dose is individualized, and consultation with a pediatric endocrinologist is advisable.

HYPONATREMIC DEHYDRATION

Hyponatremia is defined as a serum sodium level of less than 130 meq/L. There are many causes of hyponatremia, which are usually categorized on the basis of whether total body water is increased, decreased, or normal. Hyponatremic dehydration most commonly occurs when a parent replaces acute fluid losses from vomiting and diarrhea with free water. Much less common causes of hyponatremic dehydration include adrenal insufficiency states, third-space losses from ascites or pancreatitis, and diuretic use.

In severe cases of hyponatremic dehydration, shock can result. However, the most common clinical manifestations of symptomatic hyponatremia involve the central nervous system. Although a gradual reduction in serum sodium is usually well tolerated, a sudden decrease can result in irritability, lethargy, and seizures. Seizures are most common with a serum sodium level of less than 120 meq/L, but are more dependent on the rate of fall than the absolute value of serum sodium.

The management of hyponatremic dehydration associated with cardiovascular instability consists of the infusion of normal saline in 20 mL/kg boluses until the patient is stable. Many patients with gastroenteritis who suffer hyponatremic-induced convulsions will stop seizing following the administration of a bolus of normal saline alone. Subsequent management is aimed at restoring both the volume and sodium deficits. The standard formula used in correcting serum sodium is

$$(\text{Na desired} - \text{Na measured}) \times 0.6 \times \text{kg body wt}$$

in which 0.6 reflects the fractional distribution of sodium. To prevent overcorrection, the desired sodium is usually 125 meq/L, which corrects osmolarity sufficiently to prevent further seizures. In stable patients, the correction is carried out over several hours, as there is no physiologic advantage to raising the serum sodium rapidly. In patients with profound hyponatremia or persistent seizures, it may be necessary to infuse 3% NS at a dose up to 12 meq/kg; in clinical practice, this is rarely necessary. In patients with profound hyponatremia, rapid correction of serum sodium has resulted in central pontine demyelinolysis.

HYPONATREMIA WITH INCREASED TOTAL BODY WATER

Causes of hyponatremia associated with increased total body water are acute water intoxication, the syndrome of inappropriate antidiuretic hormone (SIADH), edema-forming states including nephrotic syndrome, and cirrhosis.

Acute water intoxication can result in a profound rapid decrease in serum sodium. It is often psychogenic, but can occur in young infants who are accidentally given large amounts of free water. If seizures occur, treatment with 3% saline may be necessary. In most cases, fluid restriction suffices to lower serum sodium.

SIADH occurs in a variety of disease states, including central nervous system infections, and following head trauma. ADH stimulates the resorption of free water, resulting in hyponatremia. The most important laboratory finding in SIADH is a urine osmolarity greater than serum osmolarity. Hypouricemia is also usually present. The fundamental treatment is fluid restriction.

In nephrosis and cirrhosis, hyponatremia is usually mild and chronic. Even though whole body water is increased, intravascular volume may be low due to third spacing. Treatment usually consists of diuresis, with a combination of albumin followed by a diuretic. These patients are best managed in consultation with a pediatric nephrologist.

ORAL REHYDRATION

It has been repeatedly demonstrated that oral rehydration is as effective as intravenous therapy in treating infants with mild to moderate dehydration. [7,8,9 and 10] It has had an enormous impact in developing countries, where prepackaged electrolyte solutions are available in lieu of infinitely more expensive intravenous solutions. Although time constraints may limit oral therapy in emergency departments in the United States, emergency physicians who do work in international medicine must be familiar with its use.

Water and electrolyte solutions created for treating dehydrated patients differ from maintenance solutes primarily in the composition of electrolytes. Rehydration solutions contain 60 to 90 meq/L sodium and 2% to 2.5% glucose, compared with maintenance solutions, which contain approximately 45 to 50 meq/L sodium (Table 128-3). The higher sodium content is thought to facilitate the absorption of water in the small intestine. Some controversy exists regarding the propensity of the World Health Organization's rehydrating formula, containing 90 meq/L sodium, to cause hypernatremia. In dehydrated patients, this appears to be rare, but reformulated oral rehydrating solutions containing 50 to 60 meq/L sodium are in use. Studies continue to investigate the optimum sodium content of oral rehydration solutions, as well as the optimum composition of sugars. Current evidence indicates that reduced osmolarity formulas limit the duration of diarrhea. In practice, maintenance solutions can be effectively used if rehydrating solutions are unavailable.

	Na+ (meq/L)	K+ (meq/L)	Cl- (meq/L)	Base (meq/L)	Carbohydrate (% Weight for Volume)
Maintenance Solutions					
Resol (Wyeth)*	50	20	50	Citrate, 34	2% Glucose
Ricelyte (Mead Johnson)	50	25	45	Citrate, 34	3% Rice syrup solids
Pedialyte (Ross)	45	20	35	Citrate, 30	2.5% Glucose
Rehydration Solutions					
Rehydralyte (Ross)	75	20	65	Citrate, 30	2.5% Glucose
World Health Organization formulation (for use in cholera)	90	20	80	HCO3-, 30	2% Glucose

*Include calcium, 4 meq/L; magnesium, 4 meq/L; phosphate, 5 meq/L.

TABLE 128-3   Composition of Commercial Oral Hydration Solutions

Fluid replacement is accomplished by administering 50 mL/kg over 4 h to mildly dehydrated patients and 100 mL/kg to patients with moderate dehydration. Vomiting can be reduced by administering the fluid slowly. This can be done be using a teaspoon or eyedropper. Ongoing losses from continuing diarrhea are also replaced. Once adequate hydration is reestablished, supplemental feeding should be encouraged. This is especially important in malnourished infants.

Severe dehydration, persistent vomiting, continuing severe diarrhea, or significant hypernatremia may preclude the use of oral rehydration when intravenous therapy is available. If necessary, however, the vast majority of these patients can be salvaged by persistent administration of small quantities of oral fluids. Fluid can also be administered by nasogastric tube, if necessary.

SPECIFIC SITUATIONS

Pyloric Stenosis

The protracted vomiting that characterizes pyloric stenosis can result in significant losses of hydrogen ion, chloride, potassium and, occasionally, sodium. This leads to the characteristic hypochloremic metabolic alkalosis. Fluid replacement must take into account potentially severe losses of chloride and potassium. Appropriate replacement can be accomplished with 0.9 NS with 40 meq/L potassium. Serum electrolytes should be monitored during therapy.

Adrenogenital Syndrome

The most common cause of adrenogenital syndrome in children is congenital adrenal hyperplasia secondary to deficiency of 21-hydroxylase. Defective steroidogenesis results in a deficiency of cortisol and an overproduction of intermediary metabolites. Affected infant boys appear normal, whereas infant girls have ambiguous genitalia. Adrenal insufficiency can also occur in patients who have been on long-term treatment with steroids.

Patients can present with vomiting, lethargy, and failure to thrive. Profound volume deficit can lead to shock. Glucocorticoid deficiency can result in hypoglycemia, and mineralocorticoid deficiency causes hyponatremia and hyperkalemia. Metabolic acidosis may be present.

Initial resuscitation is with 0.9 NS until adequate perfusion is reestablished. Hypoglycemia is treated with intravenous glucose. In infants, 25% dextrose in a dose of 2 to 4 mL/kg is usually adequate. In older children and adolescents, 50% dextrose in a dose of 1 to 2 mL/kg is appropriate. Neonates are best treated with 10% dextrose at 1 to 2 mL/kg, to avoid rapid shifts in osmolarity. Treatment also consists of initiating glucocorticoid therapy with cortisol at a dose of 50 mg/m ^{2}/dose intravenously every 6 h. Mineralocorticoid therapy is not necessary during the acute adrenal crisis.

Cystic Fibrosis

Patients with cystic fibrosis have an elevated content of sodium and chloride in sweat. During hot weather or strenuous exercise, affected children can suffer severe salt depletion and corresponding electrolyte abnormalities. Intercurrent pulmonary infection may be present. Profound chloride loss is compensated for by a rise in serum bicarbonate, resulting in a metabolic alkalosis. Hyponatremia is present, and serum potassium is decreased. Patients can present with lethargy and signs of hypoperfusion. Treatment is with 0.9 NS, with supplemental potassium. Resuscitation should be aggressive.

Hypokalemia

Potassium is the predominant intracellular cation. Hypokalemia occurs when the serum potassium falls below 3.4 meq/L and most commonly occurs secondary to profuse vomiting with or without diarrhea. Therapy with loop diuretics can also cause hypokalemia. In diabetic ketoacidosis, profound hypokalemia can result from osmotic diuresis, although, in the face of the hydrogen-potassium shift that accompanies acidemia, serum levels may be normal or falsely elevated. Uncommon causes of hypokalemia are renal tubular acidosis and familial hypokalemia-induced paralysis.

Severe potassium depletion can result in skeletal muscle weakness, ileus, and cardiac conduction disturbances. A prominent electrocardiographic (ECG) manifestation is the U wave. Clinical manifestations generally reflect the rate of fall of serum potassium rather than the absolute level.

In most cases, hypokalemia occurs slowly, and it is difficult to predict whole body stores based on the serum level. In general, oral replacement over several days is adequate. Dehydration must be corrected. If intravenous therapy is necessary, 0.2 to 0.3 meq/kg/h is adequate. In extremely urgent situations, such as hypokalemia-induced respiratory insufficiency, 1 meq/kg/h can be administered, with continuous ECG monitoring. This is usually done via a central line. In diabetic ketoacidosis, potassium repletion should begin early in the course of therapy, since diuresis-induced depletion can result in profound hypokalemia as acidosis is corrected and serum potassium shifts into cells.

Hyperkalemia

Hyperkalemia is defined as a serum potassium level greater that 5.5 meq/L. In infants and children, hyperkalemia is most commonly due to hemolysis that occurs during blood drawing and does not reflect serum levels. Causes of true hyperkalemia include renal failure, rhabdomyolysis, the use of potassium-sparing diuretics, and adrenal corticoid insufficiency. Metabolic acidosis can result in hyperkalemia due to the hydrogen-potassium shift.

Cardiac conduction delay is the most common manifestation of hyperkalemia and is potentially life-threatening. Peaked T waves are the first manifestation, followed by prolonged PR interval and then widening of the QRS complex, an ominous finding that can precede ventricular dysrhythmias and asystole. All patients with suspected hyperkalemia should receive an ECG evaluation. Any patient with ECG changes requires emergent therapy to reverse cardiac conduction toxicity. Asymptomatic patients with normal ECG usually do well with therapy to enhance potassium excretion. Most commonly, this occurs in patients with renal failure who have sustained a gradual rise in serum potassium.

Treatment of symptomatic hyperkalemia is directed at immediately antagonizing its deleterious effects on cardiac conduction and at enhancing potassium excretion. Calcium gluconate 10% at a dose of 0.5 to 1 mL/kg antagonizes the membrane effects of potassium within minutes, and has a duration of action of approximately 1 h. Sodium bicarbonate at a dose of 1 to 2 meq/kg elevates serum pH and causes an intracellular shift of potassium. It has an onset of action within minutes and a duration of action of up to 2 h. Intravenous insulin and glucose also produce an intracellular shift of potassium, with an onset of action of 30 to 60 min and a duration of action of 4 to 6 h. Glucose is administered at a dose of 0.5 to 1 g/kg, with 1.0 unit of regular insulin for every 3 g of glucose. Patients must then be monitored carefully for the presence of hypoglycemia. Inhaled b-agonist agents in doses used for asthma can also cause an intracellular shift of potassium, with an onset of action within minutes; this may prove an attractive alternative when treating patients with difficult intravenous access.

Sodium polystyrene sulfonate is a resin that exchanges sodium for potassium at a 1:1 ratio and therefore enhances potassium excretion. It can be administered orally or by enema. A dose of 1g/kg will lower serum potassium by up to 1.2 meq/L. When it is administered orally, it is usually given with a cathartic to enhance transit time through the gastrointestinal (GI) tract. Hypernatremia or volume overload are potential complications. In patients with hyperkalemia secondary to renal failure, dialysis is usually necessary. In patients with hyperkalemia secondary to metabolic acidosis, normalization of serum pH usually restores serum potassium to normal levels.

Disorders of Calcium

Normally, 99 percent of total body calcium is contained in bone. Normal serum levels are maintained by a complex interaction between dietary intake, absorption from the GI tract and resorption from bone, and renal excretion. Serum calcium is inversely proportional to serum phosphorus. The active form of vitamin D stimulates absorption of calcium and phosphorus from the GI tract; its formation depends on exposure to sunlight and healthy kidneys. Parathyroid hormone increases calcium resorption from bone in response to hypocalcemia and increases phosphorus excretion. Calcitonin decreases calcium resorption from bone in response to hypercalcemia.

In the serum, 45 to 50 percent of serum calcium exists in the ionized or free form; most of the remainder is bound to albumin. Ph affects the proportion of calcium that is ionized and therefore bioavailable. Acidosis increases and alkalosis decreases the fraction of ionized calcium.

HYPOCALCEMIA   This can result from hypoparathyroidism or end-organ resistance to parathyroid hormone. True hypoparathyroidism can be idiopathic, follow thyroid surgery, and can be associated with magnesium deficiency. End-organ resistance to parathyroid hormone is most commonly associated with vitamin D deficiency. The most common causes of this are dietary deficiency and chronic renal failure. Young infants fed cow's milk, which is high in phosphate, can develop significant hypocalcemia. A common cause of hypocalcemia is hyperventilation; the decreased P$_{CO_2}$ results in an acute respiratory alkalosis that rapidly decreases

ionized calcium.

Clinical manifestations of hypocalcemia include muscle weakness, vomiting, and irritability. Infants may simply appear "jittery." In severe cases, tetany, larygnospasm, carpopedal spasm, and seizures can occur. Carpopedal spasm is especially common in patients with hyperventilation syndrome. The most characteristic ECG abnormality is a prolonged QT interval.

Laboratory evaluation of hypocalcemia of unknown etiology includes total serum and ionized calcium, phosphate, total protein and albumin, measurement of parathyroid hormone, and blood urea nitrogen and creatinine.

Intravenous calcium is the treatment of choice for symptomatic hypocalcemia. Calcium gluconate 10% is administered in a dose of 0.5 to 1 mL/kg over several minutes, with continuous ECG monitoring. Further management depends on determining the etiology of hypocalcemia.

HYPERCALCEMIA   This exists when serum calcium exceeds 11 mg/dL and most often results from increased bone resorption. Probably the most common cause in children is malignancy involving the lymphoreticular system. Less common causes include vitamin D intoxication and hypervitaminosis A.

Clinical manifestations of hypercalcemia include fatigue, irritability, anorexia and vomiting, and constipation. Affected patients may be clinically dehydrated and complain of polyuria. An ECG may reveal bradycardia and a shortened QT interval.

The laboratory evaluation of hypercalcemia includes evaluation of total serum and ionized calcium levels, a complete blood count, and evaluation of total protein and albumin, and alkaline phosphatase. An evaluation of the vitamin D level may also be indicated, depending on the patient's medical history.

The treatment of hypercalcemia depends on the etiology. In the acute scenario, patients with functioning kidneys can be treated by aggressive intravenous hydration followed by furosemide, which will enhance calcium excretion.

Metabolic Acidosis

Metabolic acidosis results from the addition of acids or the removal of alkali. The differential diagnosis in pediatric patients is similar to that in adults, with a few notable exceptions. As in adults, it is useful to distinguish between metabolic acidosis with an elevated anion gap from that in which the anion gap is normal.

In infants and children, the most common cause of metabolic acidosis with a normal anion gap is diarrhea. Diarrheal fluid is rich in bicarbonate and low in chloride, and acidosis occurs when bicarbonate is lost in stool. Laboratory values will reveal a hyperchloremic acidosis. Acidosis resolves with the correction of dehydration.

Renal tubular acidosis (RTA) is the other major cause of non-anion gap acidosis in children. RTA constitutes a group of tubular transport disorders. In type 1, or distal RTA, there is impaired hydrogen secretion in the distal tubule. Inability to secrete hydrogen usually results in a urinary pH greater than 6. In type 2, or proximal RTA, there is inability to resorb bicarbonate at the proximal tubule. Accompanying hypokalemia is common and can be severe. In both types, affected infants commonly present with failure to thrive. They can acutely decompensate during diarrheal illness, when bicarbonate loss in the stool can exacerbate acidosis. Treatment of RTA usually involves the administration of supplemental bicarbonate, which improves acidosis and enables relatively normal growth and development.

The differential diagnosis of metabolic acidosis with an elevated anion gap is substantially the same in children as in adults and implies the presence of an endogenously created or exogenously ingested acid (Table 128-3). The one notable exception is the possibility of an inborn error of metabolism (IEM). Of the IEMs that cause metabolic acidosis, the most common are methylmalonic, propionic, and isovaleric acidemia. The typical emergency department presentation is a neonate with vomiting, lethargy, and failure to thrive. It is extremely difficult to distinguish these infants from those with more common disorders, especially sepsis. Helpful ancillary studies include evaluation of serum lactate, pyruvate, and ammonia levels. Management requires consultation with a pediatric endocrinologist or geneticist.

129 UPPER RESPIRATORY EMERGENCIES

Randolph Cordle
Nicholas C. Relich

STRIDOR

The physical sign common to all causes of upper respiratory tract (URT) obstruction is stridor.

Stridor is due to Venturi effects created by somewhat linear airflow through a variably collapsible tube, the airway. When one inhales, the relative pressure in the center of the tube becomes greater than that at its edges. This pressure differential leads to collapse of the airway walls. During expiration, the previously collapsed areas are reopened owing to the relative increase in air pressure during expiration. Forced expiration or expiration against a partially closed glottis may cause expiratory stridor even in patients with a normal airway. As one progresses from the supraglottic to the glottic and subglottic and finally the tracheal areas of the airway, there is an increase in physiologic support and therefore a decrease in the amount of collapse that occurs upon inspiration.

Supraglottic obstructions cause inspiratory stridor, with marked inspiratory and expiratory variation; obstructions at the glottic and subglottic areas commonly cause both inspiratory and expiratory stridor of lesser magnitude. [1] Finally, obstructions at the level of the trachea and primary bronchi may be associated with inspiratory or expiratory stridor, although usually of a much lesser degree. Although the posterior walls of the trachea and bronchi are somewhat collapsible, good support is provided by the horseshoe-shaped cartilage within its walls. In premature infants and infants with tracheomalacia, these supports are not well formed and inspiratory and expiratory stridor may be impressive. Expiratory stridor, or wheeze, is common in distal airways, since intrathoracic pressure may become much greater than atmospheric pressure during expiration. The pressure differential creates high relative laminar flow through semicollapsible bronchi, resulting in wheezes. This information can be clinically useful when one is evaluating a wheezing child. Commonly, gentle pressure over the chest wall or midabdomen during expiration will increase the intrathoracic pressure and exacerbate wheezing. This maneuver may also assist in detecting inspiratory stridor because the child will follow this relative forced expiration with a much deeper inspiration than at rest. Patients with marked variation in the pattern of stridor should be considered to have a foreign body in the airway until proven otherwise. The quality of the pitch is not clinically useful for diagnosis. The answers to two questions, the age of the patient and the duration of symptoms, will narrow the differential diagnosis considerably, since stridor in an infant below 6 months of age has different causes that it does in older children (Table 129-1).

TABLE 129-1   Differential Diagnosis of Inspiratory Stridor

Stridor in Children below 6 Months of Age

An infant under 6 months of age with a long duration of symptoms (weeks to months) characteristically has a *congenital* cause of stridor. Laryngomalacia accounts for 60 percent of all neonatal laryngeal problems. It is due to a developmentally weak larynx. [2] Collapse occurs with each inspiration at the epiglottis, aryepiglottic folds, and arytenoids. Generally, the stridor worsens with crying and agitation. It often improves with neck extension and when in the prone position. [2] In over 90 percent of cases, this is a self-limited disorder resolving by 2 years of age. Symptom exacerbations may occur with upper respiratory infections or increased work of breathing due to any cause. It only rarely is associated with respiratory distress, failure to thrive, apnea, or feeding problems. Definitive diagnosis is by fiberoptic laryngeal exam.[2] In rare cases, tracheotomy or epiglottoplasty may be needed.[2]

The next most common cause of neonatal stridor is vocal cord paralysis or paresis. Most infants will have a history of birth trauma, shoulder dystocia, macrosomia, forceps delivery, an abnormal cry, or other intrathoracic anomaly. Diagnosis is typically by flexible fiberoptic laryngoscopy with visualization of the cords during speech or crying. Endotracheal intubation can be quite difficult in a child with bilateral vocal cord paralysis. Placing the bevel of the endotracheal tube parallel to the small remaining glottic opening and rotating the endotracheal tube one-quarter turn while applying gentle pressure may assist in passing the tube. Force should not be used, as this may damage the laryngeal structures. Needle cricothyroidotomy and subsequent tracheotomy may be required to secure the airway. It is unlikely that the laryngeal mask airway (LMA) would be helpful in this case. Use of the LMA is contraindicated in abnormal or obstructed airways because the path of least resistance to flow will likely be around the mask and not into the airway. [3] Retrograde intubation may be difficult as well, owing to the size of the structures and

potential difficulty in passing the tube from the trachea into the hypopharynx.

Arnold-Chiari malformation should be considered in children with Down syndrome who present with stridor. Hydrocephalus should also be considered in children with myelomeningocele, sacral epidermal abnormalities, or sacral dimples.

Stridor in Children above 6 Months of Age

The patient above 6 months of age with a relatively short duration of symptoms (hours to days) characteristically has an acquired cause of stridor. Causes are either inflammatory, such as viral croup or epiglottitis, or noninflammatory, such as a foreign-body aspiration. The remainder of the chapter deals with the most common acquired causes of stridor: epiglottitis, peritonsillar abscess, viral croup, foreign-body aspiration, retropharyngeal abscess, and bacterial tracheitis (Table 129-2).

TABLE 129-2   Common Acquired Causes of Stridor

EPIGLOTTIS

Clinical Features

Since the introduction of the *Haemophilus influenzae* vaccine, the incidence and demographics of this disease have changed remarkably. Currently *H. influenzae* is thought to be responsible for less than 25 percent of cases. Now, gram-positive organisms such as *Streptococcus pyogenes*, *Staphylococcus aureus*, and *Streptococcus pneumoniae* are responsible for most cases in immunized children. In immunocompromised children, herpes simplex, *Candida* and varicella must also be considered.

Prior to the introduction of the *Haemophilus* vaccine, the median age of this disease was 3 years, with 25 percent occurring in children under age 2. Although epiglottitis can occur at any age, its median age of presentation is currently 7. [4]

The classic symptoms are an abrupt onset over several hours of high fever, sore throat, stridor, dysphagia, and drooling. Some cases may develop over 1 to 2 days. Physical examination reveals a toxic-appearing, apprehensive child with an ashen-gray color. The child often sits in a tripod position, or the "sniffing" position, with the neck slightly extended and the chin forward. As opposed to the child with croup, there is no cough. The voice may be muffled, but supraglottic foreign bodies, peritonsillar abscess, and retropharyngeal abscess may present similarly. If inflammatory changes extend beyond the epiglottis to include the vocal cords, voice pitch will be altered as well.

Older children and adults may have much more subtle presentations than young children. In fact, some older children will complain of only a severe sore throat. Stridor may or may not be present. The diagnosis is suggested by severe sore throat, the finding of a relatively normal-appearing oropharynx, and striking tenderness with gentle movement of the hyoid. The diagnosis needs to be confirmed by fiberoptic bronchoscopy.

Diagnosis

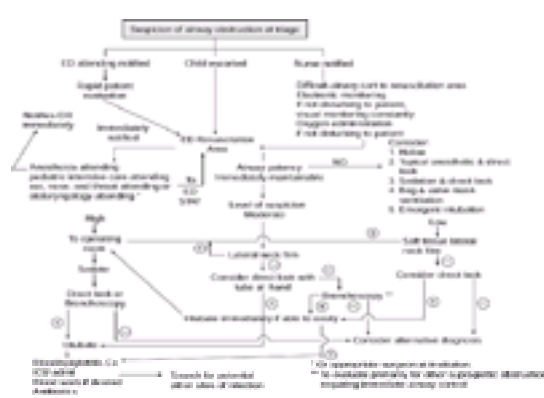
The ideal approach to the diagnosis of epiglottitis varies depending on the practice environment. Each institution should have a written "Suspected Epiglottitis Management Protocol" (Fig. 129-1). Themes necessary in all protocols include:


FIG. 129-1. Obstructed airway protocol.

1. Immediate recognition and triage to a resuscitation area
2. Continuous monitoring by someone trained in the management of the difficult airway
3. Rapid consultation of appropriate colleagues
4. Consideration and risk-benefit analysis of patient transfer with appropriate personnel present during the transfer
5. Bedside radiology without disturbing patient or, if moved to the x-ray suite, constant monitoring by a physician with appropriate airway equipment

Lateral neck radiographs are usually unnecessary in patients with a classic presentation for epiglottitis. When the diagnosis is uncertain, radiographs should be taken with the neck extended during inspiration using a high-kilovolt soft tissue technique. The child typically holds its head in the sniffing position and has prolonged inspiration, already making it quite easy to obtain these radiographs. False-positive findings may occur due to normally widened retropharyngeal space structures if the radiograph is taking during expiration or with the head flat. Lateral neck radiographs are not required if the patient is already intubated, and often the typical findings for epiglottitis will not be seen in such cases. False-negative radiographic evaluations do occur. Direct visualization of the epiglottis should occur prior to discharge if suspicion for the diagnosis still exists.

In evaluating lateral neck radiographs, the epiglottis, vallecula, hypopharynx, tracheal air column, arytenoids, and retropharyngeal or prevertebral space should be checked. The epiglottis is normally tall and thin, projecting up into the hypopharynx (Fig. 129-2). Normally there is a poorly delineated space between the epiglottis and the anteriormost aspect of the hypopharynx. In epiglottitis, the epiglottis is swollen and appears squat and flat, like a thumbprint at the base of the hypopharynx (Fig. 129-3). Commonly, the vallecular airspace is obscured. Another common finding is ballooning of the hypopharynx just above the area of the larynx. This is illustrated by the different sizes of the hypopharynx in Fig. 129-2 and Fig. 129-3. While not specific for epiglottitis, this distention does indicate significant obstruction

of the upper respiratory tract. The retropharyngeal space is normally 3 to 4 mm wide. Commonly it is stated that it should be less than the width of the adjacent vertebral body. The tracheal air column should be of uniform width without densities.

FIG. 129-2. A normal lateral neck x-ray.

FIG. 129-3. Lateral neck view of a child with epiglottitis.

In some scenarios, gentle direct visualization can be attempted. Most proponents of this practice would agree that it should be performed only at sites where experts in pediatric airway management are present with appropriate equipment to maintain the airway by whatever means necessary. Typically this is done in the following stepwise manner. In his or her position of comfort, the child is asked to open its mouth wide. If the epiglottis is not seen, the child is asked to stick its tongue out, with a tongue blade used to depress the anterior aspect of the tongue in the hope of visualizing the epiglottis. If the epiglottis is still not seen, as is more common, fiberoptic laryngoscopy by an operator skilled in the techique, and with the ability to intubate over the scope, is the safest next step.

Airway Management

Should the child develop ventilatory fatigue or if airway obstruction or apnea occurs before the airway has been secured, bag-valve-mask ventilation can be effective.

Patients with epiglottitis who are initially seen in the office, clinic, or emergency department (ED) without pediatric or ear-nose-throat (ENT) subspecialty support should be transported to a referral center by ground or air, whichever is more appropriate, accompanied by personnel who can manage the airway. Oxygen should be given, and continuous nebulized racemic epinephrine can be given to decrease airway edema. The child should be kept seated upright. Heliox can also be a temporizing measure until specialists arrive (see discussion of croup, below). The referral center should be alerted as soon as possible, so that decisions concerning intubation or tracheostomy can be made in advance. Patients usually are intubated by the most skilled individual available as soon as the diagnosis is made. Sedation, paralytics, and vagolytics are used as indicated. To reduce the incidence of postextubation stridor, a tube one size smaller than usual should be used. Tube sizes above and below this size should be immediately available. One can determine that a correct size has been by checking for the pressure at which a leak develops around the tube. The tube should be secured immediately, with as little patient movement as possible afterward so as to minimize the likelihood of tube dislodgement.

Supportive Therapy

A second- or third-generation cephalosporin such as cefuroxime, cefotaxime, or ceftriaxone is generally administered to ensure adequate coverage of *H. influenzae*. With the increasing incidence of *S. pneumoniae* as a cause for epiglottitis and the marked increase in resistance of this organism to cephalosporins, one can empirically give vancomycin also. Some recommend adding nafcillin instead, based on the increasing incidence of gram-positive cocci, including *S. aureus*, as etiologic agents. Blood cultures are positive in 80 to 90 percent of patients. Cultures of the epiglottis itself are much less sensitive. Typically oral antibiotics are continued for 7 to 10 days after the patient is extubated.

VIRAL CROUP

Viral croup (laryngotracheitis or laryngotracheobronchitis) is responsible for more than 90 percent of cases of stridor outside of the neonatal period. About $20 to $76 million per year is spent in the United States alone on health care related to viral croup. Children 6 months to 3 years of age are most commonly affected, with a peak incidence between 1 and 2 years of age.[5] It is uncommon after age 6. This is due to the much greater effect of a small amount of mucosal edema and inflammation in the airway of a small child versus that of an adult. As little as 1 mm of airway edema in an infant may cause a decrease in cross-sectional area of 50 to 60 percent. This leads to increased resistance and work of breathing. In the adult airway, 1 mm of edema is nearly inconsequential. The incidence of true croup is thought to be equal in males and females, but many authors believe that moderate to severe cases are twice as common in males. Most cases occur in the late fall or early winter.

Acute viral croup is thought to be on a continuum with spasmodic croup. It is very difficult or impossible to differentiate them prospectively. Retrospectively, spasmodic croup is seen more commonly in atopic children, has no seasonal variation, usually has almost complete symptom resolution within 6 h, is not characteristically associated with fever, and is often recurrent. Both spasmodic croup and acute viral croup have nocturnal exacerbations.

Etiology

Practically all cases are viral. Parainfluenza virus types I, II, and III are most common by far, but sometimes indistinguishable syndromes can be caused by influenza A or B, respiratory syncytial virus (RSV), rhinoviruses, adenoviruses, and even measles virus. Cases caused by adenovirus may be associated with hemorrhagic cystitis and conjunctivitis. Measles pneumonitis should be considered in atypical cases and, if suspected, treated aggressively. In unimmunized or immunosuppressed adults, measles pneumonitis is not uncommonly fatal. The incubation period for parainfluenza virus is 2 to 6 days. These viruses are usually shed for about 2 weeks. In cases caused by RSV, the shedding may continue for a much longer period and symptoms may take months to clear completely. In children over the age of 5, *Mycoplasma pneumoniae* infection has also been associated with a croup-like syndrome.

Signs and Symptoms

There is typically a 1- to 5-day prodrome consisting of cough, coryza, and occasionally other upper respiratory infection–type symptoms. This is followed by a 3- to 4-day period of barking cough. The cough is typically worse in the late evening and at night and may occur strictly during these times. Children may or may not have a low-grade fever during the illness. The typical duration of symptoms ranges from 3 to 7 days regardless of the treatment. Typically the third and fourth days are the

worst, and then the child starts to improve. Children who do not follow this general course should be reevaluated.

Viral croup is classically associated with biphasic stridor, although often the inspiratory component is much greater than the expiratory component. Stridor is unaffected by position but increases with crying or agitation. Intercostal retractions and tachypnea are common signs. The voice is often hoarse but not muffled. If inflammation extends from the trachea to the more distal bronchi, wheezing or crackles will be present.

Diagnosis

Croup is a clinical diagnosis. Generally laboratory tests are unnecessary. The white count is typically normal or with a slight lymphocytosis. Blood cultures or nasopharyngeal washings are not clinically useful, since knowing the exact etiologic agent does not change management.

Radiographs are primarily used to help rule out other causes of stridor in atypical or prolonged cases. A lateral neck film and posteroanterior (PA) chest radiograph should be obtained as appropriate. The aryepiglottic area is normal. The lateral neck radiograph may demonstrate slightly ill-defined tracheal air shadows, narrowing on inspiration greater than that on expiration, and slight distention of the hypopharynx. Typically fixed subglottic obstructions—such as papillomas, foreign bodies, hemangiomas, and subglottic stenosis—cause narrowing of the airway that does not change with the phase of respiration. Many of the latter noncroup causes also cause asymmetry in appearance, whereas croup causes symmetrical changes in the air column. The PA chest x-ray is most useful to rule out radiopaque foreign body. In cases of croup, the normally squared shoulders of the subglottic tracheal air shadow will appear more like a "steeple," "pencil tip," "nail," or "hourglass."

General Treatment

Pulse oximetry should be measured and supplemental humidified oxygen given. Children with croup should not be sedated except in the course of a rapid-sequence intubation. Antibiotics are not indicated for patients with a confident diagnosis of croup. Antipyretics should be given for fever to decrease the required minute ventilation and work of breathing. The least invasive route possible should be used to provide hydration, to replace insensible water losses from respiratory distress and fever. Urine output, or the number of wet diapers, should be monitored and intravenous hydration provided if necessary.

Exposure to humidified air, either cold night air or moist air from a shower, is used to treat this disease, but it is not known why this is effective. Nebulization tents, or "croup tents," are no longer used. A tent isolates the child and enshrouds it in a mist, making the child more anxious and difficult to monitor. Furthermore, it is very difficult to maintain an adequate concentration of oxygen within the tent.

In general, calculating a croup score (Table 129-3) is more useful as a research tool than as an adjunct to clinical practice. Its primary use is to provide a semiobjective scale by which to cohort patients for comparative studies. Its usefulness as a tool for clinical decision making with individual patients is much less clear. The score, if calculated, should only be used as one piece of data in the decision-making process. For example, a child with severe retractions and markedly decreased air entry may have a score of only 5 but would be considered at high risk by most clinicians and treated aggressively. Generally, healthy appearing children with stridor only when agitated do not require treatment with epinephrine. Children with stridor at rest or whom appear in distress should receive epinephrine as discussed below. All children receiving catecholamines should receive steroids as well. The use of steroids, as discussed below, is generally agreed upon in moderate to severe episodes of croup. In mild croup controversy exists regarding the absolute need of steroid treatment but there is some evidence showing benefit in this population as well. The use of steroids in the mildest cases should be decided on an individual case-by-case basis and may vary between reasonable clinicians. Further research, using clinically important endpoints and number-to-treat analysis, should help to clarify their use in this patient population.

TABLE 129-3   Modified Westley Croup Score

Epinephrine

Racemic epinephrine, a nearly equimolar mixture of the two isomers (D and L) of epinephrine, is a mainstay of moderate to severe croup treatment. The majority of its activity is due to the L-isomer. The D-isomer is only about 30 percent as active as the L-isomer. The drug is quite effective when nebulized. Positive effects can be seen in as little as 10 min, with maximal effects seen in about 1 h. In most cases its pharmacologic effects are practically gone by 2 h. Nebulized epinephrine has clearly been shown to decrease airway edema, most likely by vasoconstriction of the boggy mucosal vessels. Its use does not change the natural course of disease, but it does improve ventilation. Use of racemic epinephrine decreases the number of children with croup requiring intubation, intensive care unit admission, and general admission to the hospital.

L-epinephrine, a pure isomer, is used as an advanced cardiac life support (ACLS) drug in a 1:1000 concentration. Although only recently subjected to evidence-based scrutiny,[6] this form has been used exclusively in many foreign countries for years. The L-isomer is at least as effective and safe as racemic epinephrine (Table 129-4).[6] Although some forms contain sulfur dioxide, a known respiratory irritant, this has not been reported to cause any significant problems in this patient group. [6] Both racemic and L-epinephrine are relatively contraindicated in patients with severe left ventricular outflow obstruction (idiopathic hypertrophic subaortic stenosis, subvalvular aortic stenosis, etc.) because it may worsen the obstruction. [7] When the drug is used in these patients, very close monitoring is indicated.

*Diluted if necessary with normal saline to make 3–5 mL total volume.

TABLE 129-4   Epinephrine for Stridor

Ledwith's group monitored patients for 3 h after epinephrine nebulization and found that 38 percent of the patients who had a recurrence requiring admission did so between the second and third hour.[8] Prendergast et al. also demonstrated that there was an upward trend in the croup score between the second and third hours only

in those patients ultimately requiring admission. [9] The current standard of care for moderate to severe croup is to administer nebulized epinephrine with early steroids (see below) and monitor these patients in the ED for at least 3 h before considering discharge (Table 129-5).

At least 3 h since last epinephrine
Nontoxic appearance
Able to take fluids well
Not clinically dehydrated (labs not necessary)
Room-air oxygen saturation greater than 90%
Age greater than 6–12 months*
Weather conditions allow rapid return to ED for worsening
Parents have a phone and no social issues of concern
Caretaker seems able to recognize change in child's clinical status
Relatively short transit time from home to hospital

*Controversial.

TABLE 129-5   Discharge Criteria

Dexamethasone

The literature clearly demonstrates clinical benefits of steroid use in moderate to severe croup. [10,11] It suggests benefits in mild croup as well. Steroids should be given within 1 h of presentation, and early effects of steroid use may be seen at $\frac{1}{2}$ to 2 h. Most likely this is due to vasocontriction of the edematous mucosa. Their effects on immune modulation and protein synthesis occur later and may be responsible for the longer-term clinical benefits seen with these agents. Certainly any child receiving nebulized epinephrine should also receive steroids. [7]

Dexamethasone, a fluorinated derivative of prednisolone, has anti-inflammatory effects about 25 times greater than those of hydrocortisone at equal doses. It has minimal to no mineralocorticoid effect. Its half-life is about 2 days (range 36 to 72 h). [12] Peak effects are seen in 2 h with persistent effects over the next few weeks. Early studies used 0.6 mg/kg of dexamethasone, so this became the standard to which other doses and interventions were compared. It was then shown that doses greater than 0.3 mg/kg were clearly beneficial, but doses less than this had marginal benefit. More recently, Geelhoed's group demonstrated that 0.15 mg/kg was equivalent to 0.6 mg/kg when given orally. [13] Until further studies confirm these findings, the recommended dose is 0.3 to 0.6 mg/kg.

No direct comparison of oral and parenteral dexamethasone has been made, but there is no reason to suspect that the oral route would be any less efficacious than the intramuscular route. Studies primarily from the adult asthma literature demonstrate near bioequivalence of intravenous and oral steroids. Giving steroids orally has become near standard practice for asthma and is becoming so for croup as well. [14] The greatest problem with giving oral steroids is vomiting and the bitter taste. Various steroid preparations are available (Table 129-6).[11] Using crushed dexamethasone tablets or giving the medication in small aliquots over the first 30 min is said to reduce the number of children who vomit.

Steroid	Concentration	Dose	Route	Information
Dexamethasone	0.25, 0.5, 1, 1.5, 2, 4, 6 mg tablets	0.3 mg/kg	PO	Crush in juice, acetaminophen elixir, or applesauce
	4, 10, 20, 24, mg/mL	0.3 mg/kg	IV	Erratic GI absorption
	8, 16 mg/mL	0.3 mg/kg	IM	Minimize volume
	0.5 mg/5 mL elixir	0.3 mg/kg	PO	May contain 5% alcohol; Taste varies by brand
	0.1, 1 mg/mL oral solution	0.3 mg/kg	PO	May contain 30% alcohol
Budesonide	2 mg/4 mL	2 mg	Nebulized	Not readily available
Prednisolone	5 mg/5 mL syrup	1 mg/kg	PO	Prelapred; 5% alcohol
	15 mg/5 mL syrup	1 mg/kg	PO	Prelone
Prednisone	1, 2.5, 5, 10, 20, 50 mg tablets	1 mg/kg	PO	
	0.5 mg/mL syrup	1 mg/kg	PO	Poor taste

TABLE 129-6   Steroids for Croup

More recent studies have investigated the use of nebulized steroids. If steroids could be selectively deposited at the area of inflammation, they could have a greater effect on the disease process with fewer side effects. Johnson's study using dexamethasone resulted in benefits that were not clinically significant and two children in the study developed bacterial tracheitis with associated neutropenia [15]; nebulized parenteral dexamethasone is therefore not recommended. Multiple other studies using budesonide have had more encouraging results [13,14,16,17,18,19,20 and 21] In fact, one study of hospitalized children with moderately severe croup was unable to show a difference in efficacy between nebulized budesonide and nebulized epinephrine. [16] A few conclusions can be drawn. Nebulized budesonide is at best equivalent to dexamethasone in the short term but possibly not quite as good if given later in the course of the disease. [13,18,19,22] Klassen's group found an increased number of repeat visits in their budesonide cohorts when compared with their oral dexamethasone cohort. [19] Johnson et al. found an overall decrease in admissions using nebulized budesonide but a further 15 percent reduction was found using intramuscular dexamethasone. [18] Results are mixed regarding an additive effect of nebulized budesonide used with parenteral steroids. [21] Budesonide use is more expensive, requires a nebulizer, increases nursing or respiratory therapy time at the bedside, and may frighten small children. Based on the currently available information, the use of nebulized steroids is not standard care.

A child with resting stridor, increased pCO_2, decreased pO_2, decreased mental status, cyanosis, age less than 1 year (some say 6 months), or a croup score above 8 (Table 129-3) should be considered in early respiratory failure and managed aggressively to prevent progression to pulmocardiac arrest.

Fortunately, if treated aggressively, less than 1 percent of admitted patients will need intubation. Intubation should be performed whenever clinically indicated by the most experienced operator available. A number of findings should prompt the clinician to strongly consider elective intubation. These include:

1. A croup score above 8 without rapid improvement
2. Two catecholamine nebulizations required within 1 h
3. Hourly nebulizations required beyond the second hour
4. Acute mental status changes associated with respiratory distress
5. Worsening respiratory failure despite onging treatment
6. Severe croup in a child with neonatal lung disease
7. Moderately severe to severe croup in a child who needs transfer (especially if by helicopter)

The cricoid cartilage is normally the narrowest part of the young child's airway and will be especially narrow in croup owing to inflammation of the tracheal mucosa. Postintubation subglottic stenosis can be minimized by using a tube that is 0.5 to 1.0 mm smaller than would be expected. Never force a tube through the cricoid ring.

Fiberoptic laryngoscopy should be considered in atypical or recurrent presentations of a crouplike syndrome. It may also be indicated in children who fail to respond to standard therapy and occasionally in the very young to rule out laryngomalacia and other congenital causes of stridor. [7]

Heliox

Helium is much less dense than either oxygen or nitrogen, and replacing the nitrogen in air with helium decreases its resistance to flow. Helium will increase ventilation in patients with nearly all types of upper airway obstruction. [23,24] It may also restore laminar flow, improving ventilation and ventilation/perfusion matching. The work of breathing also decreases. Carbon dioxide diffuses much faster through a helium-oxygen mixture than it does through a nitrogen-oxygen mixture. This may make ventilation more effective. The indications for the use of heliox use are still somewhat controversial. [24] Most would agree that children not requiring high-flow oxygen should be given a trial of heliox for poor ventilation secondary to upper airway partial obstruction. If nothing else, this may serve as a temporizing measure and allow for a more controlled intubation. Following intubation, helium may be given through the ventilator circuit as a mixture with oxygen. Volume and flow readings from the ventilator will be inaccurate if helium is used, [24] since ventilators are calibrated for use with a nitrogen-oxygen mixture.

One easily forgotten point is that oxygen and helium gas cannot occupy the same space. Due to the rule of partial pressures, if the helium concentration is increased, the oxygen concentration must decrease. Helium's therapeutic effects are found only when its concentration makes up 60 to 80% of the inspired gas. Therefore, an individual who requires greater than 35 to 40% oxygen cannot use this modality. The flow of oxygen and helium must be high enough to exceed the patient's minute ventilation to prevent entrainment of room air and increased dead-space ventilation.

BACTERIAL TRACHEITIS

Bacterial tracheitis, also known as membranous croup or membranous laryngotracheobronchitis, is rare. It is generally caused by bacterial superinfection of an antecedent viral upper respiratory infection. It is most commonly seen in children less than 3 years of age, with a median age of incidence at $4\frac{1}{2}$ years. Nearly all reported cases have arisen in those between 3 months and 13 years of age. Typically, 2 to 7 days of a croup-like syndrome is followed by worsening symptoms and the development of a toxic appearance over a period of several hours. Children appear septic or similar in appearance to those with epiglottitis, with a few important differences.[25] As a rule, children with bacterial tracheitis have severe inspiratory and expiratory stridor, cough with occasional thick sputum production, a raspy or hoarse voice, and no dysphagia. Children with bacterial tracheitis may also complain of a gnawing or burning substernal chest discomfort.

The history, physical, laboratory, and radiologic findings may help diagnose less obvious cases in nontoxic-appearing patients. Most patients will have a markedly elevated white count with an impressive left shift. Blood cultures are typically negative. AP and lateral neck radiographs usually demonstrate subglottic narrowing of the trachea. Irregular densities may be seen within the trachea and its borders may appear ragged and indistinct.

Management is similar to that of epiglottitis. Ideally, these patients should go to the operating room for sedation, intubation, and bronchoscopy. Culture and Gram stain of the mucopurulent secretions should be obtained at this time. Gram-stain findings may help guide antibiotic therapy. In less severe cases without respiratory distress, bronchoscopy may be performed without immediate intubation. This is the exception to the rule, however, as greater than 85 percent of cases will require intubation.

Antibiotics effective against *S. aureus*, *S. pneumoniae*, and beta lactamase–producing gram-negative organisms such as *H. influenzae* and *M. catarrhalis* should be given empirically. Vancomycin and a third-generation cephalosporin, such as cefotaxime or ceftriaxone, are commonly used.

FOREIGN-BODY ASPIRATION

Demographics

The peak incidence of foreign body aspiration is in the 1- to 3-year age group. At least 90 percent of cases are seen in children under age 4, but it has been reported in infants as young as 3 months. In children younger than 6 months, foreign-body aspiration is often secondary to a feeding given by "a helpful sibling."

The most commonly aspirated foreign bodies fall into two groups: foods and toys. [26] The most dangerous objects are those that are cylindrical or small, smooth, and round. Commonly aspirated foods include peanuts, sunflower seeds, raisins, grapes, hot dogs, and smaller sausages.

Because of the large number of deaths due to the aspiration of toys, the federal government instituted the Consumer Product Safety Act of 1979, [27] which has decreased the incidence of toy aspiration. However, watch groups warn that most toys are not properly evaluated for safety prior to marketing. Consumer scrutiny by direct inspection of the toy in addition to reading any warning label and the appropriate age range printed on its carton should be stressed in providing anticipatory guidance to the parents of young children.

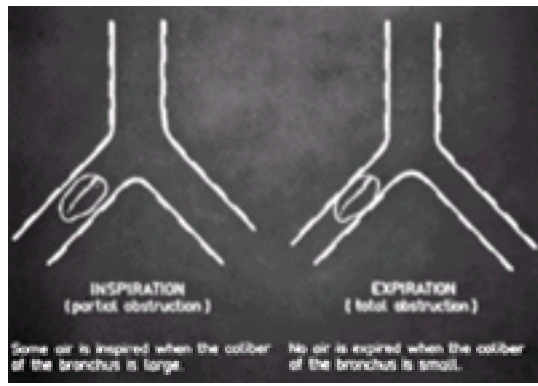
Although small, round metal objects typically do not cause tissue reactions, this is not the case with vegetable matter. Aspirated vegetable matter commonly causes an intense pneumonitis and subsequent pneumonia and/or suppurative bronchitis. Aspirated vegetable matter is commonly difficult to remove if not found early, as it swells with the absorption of moisture from the surrounding lung and, if left long enough, may even sprout.

At presentation, many patients with foreign-body aspiration may be completely asymptomatic with a normal physical exam. Some data suggest that the majority will present or have presented previously with symptoms consistent with but not specific for foreign body aspiration. The study of Laks and Barzilay demonstrated fever in 36 percent, wheeze in 35 percent, crackles in 38 percent, and tachypnea in 45 percent of patients at presentation. [29] Although the location of the aspirated foreign body does play a role in determining the symptoms and signs seen on presentation, there is overlap between groups. Classic dogma is that laryngotracheal foreign bodies cause stridor, whereas bronchial foreign bodies cause wheeze. Studies have shown, however, that about 30 percent of laryngotracheal foreign bodies and up to 10 percent of bronchial foreign bodies will demonstrate wheezing and stridor respectively. More importantly, a significant proportion will have no cough, wheeze, or stridor. It is true that the majority of patients presenting with severe immediate onset stridor or cardiac arrest after aspiration will be found to have a laryngotracheal foreign body. Patients with alternating wheezing and stridor may have a mobile foreign body. Other signs and symptoms of foreign-body aspiration may include cough, history of a choking episode, history of persistent or recurrent pneumonia, apnea, pharyngeal pain, or persistent symptoms of croup or asthma remaining after adequate treatment for 5 to 7 days. Foreign-body aspiration should be considered in all children given a diagnosis of "unilateral wheeze." Upper esophageal foreign bodies may impinge upon the posterior aspect of the trachea, leading to signs and symptoms of airway obstruction. Commonly the patient will present with stridor. Contrary to most cases of airway aspiration, patients with an esophageal foreign body typically will have dysphagia.

Diagnosis

Only one-fourth of patients who have aspirated a foreign body present within 24 h of the event. A high index of suspicion is required to diagnose this disorder. Foreign-body aspiration should always at least be considered in a young child with respiratory symptoms. If the clinical scenario clearly indicates the presence of a foreign body or airway obstruction, the hospital's protocol for obstructed airway should be implemented immediately. When a diagnosis is considered in a stable child, plain radiographs may be helpful if positive. Clinicians should never rule out a foreign-body aspiration based only on plain radiographs, as they may be entirely normal in up to one-third of bronchoscopically proven cases of foreign-body aspiration. Friedman's review found that only 7 percent of aspirated foreign bodies were radiopaque.[30]

Nonradiopaque foreign bodies at the laryngeal or tracheal locations may be identified by looking for telltale air contrast of the foreign body in relation to the surrounding normal soft tissues. Computed tomography (CT) may be helpful. In most cases, however, additional radiologic procedures are not ideal, and laryngoscopy and rigid bronchoscopy are indicated.

In cases of complete obstruction, segmental atelectasis may be seen on plain radiographs. In other cases, intermittent or partial obstruction occurs, creating a ball-valve effect (Fig. 129-4). In these cases, additional radiographs or fluoroscopy may be helpful. Partial obstruction, most commonly of the right mainstem bronchus, may cause obstructive emphysema of the involved lung by allowing air past the obstruction on inhalation but preventing its passage on exhalation. In cooperative, stable children, inspiratory and expiratory PA chest radiographs looking for hyperinflation of the involved lung with contralateral mediastinal shift and decreased excursion of the ipsilateral diaphragm may be indicated. Forced expiration by having a parent gently push on the child's lower abdomen during expiration may increase the sensitivity, but this has not been adequately studied. In young or uncooperative children, the ball-valve phenomenon may best be demonstrated by fluoroscopy. Bilateral decubitus PA chest radiographs may also be used but are less sensitive than fluoroscopy. The obstructed side will remain fully inflated with the ipsilateral diaphragm inferiorly displaced when the involved side is down. When the unobstructed side is down, it will show the normal findings of diaphragmatic elevation, rib splinting, and decreased relative volume compared to the upside (Fig. 129-5 and Fig. 129-6) . Series have demonstrated that bronchoscopically proven cases of foreign-body aspiration were definitively diagnosed preoperatively in only 60 percent of cases. Clinically suspected foreign-body aspiration should ultimately


be ruled out by bronchoscopy.

FIG. 129-4. Inspiratory and expiratory films in foreign-body aspiration.

FIG. 129-5. Normal decubitus film with left side down.

FIG. 129-6. Decubitus film, right side down, with foreign-body aspiration on the right side.

Although uncommon, esophageal foreign bodies may cause stridor. Esophageal foreign bodies more commonly are radiopaque and are, therefore, more easily seen on plain radiography. In general, narrow, flat foreign bodies such as coins will be oriented in the coronal plane if they are in the esophagus. The tracheal cartilages with the exception of the cricoid ring are incomplete and horseshoe-shaped, with the opening directed posteriorly. These anatomic characteristics cause most narrow, flat radiopaque tracheal foreign bodies to be sagittally oriented on radiography. Certainly exceptions to these generalities do occur. Radiolucent foreign bodies in the esophagus may be suspected in many cases due to an air-fluid level or soft tissue changes in the area just cephalad to the obstruction. Older children may complain of something stuck in the throat. Discussion of esophageal foreign-body management is found in Chap. 72.

Treatment

If a child who is presumed to have aspirated a foreign body has severe signs and symptoms but is maintaining the airway, alert, and able to speak, the predetermined obstructed airway protocol should be instituted. If local personnel are not able to remove the foreign body, a transport team experienced in the management of the difficult pediatric airway should be summoned to the patient's location. Ideally, the transport team will have a physician member trained and experienced in the removal of foreign bodies and in the management of the difficult pediatric airway. In general, the foreign body should be removed. If not possible, in the case of a supralaryngeal foreign body, the child should be electively intubated prior to transport. Exceptions may occur based on clinical circumstances. Racemic epinephrine or heliox may be an alternative.

The outcome of patients with laryngotracheal foreign-body aspiration and sudden collapse or cardiopulmonary arrest primarily depends upon appropriate bystander basic life support and emergency medical system response. Basic pediatric cardiopulmonary resuscitation (CPR) and foreign-body removal are discussed in Chap. 10. If no spontaneous breathing is detected, two slow breaths should be given. If air does not enter easily, causing a rise of the chest, then the head-tilt chin-lift maneuver should be reapplied and rescue breaths reattempted. If still no air enters the lungs, foreign-body obstruction is likely. The child's mouth should be opened, and if a foreign body is visualized, it should be removed.

Relief of obstruction in the infant is performed by holding the infant in the head-down prone position and giving up to five forceful back blows between the infant's shoulder blades with the heel of one hand. The infant is then turned to the supine position and given five quick chest compressions one finger's breadth below the intermammillary line. Once again, the oropharynx should be opened, and if a foreign body is visualized, it should be removed. If not, the airway should be opened by the jaw-thrust chin-lift maneuver and rescue breathing should be attempted. If air does not enter the lungs, the head should be repositioned and the jaw-thrust chin-lift maneuver reapplied and rescue breathing reattempted. If still no air enters the lungs, back blows and chest thrusts should once again be administered.

In a child over 1 year of age, the same sequence should occur with the exception that no back blows are given and the Heimlich maneuver is used instead of chest thrusts. The Heimlich maneuver should be performed in the standard fashion well below the tip of the xiphoid and slightly above the navel in the midline. Five distinct upward thrusts should be administered followed by reevaluation of the airway and another attempt at rescue breathing. If, after two cycles, the airway in the infant or child is not opened, allowing passage of air during rescue breathing, direct laryngoscopy should be used to locate and remove the foreign body, if possible using McGill forceps.

If, upon laryngoscopy the foreign body is noted to be below the cricoid ring within the trachea, an endotracheal tube should be placed. The child can often be ventilated after this maneuver. One must be absolutely certain that air is actually entering the lungs, however, and not just filling the pharynx and stomach. If, after an endotracheal tube is placed, the child still cannot be ventilated, the endotracheal tube should be gently advanced in hope of pushing the foreign body from the trachea into one of the mainstem bronchi. The endotracheal tube is then withdrawn to its normal position and ventilation is attempted. If the foreign body is visualized at the glottis but cannot be removed, a needle cricothyroidotomy may be lifesaving. Esophageal foreign-body removal is typically a semielective procedure. Those esophageal foreign bodies causing a respiratory embarrassment or serious potential for gastrointestinal injury due to puncture, laceration, or corrosion should be

removed by endoscopy. Esophageal foreign bodies not causing respiratory distress and thought to be of low risk to the gastrointestinal system if allowed to pass should be monitored for progression toward the stomach over 8 to 12 h.

PERITONSILLAR ABSCESS

Peritonsillar abscess in children most commonly presents in adolescents with an antecedent sore throat. Often there is a period of improvement prior to the onset of progressive worsening symptoms. Peritonsillar abscess may rarely occur in the younger child. Most commonly, patients appear acutely ill with fevers, chills, dysphagia, trismus, drooling, or a muffled or "hot potato" voice. When present, trismus is thought to be due to secondary inflammation of the neighboring pterygoid muscles. These children may have ipsilateral ear pain and torticollis. Torticollis may represent an attempt to relax the ipsilateral sternocleidomastoid muscle so as to decrease pressure on the peritonsillar space.

The peritonsillar space is not limited to the area surrounding the superior aspect of the tonsil visualized during the oropharyngeal exam. In fact, this potential space extends from the area lateral to the adenoids to the area of the pyriform sinus. Once a tonsillar infection has escaped the boundary of the tonsillar capsule, purulent material may flow relatively freely throughout this area. These anatomic relationships are important to remember, as they help to explain the classic physical findings of this disease process.

Careful visualization of the oral cavity is a must to reliably rule out this infection. The majority of cases will involve the superior aspect of the peritonsillar space, which can lead to discovery with meticulous examination. This may be nearly impossible in the young child with trismus. Diagnosis in this case is much more difficult. In this instance, some have recommended CT scanning of the oropharyngeal and cervical soft tissues, while others believe that this practice may be dangerous as the child could acutely obstruct the airway.[31] One possible alternative is an ultrasound examination at the bedside. Ultrasound has been used for drainage of peritonsillar abscess in difficult or complicated cases for some time with good success.

Typically, however, bilateral tonsillar erythema and exudate will be noted on exam. The uvula and anterior pillar of the tonsil on the affected side may be displaced away from the involved tonsil. The involved tonsil is, as a rule, anteriorly and medially displaced. Cervical adenopathy is often present but does not differentiate this process from the much more common causes of pharyngitis.

When uvular deviation, marked soft palate displacement, severe trismus, airway compromise, or localized areas of fluctuance are noted, the diagnosis of peritonsillar abscess can be made with confidence and no imaging study is required. In less obvious cases with minimal or no trismus, no localized areas of fluctuance, and no displacement of pharyngeal structures, differentiating peritonsillar abscess from peritonsillar cellulitis is difficult. If a child appears toxic, the diagnosis should certainly be considered peritonsillar abscess until proven otherwise. In younger children, imaging may be required to help differentiate these processes (see above). In nontoxic-appearing adolescents with good follow-up, involved parents, and findings most consistent with peritonsillar cellulitis, a trial of antibiotics may be the best choice for initial treatment. Penicillin or clindamycin are most commonly used.

The definitive treatment of peritonsillar abscess has changed significantly over the last decade. Previously, most cases were taken to the operating room for incision and drainage. Today, the majority of cases are treated as outpatients with needle aspiration, antibiotics, and pain control. Clearly, definitive follow-up is a must. The local protocol and individual physician comfort should dictate who performs the peritonsillar abscess aspiration. Very young and uncooperative children may be better served with formal incision and drainage in the operating room. The patient must be under control during needle aspiration to prevent injury the jugular vein and carotid artery.[30] In general, a single episode of peritonsillar abscess is not an indication for tonsillectomy.

RETROPHARYNGEAL ABSCESS

Demographics

Retropharyngeal abscess, although rare, is the second most commonly seen infection of the deep neck space.[33] The usual age range is 6 months to 4 years, with peak incidence in infants. Retropharyngeal abscess is quite rare after age 4 because repeated upper respiratory–type infections have obliterated the retropharyngeal lymph nodes by this age in most children. Most cases of retropharyngeal abscess evolve insidiously over a few days after a relatively minor upper respiratory infection or pharyngitis. Localized trauma to the posterior pharyngeal wall is another cause. This most commonly occurs in children who fall with a stick or similar object in their mouths.

Anatomic Relationships

Two major cervical lymph node chains enter the retropharyngeal space. They drain lymph not only from the nasopharynx but also the adenoids and the posterior paranasal sinuses. The retropharyngeal space is the potential space located between the posterior pharyngeal wall (more properly the buccopharyngeal fascia) and the prevertebral fascia. It extends from the base of the skull to the level of T1 or T2 in the area of the posterior mediastinum. It is the only deep neck space that extends the entire length of the neck. Anatomists believe that it may actually be in continuity with the prevertebral space, which extends to the level of the psoas muscle. For this reason or due to erosion through the prevertebral fascia, infections in the retropharyngeal space are known to have extended this entire length.

Signs and Symptoms

The symptoms most commonly found in patients with retropharyngeal abscess are, individually, not specific for this disease, but, taken together, they point toward the correct diagnosis. Although the symptoms are not commonly recognized in preverbal children, older children will complain of sore throat and most have a history of high fever. Other symptoms include dysphagia, decreased oral intake, and stiff neck.

In general, children with retropharyngeal abscess appear quite ill. Signs of retropharyngeal abscess include muffled voice, persistently hyperextended neck, inspiratory stridor, meningismus, and, if partial airway obstruction is present, respiratory distress and tachypnea. Ipsilateral cervical adenopathy has also been described but is not specific. Often a unilateral or bilateral retropharyngeal mass can be visualized during examination of the oropharynx. Unilateral masses are typically easier to detect than bilateral ones. Although palpation will commonly demonstrate fluctuance, this practice is dangerous and unnecessary. Laboratory testing is neither sensitive nor specific for retropharyngeal abscess.

Classic teaching is that a lateral neck radiograph should be obtained when one suspects this infection. This radiograph should be taken during inspiration with the neck extended so as to limit false-positive results. Diagnostic criteria for this radiograph are controversial (Fig. 129-7). Most would agree that the normal prevertebral soft tissue should be no wider at the second cervical vertebra than the diameter of the vertebral body at the same level. Radiographs showing slightly wider prevertebral soft tissues at this level without obvious bulging have a low specificity for retropharyngeal abscess. If the criterion for a positive test is considered two times the diameter of the vertebral body at the same level, the sensitivity is about 90 percent, but the specificity still not very good unless air-fluid levels are seen within the retropharyngeal soft tissues.[5] Still others have suggested using values of 7-mm prevertebral soft tissue width at C2 and 14-mm prevertebral soft tissue width at C6 as the criteria for the presence of a retropharyngeal abscess. The sensitivity and specificity of these criteria would seem to be quite dependent on the age and position of the patient. Ravindranath et al. found no correlation between the findings on lateral neck radiographs and CT scans in patients who clinically appeared to have a retropharyngeal abscess.[34] Therefore, definitive diagnosis should be based on CT scan results whenever possible. CT scan differentiates cellulitis from abscess and helps with surgical planning by demonstrating the degree of extension that has occurred.[5] It can also be used to clarify equivocal x-ray findings.[34] CT's sensitivity for retropharyngeal abscess is thought to be near 100 percent.[5] Unstable patients should be intubated before going to the CT scan suite. A physician accustomed to managing the difficult pediatric airway and appropriate equipment should accompany stable patients.

FIG. 129-7. Lateral neck view of a child with retropharyngeal abscess and widened retropharyngeal space.

Treatment

After the airway has been stabilized, the patient should receive analgesia and in most cases be prepared for surgery. Retropharyngeal cellulitis and very small localized abscesses may do well with antibiotics alone. All other cases should undergo an incision and drainage procedure. These decisions should be made in consultation with an otolaryngologist.

Most retropharyngeal abscesses are found to contain mixed flora when cultured. Common organisms include *S. aureus*, *S. pyogenes*, *S. viridans*, and beta lactamase–producing gram-negative rods such as *Klebsiella*. Oral anaerobes such as *Peptostreptococcus* species, *Fusobacterium* species, and *Bacteroides* species are also frequently seen. Antibiotic choice is controversial. Single-agent therapy with ampicillin/sulbactam may be best. Others use clindamycin and/or nafcillin with a third-generation cephalosporin. Some believe that high-dose penicillin G is most appropriate. In patients who are not allergic to penicillin, ampicillin/sulbactam provides the broadest coverage of the potential etiologic agents. Penicillin-allergic patients who are not known to be allergic to cephalosporins may achieve the best results with clindamycin and a third-generation cephalosporin.

Most patients do quite well, but complications do occur. Airway obstruction from sudden rupture of the abscess cavity can be rapidly fatal. Aspiration pneumonia, empyema, and frank asphyxia are described. Abscess extension throughout the neck and even to the psoas may occur. With extension, mediastinitis may develop. Erosion into the carotid artery and internal jugular vein thrombosis has been reported.

130 ACUTE PAIN MANAGEMENT AND SEDATION IN CHILDREN

Erica Liebelt
Nadine Levick

Appropriate and safe treatment of pain and anxiety in children is an integral component of an emergency department's clinical practice. Children are reported to be less adequately treated for pain than their adult ED cohorts. [1]

Pediatric pain experience, perception, and expression is determined by many factors, including the nature of the illness, injury, or procedure, developmental level, emotional and cognitive state, personal concerns, the meaning of pain, family attitudes, culture, and the environment. Basically, anything that is painful for an adult is likely to be painful for a child.

Children experience fear and anxiety in addition to physical pain, and all must be assessed and managed in an age and developmentally appropriate fashion. Parents or caregivers are also distressed about the child's pain. The QUESTT approach is a useful tool in addressing pediatric pain management. [2]

*Q*uestion the child for a description and location of the pain, using age and culturally appropriate and familiar language. Toddlers, and some older children who have difficulty understanding pain scales, can usually locate pain by pointing to the affected part.

*U*se a pain rating scale (Fig. 130-1 and Fig. 130-2) to provide a quantitative measure of pain intensity. Scales differ in their developmental appropriateness, i.e., the child's ability to grasp numeracy, abstract thought, pictorial appreciation.

FIG. 130-1. FACES pain scale. (From Wong DL, Hockenberry-Eaton M, Wilson D, et al: *Whaley and Wong's Nursing Care of Infants and Children,* 6th ed. St Louis, Mosby, 1999, p 1153. Copyright © Mosby. Reprinted by permission.)
FIG. 130-2. Oucher pain scale. (From Beyer JE, Aradine CR: Patterns of pediatric pain intensity: A methodological investigation of a self-report scale. *Clin J Pain* 3:130, 1987.)

*E*valuate behavior and physiologic responses to pain, such as facial expression. This is particularly useful in nonverbal children.

*S*ecure parents'/caregivers' involvement. They know their child best. Encourage their involvement in pain assessment, and facilitate participation in the management.

*T*ake cause of pain into account. The nature of the pathology or type of procedure permits anticipation of the type, duration, and intensity of pain.

*T*ake action: Ensure that all appropriate modalities are enlisted to treat the specific disorder and the pain, with ongoing assessment and documentation of pain until it is resolved.

A child who presents to the ED without a guardian or adult consent should have life- and limb-threatening conditions and severe pain managed without delay. Each institution should have policies that outline the procedures to follow in such cases.

PAIN ASSESSMENT

Well-validated pain assessment tools are available. [3] Tools specific to an age group or developmental stage should be selected. Children who are developmentally delayed, emotionally disturbed, or non-English speaking require special assessment. Pain severity in infants must be inferred from physiologic and behavioral responses, but for the toddler and older child, subjective measures can be included. Parental involvement in pain assessment can be a valuable adjunct for relieving pain and anxiety. [4] Finally, pain measurement should be repeated and improvement assessed until pain has abated.

Objective (Nonself-Report) Pain Assessment

Physiologic changes from pain include tachycardia, tachypnea, crying, sweating, blood pressure elevation, decreased oxygen saturation, pupil dilation, flushing or pallor, nausea, and muscle tension. These parameters can be muted in persistent pain and can be confounded by fear, anxiety, or fever. Specific behaviors associated with pain include withdrawal of the painful part, pulling ears, or refusing to use a body part. The characteristic facial features of an infant in pain have been described: brows—lowered, drawn together; forehead—bulge between brows, vertical furrows; eyes—tightly closed; cheeks—raised; nose—broadened, bulging; mouth—open, squarish.

A number of objective numeric scores have been developed and validated for the assessment of pain intensity for infants and nonverbal toddlers. The CRIES scale was developed for the assessment of postoperative pain in neonates, or those 32 to 60 weeks of gestation, with a score of 4 or more requiring intervention (see Table 130-1). The CHEOPS score, a 13-point behavioral score for infants, which ranges from 4 (no pain) to 13 (worst pain) (see Table 130-2), is reliable in children under 5 years of age.

	0	1	2
Cry quality	No	High pitched	Inconsolable
Requires O₂ for sat >95%	No	<30% O₂	>30% O₂
Changes in heart rate (HR) and blood pressure (BP)	= or < preop	Increase <20% preop	Increase >20% preop
Expression	None	Grimace	Grunt
Sleepless	No	Frequent waking	Constantly awake

TABLE 130-1   CRIES—for Neonates and Those 32 to 60 Weeks Gestation: A Score of 4 or More Requires Intervention

Item	Behavior	Score
Cry	No cry	1
	Crying/moaning	2 for either
	Scream	3
Facial	Smiling	0
	Composed	1
	Grimace	2
Verbal	Positive, without complaints	0
	Not talking/nonpain complaints	1 for either
	Pain complaints	2
Torso	Neutral	1
	Shifting/tense/upright/shivering	2 for either
	Restrained	2
Touch	Not touching	1
	Reaching/touching/grabbing	2 for either
	Restrained	2
Legs	Neutral	1
	Squirming/kicking/drawn up/tensed	2 for either
	Restrained	2

TABLE 130-2   CHEOPS (Children's Hospital of Eastern Ontario's Pain Scale)

Subjective (Self-Report) Pain Assessment

Self-reports can be used reliably for developmentally normal children over the age of four years. The pictorial FACES pain scale, which can be used for children age three years and up, demonstrates six cartoon facial expressions from no distress to extreme distress (Fig. 130-1): Face 0: happy, no hurt; Face 1: hurts a little bit; Face 2: hurts a little more; Face 3: hurts even more; Face 4: hurts whole lot; Face 5: hurts as much as you can imagine. It is useful in the ED setting as the scale is compact, can be purchased in the form of a pin or badge, and can pinned to a coat, making it always available. The Oucher pain scale is a photographic serial representation of children demonstrating the facial appearance of increasing intensity of pain. There are a number of versions of this assessment tool depicting various ethnic/racial groups. There are some limitations to its utility in the ED in that the photographic depiction cards are awkwardly large and are prone to being misplaced or removed. Numeric scales can be used with children age five years and older provided that they can count and have a concept of the relative magnitude of numbers. They also have the advantage of not requiring special photographic images. The Visual Analogue Scale (VAS) is a 0 to 10 numeric scale, which requires a degree of abstract thought, can be used in children age 7 years and older. The VAS and numeric scales are easy to use in the ED, and require no specific equipment.

PAIN TREATMENT

Nonpharmacologic Modalities

Cognitive behavioral and physical techniques are useful nonpharmacological adjuncts to pediatric acute pain management. [5] Several simple, age- and development-specific interventions can significantly decrease a child's anxiety and later pain perception. Cognitive behavioral modalities include reassurance and explanation, relaxation, distraction, music, psychoprophylaxis, biofeedback, and guided imagery. Environmental alterations, such as dimmed lights, a quiet room, or stereo headphones may relieve anxiety. Distraction techniques such as story telling, singing, and games are effective. Guided imagery can be used with children as young as three or four years who have a rich fantasy world and can be encouraged to imagine their favorite place or activity. General strategies for nonpharmacological pain relief techniques are outlined in Table 130-3. Table 130-4, Table 130-5, Table 130-6, Table 130-7 and Table 130-8 suggest strategies that are best suited for infants, toddlers, preschoolers, school-age children, and adolescents. Physical techniques include kinesthetic or tactile stimulation, heat and cold applications and massage as well as the more complex modalities of transcutaneous electrical nerve stimulator (TENS), acupuncture, acupressure and electro-acupressure.

Before Procedure	During Procedure	After Procedure
Preparation rehearsal	Parental presence	Medical play
Medical play	Distraction	Positive incentive reward
Breathing/relaxation	Breathing/relaxation	Breathing/relaxation
Guided imagery	Guided imagery	Tactile stimulation
Desensitization	Muscle relaxation	
Thought stopping	Music	
Hypnosis	Hypnosis	
	Positive self-talk	
	Comfort measures	
	Tactile stimulation	

TABLE 130-3   Nonpharmacological Pain Relief Techniques for Children

Cannot verbalize pain

Displays pain by:
  Crying and facial expressions
  Physiologic changes; i.e., heart rate and respirations

Receptive to voice, touch, texture (i.e. warm blanket or heated room)

Benefit from tactile stimulation:
  Rocking, swaddling, patting, stroking and massaging

Comforted by:
  Sucking a pacifier during a procedure
  Sucking on the breast or bottle after a procedure

Can be distracted using bubbles, novel toys

TABLE 130-4   Highlights of Child Development and Nonpharmacologic Pain Management Specifics: The Infant (0 to 12 Months)

Capacity for basic reasoning and some understanding of causality

Age-appropriate language necessary

Benefit from tactile stimulation:
  Holding, patting, stroking, massage of the area

Easily distracted with:
  Books, puppets, music, action rhymes, bubble blowing, or other toys

Parental presence:
  Give parent a task
  Can help to calm a child
  Not to hold the child down or to performs any painful procedures

Cognitive/behavioral:
  Guided imagery
  Comfort from a blanket or toy from home
  Medical play with a doll and equipment before procedure
  Toy or small keepsake is a good reward after procedure

TABLE 130-5   Highlights of Child Development and Nonpharmacologic Pain Management Specifics: The Toddler (1 to 3 Years)

Thinks intuitively, believes there is a cause for everything

Does not understand temporal causality

Longer attention span and a higher level of interest than a toddler

Mixes fact with fiction, thinks magically

May still need to be held and stroked

May benefit from a comfort toy/blanket from home

Cognitive/behavioral:
  Some preschoolers like to watch the procedure, can hold pieces of equipment, etc. in preparation
  A doll and medical equipment can be used to explain procedure
  Guided imagery to remember and play out a super hero story or a cartoon character
  Distraction music, story telling, singing a song, remembering a movie, reciting nursery rhymes
  A reward of a toy after procedure with discussion of this prior to procedure is effective

TABLE 130-6   Highlights of Child Development and Nonpharmacologic Pain Management Specifics: The Preschooler (4 to 5 Years)

Concrete operation, logical reasoning, can concentrate, delays gratification, knows the function and names of body parts, understands time, and generalizes from experience

May still need and benefit from a hug, a pat or a massage

Procedural rehearsal and preparation is effective

Benefit from: Verbal reward along with a toy or other incentive

Cognitive/Behavioral:
  Guided imagery used prior to and during the procedure
  Can be taught breathing and muscle relaxation techniques prior to the procedure
  Can use thought stopping and positive self-talk during procedure
  Parental presence is often welcome with this group, but ask the child
  May like to use a headset and listen to music or watch television or play video game

TABLE 130-7   Highlights of Child Development and Nonpharmacologic Pain Management Specifics: School Aged Child (6 to 12 Years)

Can deal with reality, uses abstract thinking, can synthesize direct information

Apprehension about self-image

Often does not want a parent in the room for procedures; ask the patient to decide

Any cognitive/behavioral techniques can be used

Discuss openly issues involving pain, and allow the teen to choose useful techniques

TABLE 130-8   Highlights of Child Development and Nonpharmacologic Pain Management Specifics: Adolescence (>13 Years)

Pharmacologic Modalities

The choice of a pharmacologic agent for a pediatric patient's pain management should consider the nature of the procedure, the duration of the procedure, and the most appropriate route of administration. It should be made in conjunction with nonpharmacological techniques. Pharmacologic analgesic therapy can be systemic (opioids and nonopioids), or nonsystemic (local anesthetic agents with topical, local, or regional administration). There is a continuum between systemic analgesia and sedation. When narcotics are used, closely monitor patients, precalculate the appropriate dose of naloxone, and have resuscitation equipment readily available. Suggested systemic medications, dosages, routes of administration, and comments for non-opioid analgesics are outlined in Table 130-9 and for opioids in Table 130-10. Nonsystemic medications and techniques for administration, such as local anesthetic (LA) topical, local and regional procedures are discussed in detail in Chap. 32.

TABLE 130-9   Non-Opioid Analgesics

TABLE 130-10   Opioid Analgesics

Avoidance of painful intramuscular and subcutaneous injections is particularly important when treating children. The intravenous route is recommended for titration of narcotic medications. Noninvasive topical or mucosal techniques for the delivery of systemic pharmacologic agents should be used where appropriate.

Systemic Pharmacologic Agents

ACETAMINOPHEN   Acetaminophen is a commonly used analgesic and antipyretic that is useful for mild pain and as an adjunct for moderate pain in combination with codeine. Acetaminophen is rapidly absorbed from the gastrointestinal tract and is distributed throughout most body tissues. The plasma half-life is 1.25 to 3 h, but may be increased by liver disease and following overdosage. Elimination of acetaminophen is principally by liver metabolism (conjugation) and subsequent renal excretion of metabolites.

ASPIRIN   Salicylates such as aspirin exhibit analgesic, anti-inflammatory, and antipyretic activity, and inhibit platelet aggregation. There is a strong association between Reye's syndrome and the use of aspirin in children, but the pathogenesis has not been determined. Aspirin must be used with caution, if at all, in children. Dehydrated patients who are more susceptible to salicylate toxicity even in therapeutic doses. The FDA advises that aspirin not be used in children with varicella or influenza.

NSAIDs   Ibuprofen is a racemic mixture of two isomers. It has anti-inflammatory, antipyretic, and analgesic properties. The analgesic effect is related to inhibition of prostaglandin synthesis. It is used for children over six months of age as an alternative to acetaminophen. The most frequent adverse effects involve gastrointestinal (GI) tract irritation and renal dysfunction. Renal failure has been reported. Dehydrated patients are at higher risk for renal failure. There is a rare association with aseptic meningitis and severe hepatic reactions. Safety and efficacy have been established for children over six months of age.

Ketorolac is a pyrrolizine carboxylic acid derivative. It is an anti-inflammatory, antipyretic, and potent analgesic agent with similar actions and side effect profile to other NSAIDs, with slightly less GI irritation when given IV/IM than for oral NSAIDs. Overall, ketorolac has a lower incidence of side effects and longer duration of action than morphine. It acts peripherally, does not affect opiate receptors, and does not cause respiratory depression. Ketorolac is the only IV NSAID approved by the FDA. It may be used in combination with opioids, but has an opioid-sparing effect. Thus, smaller opioid dosages may provide adequate pain relief. It should not be admixed in the same syringe as opiates or hydroxyzine due to incompatibilities. Ketorolac also has good oral bioavailability, but has not been shown to be more efficacious than less expensive NSAID oral preparations. There is limited data on the use in children less than 16 years of age. In addition to GI irritation and platelet effects, ketorolac has been reported to adversely effect renal function, particularly in the dehydrated patient. Additionally, an increased risk of renal failure in patients on diuretics has been reported. Because ketorolac is highly protein-bound, it should be used cautiously in the presence of other protein-bound drugs such as warfarin. Interactions with renal clearance of lithium resulting in increased lithium levels have been reported. There is potential for cumulative adverse effects if ketorolac is combined with aspirin or other NSAIDs. There have been reports of bronchospasm and anaphylactoid reactions in adults. Duration of ketorolac therapy should not exceed five days.

OPIOIDS   Narcotic or opioid medications remain the mainstay of analgesic pharmacotherapy for severe pain. Opioids include the phenanthrene derivatives (e.g., morphine, codeine, and hydromorphone), the phenylpiperidine derivatives (e.g., meperidine and fentanyl) and the diphenylheptane derivative (methadone). Close clinical and physiologic monitoring is essential with the use of opioids in the pediatric ED patient, as is an understanding of the relationship between level of pain, narcotic dose, and conscious state. Opioids in general have analgesic effects at lower doses than those required for sedation. A detailed discussion of opioid drugs is outlined in Chap. 34.

Morphine remains the gold standard opioid for the management of moderate to severe acute pain; it is widely used and easily reversed with naloxone. Its oral bioavailability is poor. Infants less than three months old are particularly sensitive to its respiratory depressant effects.

Hydromorphone (Dilaudid) is a hydrogenated ketone of morphine. It is well absorbed following oral, rectal or parenteral administration. It has a more rapid onset and a

shorter duration of action than morphine when given orally. Side effect profile is similar to morphine but less marked.

Meperidine is a synthetic derivative of morphine and is one-tenth as potent an analgesic per milligram of drug. Onset and duration of action is shorter than morphine and meperidine has slightly better oral bioavailability. Normeperidine (6- *N*-desmethylmeperidine) is a toxic meperidine metabolite excreted through the kidney. Normeperidine is a cerebral irritant that can cause effects ranging from dysphoria and irritability to convulsions. Because of its unique toxicity, meperidine is contraindicated in patients with impaired renal function and in those receiving antidepressants of the monamine oxidase inhibitor class. These effects have been observed even in young, otherwise healthy patients who were given sufficiently high doses of normeperidine. Therefore, meperidine should be reserved for very brief courses in otherwise healthy patients who have demonstrated an unusual reaction or allergic response during treatment with other opioids, such as morphine or hydromorphone.

Fentanyl is a short-acting synthetic opioid, 80 to 100 times as potent as morphine. When administered intravenously it has a rapid onset of action of less than 1 min and a short duration of action (15 to 30 min), due to its high lipid solubility and rapid redistribution. The major ED role for fentanyl is as an analgesic component for conscious sedation. In infants, it is less of a cardiovascular and respiratory depressant than morphine, and causes less histamine release, but the respiratory depressant effect may lag behind the analgesic effect. Fentanyl is associated with an idiosyncratic reaction of chest wall rigidity. This is more likely to occur with a high bolus dosing (5 µg/kg), but can occur with lower dosing (1 to 2 µg/kg). Small infants, less than 6 months of age, are at greater risk. The management approach for chest wall rigidity includes: naloxone 0.001 to 0.01 mg/kg or neuromuscular blockade (succinylcholine 2 mg/kg, or rocuronium 0.6 to 1.0 mg/kg, or pancuronium 0.1 mg/kg) and mechanical ventilation with 100 percent oxygen. Given the high concentration of fentanyl, exercise caution to avoid inadvertently flushing a residual bolus of the drug remaining in the IV line.

The new oral transmucosal fentanyl citrate (OTFC) (Oralet) preparation is a raspberry-flavored fentanyl-impregnated lozenge that allows administration of an opioid through oral transmucosal absorption. This nonthreatening "needleless" mode of drug delivery has been demonstrated in recent years to be an efficacious and safe method for inducing conscious sedation in children undergoing diagnostic or therapeutic procedures that are painful, such as bone marrow aspiration, laceration repair, gynecologic examination, and fracture reductions. [6] The transdermal fentanyl patch currently has no role in ED acute pain management. Steady-state levels are not reached until 12 to 24 h, and the subdermal depot remains for 24 h after the patch is removed.

Codeine is readily absorbed from the gastrointestinal tract, and a very useful agent in the ED for adjunct oral pain therapy with acetaminophen. Codeine can be given IM, but IV administration is not recommended due to a higher side-effect profile. At therapeutic doses, the analgesic effect reaches a peak within two hours and persists between four and six hours. The plasma concentration does not correlate with brain concentration or relief of pain. Codeine crosses the blood-brain barrier, is found in fetal tissue and breast milk, but is not bound to plasma proteins. The plasma half-life is about 2.9 h. The elimination of codeine is primarily by the kidneys, and about 90 percent of an oral dose is excreted by the kidneys within 24 h of dosing.

ADJUNCTS   Benzodiazepines have sedative, anxiolytic, amnestic, and muscle-relaxant properties. They have no analgesic action. They are adjuncts for acute pain management in the child over the age of 10 years where anxiety or muscle spasm is a prominent feature. Benzodiazepines can be given IV, orally, or rectally. Benzodiazepines are discussed in detail in the following sedation section.

Hydroxyzine is an H_1-receptor antagonist that is indicated for anxiety and allergic pruritus; it also has sedative properties. Hydroxyzine has no analgesic action. It is available in oral and IM preparations (dosage 0.5 mg/kg oral or IM); IV administration is not recommended. It should be considered as a second-line drug to benzodiazepines, and IM injections generally should be avoided for pain-control medications. Promethazine (Phenergan) is also an H_1-receptor antagonist, with sedative, anxiolytic, and antiemetic properties, in addition to providing relief of minor allergic conditions. It is not recommended for children less than two years of age. Promethazine can be given orally, rectally, IV (slowly), or IM. The evidence to support a synergistic analgesic effect of H_1-antagonists with opioids is limited, and they may potentiate the sedative effects of opioids.

Nonsystemic Pharmacologic Agents

Nonsystemic topical, local and regional techniques are of great value in the management of painful conditions or procedures fvor the pediatric ED patient and may minimize the need for use of narcotics and sedatives. The amide and ester local anesthetic medications (lidocaine, bupivacaine, prilocaine, and procaine) and refrigerant agents are the most commonly used nonsystemic agents. Techniques range from topical applications such as tetracaine, adrenaline, and cocaine (TAC); lidocaine, epinephrine, and tetracaine (LET); eutectic mixture of local anesthetic (EMLA); and ethyl chloride, local infiltration of LA, peripheral nerve block, hematoma block, and IV Bier's block. The general discussion of these agents as well as specific comments regarding their use in children is found in Chap. 32.

CONSCIOUS SEDATION

Conscious sedation is a medically controlled state of depressed consciousness that allows protective reflexes to be maintained, retains the patient's ability to maintain a patent airway independently and continuously, and permits appropriate response by the patient to physical stimulation or verbal command.

The goals of conscious sedation are to minimize fear and anxiety, maintain patient safety, control behavior, provide amnesia, and return the patient to a state for safe discharge. Factors involved in the selection of the sedation regimen include the specific procedure being performed, duration of procedure, the developmental age and physical condition of the child, and physician experience with the agents. Practice guidelines for the sedation of children are noted in Table 130-11.

TABLE 130-11   Universal Practice Guidelines for Sedation in Children

In the ED environment, conscious sedation should only be performed by physicians appropriately skilled in airway and resuscitation management, and only for patients considered to be class I or class II (Table 130-11). The American Academy of Pediatrics and the American Society of Anesthesiologists (ASA) have published guidelines for monitoring and management of pediatric patients during and after sedation for diagnostic and therapeutic procedures. [7,8] Salient features of these documents are discussed below and should be incorporated into the ED's sedation policy.

Patient Evaluation

The first step is assessment of the patient for sedation in the emergency department. The history should identify any abnormalities of the major organ systems and airway; previous adverse experience with sedation, analgesia, or anesthesia; any neurologic disorder or impairment; medications and allergies; and time and nature of the patient's last oral intake. Focused physical examination should include baseline vital signs and oxygen saturation, evaluation of cardiorespiratory status and the oropharynx and airway.

Appropriate candidates for sedation protocols in the ED are healthy patients or patients with mild systemic disease (Table 130-12). Children with severe systemic disease (ASA III or IV); infants <3 months of age; premature infants <60 weeks postconceptual weeks of age; and children with underlying respiratory/airway disease,

neurologic conditions, CNS injury, multiple trauma, or liver/kidney disease are at increased risk for sedation complications and require consultation with an anesthesiologist.

I	Healthy, no underlying organic disease
II	Mild or moderate systemic disease that does not interfere with daily routines
III	Organic disease with definite functional impairment
IV	Severe disease that is life threatening
V	Moribund
E (suffix)	a procedure undertaken as an emergency

Abbreviation: ASA, American Society of Anesthesiologists.

TABLE 130-12   ASA Physical Status Classification System

For nonemergent sedation, fasting for two hours from clear liquids and four to eight hours for solids and nonclear liquids, is recommended. Children requiring urgent or emergent sedation despite recent oral intake should not receive deep sedation to avoid depression of protective airway reflexes that may result in aspiration. Procedures should be delayed, if possible, to facilitate gastric emptying that may decrease the risk of regurgitation and aspiration. Ranitidine (1 mg/kg IV) and metoclopramide (0.15 mg/kg IV) given 30 to 60 min prior to sedation may increase gastric pH and reduce gastric volume. Obese patients or patients with a history of gastroesophageal reflux may also benefit from premedication with these drugs.

Informed consent should be obtained from the child's parent or legal guardian with explanations about the procedure, sedation and analgesia plan, and associated risks. All information can be documented on a sedation assessment and monitoring chart.

Equipment and Monitoring

The ED must be appropriately equipped for administering sedation to children of all ages and sizes. An oxygen source capable of delivering >90 percent oxygen and positive pressure ventilation, appropriate size masks, and functioning suction apparatus with Yankauer-tip catheters must be at the child's bedside. Appropriately-sized laryngoscopes, endotracheal tubes, intravenous catheters, and emergency medications must be readily available. Airway management and breathing equipment must be checked before each sedation procedure.

The child should be attached to a cardiac monitor and pulse oximeter. During the procedure, one person whose sole responsibility is monitoring the patient, preferably a registered nurse with basic life support and PALS training, or a physician who is not performing the procedure, must be present. Continuous quantitative monitoring of oxygen saturation (pulse oximetry) and heart rate, and intermittent monitoring of respiratory rate and blood pressure should be recorded at 5- to 10-min intervals. Level of consciousness (response to verbal commands/tactile stimuli) and pulmonary ventilation (observing chest wall excursion and/or auscultation of breath sounds and/or capnography) should also be monitored. All drugs and doses administered must be clearly documented, with special attention to calculation of single and cumulative doses in mg/kg.

After the procedure, the child must be observed and monitored in an area with suitable equipment and vital signs recorded every 15 minutes. Pulse oximetry should be maintained until the patient is fully alert. Observation should be continued until all discharge criteria are met (Table 130-13). Appropriate discharge instructions with follow-up should be conveyed to the child's caretaker.

Cardiovascular function and airway patency are satisfactory and stable.

The patient is easily arousable, and protective reflexes are intact.

The patient can talk (if age-appropriate).

The patient can sit up unaided (if age-appropriate).

For a very young or handicapped child, incapable of the usually expected responses, the pre-sedation level of responsiveness or a level as close as possible to the normal level for that child should be achieved.

The state of hydration is adequate.

TABLE 130-13   Recommended Discharge Criteria

SEDATION AGENTS AND TECHNIQUES

Indications for sedating infants and children in the emergency department include diagnostic procedures (CT scans) and as an adjunct to analgesia and anesthesia for painful procedures.[9] Table 130-14 lists common pharmacologic options for sedation. Nonpharmacologic techniques should also be considered when preparing to sedate children and should not be forgotten in the midst of a busy emergency department. As previously discussed, parental involvement, verbal preparation, relaxation, tactile stimulation, and distraction techniques are all effective. Manual restraint (sheets or papoose boards) may be required as an adjunct to the nonpharmacologic and pharmacologic approach to procedures for infants and toddlers. Parent should not be requested to provide or be responsible for the restraint of the child, but rather should be encouraged to provide comfort.

TABLE 130-14   Sedative Drugs for the Pediatric Patient

An ideal pharmacologic agent for sedation is one that is effective, has rapid onset, is easily titratable with a predictable duration of action, is quickly eliminated or

reversible, has no adverse effects, and is easy and painless to administer. Although the ideal agent does not exist, there are several good drugs and regimens that when administered appropriately can provide safe and adequate analgesia and/or anesthesia.

Sedatives can be administered by a variety of routes including IV, IM, oral, rectal, sublingual, transmucosal, and intranasal; each route has advantages and disadvantages. Intravenous administration allows the most precise titration of drug to the desired effect; IM administration usually is painful and not titratable. Oral and transmucosal routes are more readily accepted by children than nasal or rectal routes. Despite the options for administration routes, side effects can occur with any route of administration.

Benzodiazepines

Benzodiazepines provide anxiolysis and amnesia but not anesthesia. They can be used alone as a sedative, or in conjunction with a narcotic or local anesthetic for a painful procedure. Midazolam (Versed) is a short-acting benzodiazepine that has an onset of action within 5 min and a duration of action of 30 to 45 min. Midazolam is safe and effective for use in the ED in children undergoing laceration repair, fracture reduction, and other painful procedures. [10] Adverse effects include respiratory depression and paradoxical inconsolability. [11] Anecdotally, this latter effect appears to happen with increased frequency in children with attention deficit hyperactivity disorder, and is reversible with flumazenil.

Diazepam is a longer-acting benzodiazepine that has been used extensively as a sedative for children and has amnestic properties. Diazepam can be used for extended diagnostic procedures and for muscle relaxation for orthopedic reductions. It has been largely replaced by midazolam.

Sedative/Hypnotics

Chloral hydrate is a pure sedative/hypnotic with no analgesic properties that is used primarily for sedation of infants and young children requiring painless diagnostic procedures. [12] The time to sedation is relatively long (45 to 60 min) and its effects can last several hours because of its active metabolite, making it an impractical agent for use in the ED. Adverse effects include nausea, vomiting, and paradoxical delirium/excitement, which are not reversible. Serious adverse effects including airway obstruction and death have been reported with chloral hydrate use.

The short-acting barbiturates can provide rapid onset of sedation for painless procedures such as computed tomography and magnetic resonance imaging studies in children with no preexisting central nervous system depression. [13] Again, they have no analgesic or amnestic properties. Intravenous pentobarbital has an onset of action within 30 s and children are usually appropriately sedated within 5 min. Its duration of action is 30 to 60 min, making it a better choice for children undergoing emergent procedures. Respiratory and central nervous system depression can occur which can be exacerbated in the presence of other depressants such as opioids and benzodiazepines.

Narcotics

A discussion of individual narcotics is found in the preceding analgesia section. Narcotics can be administered intravenously in conjunction with an anxiolytic such as benzodiazepines for sedation for painful procedures.

The oral transmucosal fentanyl citrate lozenge (Oralet) comes in three dosage strengths (200, 300, and 400 μg) and is administered over 10 to 20 min by asking the patient to suck, not chew, the lozenge. It can be removed by the physician or "self-removed" by the patient when sedation is achieved. Onset of action is within 5 to 15 min with maximum effect occurring in 20 to 30 min. Suitable candidates for OTFC are children at least two years of age, weighing greater than 15 kg. Children receiving MAO inhibitors in the past 14 days should not use this drug. Vomiting is the most frequently reported adverse affect as well as pruritus and hypoventilation.

Nitrous Oxide

Limited studies in children have shown nitrous oxide (N_2O) to be an effective and safe sedative/analgesic either alone or in combination with a local anesthetic for laceration repair, orthopedic procedures, and other minor surgical procedures. [14],[15] It offers many advantages over other pharmacologic agents for use in the outpatient setting and emergency department. It provides analgesia, anxiolysis, and sedation without the need for IV line placement, has a low incidence of complications and adverse effects, and can result in shorter ED lengths of stay due to rapid recovery. Nitrous oxide interacts with the endogenous opioid system to confer analgesia and appears to blunt the patient's reaction to pain. It produces a sense of euphoria, relief from anxiety, and an almost "detached" attitude toward pain and the patient's surroundings.

In the outpatient setting, nitrous oxide should be delivered via a fixed-ratio mixture of nitrous oxide to oxygen, usually 50 percent N_2O:50 percent oxygen (oxygen concentration must be a minimum of 30 percent) by a self-administered demand-valve apparatus with a scavenger device. This mode of administration protects against equipment failure and/or human error, which may result in too high concentration of nitrous oxide. The gas is routinely delivered by an inspiratory effort of the patient, minimizing the risk of loss of consciousness and protective reflexes because the mask will fall off when the patient is sedated. The gas/oxygen mixture can be inhaled through a face mask, mouthpiece, or nasal hood in which a flavored Chapstick lining or concentrated "child-friendly" scent can be applied to disguise the odor of the gas. For younger children unable to hold their own mask, the physician or parent can assist in the delivery of the mixture by placing the mask lightly on the child's face.

Nitrous oxide has a rapid onset of action of three to five minutes and a short duration of action on withdrawal of three to five minutes. The gas is not metabolized, and is eliminated by the lungs unchanged. Short-term use has no significant effects on other organs. The most common reported side effects are nausea and vomiting. Diffusional hypoxia is another potential concern since nitrous oxide rapidly diffuses out of the blood and into the alveoli, where it can displace oxygen and cause hypoxia. This theoretical concern has not been supported by clinical evidence. Nevertheless, supplemental oxygen should be administered throughout the recovery phase. Nitrous oxide use in the ED also has the potential for abuse, environmental contamination, and potential teratogenic effects especially with chronic exposure. The use of nitrous oxide is contraindicated in patients with pneumothoraces, bowel obstruction, middle ear effusions, and patients undergoing procedures using balloon-tipped catheters because of its rapid diffusion into gas-collecting areas of the body, which could cause acute expansion, over distension, and perforation. It also should be avoided in patients with head injuries, psychiatric diseases, or drug intoxication. Because of nitrous oxide's opioid agonist properties, it may result in deep sedation or general anesthesia if combined with a sedative or opioid. Thus, extreme caution should be exercised when administering it to a patient with recent administration of either of these medications. [16]

Ketamine

Ketamine is a unique sedative analgesic that has been studied extensively in children undergoing outpatient procedures. [17],[18] and [19] A derivative of phencyclidine, ketamine produces a dissociative effect resulting in a trance-like cataleptic state, providing a combination of sedation, amnesia, and analgesia. Spontaneous respirations and pharyngeal muscular tone are maintained, as well as protective airway reflexes of coughing and swallowing. Ketamine has very few negative inotropic effects making it a reasonable option for acutely ill patients. Its sympathomimetic actions may produce mild to moderate increases in heart rate, blood pressure, and cardiac output. However, in the catecholamine-depleted child, ketamine may result in hypotension due to unopposed direct vasodilatory effects. It also is a good option for the difficult-to-control child with mental retardation or behavioral disorder where initial IV access can be difficult. Clinical effects from intravenous and intramuscular ketamine occur within several minutes and last about 30 min. It has also been shown to be effective when administered via the transmucosal, oral, and rectal routes. [20]

Because ketamine stimulates salivary and tracheobronchial secretions, it should be administered concurrently with an anticholinergic drug, either atropine or glycopyrrolate. Both agents may be combined in a single IM injection. Hallucinatory emergence reactions have been reported with ketamine although less frequently in children less than 10 years of age. These reactions can be reduced with premedicating the child with a benzodiazepine such as midazolam. However, this combination may prolong the patient's recovery time because benzodiazepines will inhibit ketamine's metabolism. Ketamine can also cause increased intracranial and intraocular pressure because of increased cerebral blood flow.

Other adverse effects are nystagmus, random limb movement, and vomiting. Ketamine has the potential for causing laryngospasm and thus should not be used in patients with upper respiratory or pulmonary infections or who have increased salivary secretions. If laryngospasm occurs, the child should be ventilated with a bag-valve mask. Paralysis and emergent intubation must be performed if this is unsuccessful. Contraindications to ketamine's use are age £3 months; history of

airway instability or tracheal stenosis; procedures involving stimulation of the posterior pharynx; cardiovascular disease including congestive heart failure and hypertension; head injury associated with loss of consciousness, altered mental status, central nervous system masses, abnormalities, or hydrocephalus; poorly controlled seizure disorder; glaucoma; acute globe injury; or psychosis.

Other Agents

Propofol is an ultrashort-acting intravenous anesthetic marketed in the United States as Diprivan. It has been reported as a safe and effective nonanesthetic sedative for adults undergoing fracture reduction, reduction of joint dislocations, minor surgical procedures (I&D of abscesses), cardioversion, and chest tube placement in the ED.[21] It has been used in children in the ED for difficult fracture reduction, incarcerated inguinal hernia reductions, and cardioversion, although there are no published reports. Propofol's onset of action occurs within seconds and its duration of action is extremely short, requiring continuous infusion for maintenance of clinical effects. After discontinuation of the drug in sedative doses, patients are usually awake and responsive within minutes. It does not possess any analgesic properties in sedative doses and must be used in conjunction with narcotics for painful procedures. Propofol has potent dose-related respiratory depressant effects, may quickly result in deep sedation, and may produce hypotension. More experience is needed before it can be recommended for routine use in children in the ED.

In the past, the "DPT cocktail," consisting of Demerol (meperidine), Phenergan (promethazine), and Thorazine (chlorpromazine), was a popular sedative/analgesic choice for children in the emergency department. Unfortunately, the intramuscular route does not allow for titration of effects and its onset of action is variable. The wide range of doses used and combination of three sedatives adds to confusion and potential for serious respiratory depression. In addition, the efficacy of this "cocktail" can be variable while its duration of action can be several hours, not making it a preferable choice for sedation in the ED. [22]

Reversal Agents

Naloxone is an opioid antagonist and should be readily available for reversal of respiratory depression, apnea, and severe hypotension. It can be administered in incremental doses of 0.01 to 0.1 mg/kg (maximum single dose 2 mg) to the desired reversal of life-threatening effects, because it would not be desirable to reverse all of the analgesia in a patient undergoing a painful procedure. Naloxone's duration of action is short (approximately 45 min); thus, reversal of toxic effects of longer-acting opioids, such as morphine, or large doses of short-acting opioids, such as fentanyl, may require additional doses.

Flumazenil is a benzodiazepine antagonist that reverses the central nervous system depression and, to some degree, respiratory depression secondary to inadvertent excess sedation.[23] Incremental doses of 0.01 to 0.02 mg/kg (maximum single dose 0.2 mg) every 1 to 2 min can be titrated to the desired reversal effect. Respiratory depression and hypoventilation should be managed with standard airway management techniques and assisted ventilation if necessary. Flumazenil has also been shown to reverse the paradoxical delirium secondary to midazolam. [24] In the setting of a polypharmaceutical overdose, flumazenil should not be administered. It should not be used in patients on chronic benzodiazepine therapy or on tricyclic antidepressant medications because of the risk of seizures. Flumazenil's duration of action is about 40 to 60 min. Because the duration and degree of reversal depends on the plasma concentrations of benzodiazepine as well as the amount of flumazenil given, the sedative and respiratory depression effects of the benzodiazepine may last longer than the antagonism produced by flumazenil. Both drugs should be readily available and appropriate doses calculated prior to initiation of the procedure.

131 PEDIATRIC EXANTHEMS

Michael S. Weinstock
Michael S. Catapano

Rashes with diverse etiologies can look alike. Assessing the signs and symptoms preceding or presenting with the exanthem and obtaining an accurate history of prior immunizations, potential human or animal contacts, and recent environmental exposure helps to determine the diagnosis. The various etiologic agents and associated exanthems are noted in Table 131-1 . Further discussion of cutaneous disorders is found in Section 19, "Disorders of the Skin."

TABLE 131-1   Differential Diagnosis of Exanthems

BACTERIAL

Bullous Impetigo

Bullous impetigo, or staphylococcal impetigo, is a local skin infection caused by phage group II staphylococci. The staphylococci produce an epidermolytic toxin that acts locally to cause separation of the skin at the granular layer, giving rise to bullae. The infection occurs primarily in newborn infants and young children. The characteristic skin lesions of bullous impetigo are superficial, flaccid, thin-walled bullae that occur most often on the extremities but can occur anywhere. They range in size from 0.5 to 3 cm. They can arise from normal skin or may have a thin, red halo. The bullae are filled with a clear, pale-to-yellow fluid and rupture easily, leaving a moist, denuded base that dries rapidly with a shiny coating. Extensive areas of skin may be involved if untreated.

The clinical appearance of the lesions usually makes diagnosis easy. However, single lesions or extensive involvement may not be as typical. Staphylococci cultured from fluid from aspirated bullae will establish the diagnosis.

Systemic antistaphylococcal antibiotics, usually oral, along with local wound cleansing and topical antibiotics (such as neosporin) are effective in eradicating the infection. Prognosis for complete recovery is good.

Impetigo Contagiosum

Impetigo is a superficial pyoderma caused by infection with staphylococci, although group A b-hemolytic streptococci may also be cultured. It is a common skin infection, primarily affecting young children, especially in warm, humid conditions. Impetigo can arise at the site of insect bites or superficial cutaneous trauma; sometimes there is no apparent predisposing skin lesion. Fever and systemic signs are uncommon.

The skin lesions start as small erythematous macules and papules. These develop into discrete, thin-walled vesicles which become pustular and quickly rupture (see Fig. 131-1). As the vesicles rupture, a yellow fluid forms an exudate, which dries to form a stratified golden, yellow crust that accumulates. The crusts can be readily removed, leaving a smooth, red surface. The crusts can spread the infection to other parts of the body. Initially, the lesions are discrete, but they may enlarge and become confluent. Local adenopathy may be present. The infection occurs most frequently on the face, neck, and extremities.

FIG. 131-1. Impetigo contagiosum. [From Marples RR, Leyden JL: Bacterial infections, section I. Fundamental cutaneous microbiology, in Moschella SL, Hurley HJ

The diagnosis of impetigo can be readily made on the basis of the typical clinical appearance. Cultures are generally not necessary. Systemic antibiotic therapy must be combined with wound scrubbing and cleansing and application of neosporin or mupirocin ointment for optimal results. Effective antibiotics include oral antibiotics such as erythromycin, clindamycin, cephalosporins, and dicloxacillin.

Erysipelas

Erysipelas, or St. Anthony's fire, is cellulitis and lymphangitis of the skin caused by group A, b-hemolytic streptococci. It is frequently accompanied by fever, chills, malaise, headache, and vomiting.

The rash is characterized by local redness, heat, swelling, and a raised, indurated border. There is marked involvement of the superficial dermal lymphatics. The rash starts as an erythematous plaque that rapidly enlarges by peripheral extension. At first, it is scarlet, hot, brawny, swollen, and tender. The edge is raised and sharply demarcated. The rash can vary in appearance from a transient hyperemia to intense inflammation, vesiculation, and bulla formation. The face is the most frequent site. A skin wound, fissure, or ulcer may act as a portal of entry.

Diagnosis is made on clinical grounds, although aspiration of the leading edge of the lesion will frequently demonstrate streptococci. A brief course of parenteral penicillin is usually warranted because of the rapid advancement of the infection, the acutely toxic state of the patient, and the possibility of suppurative complications. Rapid clinical response is usually obtained. Erythromycin may be used in patients unable to take penicillin.

Mycoplasma Infections

Mycoplasma pneumoniae infections are a common cause of pneumonia, upper respiratory infections, and bronchitis in children between 5 and 19 years of age. The most frequent presenting clinical findings in children and adults are fever, cough, sore throat, malaise, headache, chills, and rash. An erythematous maculopapular rash, the most frequent presentation, is located on the trunk and may be discrete or confluent. However, the most frequently reported exanthem is consistent with erythema multiforme and Stevens-Johnson syndrome, with lesions occurring primarily on the trunk, legs, and arms. The rash occurs most commonly during the febrile period. An enanthem of generalized ulcerative stomatitis or pharyngitis-tonsillitis associated with the exanthem is common. The diagnosis can be confirmed by the use of either serum cold agglutinins or several specific antibody tests.

Mycoplasma responds to several antimicrobials, including erythromycin, tetracycline, chloramphenicol, and aminoglycosides. Infection with *M. pneumoniae* should be suspected in patients with pneumonia and a rash.

Scarlet Fever

Scarlet fever is an acute febrile illness, primarily affecting young children, caused by group A b-hemolytic streptococci. Recently group C streptococci have been implicated as well. Clinical manifestations include acute onset with fever, sore throat, headache, vomiting, and abdominal pain followed by a distinctive exanthem in 1 to 2 days.

There are both an exanthem and an enanthem associated with scarlet fever. They are caused by an erythrogenic toxin elaborated by the streptococcal organism. The tonsils and pharynx are red and covered with exudate, although occasionally pharyngeal findings are minimal. The tongue has a white coating through which red and hypertrophied papillae project, creating the appearance of a "white strawberry tongue." The white coating disappears by day 4 or 5, and the tongue acquires a bright-red appearance, the "red strawberry tongue." Bright-red or hemorrhagic spots may be seen on the soft palate or anterior pillars of the tonsillar fossae.

The exanthem of scarlet fever begins 1 or 2 days after the onset of the illness. It starts on the neck, axillae, and groin, spreading to the trunk and extremities. The rash is red and finely punctate, consisting of 1- to 2-mm papules giving the rash a characteristic rough, sandpaper feel. It is sometimes easier to identify the rash by palpation. The rash blanches with pressure. Linear petechial eruptions, Pastia's lines, are often present in the antecubital and axillary folds. There is facial flushing with circumoral pallor. A brawny desquamation occurs at 2 weeks, yielding fine flakes of dry skin.

The diagnosis of scarlet fever is readily made on clinical grounds. Throat swabs usually culture group A b-hemolytic streptococci, although group C may be cultured as well. Treatment with antibiotics is necessary to reduce the incidence of rheumatic fever and nephritis and will probably ameliorate the course of the disease. Penicillin is the antibiotic of choice, or erythromycin for those who are penicillin-allergic.

RICKETTSIAL

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever (RMSF) is an infectious disease caused by *Rickettsia rickettsi* which is transmitted by ticks. The prominent clinical manifestations of RMSF can be directly related to the primary pathologic lesion in the endothelial cells lining small blood vessels where the rickettsia multiply. Rash, headache, mental confusion, terminal heart failure, and shock are manifestations of the generalized vasculitis.

The incubation period is from 2 to 12 days with either a sudden or gradual onset of symptoms. Peak severity usually occurs within 1 to 2 weeks. Headache, fever, toxicity, rash, and myalgia are the major clinical features. The rash (Fig. 131-2), a pathognomonic feature of the disease, usually appears on the second or third day. The initial lesions first appear on the wrist and ankles spreading rapidly to the extremities and trunk. These lesions also are found on the palms and soles of the patient. Initially, lesions are small, erythematous macules which blanch on pressure. They rapidly become maculopapular and petechial.

FIG. 131-2. Rocky Mountain spotted fever. [From Burnett JW, Crutcher WA: Viral and rickettsial infections, in Moschella SL, Hurley HJ (eds): *Dermatology.* Philadelphia, Saunders, 1985, vol 1, chap 12, pp 673–738, with permission.]

Laboratory diagnostic confirmation is difficult during the early phase of the disease, frequently mandating treatment based on clinical criteria. Serologic tests are used to confirm the diagnosis of RMSF. Some laboratory data may be helpful in establishing the presumptive diagnosis early, such as hyponatremia, leukopenia, and thrombocytopenia.

Specific therapy consists of tetracycline or chloramphenicol. In seriously ill children 100 mg/kg per 24 h of chloramphenicol up to 3 g total dose is advised. As improvement is noted, therapy can be changed to 50 mg/kg per 24 h in four divided doses orally. Treatment can be terminated 2 or 3 days after fever returns to normal for 24 h. The mortality of RMSF in the United States has held steady for a decade at 3 to 6 percent of identified cases despite treatment.

VIRUSES

Enteroviruses

Enteroviruses are an exceedingly common cause of illness and exanthem in young children. Enteroviruses are small, single-stranded RNA viruses belonging to the picornavirus group and consist of polioviruses and nonpolioviruses (coxsackievirus and echovirus). There are many types of coxsackieviruses and echoviruses that have been associated with illnesses. They usually occur in epidemics and are most prevalent in the summer and early fall. Transmission usually occurs by fecal-oral route and possibly by the respiratory route.

The clinical manifestations of infection with coxsackieviruses and echoviruses are extensive. The spectrum of disease includes nonspecific febrile illness, upper respiratory infection, parotitis, croup, bronchitis, pneumonia, bronchiolitis, vomiting, diarrhea, abdominal pain, hepatitis, pancreatitis, conjunctivitis, pericarditis, myocarditis, orchitis, nephritis, arthritis, meningitis, and encephalitis.

Similarly, the associated skin manifestations include an array of exanthems. Diffuse macular eruptions, morbilliform erythema, vesicular lesions, petechial and purpural eruptions, rubelliform rash, roseola-like rash, and scarlatiniform eruptions have been reported.

Strict clinical-virologic associations have been difficult to demonstrate. A single clinical syndrome can be associated with many types of coxsackieviruses and echoviruses. On the other hand, some types of coxsackieviruses and echoviruses have been associated with multiple illnesses and exanthems.

Hand, foot, and mouth disease is an acute infectious illness, caused by enteroviruses, that primarily affects children. Initial manifestations include fever, anorexia, malaise, and sore mouth. Oral lesions appear 1 to 2 days later and cutaneous lesions shortly thereafter. The oral lesions begin as vesicles on an erythematous base which ulcerate. The vesicles are usually 4 to 8 mm in size, and are very painful. They are located on the buccal mucosa, tongue, soft palate, and gingiva. The exanthem starts as red papules which change to gray vesicles about 3 to 7 mm in size. They are found on the palms and soles but may occur on the dorsum of the feet and hands and on the buttocks, as well. They may be oval, linear, or crescentic and may run parallel to skin lines. They heal in 7 to 10 days.

Herpangina is a febrile disease of children associated with many types of coxsackieviruses and echoviruses. The onset is acute with fever to 40°C, headache, sore throat, dysphagia, anorexia, and, occasionally, stiff neck. In the pharynx, there are one or more yellowish-white 2-mm vesicles with hyperemic borders. They are located in the posterior pharynx on the tonsils, uvula, soft palate, and anterior faucial pillars. The vesicles will usually ulcerate, leaving a shallow, gray-yellow crater 2 to 4 mm in size. The lesions persist for 5 to 10 days.

Boston exanthem is caused by echovirus 16. It is an acute illness with fever, anorexia, pharyngitis, and lymphadenopathy. An enanthem similar to herpangina may be present. The exanthem begins as small, discrete, pink macules that develop into papules. It appears on the face and chest, spreads centrifugally, and may involve the palms and soles. As in roseola, the rash may appear with defervescence of the fever.

Infection due to echovirus 9 is common and produces a typical enteroviral illness. Clinical manifestations include fever, headache, nausea, vomiting, abdominal pain, cough, coryza, pharyngitis, and nuchal rigidity. The exanthem is rubelliform, a maculopapular rash beginning on the face and neck or extending to the trunk and feet and sometimes the palms and soles. Occasionally, there are lesions on the buccal mucosa and soft palate that resemble Koplik spots. Petechiae may occur. The appearance of this rash and the presence of nuchal rigidity makes this illness occasionally mimic meningococcemia. The exanthem persists for about 5 days.

Infection with coxsackievirus A9 is a common cause of exanthem. It is an acute febrile illness with a discrete erythematous maculopapular rash that begins on the face and neck and extends to the trunk and extremities. Aseptic meningitis may occur. The rash may also be vesicular or urticarial.

The clinical differentiation of enteroviral disease is difficult. Since there is no specific therapy for enteroviral infection, it is more important to consider bacterial diseases in the differential diagnosis in order to exclude treatable causes of sepsis, meningitis, myocarditis, and pneumonia. Symptomatic therapy for enteroviral infections includes adequate hydration, antipyretics, and viscous lidocaine gel for painful oral lesions.

Erythema Infectiosum

Erythema infectiosum (fifth disease) is an acute, febrile illness with a unique exanthem. Outbreaks of erythema infectiosum occur primarily in the spring. During epidemics, the attack rate is highest in children 5 to 15 years of age, but all age groups can be affected. The illness is caused by infection with human parvovirus, a single-stranded DNA virus.

The abrupt appearance of the rash is frequently the first manifestation of erythema infectiosum. It begins with a characteristic fiery red rash on the cheeks. The rash is a diffuse erythema of closely grouped tiny papules on an erythematous base. The edges are slightly raised. The erythema is most intense below the eyes and extends over the cheeks in a pattern reminiscent of butterfly wings; it is sometimes referred to as a *slapped-cheek appearance*. There is circumoral pallor as well as sparing of the eyelids and chin. The facial rash fades after 4 to 5 days. Approximately 1 to 2 days after the appearance of the facial rash, a nonpruritic macular erythema or erythematous maculopapular rash occurs on the trunk and limbs. It is at first localized to the deltoid areas, trunk, and forearms but usually extends to involve a large area. This stage of the exanthem may last 1 week. A distinctive aspect of the rash is that it fades with central clearing, giving a reticulated or lacy appearance. The palms and soles are rarely affected.

The exanthem may recur in the ensuing 3 weeks, sometimes briefly. The intensity of the recurrent exanthem varies and may be related to exposure to environmental factors such as sunlight, hot baths, and, perhaps, physical exertion or emotional upset. Associated symptoms frequently occur and may include fever, malaise, headache, sore throat, cough, coryza, nausea, vomiting, diarrhea, and myalgia. Arthralgias and arthritis can occur, but usually only in adults. These symptoms may occur before or after the onset of the rash.

There is no specific treatment for human parvovirus infection. Symptomatic therapy is all that is required. Recovery is usually complete.

Measles

Prior to a nationwide immunization program in 1965 measles was an expected disease of childhood. It is a highly contagious, endemic myxovirus infection. It is a winter-spring disease in temperate climates, but it occurs throughout the world.

After exposure, the incubation period for the disease is about 10 days. The prodromal period lasts approximately 3 days and is characterized by upper respiratory symptoms. The onset of clinical measles is characterized by general malaise, systemic toxicity, fever, coryza, conjunctivitis, photophobia, and cough.

The exanthem develops about the fourteenth day following exposure. The rash first appears behind the ears and at the hairline of the forehead. It spreads in a centrifugal pattern from the head to the feet. It is initially erythematous and maculopapular but rapidly progresses to confluence, especially on the face. Initially the rash is red and blanches on pressure. As it fades, it takes on a copper-to-brownish hue. With healing there may be some fine desquamation. The rash generally lasts 7 days.

Koplik spots are an associated pathognomonic enanthem. The lesions are white, 1-mm discrete spots which first appear on the buccal mucosa opposite the lower molars and then spread to involve the entire buccal mucosa. The treatment of measles is supportive.

Infectious Mononucleosis

The diagnosis of infectious mononucleosis can be entertained in those children, adolescents and young adults who present with fever, sore throat, malaise, and fatigue accompanied by tonsillopharyngitis and lymphadenopathy.

There is strong evidence for Epstein-Barr virus (EBV) as the etiologic agent of the "mononucleosis syndrome." The age of initial (primary) infection varies and appears to depend upon socioeconomic status. The mononucleosis symptom complex is associated with the primary infection. A 2- to 5-day prodromal period of malaise and fatigue with or without fever may precede the full onset of the syndrome. The adenopathy is usually confined to the anterior and posterior cervical chain but may be generalized. There is a 5-percent incidence of a generalized erythematous maculopapular rash associated with an enanthem consisting of petechiae on the soft palate. The incidence of the rash increases to almost 100 percent in those patients taking ampicillin or its congeners. The treatment for infectious mononucleosis is supportive.

Rubella

Rubella (German measles) was once a common childhood disease that had its highest incidence during the spring. The incubation period is 12 to 25 days following exposure with a 1- to 5-day prodrome of fever, malaise, headache, and sore throat.

The exanthem varies and is sometimes difficult to identify. It may present as a short-lived blush, or it may have the more common 2- to 3-day course. The exanthem begins as irregular pink macules and papules on the face spreading to the neck, trunk, and arms in a centrifugal distribution. It coalesces on the face as the eruption reaches the lower extremities and then clears in the same fashion. As enanthem of pinpoint petechiae involving the soft palate (Forschheimer spots) may accompany the rash but is nonspecific.

Lymphadenopathy is a clinical manifestation of rubella, with the enlargement characteristically in the suboccipital and posterior auricular nodes. The clinical diagnosis of the individual case is often difficult, but the epidemic nature of the illness, along with the seasonal variation and high expression rate of the exanthem, help in establishing the diagnosis. A history of inadequate immunizations may assist in the diagnosis. There is no specific therapy.

Varicella

Varicella, or chickenpox, is a result of infection with varicella-zoster virus, a herpes virus. In normal children it is characterized by a pruritic generalized vesicular exanthem with mild systemic manifestations. Cases generally occur in late winter and early spring. It is highly contagious in the prodromal and vesicular stage. Varicella most frequently occurs in children less than 10 years old, but it may occur at any age.

The exanthem starts on the trunk or scalp and first appears as faint, red macules. Within 24 h, the rash acquires the typical vesicular appearance of varicella. The rash consists of teardrop vesicles on an erythematous base, which then dry and crust over (see Fig. 131-3). Successive fresh crops may appear for a few days. The extent of the rash may be minimal but usually will spread centrifugally and become widespread. Palms and soles are spared. Vesicles may occur on mucous membranes and proceed to rupture and form shallow ulcers. Low-grade fever, malaise, and headache are frequently present but are usually mild. The diagnosis of varicella is usually made clinically on the basis of its distinctive rash. A Tzanck smear of the vesicle contents will demonstrate varicella giant cells with inclusion bodies.

FIG. 131-3. Varicella. [From Burnett JW, Crutcher WA: Viral and rickettsial infections, in Moschella SL, Hurley HJ (eds): *Dermatology*. Philadelphia, Saunders, 1985, vol 1, chap 12, pp 673–738, with permission.]

Complications of varicella can occur, including encephalitis, pneumonia, nephritis, and infection of the vesicles with staphylococci or streptococci. Neonates born to mothers with perinatal varicella infection may develop serious illness.

Uncomplicated varicella requires no specific therapy. Acetaminophen may be used as needed, but aspirin should be avoided as it may predispose to the development of Reye syndrome. Oral antihistamines may be useful to reduce itching. Most importantly, lesions should be cleansed regularly to prevent secondary infection. In the absence of central nervous system complications, the prognosis is excellent. Routine use of acyclovir for uncomplicated varicella infections in children is not recommended. While limited data are available on pediatric use, no unusual toxicity or problems have been noted.

Immunocompromised patients with varicella require aggressive treatment with antiviral drugs such as acyclovir. The dose of acyclovir is 80 mg/kg per day in four divided doses up to 800 mg/dose. Administration of varicella zoster immune globulin (VZIG) should be considered for immunocompromised patients exposed to individuals with varicella.

Roseola Infantum

Roseola infantum, or exanthem subitum, is a common acute febrile illness of childhood. There appears to be no seasonal preponderance to its occurrence. The most likely etiologic agent has been identified as the human herpesvirus 6, although other viruses have been associated with a roseola-like illness.

Roseola is characterized by a febrile period of 3 to 5 days, defervescence, and the appearance of a rash for 1 or 2 days. Primarily, young children are affected, with most patients being between 6 months and 3 years. The illness begins abruptly with high fever, sometimes as high as 40.6°C. The child is usually alert and active but may be irritable, especially with very high fever. Associated symptoms are usually mild and may include cough, coryza, anorexia, and abdominal discomfort. Lymphadenopathy may be present. Febrile convulsions may occur. The fever persists for 3 to 5 days, and most often returns to normal by crisis. The child rapidly becomes well.

The exanthem in roseola usually coincides with defervescence of the fever, but it may follow a short afebrile interlude. The rash is an erythematous macular or maculopapular eruption that consists of discrete, rose or pale-pink lesions 2 to 5 mm in size. It is most prominent on the neck, trunk, and buttocks, but the face and proximal extremities may also be involved. The lesions blanch with pressure. There is no mucous membrane involvement. The rash lasts 1 to 2 days but may fade rapidly, usually without desquamation.

There is no specific treatment for roseola. Acetaminophen is useful for fever control and convulsions should be treated vigorously. Recovery is usually complete.

ETIOLOGY UNCLEAR

Erythema Nodosum

Erythema nodosum is an inflammatory exanthem of unknown etiology. It is probably an inflammatory reaction to a stimulus. In the past, erythema nodosum was associated with streptococcal infections, tuberculosis, sarcoid, fungal infections, *Yersinia* infections, vasculitis, inflammatory bowel disease, and leukemia. Now it is more commonly associated with drugs, especially oral contraceptives. Any age can be affected. Constitutional symptoms may be present at the onset, including fever, malaise, myalgias, and arthralgias.

Erythema nodosum presents a distinctive clinical appearance. Bilateral, very tender nodules develop symmetrically. They usually occur on the shins but can occur on the arms, thighs, calves, and buttocks. The nodules are 1 to 5 cm in diameter, and individual lesions may coalesce to form sizable areas of induration. The skin over the nodules is red, smooth, and shiny. No ulceration occurs. After a week or two, the color of the lesions changes from red to blue and may achieve a dull, purple, bruised appearance. The eruption lasts several weeks.

The diagnosis of erythema nodosum is usually readily made on clinical grounds. A thorough history and physical, and perhaps laboratory evaluation, must be performed to exclude an underlying cause. There is no known therapy to alter the course of the disease. Nonsteroidal anti-inflammatory drugs may provide relief from the sometimes significant pain associated with these lesions.

Kawasaki Disease (Mucocutaneous Lymph Node Syndrome)

Kawasaki disease, or mucocutaneous lymph node syndrome (MLNS) is a disease of unclear etiology found predominantly in children under 9 years of age.

The diagnosis of this disorder is based on a constellation of clinical findings. The patient must exhibit a prolonged fever associated with at least four of the following: (1) conjunctivitis, (2) rash, (3) lymphadenopathy, (4) changes in the oropharynx consisting of injection of the pharynx and lips with prominent papillae of the tongue (strawberry tongue), and (5) extremity erythema and edema.

The rash has been described as erythematous, morbilliform, urticarial, scarlatiniform, or erythema multiforme–like. It has a predilection for the perineum. Additional supportive evidence which may help in the presumptive diagnosis are leukocytosis, elevation of acute-phase reactants, elevated liver function tests, arthritis, arthralgia, and irritability.

In the second phase, there is usually a sharp rise in the platelet count, desquamation of the fingers and/or toes, and the most serious complication, the development of coronary artery aneurysm. A small percentage (1 to 2 percent) of patients with coronary artery aneurysm develop sudden cardiac failure, resulting in death from myocardial infarction with coronary artery thrombosis.

The differential diagnosis includes drug allergy, toxic epidermal necrolysis, staphylococcal toxin–mediated syndromes, erythema multiforme, and scarlet fever. The etiologic speculations include a hyperimmune response to a variety of infections, a viral syndrome, allergic or toxic response to pollutants, drugs, toxic agents, and a possibility of a rickettsial disease.

Treatment of Kawasaki disease is controversial and includes various antibiotics, salicylates, and steroids. Intravenous gamma globulin is now routinely recommended. Aspirin may be the most promising therapy. Bed rest, supportive therapy, and frequent monitoring are mainstays of treatment.

Pityriasis Rosea

Pityriasis rosea is a mild inflammatory exanthem of unknown cause. The available evidence suggests a viral etiology. Pityriasis rosea affects all age groups but occurs most commonly in patients 10 to 35 years old. It tends to occur in spring and fall but not in epidemics. Pityriasis rosea is not contagious. A pityriasis rosea–like eruption has been associated with some drugs and viruses. Occasionally there are prodromal symptoms including malaise, headache, sore throat, fatigue, and arthralgia.

The rash of pityriasis rosea evolves over a period of several weeks. It begins with a "herald patch," a solitary, erythematous lesion with a raised edematous border most frequently occurring on the chest or back. It is 2 to 6 cm in diameter. About 1 or 2 weeks later, there is a widespread, symmetrical eruption of pink- or salmon-colored maculopapular lesions. The patches are oval and are covered with dry epidermis which desquamates to form a ring of scale at the periphery. The lesions are 0.5 to 1.5 cm in diameter and are at first discrete, but can become confluent. The long axes of the patches frequently run parallel to lines of skin tension, giving rise to the Christmas tree pattern seen on the back. The eruption is generalized and chiefly affects the trunk, although it can occur anywhere. The lesions can be localized. Mucous membranes can be involved with plaques, hemorrhagic punctate spots, or ulcers. Successive crops of skin lesions can occur, and the entire illness can last 3 to 8 weeks. Healing is complete, without sequelae or evidence of organ involvement.

The diagnosis of pityriasis rosea is made by the clinical appearance. It can be confused with viral exanthem, drug eruptions, syphilis, and seborrheic dermatitis. Potassium hydroxide preparation of skin scrapings will serve to distinguish pityriasis rosea from tinea corporis. A serologic test for syphilis must be done to exclude that diagnosis.

Therapy is directed at alleviating symptoms. No treatment has been shown to shorten the duration of the rash. The rash is sometimes very itchy. Oatmeal baths and oral antihistamines will provide temporary relief. Emollients will help dryness and irritation. Secondary infection must be prevented with thorough cleansing.

PHYSIOLOGY OF MUSCULOSKELETAL SYSTEM IN CHILDREN

The child's musculoskeletal system differs from the adult's in multiple respects, reflecting the child's active growth and development. These differences relate to the patterns of injury and illness manifested by children presenting to the emergency department. In utero, fetal positioning leads to a flexor pattern in the extremities, with external rotation of the hips and internal rotation of the tibiofibular apparatus. The ankle is in dorsiflexion, and the feet are inverted. Upon the newborn's arrival, motor development progresses predictably in a rostral-to-caudal direction and in a proximal-to-distal direction. Thus, the infant achieves head and trunk control prior to extremity control. Proficiency in movements of the upper extremity precedes lower extremity control.

The joint contractures brought about by fetal positioning and motor development influence the child's gait. The child requires a broad base of support and maintains distinct flexion of hips and knees and dorsiflexion of the ankles, resulting in a high-stepping gait. The arms of the toddler are abducted at the shoulder and flexed at the elbow. The child does not develop reciprocating arm swinging until about 2 years of age.

Simultaneously with development of the central nervous system and the maturation of motor milestones and gait, the child is growing most actively in early childhood. Bone growth occurs through two types of ossification. Growth in circumference occurs at the periosteal surface, as mesenchymal cells differentiate into osteocytes, which lay down new bone in a process known as *intramembranous ossification.* Longitudinal growth is achieved through *endochondral ossification,,* consisting of a proliferation and hypertrophy of cartilage cells at a physis. An organized vascular invasion of this cartilage results in delivery of mesenchymal cells to the area, which then differentiate into osteocytes, completing the transformation of cartilage to bone.

It is helpful to think of long bones as consisting of discrete anatomic areas. Long bones may have physes, or areas of growth cartilage, at both ends (e.g., tibia and femur). Other long bones (e.g., the phalanges) have a physis at only one end. The area of the long bone between a physis and the adjacent joint is the epiphysis, and the area of bone between a physis and a point for muscle or ligamentous attachment is an apophysis. The metaphysis of a long bone represents the area of widening, or flaring, of the long bone between its midshaft (the diaphysis) and the physis.

The long bones of children are generally less dense and more porous than the long bones of adults. The resulting increased compliance contributes to the tendency of children's long bones to respond to mechanical stress by bowing and buckling, rather than fracturing through and through, as in adult fracture patterns. The periosteum of the diaphysis and the metaphysis is thicker in children and is continuous from the metaphysis to the epiphysis, surrounding and protecting the mechanically weaker physis. This physeal weakness is related to the reduced oxygen tension found in the hypertrophic zone of the physis, a location of frequent fractures within the physis. The physis is sensitive to alterations in the blood supply to this hypertrophic zone as well as to nutritional, hormonal, and mechanical influences.

Growth of the musculoskeletal system and its response to illness, injury, and nutrition are also influenced by the growth of muscle and connective tissues. The ligaments of children are stronger and more compliant than those of adults, often tolerating mechanical forces at the expense of apophyseal attachments or epiphyseal integrity. While the absolute number of muscle fibers is fixed at birth, the fibers of tendons can increase in number and in size. The growth of muscle through hypertrophy and the growth of tendons through hypertrophy and proliferation depend on the mechanical forces applied to them.

CHILDHOOD PATTERNS OF INJURY

Physeal Injuries

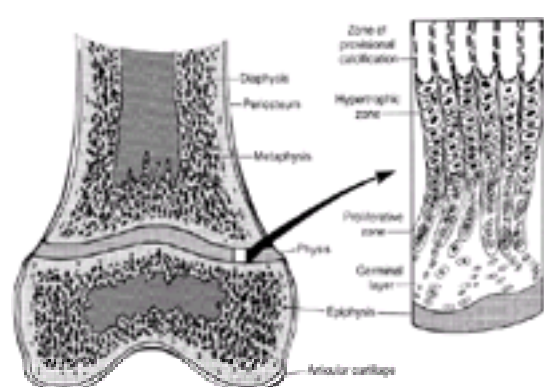
The weakest zone, or layer, of the physis is its third layer of cells and matrix (hypertrophic cell zone). It is particularly susceptible to shearing, bending, and tension stresses. It represents the layer of the physis that is most consistently fractured. Consequently, the reserve and proliferative cartilage cells in the first two zones of the injured physis usually remain with the epiphysis. This is relevant in that the predominant circulatory support of the cells in these two reproductive zones of the physis arises through the epiphyseal vasculature and thus is more likely to be spared in the event of physeal injury (Fig. 132-1).


FIG. 132-1. Relationship between anatomic regions of a typical long bone and and the physis. Detail: cellular zones of physis. (Reproduced with permission from Tolo and Wood, 1994.)

It has been demonstrated that compression forces applied to the physis can affect bone growth. This is particularly true when compression forces are applied to the epiphyseal side of the physis. The injury to bone growth caused by compression results from interruption of the epiphyseal circulation to the reproductive cells of the physis.

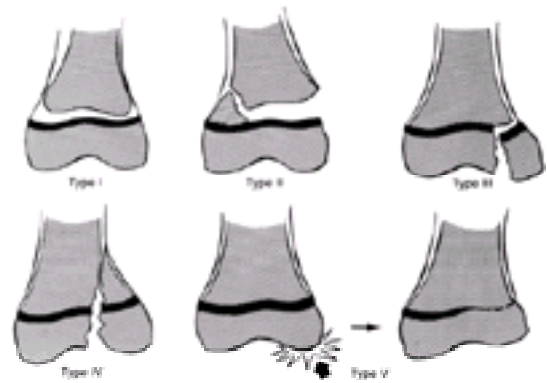
Although several authors have classified injuries to the physis, the Salter and Harris classification system offers a thorough and practical classification based on the mechanism of injury, the relationship of the fracture line to the germinal (reproductive zone) layer of the physis, and the prognosis for disturbance of bone growth (Fig. 132-2).


FIG. 132-2. Salter-Harris classification of physeal injuries. (Reproduced with permission from Tolo and Wood, 1994.)

TYPE I PHYSEAL FRACTURE   In type I physeal fracture (representing 6 percent of physeal injuries), the epiphysis separates from the metaphysis. The cleavage is through the hypertrophic cell zone of the physis. The reproductive cells of the physis remain with the epiphysis. There are no associated fragments of bones, since the thick periosteal attachments surrounding the physis remain intact. However, the epiphysis may be somewhat displaced from the metaphysis. Bone growth is not usually disturbed (Fig. 132-2).

Diagnosis is suspected clinically in a child with point tenderness over a physis. Radiographically, the only abnormality may be an associated joint effusion. Any epiphyseal displacement is usually apparent on one or more views. In the absence of epiphyseal displacement, the diagnosis is a clinical one, supported by the appearance of the typical joint effusion.

Treatment consists of immobilization of the suspected fracture using an appropriate splint, the application of cold compresses for 48 h, and elevation. Referral to an orthopedic surgeon is probably warranted in order to render aftercare and to ensure monitoring for bone growth disturbances. Analgesia may be necessary, despite immobilization, for 24 to 72 h, after which time the child usually remains quite comfortable in the immobilization device.

TYPE II PHYSEAL FRACTURE   Type II physeal fractures are the most common, representing 75 percent of physeal injuries. The line of fracture extends a variable distance along the hypertrophic cell zone of the physis and then out through a piece of metaphyseal bone. The periosteum on the concave side (overlying the metaphyseal fragment) remains intact, whereas the periosteum on the convex (opposite) side of the fracture is torn away from the diaphysis while remaining adherent to the epiphysis (Fig. 132-2). Growth is preserved, since the reproduction layers of the physis maintain their position with the epiphysis and the epiphyseal circulation. Diagnosis is made radiographically by noting the triangular fragment of metaphysis (Holland sign) unassociated with discernible injury to the epiphysis.

Reduction of the fracture should be gentle and is usually easily achieved. Analgesia with or without sedation should be offered to the child prior to any reduction maneuvers. When using sedation and analgesics, precautions should be taken as to patient selection, premedication assessments, monitoring, and postmedication observation consistent with institutional guidelines. Overreduction of the type II fracture is usually prevented by the periosteal hinge remaining on the concave side of the fracture.

Immobilization, cold compresses, and elevation are principles of management, as in the case of type I fractures. Referral to an orthopedic surgeon for aftercare and observation is important, as is the provision of adequate analgesia in the initial days following the fracture.

TYPE III PHYSEAL FRACTURE   The hallmark of this injury is an intraarticular fracture of the epiphysis extending to the hypertrophic cell zone of the physis, with the cleavage plane continuing along the physis to the periphery (Fig. 132-2). The injury, usually involving the proximal or distal tibia epiphysis, is caused by severe intraarticular shearing forces. The prognosis for subsequent bone growth is related to the preservation of circulation to the epiphyseal bone fragment and is usually favorable. The type III physeal fracture represents less than 10 percent of physeal injuries.

Diagnosis is a radiographic one based on the appearance of an epiphyseal fragment unassociated with an apparent metaphyseal fracture. There may or may not be an associated periosteal injury.

Reduction of the unstable epiphyseal fragment with careful restoration of the alignment of the articular surface is critically important. Open surgical techniques are frequently necessary in order to ensure the necessary anatomic reduction of the articular surface, especially with severely displaced fractures. This fracture warrants consultation with an orthopedic surgeon in the emergency department.

Decisions regarding admission or operative open reduction are made in consultation with an orthopedic surgeon experienced in the management of physeal injuries. If closed reduction techniques are successfully employed by the orthopedic consultant, aftercare instructions are similar to those offered to patients suffering from type II physeal injuries.

TYPE IV PHYSEAL FRACTURE   The fracture line originates at the articular surface and extends through the epiphysis, the entire thickness of the physis, and through the metaphysis (Fig. 132-2). It is an injury pattern most often involving the distal humerus and represents about 10 percent of physeal injuries. Future bone growth is at risk. Perfect anatomic reduction of the articular surface and of the physis is required to minimize the potential for premature bone growth arrest.

The diagnosis is made upon identification of epiphyseal and metaphyseal fragments radiographically. The fragments may or may not be variably displaced. Radiographic interpretation of fractures involving the distal humerus and elbow can be challenging because of the dynamic nature of the ossification centers of the region.

Open surgical reduction should be performed early by an experienced orthopedic surgeon. Internal fixation of the fragments is accomplished using fine, smooth Kirschner wires traversing the physeal growth plate perpendicularly.

TYPE V PHYSEAL FRACTURE   This fortunately rare injury pattern (1 percent of physeal injuries) usually involves the knee or ankle. It is the result of severe abduction or adduction to the joint, which transmits profound compressive forces to a local segment of the physis, crushing the reproductive chondrocytes of the reserve zone and proliferative zone. Minimal or no displacement of the epiphysis occurs (Fig. 132-2).

The diagnosis of type V physeal injuries may be very difficult initially. Often, the seriousness of the injury is underappreciated. An initial diagnosis of sprain or possible type I physeal fracture may prove incorrect in view of subsequent development of premature growth arrest. Radiographs may appear normal or may demonstrate focal narrowing of the physeal plate. An associated joint effusion is the norm, although its presence is nonspecific.

Treatment of type V physeal injuries consists of cast support of the knee or ankle, non-weight-bearing for at least 3 weeks and close orthopedic outpatient follow-up in anticipation of the nearly inevitable focal bone growth arrest.

Torus Fractures

The porosity and compliance of the metaphyses of children's long bones, coupled with the relative thickness of the periosteum in this area, confer unique fracture characteristics. Compressive forces often result in a bulging or buckling of the periosteum rather than a more complete fracture line. Cortical, or *torus,* fractures are so named to describe a prominence or bulging of the bony cortex, usually involving the metaphysis.

Diagnosis is based on point tenderness over the site of the torus fracture. While a simple torus fracture does not produce a visible deformity of the extremity, soft tissue swelling routinely overlies the bone injury. In children who are not morbidly obese, the torus fracture is frequently palpable as a ridge over the metaphyseal area of the long bone.

Radiographically, the manifestation of a torus fracture may be somewhat subtle. Interpretation of radiographs is aided by following the contour of the metaphyseal flare, observing any asymmetry, bulging, or deviation of the cortical margin. With magnification, deviations in the trabecular pattern of the cortical markings can be seen to be associated with the bulging prominence of the cortical margin.

Since torus fractures are not typically associated with severe angulation, displacement, or rotational abnormalities, most can be competently managed by the emergency physician. Reduction techniques are rarely, if ever, necessary. The extremity is splinted in a position of function for 3 to 4 weeks. Aftercare can be arranged through the child's primary care physician or an orthopedic consultant, usually in 2 weeks. Analgesia requirements in the immediate days after the injury are usually minimal following the application of the splint.

Greenstick Fractures

Stresses and forces can be applied to the porous, compliant bones of children in such a way as to create an incomplete cortical fracture. A greenstick fracture is characterized by cortical disruption and periosteal tearing on the convex side of the bone, with an intact periosteum on the concave side of the fracture. Greenstick fractures are more stable and somewhat less painful than complete fractures, since the area of intact periosteum protects the child from bony crepitance.

The need for reduction is related to the degree of angulation of the fracture, the age of the child, and the anatomic location of the injury. Orthopedic consultation may be helpful in the decision analysis regarding possible reduction and outpatient management.

Plastic Deformities

Plastic deformities (sometimes known as bowing or bending fractures) are almost exclusively limited to the forearm and lower-leg long bones. Usually this pattern of injury is noted in combination with a completed fracture of the other bone of the forearm or lower leg. The cortex of the diaphysis of the long bone is deformed, with preservation of the periosteum all along the diaphysis. Such injuries result from the compliance and porosity of the child's bones, with the associated tendency to deform (bend) rather than fracture in the traditional sense.

Diagnosis is made radiographically. Proper interpretation of the radiographs requires an awareness of the normal shape of the long bones involved, since fracture lines and disruptions in the periosteum are absent.

Prompt orthopedic consultation is important.

FRACTURES ASSOCIATED WITH CHILD ABUSE

It is important to remember that all of the skeletal injuries associated with accidental trauma can also be inflicted as a result of nonaccidental injury (e.g., child battering, shaken baby syndrome, or child abuse). However, certain injury patterns are encountered consistently as a result of child maltreatment, particularly multiple fractures in various stages of healing. An understanding of the various mechanisms of inflicted injury will facilitate better awareness of the patterns of injury suggesting abuse. Correlation of the child's age, motor capabilities, and the alleged mechanism of injury with the injury pattern being evaluated is fundamental to the evaluation of childhood skeletal injuries, as is the identification of coexisting cutaneous signs suggestive of abuse (e.g., suspicious bruises, burns, etc.).

Direct Blows

Direct blows may result in transverse, oblique, longitudinal, greenstick or torus fractures. All of these fractures are commonly associated with accidental mechanisms and are nonspecific for child abuse. Correlation with the child's age or motor development, however, may arouse suspicions. A transverse or oblique fracture of the humerus of a 2-month-old infant is quite a different situation from an isolated similar fracture in an 8-year-old.

Twisting Injuries

Twisting injuries create spiral fractures in long bones, highly specific for child abuse in children who are not yet ambulatory. Spiral fractures in ambulatory children lose their specificity for child abuse but remain a potential manifestation of abuse and warrant careful consideration. Whereas toddlers (1 to 3 years of age) commonly suffer spiral fractures of the lower one-third of the tibia accidentally as the result of a trivial fall or by twisting themselves on a planted foot (the so-called toddler's fracture), spiral fractures of the tibia may occur with child abuse. Spiral fractures of the femur may be accidental in toddlers but can also be seen in child abuse in this age group. Spiral femur fractures in newborns and preambulatory infants are highly suggestive of nonaccidental trauma. Correlation with the alleged mechanism of injury and a discrete but careful inspection for other evidence of abuse will prove helpful, along with a review of past injuries experienced by the child or the child's siblings.

The injury pattern most closely related to inflicted injury is that of metaphyseal-epiphyseal fractures. More specifically, chip fractures of the metaphyses or epiphyses, particularly in various stages of healing, are seen as the result of twisting or jiggling forces. Callus formation becomes striking during the healing process, along with remarkable new bone deposits along the periosteum. Subperiosteal hemorrhage may create an elevation of the periosteum away from the underlying bony cortex. Fragmentation of the clavicle and acromion and separation of the costochondral junctions of the ribs are especially suggestive of abuse.

Distraction Injuries

Distraction injuries to the long bones create hemorrhagic separation of the distal metaphyses, creating a lucency parallel and proximal to the physis. The result is a bucket-handle fracture.

Shaking Injuries

Shaking injuries create fractures similar to those caused by twisting mechanisms. In addition, retinal hemorrhages, intracranial injuries, and intraabdominal injuries may result. Spinal compression fractures, vertebral subluxations and dislocations, and anterior notching of vertebral bodies can be seen.

Squeezing Injuries

Squeezing injuries create encirclement bruises and rib fractures highly suggestive of abuse. Particular attention should be given to multiple rib fractures and rib fractures in various stages of healing, the presence of which is classically associated with the battered child syndrome. Appreciation of this phenomenon is related to an understanding of normal bone healing and an ability to date the approximate age of any bone injuries identified in the child's workup. By looking for associated soft tissue findings, the appearance of a distinct fracture line, callus formation and calcification, and ossification of newly laid periosteal bone, the physician will be in a better position to detect discrepancies between the alleged history of the injury(ies) and the radiographic evidence of injury.

CLAVICLE FRACTURE

The clavicle, extending from the scapular acromion process to the manubrium sterni, serves as the sole skeletal connection between the upper extremity and the trunk and absorbs all medial forces imposed upon the upper arm. The clavicle consists of a double curve in the horizontal plane. Viewed from the front, the medial two-thirds is convex, while the lateral one-third is concave. The junction between the two curves represents its structurally weakest area and most frequently fractured site. The clavicle is the most commonly fractured bone in children.

Clavicle fractures may occur in the newborn as a result of shoulder compression during a difficult delivery. In the older infant, toddler, or child, the usual mechanism of fracture is a fall onto an outstretched hand or elbow or onto the side of a shoulder. Often, in younger children, the fracture is of the incomplete, or greenstick, type. A direct blow to the clavicle may also cause a fracture.

Diagnosis of clavicular fracture is facilitated by its subcutaneous location and the ease of its palpation on examination. Newborns with clavicle fractures may not be symptomatic. When they are symptomatic, it may come in the form of "pseudoparalysis," or nonuse of the ipsilateral upper extremity. Alternatively, parents or health care providers may notice the bone callus at 2 to 3 weeks of age, indicative of a fracture previously unappreciated.

Older infants and children with clavicular fractures have pain on attempted range-of-motion movement of the neck or upper extremity. Soft tissue swelling, point tenderness, and bone crepitance are indicative of the fracture site. In view of the close proximity of the clavicle to the subclavian vessels and lung, careful assessment of the circulation to the ipsilateral upper extremity and chest auscultation are important. Anteroposterior radiographs of the clavicle and shoulder are principally useful in excluding other associated skeletal injuries, particularly those involving the proximal humerus and scapular prominences. Dislocations of the sternoclavicular joint, particularly posterior dislocations of the proximal clavicle, are optimally visualized by lordotic views.

Care of the child with a clavicle fracture is principally directed toward comfort and analgesia for the child. The child's future bone growth and the modeling potential confer great healing and restorative capability to the fractured clavicle. Even displaced fractures nearly always heal well, whether or not strict anatomic reduction is accomplished in the emergency department.

"Figure-of-eight" shoulder abduction restraints are available in various sizes and can be offered to children outside infancy. Application should ensure a snug, symmetrical fit without excessive tightness or pinching. As is the case with the application of any orthopedic appliance, subsequent assessment of the child's neurovascular status in the upper extremities is mandatory. Some children, however, complain of greater discomfort with the figure-of-eight restraint than without. In such instances, the use of an upper extremity sling-and-swathe or shoulder immobilizer will offer adequate protection from the discomfort associated with shoulder and upper extremity movements.

Children with either type of immobilizing or restraint device are encouraged to wear the restraint day and night for 2 weeks, followed by daytime use for another 2 to 3 weeks. Oral analgesia sufficient to ensure the child's comfort is of paramount importance. Follow-up care can be arranged through the child's primary care physician or an orthopedic surgeon.

SUPRACONDYLAR FRACTURES

The most common elbow fracture in childhood is the supracondylar fracture of the distal humeral metaphysis. It is an important injury pattern not only by virtue of its frequency but also because of its associated potential neurovascular complications. Hyperextension forces during a fall against an outstretched arm displace the distal fragment posteriorly and proximally.

The close proximity of the brachial artery to the supracondylar fracture predisposes the artery to contusion, laceration, or entrapment by fractured fragments. Subsequent arterial spasm or compression by splints, casts, or other dressings may further embarrass the arterial blood supply to the muscles of the forearm and to the hand. A resultant forearm compartment syndrome may ensue, with the development within hours of permanent injury and disability to the function of the involved forearm and hand. This is called *Volkmann's ischemic contracture* and is presaged by (1) pain referred to the proximal forearm upon passive extension of the fingers, (2) "stocking-glove" anesthesia of the ischemic hand, and (3) rock hard forearm swelling. Skin perfusion is usually normal despite the severe ischemic insult to the entire forearm and hand, and pulses may remain palpable at the wrist despite serious vascular compromise. The clinical suspicion of a potential ischemic compartment syndrome involving the forearm necessitates an immediate consultation by an orthopedic surgeon who is prepared to offer a complete and radical forearm decompression if reduction of the fracture does not satisfactorily restore vascular integrity.

The diagnosis of a supracondylar fracture of the distal humerus is suspected when tenderness is elicited upon palpation of the distal humerus and the child complains of pain on passive flexion of the elbow. The child usually prefers to maintain the forearm in pronation. The degree of soft tissue swelling and ecchymosis of the elbow ranges from severe to subtle.

As mentioned above, neurovascular assessment of the hand and forearm is the most critical step in the evaluation of elbow injuries in children. In addition to assessments of vascular integrity, injuries to the ulnar, median, or radial nerves should be noted. Such associated injuries are common, occurring in 5 to 10 percent of children with supracondylar fractures.

Differential diagnostic considerations include fractures to the humeral condyles, intercondylar fractures, fractures of the radial head and the olecranon of the ulna, and subluxation of the radial head ("nursemaid's elbow"). The physical examination of all these conditions may be undistinguishing except for that of nursemaid's elbow.

Definitive diagnosis of supracondylar fractures rests with radiography, which usually delineates the injury. Occasionally the appearance of the fracture line is subtle. Observations of a loss of the usual anterior angulation of the capitellum or of a posterior fat pad sign, indicative of an intraarticular elbow effusion (usually of blood), may confer indirect evidence of a supracondylar fracture if the fracture line itself is inapparent. An anterior humeral line, an imaginary line drawn along the anterior margin of the distal humeral diaphysis, normally bisects the posterior two-thirds of the capitellum in the lateral view of the elbow. In subtle supracondylar fractures with loss of the normal anterior angulation of the capitellum, the anterior humeral line may bisect the anterior portion of the capitellum. In association with a posterior fat pad sign, such a loss of the normal anatomic relationships may well indicate a supracondylar fracture.

Management of a child's supracondylar fracture is begun immediately upon arrival in the department. Splinting of the affected elbow in extension is recommended in order to safeguard against development of secondary injury to the vessels, nerves, and soft tissues surrounding the fracture. Frequent reassessments of neurovascular status of the forearm and hand are important. Consultation with an orthopedic surgeon is necessary in all cases of supracondylar fracture. In cases of neurovascular compromise, immediate fracture reduction is mandatory. Careful monitoring of neurovascular status following fracture reduction and maintenance of the elbow in extension are in order. If an ischemic volar forearm compartment is still suspected over the succeeding 6 h, surgical decompression and/or arterial exploration may be indicated.

In the absence of neurovascular compromise, therapy is influenced largely by the degree of displacement of the distal fragment, associated soft tissue swelling, and the reliability of the follow-up arrangements. Admission is indicated for all children whose supracondylar fracture is displaced, who manifest significant soft tissue swelling, or whose parents cannot ensure reliable outpatient follow-up. Open reduction is indicated if closed reduction techniques are unsuccessful, especially for oblique fractures. Outpatient management is considered for the child whose fracture is nondisplaced and has minimal swelling. The orthopedic surgeon should reexamine such children within 24 h of injury.

Lateral and medial condylar fractures, intercondylar fractures, and transcondylar fractures carry their own associated risks of neurovascular compromise. Children with such fractures typically present with moderate-to-severe soft tissue swelling and tenderness of the elbow, which is maintained in a moderate degree of flexion.

Circulatory integrity of the forearm and hand should be assessed immediately. Peripheral nerve function, particularly ulnar nerve function, is at risk.

Immediate orthopedic consultation is indicated, since such fractures often require open reduction and carry risks of long-term sequelae. Neurovascular insults usually resolve nicely with appropriate management of the fracture. Growth arrest is rare.

RADIAL HEAD SUBLUXATION

Radial head subluxation is an extremely common injury (nursemaid's elbow) with a peak incidence between 1 and 4 years of age. It has been recognized for centuries. While a history of linear traction upon a hand or wrist is frequently elicited, it is not uncommon to receive a history of an incidental fall in which the arm, elbow, and forearm were impacted between the ground and the child's trunk. Occasionally there is no history of trauma, and the parents note only nonuse of the affected limb.

The child maintains the arm partially flexed at the elbow and in forearm pronation. Typically, the arm is kept close to the trunk. The child usually is found seated in the parent's lap and appears quite contented and playful but declines to actively move the affected arm.

A slow and pleasant approach to the child's examination demonstrates no tenderness to palpation of the clavicle, shoulder, humerus, elbow, forearm, wrist, or hand. By carefully avoiding movements involving the elbow and forearm, the physician will note painless passive range of motion of the shoulder, hand, and wrist. In contrast, even modest attempts to supinate the forearm or to flex or extend the elbow elicit pain and anguish.

There is seldom clinical doubt if the child's age, mechanism of injury, body positioning, and examination (nonuse as opposed to tenderness to palpation) are consistent with the diagnosis. Radiographs in such a situation are superfluous, since there are no radiographic abnormalities associated with this condition and since the examination effectively excludes other entities. Radiographs should be considered, however, if the child exhibits point tenderness, soft tissue swelling, or ecchymosis of the elbow.

Reduction is usually easily accomplished. The physician's thumb is placed over the child's radial head. The child's hand is grasped by the physician. Beginning with the child's elbow in extension and the forearm in pronation, three simultaneous maneuvers are rapidly accomplished: (1) downward pressure on the child's radial head by the physician's thumb, (2) passive *full* supination of the child's forearm, and (3) passive *full* flexion of the child's elbow. A "click" is often but not always palpated by the physician's thumb as reduction is accomplished. The child cries out for a few seconds but is usually and easily soon distracted. Observation for up to 15 min typically demonstrates a full return to normal function and use, especially if the physician notes the click. If function and use have not normalized within 15 min, a repeated attempt at reduction is recommended. Alternative diagnoses should be considered if the child's arm does not return to normal function and use following a second reduction attempt. Radiographic studies may then be indicated.

For children who recover full, unrestricted use after one or two reduction maneuvers, further therapy is unnecessary. A sling may be offered to the child whose function and use have improved but are not complete. The toddler will often discard the sling within minutes or hours, however. Parents should be gently reminded to avoid lifting the child by the hand, wrist, or forearm and should be informed of the increased risk of recurrence until the child reaches 5 to 6 years of age.

DISORDERS OF THE HIP AND LOWER EXTREMITY

Slipped Capital Femoral Epiphysis

Associated with obesity and puberty, slipped capital femoral epiphysis (SCFE) is of multifactorial etiology, including physeal cartilage fatigue, genetic predisposition, endocrinologic factors, and trauma. There is a male-to-female predominance of 8:3, and it is more common in blacks than in whites. Peak incidence occurs between 12 and 15 years in males and between 10 and 13 years in females. The child with SCFE may present clinically with either a chronic slip or an acute slip.

With a chronic SCFE, the child complains of pain in the groin referred to the anteromedial thigh and knee. The pain is dull, vague, intermittent or continuous, and is exacerbated by physical activity. It may or may not be related to a history of trivial or significant injury. If walking is observed, the lower limb is held in external rotation, and the gait is antalgic. Typically, the examiner notes that attempts at hip flexion are accompanied by lateral rotation of the thigh. Full flexion is restricted, and the child cannot touch his or her thigh to the abdominal wall. Limb shortening of 1 to 2 cm may be noted, as may disuse atrophy of the muscles of the proximal thigh.

Acute SCFE may be the result of an acute traumatic event or may represent an acute-on-chronic slip in which sudden, severe pain and inability to bear weight develop in a patient who has been experiencing weeks to months of pain in the hip-thigh-knee region. Examining a patient with a suggested acute slip elicits great pain. Marked external rotation of the thigh is noted, as well as readily apparent limb shortening. Great gentleness is required of the examining physician, and the hip should not be forced into maximum range of motion, which can aggravate the displacement of the fracture. The child is not asked to walk to observe the gait.

The differential diagnosis includes septic arthritis, toxic tenosynovitis, Legg-Calvé-Perthes disease, and other hip fractures. Differentiating SCFE from septic arthritis is usually not difficult, since the child with SCFE is not febrile or toxically ill appearing and demonstrates no remarkable elevation in peripheral white blood cell (WBC) level or erythrocyte sedimentation rate (ESR). Differentiation from the other entities requires radiographs, including AP films and bilateral "frog-leg" lateral radiographs.

Medial slips of the femoral epiphyses will be noted on the AP views, while the frog-leg lateral films of both hips are used in comparison to detect posterior slips. In the AP view, a line drawn along the lateral (superior) aspect of the femoral neck should transect the lateral quarter of the femoral epiphysis (Fig. 132-3). The slipped epiphysis will not be transected by the line at all or will be transected less than noted on the unaffected hip. Moderate to severe slips will be detected by this method (Fig. 132-4), while mild slips require the interpretation of the frog-leg lateral x-rays of both hips. If the diagnosis of SCFE is suspected, both types of radiographs are necessary.

FIG. 132-3. A line drawn along the lateral (superior) aspect of the femoral neck fails to transect the lateral quarter of the femoral head in medial SCFE, seen in **A** and **C**. The normal anatomic relationship is illustrated in **B** and **D**.

FIG. 132-4. AP radiograph illustrating a medial SCFE involving the left hip.

Management in the emergency department consists of (1) confirmation of the diagnosis, (2) assurance of absolute non-weight-bearing, (3) orthopedic consultation, and (4) admission to the hospital. No patient with SCFE is treated as an outpatient, even if the intent is to perform surgery the following day. The management of SCFE is operative reduction and fixation, although there exists a certain amount of discussion in the orthopedic literature as to the optimal technical approach. Subsequent immobilization of the hip is maintained for at least 12 weeks, and careful observation for 1 to 2 years thereafter is necessary in anticipation of the development of this condition's most serious complication, avascular necrosis of the femoral head.

Transient Tenosynovitis of the Hip

Acute transient tenosynovitis of the hip is the most common cause of hip pain in children less than 10 years of age (peak, 3 to 6 years). There is a boy-to-girl predominance that is variously described as 3:2 to 5:1. The right hip is somewhat more commonly affected than the left, and the condition is bilateral in 5 percent of cases. The etiology of the condition is not known, although trauma, viral and bacterial infection, and allergy (hypersensitization) have been proposed by authors to explain the condition.

Symptoms may be acute or gradual in onset. There may be a history of recent upper respiratory symptoms offered by the parent. Considering the age group, such an association is probably best interpreted casually. The child complains of pain in the anteromedial or anterolateral thigh and knee. The gait is antalgic. Tenderness is elicited upon palpation of the anterior hip, and range of motion is limited by the discomfort. The child's systemic temperature is normal or minimally elevated. The child does not appear toxically ill.

The peripheral WBC and ESR are usually normal. If performed, tuberculin skin tests, rheumatoid factor titers, and antistreptococcal antibodies titers are negative. Radiographs of the hip are either normal or demonstrate mild to moderate hip effusion (Fig. 132-5). There are no bone changes associated with the condition.
FIG. 132-5. Widening of the joint space, indicating an effusion, is a nonspecific finding seen in children with toxic tenosynovitis, Legg-Calvé-Perthes disease, suppurative arthritis, and hemarthrosis.

The differential diagnosis includes SCFE and other hip fractures, Legg-Calvé-Perthes disease, and suppurative arthritis of the hip. Less common differential considerations include rheumatic fever, juvenile rheumatoid arthritis, and, rarely, tuberculosis of the hip.

If the peripheral WBC and ESR are substantially elevated and a hip effusion is noted on the radiograph, a diagnostic arthrocentesis should be performed to exclude suppurative arthritis. Consideration should be given to open irrigation of the hip joint in the operating room by an orthopedic consultant after obtaining samples of synovial fluid for laboratory studies (Gram stain, aerobic and anaerobic cultures, and acid-fast bacilli stain and culture). The synovial fluid in transient tenosynovitis of the hip is clearly transudative, will have negative stains for microorganisms, and will yield sterile cultures.

If further differentiation of transient tenosynovitis of the hip from Legg-Calvé-Perthes disease is necessary, a technetium-99m bone scan or a magnetic resonance imaging (MRI) scan will confirm the absence of avascular necrosis of the femoral head. This aspect of the diagnostic workup can be performed in the ambulatory setting.

Admission to hospital is necessary only for management of SCFE, other hip fractures, and septic arthritis of the hip. Once these diagnostic considerations are effectively eliminated, the child with suspected transient tenosynovitis of the hip can be managed as an outpatient. Weight bearing is eliminated, and anti-inflammatory agents are recommended until the child's hip is painless and range of motion returns to normal (3 to 7 days). Some authors recommend an additional period of rest (7 to 10 days) after symptoms have resolved. Antibiotics are of no value; glucocorticoids are not recommended.

Various authors have noted an association between transient tenosynovitis of the hip and the subsequent development of Legg-Calvé-Perthes disease, ranging from 0.5 to 10 percent. It remains unclear whether the association is one of cause and effect or misdiagnosis of early Legg-Calvé-Perthes disease. Follow-up clinical evaluations of patients with a diagnosis of transient tenosynovitis of the hip should occur at 2 weeks with the child's primary care physician. Subsequent clinical elevations (possibly to include radiographs) are performed by the primary care physician at 2 months and 6 months after the initial episode.

Legg-Calvé-Perthes Disease (Coxa Plana)

The incidence of Legg-Calvé-Perthes disease varies worldwide from 1 in 1200 to 1 in 12,500. The onset of symptoms is between 4 and 9 years of age in 80 percent of patients, with a range of age between 2 and 13 years of age. It is bilateral in 10 percent of cases.

The disease process is characterized as an avascular necrosis of the femoral head complicated by subsequent subchondral stress fracture. Resorption of areas of bone within the femoral head (rarefaction) is followed by the laying down of new bone. Collapse and flattening of the femoral head may ensue, along with the potential for subluxation. The result is a painful hip joint associated with restricted range of motion, muscle spasm, and soft tissue contractures.

Clinically, the child with Legg-Calvé-Perthes disease presents with limp and pain of weeks' to months' duration. Pain is usually mild, chronic, and dull. It is most noticeable in the groin, the anteromedial thigh, and the knee. It is exacerbated by physical activity, relieved by rest, and associated with an antalgic limp. There are no associated systemic symptoms. Hip range of motion is restricted; there may be a flexion-abduction contracture as well. Thigh muscle atrophy, due to disuse, is

common.

The radiographic findings associated with Legg-Calvé-Perthes disease depend on the stage of the disease process. During the incipient stage (1 to 3 months), the radiograph of the hip demonstrates only widening of the cartilage space of the affected hip and a smaller size of the ossific nucleus of the femoral head (Fig. 132-6). The second radiographic sign is the appearance of the subchondral stress fracture line in the femoral head (Caffey's sign). The third radiologic finding is increased opacification of the femoral head, brought on by deposition of new bone upon avascular trabeculae, calcification of the sclerotic marrow, and collapse and crowding of the avascular trabeculae in the dome of the epiphysis. Ultimately, deformities of the femoral head and neck become apparent, along with subluxation and extrusion of the femoral head from the acetabulum.
FIG. 132-6. Legg-Calvé-Perthes disease. The right hip illustrates joint-space widening, reduced size of the ossific nucleus of the femoral head, and increased opacification of the femoral head.

The other commonly employed imaging modalities include the technetium-99m bone scan and MRI. The scan demonstrates markedly reduced uptake of nuclide within the affected femoral head. These findings precede apparent plain film radiographic abnormalities. MRI offers superior resolution and sensitivity, with areas of low signal intensity reflecting necrotic regions within the femoral head. Arthrogram-like images of the cartilaginous portions of the femoral head and acetabular rim are produced. Excellent visualization of deformities and flattening of the femoral head is possible as well as subluxation or anterolateral extrusion of the femoral head from the acetabulum.

The differential diagnosis of coxa plana includes toxic tenosynovitis of the hip, which shares many similar features with early Legg-Calvé-Perthes disease. Careful review of the radiographs is necessary to exclude the findings associated with coxa plana, as mentioned previously. If doubt exists, technetium-99m bone scan or MRI imaging studies should be considered.

The differentiation of coxa plana from acute rheumatic fever (ARF) is based on the natural history and responsiveness of ARF to salicylates. Tuberculous arthritis of the hip may mimic coxa plana. Differential screening tests should include a tuberculin skin test and determination of the ESR. Unilateral tumors, such as eosinophilic granuloma, osteoid osteoma, osteoblastoma, and lymphoma, should be considered and excluded by laboratory studies and computed tomography (CT) scan. Bone dysplasias are often confused with Legg-Calvé-Perthes disease. Hypothyroidism, sickle cell disease, and Gaucher disease should also be excluded.

Care in the emergency department involves the consideration or establishment of the accurate diagnosis and orthopedic consultation. Treatment efforts are directed toward restoration of full range of motion of the hip and stabilization of the femoral head within the acetabulum, with resumption of normal activities as rapidly as possible. All except the most mildly affected children are hospitalized initially and treated with traction. The duration of traction and the timing of further therapy directed at containing the femoral head within the acetabulum (orthotics versus surgical containment) depend on the severity of the coxa plana and the responsiveness of the hip irritability to traction therapy.

Other Avascular Necrosis Syndromes

KOHLER DISEASE OF THE TARSAL NAVICULAR   This is an uncommon condition affecting boys more commonly than girls (4:1), occurring at about 5 years of age in boys and at about 4 years of age in girls. It appears to result from repetitive compressive forces applied to the tarsal navicular, the last bone of the foot to ossify in normal children. Affected children appear to have a delayed ossification of this bone during a critical phase in its growth, predisposing it to the compressive stresses of preschool ambulation.

The child presents with an antalgic limp, bearing weight on the lateral side of the foot, thus splinting the medial longitudinal arch. The child complains of local pain and tenderness over the navicular bone of the foot and often has induration over the area. There is no fever or other constitutional symptoms. Range of motion of the other joints of the foot is intact.

Radiographically, the picture is classic. The tarsal navicular is narrowed, as seen in the lateral view of the foot and ankle, and flattened, with irregular rarefaction and sclerosis. Comparison of radiographs of the contralateral foot is often helpful.

Treatment is as an outpatient using a short-leg walking cast. The use of crutches to ensure non-weight bearing is recommended for the initial 3 weeks. Orthopedic aftercare should be arranged. The prognosis is very good.

FRIEBERG INFARCTION   This condition of adolescents is seen much more commonly in girls (3:1). The usual site of involvement is the head of the second metatarsal, although other metatarsals can be affected, and it is occasionally bilateral. While its etiology is not known with certainty, it is generally presumed to be caused by a vascular insufficiency (aseptic necrosis).

Clinically, the patient complains of pain and tenderness under the affected metatarsal head. This is associated with local soft tissue swelling and restricted range of motion of the metatarsophalangeal joint. Radiographs of the foot demonstrate flattening, sclerosis, and irregularity of the metatarsal head. CT scan or technetium-99m bone scan may serve to clarify the diagnosis in selected patients whose diagnosis remains obscure.

Management is as an outpatient, utilizing a short-leg walking cast for 3 to 4 weeks. Follow-up care is provided by an orthopedist who may recommend a surgical excision of the affected area of metatarsal if conservative therapy is ineffective.

Osgood-Schlatter Disease

This very common syndrome affects preadolescent males three times more often than females. The etiology is a traumatic stress imposed upon the proximal tibial tuberosity by a contracted quadriceps muscle mechanism. The ligamentum patellae detaches cartilaginous fragments from the tibial tuberosity without necrosis. However, an inflammatory process is established by the reparative process, resulting in a patellar tendinitis and a remarkable prominence, induration, and tenderness of the tibial tuberosity. There is no avascular necrosis of the tibial tuberosity.

The patient complains of pain and tenderness over the anterior aspect of the knee and of the tibial tuberosity. It is exacerbated by running, climbing stairs, jumping, and kneeling. Symptoms are relieved with rest. Examination reveals thickening and tenderness of the patellar tendon, with maximum palpation tenderness over the insertion point of the patellar tendon onto the tibial tubercle. The tibial tuberosity is noticeably enlarged and indurated. There is no knee effusion.

Radiographs illustrate patellar tendon thickening and soft tissue swelling over the tibial tuberosity without knee effusion. The irregularity of the ossification of the tibial tubercle is normal for this age group and is *not* a diagnostic feature of Osgood-Schlatter disease. However, prominence of the tibial tuberosity, with or without a small,

free bone fragment located anterior and superior to the tibial tubercle, *is* characteristic of the disorder.

The disease is self-limited. Acute symptoms subside following restriction from excessive physical activities for a period of approximately 3 months. Severely painful knees may benefit symptomatically from the use of crutches. Contracted, taut, hypertrophic quadriceps and hamstring muscles require stretching exercises. Rarely, more aggressive strategies to ensure rest of the knee are utilized, such as the use of a knee immobilizer or long leg cylinder cast. Even so, the stretching exercises of the quadriceps and hamstring groups are continued. The use of glucocorticoid injection into the patellar tendon and the parapophyseal soft tissues is controversial and is to be discouraged.

ACUTE SUPPURATIVE ARTHRITIS

Acute suppurative arthritis, an inflammation of a joint caused by pyogenic organisms, occurs in all age groups but is more common in neonates, infants, and children less than 3 years of age. The hip is the most commonly involved joint, followed in frequency by the knee and the elbow. Any joint can be involved. Simultaneous infection of more than a single joint can occur.

Bacteria may access the joint through hematogenous transmission, from direct extension of infection from an adjacent area of infected metaphyseal bone, or via direct inoculation during arthrocentesis, or accidentally during femoral venipuncture. The etiologic organisms encountered in septic arthritis vary with the age of the child (Table 132-1). The relative frequency of *Haemophilus influenzae* is decreasing as a consequence of immunization practices.

Newborn (0–2 Months)	% of Cases	Infant (2–36 Months)	% of Cases	Child (>36 Months)	% of Cases
Staphylococcus aureus	15–40	H. influenzae†	30–35	Staph. aureus	30–45
Group B Streptococcus	20–25	Streptococcus species	12	Streptococcus species	18–26
Gram-negative bacilli	10–20	Staph. aureus	11	Gram-negative bacilli	10–15
Neisseria gonorrhoeae	5–7	Gram-negative bacilli	8	Strep. pneumoniae	7
Haemophilus influenzae	1	Unknown or unidentified	35	N. gonorrhoeae	5–10
Candida albicans*	7–17				

*Hospital acquired.
†Data collected prior to implementation of H. influenzae B (Hib) vaccine.

TABLE 132-1   Causes of Suppurative Arthritis in Children

The pathophysiology of septic arthritis exemplifies the seriousness of the condition and the risks of long-term sequelae. Synovial edema and hyperemia accompany increased secretion of synovial fluid, which may be serosanguinous early on, cloudy, or suppurative with polymorphonuclear (PMN) leukocyte counts ranging from 5000 to 200,000 and exceeding 50,000/μL^3 after the earliest stages. Synovial fluid glucose concentration is decreased, and the protein content is elevated. The mucin string is poor to very poor. Within days, the synovial fluid becomes frankly purulent, if it was not so initially. The hyaline articular cartilages degenerate initially at points of contact between opposing articular surfaces. The synovium itself is eventually replaced by granulation tissue, and the infection invades surrounding bone, particularly epiphyseal and metaphyseal bone. Adhesions are created within the joint and restrict motion. Subluxation or dislocation may occur in the setting of marked distention of the damaged joint capsule. In the hip joint, avascular necrosis of the femoral head ensues. Eventually, the untreated infection leads to ankylosis or total destruction of the joint.

Although systemic symptoms can be subtle in the newborn, the diagnosis is not usually in doubt in the older infant or toddler. Symptoms are acute in onset and predominantly involve pain in the affected joint. The child with a lower extremity septic arthritis walks with a severely antalgic limp or, more typically, cannot bear weight at all. Profound signs of constitutional and systemic illness are the rule, with high fever [40 to 40.5°C (104 to 105°F)], apprehension, irritability, anorexia, and prostration manifestly apparent. Examination of the affected joint demonstrates warmth, soft tissue swelling, and exquisite palpation tenderness. The child maintains an infected hip in 30° to 60° of flexion, with milder degrees of abduction and external rotation.

Radiographic imaging studies are helpful but nondiagnostic. They are important in order to ensure the absence of changes that would indicate adjacent osteomyelitis, fracture, or other processes. The expected findings are those of joint effusion and distention (Fig. 132-7). Comparison films of the contralateral joint in question are often helpful.

FIG. 132-7. Large left hip effusion in child with suppurative arthritis.

The differential diagnosis includes osteomyelitis, ARF, acute pauciarticular juvenile rheumatoid arthritis (JRA), transient tenosynovitis, cellulitis and suppurative bursitis, hemarthrosis, Legg-Calvé-Perthes disease, and SCFE (when the involved joint is the hip).

Distinguishing suppurative arthritis from osteomyelitis involving an adjacent metaphysis is probably the most difficult problem in the differential diagnosis. Gentle examination may enable the physician to ascertain the area of greatest tenderness. Osteomyelitis is most tender over the metaphysis, while septic arthritis manifests greatest tenderness directly over the joint line. Motion of the joint is much more painful and more restricted in septic arthritis compared to osteomyelitis. Osteomyelitis creates more swelling over the limb as a whole. Arthrocentesis is necessary to establish the diagnosis of suppurative arthritis. Care is necessary during the arthrocentesis to avoid contaminating a noninfected joint by introducing organisms from an infected metaphysis, cellulitis, or bursa. A sympathetic effusion from an area of metaphyseal osteomyelitis usually is serous and contains only a few thousand PMNs.

The other differential diagnostic considerations usually pose fewer problems to the clinician. Transient tenosynovitis does not manifest symptoms and signs of systemic toxicity. The peripheral WBC and ESR are normal or only minimally elevated. Occasionally, arthrocentesis is necessary to adequately exclude the diagnosis of suppurative arthritis, however. JRA of the pauciarticular form may present with an isolated inflamed joint but is usually an illness of gradual onset, and the child does not appear toxically ill. The affected joint is not as tender as in septic arthritis and has better range of motion. Although the WBC is elevated and the mucin string is poor in both conditions, the Gram stain of synovial fluid in JRA is negative and its culture is sterile.

Rheumatic fever is characterized by the fleeting, migratory nature of the arthritis and may be associated with other stigmata, such as carditis, as illustrated by Jones' revised criteria for the diagnosis of ARF (see Table 132-5). There is a remarkable responsiveness of the arthritis of ARF to salicylates. The response of the arthritis to salicylates should be used as a diagnostic tool only after the diagnosis of suppurative arthritis has been excluded by arthrocentesis, with Gram stain and culture of the

synovial fluid.

Major	Minor
Carditis	Fever
New or changing murmurs	Arthralgia
Cardiomegaly, congestive heart	History of previous attack of ARF
failure	Elevated ESR, C-reactive protein
Pericarditis	Prolonged PR interval on
Migratory polyarthritis	electrocardiogram
Chorea	Rising titer of antistreptococcal
Erythema marginatum	antibodies
Subcutaneous nodules	

Note: Diagnosis is likely when two major criteria or one major and two minor criteria are met. Group A *Streptococcus* may be documented by a history of scarlet fever, isolation of group A *Streptococcus* from throat culture, or rising titers of antistreptococcal antibodies.

TABLE 132-5   Revised Jones' Criteria for the Diagnosis of Acute Rheumatic Fever

Cellulitis is notable for local skin erythema, induration, and tenderness. The adjacent joint has relatively preserved motion and is less tender. Lymphangitis or regional lymphadenitis is commonly encountered with cellulitis. Often the patient or examiner will note the presence of a minor abrasion, laceration, puncture, or furuncle within the cellulitis, serving as an entrance site for local invasion of bacteria.

Hemarthrosis can rarely pose a problem in the differential diagnosis of septic arthritis. In the absence of a history of trauma, a congenital or acquired coagulopathy is suspected (hemophilia A, factor IX deficiency, Von Willebrand disease, leukemia, etc.). Henoch-Schönlein purpura may present with one or more painful joints prior to manifestation of the other cardinal symptoms of the disease (abdominal pain, nephritis, purpura). The arthralgia with this condition is migratory, however, and represents a periarticulitis rather than an actual arthritis. If the joint of involvement happens to be the hip, a diagnosis of Legg-Calvé-Perthes disease may come to mind. This condition is not, however, associated with high fever, systemic signs of illness, and prostration, and the examination and culture of the synovial fluid will easily distinguish this condition from septic arthritis.

The management of acute suppurative arthritis consists of (1) establishing the diagnosis by obtaining synovial fluid from the infected joint for Gram stain and culture as well as other microscopic and laboratory studies; (2) drainage of the infected joint of bacterial products and infectious debris [suppurative arthritis of the hip requires open surgical drainage (arthrotomy), while more superficial joints can frequently be drained arthroscopically or even through arthrocentesis]; (3) emergent initiation of appropriate initial antibiotic therapy (Table 132-2); and (4) local care of the joint (support by skin traction for larger joints; splinting of the wrist, ankle, and smaller joints).

Age	Suspected Organism	Antibiotics
Newborn (0–2 months)	*Staph. aureus*	Methicillin or nafcillin*
	Group B *Streptococcus*	Ampicillin or penicillin and gentamicin
	Gram-negative bacilli	Cefotaxime/ceftriaxone
	N. gonorrhoeae	Cefotaxime/ceftriaxone
	Unknown	Methicillin or nafcillin* and cefotaxime/ceftriaxone
Infant (2–36 months)	*H. influenzae*	Cefuroxime or cefotaxime/ceftriaxone
	Streptococcus species	Penicillin G
	Staph. aureus	Methicillin or nafcillin*
	Gram-negative bacilli	Cefotaxime/ceftriaxone
	Unknown	Methicillin or nafcillin* and cefotaxime/ceftriaxone
Child (>36 months)	*Staph. aureus*	Methicillin or nafcillin*
	Streptococcus species	Penicillin G, other β-lactams, clindamycin
	Gram-negative bacilli	Cefotaxime/ceftriaxone
	N. gonorrhoeae	Ceftriaxone or penicillin G
	Unknown	Methicillin or nafcillin* and cefotaxime/ceftriaxone

*Vancomycin, if methicillinase-resistant *Staph. aureus* is suspected.

TABLE 132-2   Initial Antibiotic Therapy of Acute Suppurative Arthritis in Children

An analysis of the cerebrospinal fluid (CSF) is indicated in children suspected of suppurative arthritis or osteomyelitis caused by *H. influenzae*. This is necessary, since meningitis is a frequently coexisting illness in children with *H. influenzae* suppurative arthritis and since the antibiotic dosages for meningitis differ from the dosages used in suppurative arthritis. Follow-up considerations (e.g., hearing tests and cognitive tests) will also vary in the setting of coexisting meningitis.

The prognosis of suppurative arthritis is influenced by (1) the length of time between onset of symptoms and initiation of treatment, (2) the joint involved (prognosis is poorer if the hip is involved), (3) the presence of associated osteomyelitis (poorer), and (4) the age of the patient, with neonates and younger infants having a less favorable prognosis than older children due to the typically longer delay in initiation of specific treatment.

STRUCTURAL SCOLIOSIS

Scoliosis is a lateral deviation of a series of vertebral bodies from the normal spinal axis. If scoliosis is progressive, structural deformities occur in the vertebral bodies and the rib cage. Scoliosis is a physical sign and is not itself a diagnosis. Eighty percent of structural scoliosis is idiopathic: it is not related to a paralytic or neurologic etiology, and there are no causative congenital vertebral anomalies.

There are three peak periods of onset of idiopathic structural scoliosis: infantile (0 to 3 years), juvenile (4 years to puberty), and adolescent (onset of puberty to physeal closure). Prevalence data have been obtained in two ways historically: school screening and chest radiographs obtained for screening of tuberculosis. The prevalence of curves of less than 10° is 2 to 3 percent in North America, while the prevalence of more severe curves decreases as the severity of the curve increases. While the prevalence of minor (<10°) curves is equal among boys and girls, there is a distinct female gender predilection for curves exceeding 15° to 20°. This presumably is related to the observation that curve progression is more common in girls.

Large-scale screening programs remain somewhat controversial. Overreferral to orthopedists is common and is to be expected. Use of a scoliometer can dramatically reduce overreferral. The potential for excessive exposure to ionizing radiation is minimized by ensuring that an experienced orthopedic surgeon reexamines all referred patients prior to the ordering of the diagnostic scoliosis radiogram (single, standing AP radiogram of the entire spine with the iliac crests as high as possible). Another difficulty with screening programs is parental noncompliance. Finally, the cost effectiveness of large-scale screening programs is yet to be firmly established.

Despite the difficulties and controversies of large-scale screening programs, primary care physicians and emergency physicians are in a strong position to rapidly and easily identify scoliosis in children presenting to the emergency department for unrelated problems. Children with scoliosis do not usually complain of backache or fatigue. Their complaints, if they have any, relate to concerns of high shoulder; prominent scapula or breast; prominent hip; asymmetry of rib cage, trunk, or flank creases; or poor posture; or they have noticed the curve itself.

When the diagnosis is being considered, the examination of the child and the spine should be orderly. The child is observed standing, first clothed, then unclothed (but with appropriate draping for modesty), for body habitus, posture, and alignment. Lateral deformity of the spine is usually best visualized from behind the standing child. Look for balance of the head, neck, and shoulders over the pelvis. A plumb line held over the spinous process of the seventh cervical vertebra normally should pass right over the intergluteal cleft. Lateral deviation from the midline should be noted and can be measured in centimeters.

The Adams forward bending test optimally demonstrates the degree and direction of any associated rotation of the vertebrae. The patient's knees should be straight and the feet placed together. The child bends forward at the hips with the arms dependent and the palms held in opposition. The child is inspected head on for cervical and thoracic rotation and from the rear for thoracolumbar and lumbar rotation. The right and left posterior rib cage and the paravertebral lumbosacral muscles

are inspected and compared for asymmetry. Rotational abnormalities of the vertebral bodies, associated with the lateral curvature of scoliosis, will result in one side (rib cage and paravertebral lumbar muscles) being higher than the other. In structural scoliosis, the vertebral body rotation is toward the convex side of the curve of the scoliosis and toward the elevated side of the rib cage or paravertebral lumbar muscles. This asymmetry can be quantified by use of a scoliometer, a gravity level device that measures in degrees of rotation. Scoliosis manifesting greater than 10° of vertebral rotation warrants referral to an orthopedic surgeon.

Conservative management of scoliosis is employed for structural scoliosis manifesting less than 50° of vertebral rotation or 50° of curve when measured radiographically. Various orthotic braces are utilized with varying success. Nonoperative candidates with more severe curves (35° to 50°) usually obtain better results using orthotic devices worn nearly continuously (23 h daily), compared to nighttime-only braces. All of these devices are fitted to a particular child's torso. They require substantial discipline on the part of the child and the parents, however. Careful follow-up care is provided by the orthopedic surgeon, who must be particularly vigilant for progression of the scoliosis, defined as an increase in the curvature of more than 5° on two or more successive visits. Such curve progression is ominous in that it is associated with the development of more severe curvatures ultimately requiring surgical stabilization.

SELECTED RHEUMATOLOGIC DISORDERS IN CHILDREN

Kawasaki Syndrome

Kawasaki syndrome is a generalized vasculitis involving small and medium size arteries, with characteristic involvement of the coronary arteries. There is growing evidence to suggest that Kawasaki syndrome is caused by superantigen bacterial toxins, which stimulate large populations of T cells expressing particular T-cell receptor β chain variable-gene segments. Superantigen stimulation induces massive proliferation and expansion of the target T cells, with subsequent production of proinflammatory cytokines. Vascular endothelial cells are recruited into this inflammatory process with resulting vascular damage. Toxins elaborated by *Staph. aureus* and *Streptococcus pyogenes* are known to possess superantigen properties. There is increasing evidence to suggest that these organisms elaborate superantigen toxins in children with Kawasaki syndrome.

Epidemiologically, Kawasaki syndrome affects 3000 to 5000 children annually in the United States. There is a male-to-female preponderance of 1.5 to 1. The peak age of onset is 1 to 2 years, with 80 percent of patients being less than 4 years of age.

The diagnosis of Kawasaki syndrome is established by the presence of clinical criteria listed in Table 132-3. The fever is high, spiking, and prolonged, persisting for 1 to 2 weeks in untreated patients. The conjunctivitis is nonpurulent and bilateral and has an onset shortly after the appearance of the fever. The oropharyngeal features are prominent during the acute febrile period. The extremities, particularly the palms and soles, are often quite painful. The polymorphous rash is most commonly a raised, deep-red, plaquelike eruption. Less commonly, it may be scarlatiniform, a morbilliform maculopapular rash, or even a fine pustular eruption. It is most widespread on the trunk and proximal extremities, with particular involvement of the perineum. At least one cervical lymph node measuring 1.5 cm in diameter is necessary to fill the lymphadenopathy criterion. There are a wide variety of associated findings in Kawasaki syndrome, as illustrated in Table 132-4.

Fever of at least 5 days' duration (100%)

Presence of at least four of the following five conditions:
1. Bilateral conjunctivitis (85%)
2. Changes of the lips and oral mucosa (90%)
   Dry, red, fissured lips
   Strawberry tongue
   Oropharyngeal edema
3. Changes of the extremities (75%)
   Erythema of palms and soles
   Edema of hands and feet
   Periungual desquamation
4. Polymorphous rash (80%)
5. Cervical lymphadenopathy (70%)

Illness not explained by other known disease process

TABLE 132-3   Diagnostic Criteria for Kawasaki Syndrome

Cardiovascular system	Genitourinary system
Coronary artery aneurysms	Urethritis with sterile pyuria
Myocarditis-pericarditis	Proteinuria
Mitral or aortic insufficiency	Pulmonary system
Dysrhythmias	Pneumonitis
Peripheral ischemia	Cough, coryza
Central nervous system	Gastrointestinal system
Irritability	Hydrops of the gall bladder
Aseptic meningitis	Hepatitis
Anterior uveitis	Nausea, vomiting, diarrhea
Sensorineural hearing loss	Abdominal pain
Hematologic system	
Thrombocytosis (subacute phase)	
Anemia	

TABLE 132-4   Associated Features of Kawasaki Syndrome

The acute febrile phase of the disease lasts 7 to 14 days and is marked by the features listed in Table 132-3. The subacute phase, lasting 2 to 4 weeks, is indicated by a gradual resolution of the fever, rash, and lymphadenopathy. The irritability and conjunctival injection may persist. The characteristic desquamation of the fingers and toes occurs during this subacute phase, as does the associated symptom of arthralgia or arthritis. Thrombocytosis approaching $1,000,000/\mu L^3$ is also noted during this subacute phase, during which time the patient is at greatest risk for the development of coronary artery thrombosis. The convalescent phase begins when all clinical and associated signs and symptoms have disappeared and continues until the ESR and the platelet count return to normal (6 to 10 weeks).

An acute carditis develops in 50 percent of patients, usually manifested by a myocarditis with symptoms of tachycardia and gallop rhythms indicative of mild to severe congestive heart failure. Pericarditis, conduction disturbances, and valvular insufficiencies are less frequent manifestations of carditis.

Most seriously, coronary artery aneurysmal dilatations occur in 20 percent of untreated patients. Coronary artery involvement can be detected as early as the seventh day, with a peak frequency of coronary aneurysm formation occurring 4 weeks after the onset of illness. Untreated, the coronary artery aneurysms are quite prone to thrombosis during the subacute phase because of the hypercoagulable state created by the thrombocytosis. Sudden death can occur in 1 to 2 percent of untreated patients, and the remainder are at risk for long-term consequences such as coronary artery stenosis and subsequent cardiac ischemia.

The laboratory features of Kawasaki syndrome reflect the marked inflammatory and immune activation characteristic of the disease. Such findings, however, are nonspecific. A moderate leukocytosis with a left shift, a remarkable thrombocytosis appearing during the second week of the illness, and other secondary laboratory abnormalities consistent with a diffuse systemic vasculitis may be present.

The care of the child with Kawasaki syndrome in the emergency department consists primarily of establishing the diagnosis. Patients meeting diagnostic criteria with consistent laboratory findings are usually admitted. The use of intravenous immunoglobulin (IVIG) has substantially decreased the morbidity and mortality associated with the disease. Rapid resolution of fever and the other clinical stigmata and reversal of the laboratory abnormalities occur following IVIG infusion. More importantly, the use of IVIG within the first 10 days of the illness reduces the incidence of coronary artery aneurysms to 3 to 4 percent. It also has been demonstrated to be effective in promoting the resolution of established aneurysms. A single infusion of intravenous IVIG in a dose of 2 g/kg infused over a 10-h period has been demonstrated to be the most effective regimen. Aspirin can be used as adjunctive therapy in anti-inflammatory doses of 80 to 100 mg/kg/day until the fourteenth day of the illness. The dose is then reduced to 3 to 5 mg/kg/day for its platelet antiadhesive effect during the period when the child is at risk of clotting coronary artery

aneurysms due to the thrombosis. Usually, the low dose aspirin therapy is continued until the platelet count returns to normal. However, patients exhibiting coronary aneurysms despite IVIG therapy should receive low dose aspirin indefinitely or for at least 1 year following the resolution of the aneurysms. Echocardiography, necessary to identify coronary artery aneurysms, provides valuable baseline information for the child who does not initially manifest abnormalities. The echocardiogram is repeated 3 to 6 weeks after IVIG therapy in order to guide further aspirin therapy decisions.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura is a common, self-limited generalized leukocytoclastic vasculitis. Vasculitis involves primarily small vessels and is mediated by immune complexes produced through IgA and the alternate complement pathways. A variety of infectious and noninfectious stimuli appear to precipitate the immunologic mechanisms of the vasculitis.

The disorder is classically characterized by the appearance of a dermovasculitis with a propensity for the lower trunk, buttocks, perineum, and lower extremities, as is characteristic of generalized vasculitides (Fig. 132-8). In addition, the vasculitis includes involvement of the glomeruli, with the subsequent development of hematuria and with the potential for long-term renal sequelae. Involvement of the bowel wall causes recurrent colicky abdominal pain and frequently leads to the development of melena or hematochezia. Eight percent of children with severe abdominal colic caused by Henoch-Schönlein purpura experience massive gastrointestinal hemorrhage or intussusception. Arthritis, or, more specifically, a polymigratory periarticulitis, occurs in most affected children. Rarely, massive pulmonary hemorrhage can occur.
FIG. 132-8. Henoch-Schönlein purpura. Purpuric lesions of dependent body areas, particularly on flanks, buttocks, and lower extremities.

The clinical diagnosis is not usually obscure in those children manifesting all or several characteristics of the disorder. The child with hematuria, abdominal pain, a history of migratory periarthritis, and a palpable, purpuric tender rash on the buttock and lower extremity is not a diagnostic dilemma. Difficulty ensues upon the evaluation of a child manifesting exclusively abdominal colic or apparent arthritis.

Care of the child with suspected Henoch-Schönlein purpura in the emergency department consists of establishing the diagnosis or maintaining a high index of suspicion for the diagnosis. Otherwise, emergency care is entirely supportive. Consideration of specific laboratory or imaging studies is influenced by the specific symptoms manifested by the child. For example, the child presenting exclusively with hematuria and abdominal pain may require a urine analysis and urine culture, a kidney-ureter-bladder abdominal radiograph, assessment of renal function, and a complete blood count. Such circumstances might even serve as an indication for a renal ultrasound or an intravenous pyelogram if the clinician suspects ureterolithiasis as the cause of the child's symptoms. Similarly, a child with migratory polyarthritis might reasonably be expected to undergo an evaluation of arthritis, including plain radiographs of affected joints, complete blood count, rheumatoid factor titer, antinuclear antibody titer (ANA) and complement levels. In summary, the diagnostic evaluation in the emergency department is often influenced by the need to exclude other disease processes that share common features with this generalized vasculitis. When the entire clinical picture presents itself, however, the extent of the diagnostic workup is much reduced.

Children with Henoch-Schönlein purpura are admitted to the hospital when the diagnosis is in doubt, for observation and control of abdominal pain, for monitoring of renal function, and for fluid hydration in the setting of recurrent emesis. Children with extremely mild symptoms can be safely and expectantly observed as outpatients, as long as an experienced primary care provider is available. Arthritis, when present as an isolated symptom, is usually easily controlled with aspirin. Prednisone is not utilized in the management of arthritis when it represents the child's only symptom of active vasculitis. The child's primary care physician maintains contact with the family on a daily basis and evaluates the child in the office at frequent intervals in the initial weeks following the establishment of the diagnosis. Particular attention is directed to the development of symptoms suggestive of abdominal colic, gastrointestinal hemorrhage, intussusception, and the development of chronic renal disease. Chronic renal sequelae are reported in approximately 7 to 9 percent of children with Henoch-Schönlein purpura and do not respond well to glucocorticoid therapy.

Poststreptococcal Reactive Arthritis

As a result of an increase of reported cases of group A b-hemolytic streptococcal infections in recent years, emergency physicians have joined the ranks of clinicians concerned about poststreptococcal nonsuppurative sequelae. In addition to ARF, discussed previously, an understanding has emerged recently that poststreptococcal reactive arthritis represents a distinct clinical entity that may also be seen with increasing frequency.

Reactive arthritis is a sterile inflammatory mono- or oligoarthritis that occurs in association with a primary infection at a distant site. The primary infection associated with reactive arthritis may be caused by a variety of reported organisms. In addition to group A b-hemolytic streptococci, primary infections with *Salmonella, Staphylococcus,* and other groups of *Streptococcus* have been reportedly associated with reactive arthritis. Unlike ARF, reactive arthritis is not associated with carditis.

The differences in pathogenesis between poststreptococcal reactive arthritis (PSRA) and ARF are incompletely understood. Both syndromes occur secondary to group A b-hemolytic streptococcal throat infection. It has been speculated that differences in virulence among streptococcal M serotypes or the presence of coinfecting viruses may explain the development of ARF rather than the more benign reactive arthritis. Human host factors, such age-related and gender-related differences in immune response, may contribute to the different paths of clinical sequelae.

The differentiation between ARF and PSRA rests entirely on clinical grounds. The arthritis of PSRA predominantly affects females, while the arthritis of ARF is more commonly in males. Of poststreptococcal nonsuppurative sequelae, ARF is observed more commonly in younger patients (mean age, 12 +/- 4 years). While the typical patient with reactive arthritis is older, it may occur in children as young as 4 years of age. The arthritis of ARF is classically a migratory polyarthritis, while the arthritis of PSRA is described as a nonmigratory mono- or oligoarthritis. Erythema nodosum and erythema multiforme are frequently associated with PSRA while encountered only sporadically and infrequently in cases of ARF. Both reactive arthritis and ARF have been sporadically reported to be associated with a cholestatic hepatitis with piecemeal necrosis. Finally, patients experiencing the full clinical expression of reactive arthritis suffer a much milder illness than is seen in classic ARF.

Management of PSRA consists of nonsteroidal anti-inflammatory medications, to which the inflammatory arthritis is highly responsive. The issue of penicillin prophylaxis, a mainstay in the long-term management of ARF, is controversial with PSRA, and almost certainly will be resolved only following long-term prospective study.

Acute Rheumatic Fever

An acute inflammatory disease affecting widely disparate organ systems, ARF primarily affects children of school age. The incidence of ARF has steadily fallen in developed countries over the past 50 years. However, a resurgence in cases of group A b-hemolytic streptococcal infections over the past 10 years has increased concerns about ARF and other nonsuppurative sequelae of streptococcal infections. Outbreaks of ARF are regularly reported in North America. It is preceded by infection with certain strains of group A b-hemolytic *Streptococcus* (mucoid types 3, 5, and 18). Different layers of the cell wall of the streptococcal organism appear to

stimulate antibody production to variable host tissues. The hallmark histologic feature of rheumatic fever is the Aschoff body, found in the connective tissue and created by edematous, fragmented collagen fibers. The connective tissue of the heart, joints, central nervous system, and subcutaneous tissues and skin are targeted by the immune reaction. The carditis is an endomyocarditis, with valvulitis primarily involving the mitral and aortic valves. The arthritis is characterized by synovial edema and periarticular swelling with joint effusions.

The child develops the disorder 2 to 6 weeks following a streptococcal pharyngitis. While nonspecific symptoms of systemic illness predominate early on, physical examination eventually reveals evidence of arthritis, carditis, choreiform movements, erythema marginatum, or subcutaneous nodules, individually or in combination. Jones' criteria for establishing a diagnosis of acute rheumatic fever are illustrated in Table 132-5. Either two major criteria or one major and two minor criteria plus evidence of an antecedent streptococcal infection are necessary to establish the diagnosis.

Arthritis (occurring in 60 to 75 percent of initial attacks) is characterized as a migratory, fleeting polyarticular arthritis primarily affecting the large joints. The carditis occurs in a third of new cases and may be mild or severe. Its presence is heralded by any combination of a new cardiac murmur, tachycardia, a gallop rhythm, a pericardial friction rub, congestive heart failure, or a hyperactive precordium. Sydenham's chorea occurs in 10 percent of cases and may have its initial appearance months following a streptococcal infection. Chorea may be the sole manifestation of acute rheumatic fever. The skin rash of acute rheumatic fever (erythema marginatum) is described as serpiginous and persists only for several days. It usually coexists with the presence of carditis in some form. Subcutaneous nodules are more rare and are located on the extensor surfaces of the wrists, elbows, and knees. The greatest morbidity and mortality is associated with the development of carditis.

Diagnostic studies are utilized to clarify the associated antecedent infection by group A streptococcus (a pharyngeal swab for culture, antistreptolysin titers, or streptozyme titers), or are employed to identify and assess the presence and extent of carditis. An electrocardiogram, is obtained to assess for conduction delays or hypertrophy. A chest x-ray serves to identify cardiac dilatation or pulmonary vascular congestion or edema. Echocardiography is utilized to identify evidence of valvulitis or valvular insufficiency and also to exclude other diagnostic considerations.

The differential diagnosis includes JRA, septic arthritis, Kawasaki syndrome, viral or other forms of cardiomyopathy, leukemias, and other forms of vasculitis, including drug reactions. Rarely, tumors of the central nervous system require differentiation from ARF when the child's sole clinical manifestation is chorea.

Treatment of ARF in the emergency department is directed primarily toward the management of complicating features of carditis. In the absence of cardiac or hemodynamic instability (and such is the rule), early consultation with a pediatric cardiologist is recommended, and admission to the hospital is generally advised in the early stages until the diagnosis is confirmed. Arthritis is managed with high-dose aspirin therapy (75 to 100 mg/kg/day) in order to effect a serum salicylate level in the range of 20 to 30 mg/dL. The aspirin dose is reduced after approximately 1 week to 50 mg/kg/day for an additional 4 to 6 weeks. Significant carditis or congestive heart failure is managed with glucocorticoids, usually in the form of prednisone in a dose of 1 to 2 mg/kg/day. This is continued for 2 weeks following the resolution of symptoms and the return of the ESR to normal. The duration of glucocorticoid therapy requires a subsequent taper of the steroids over a 4 to 6 week period. Chorea can be managed with haloperidol, 0.01 to 0.03 mg/kg/day in four divided doses. All children with ARF are treated with penicillin, even if the cultures for group A *Streptococcus* are negative. Benzathine penicillin G can be administered in a single dosage of 1.2 MU. Alternatively, procaine penicillin G 600,000 U can be administered daily for 10 days. Penicillin V 25,000 to 50,000 U/kg/day divided into four doses and administered orally is also effective. Erythromycin may be substituted for the penicillin-allergic patient. All therapy, if pursued, is administered for 10 days. Long-term prophylactic therapy against group A *Streptococcus* is begun upon completion of the acute phase of therapy. Acceptable prophylactic regimens include benzathine penicillin G, 1.2 MU administered intramuscularly every month, penicillin V 200,000 U administered orally twice daily, or sulfadiazine 1 g administered orally each day. The duration of required prophylactic therapy is incompletely understood, but 5 years of prophylactic antibiotics for those children without cardiac involvement represents the minimum. Patients with manifestations of carditis are placed on life-long prophylactic antibiotic regimens.

Juvenile Rheumatoid Arthritis

JRA is not a single entity. Rather, it encompasses a group of disorders characterized by chronic noninfectious synovitis and arthritis and is associated with a wide range of systemic manifestations. The hypothetical etiology of the arthritis is that of an autoimmune response to a number of antigens not yet completely identified.

Pauciarticular disease is the most common form of the disease in children. It usually involves a single large joint, typically the knee. Serologic findings for rheumatoid factor are negative, while ANA titers are positive in 90 percent of patients. Extraarticular manifestations of this form of the disease include the development of iridocyclitis, Reiter's syndrome, and inflammatory bowel disease. Ultimate joint damage occurs only infrequently.

Polyarticular disease occurs in approximately a third of cases. Rheumatoid factor (RF) serology may be positive or negative, while ANA titers are positive in 25 percent of the RF-negative patients and 75 percent of RF-positive patients. There is a female preponderance, and both large and small joints may be affected. Contrary to the case in pauciarticular JRA, long-term morbidity with polyarticular disease is related to progressive joint destruction, particularly of the hips and knees.

Systemic JRA is the least common presentation, occurring in only about 20 percent of children with the disease. This form is associated with the particularly high fevers commonly associated with the disease, which characteristically produces one or two fever spikes per day exceeding 39.5°C, and is often associated with shaking chills. In addition, there are other prominent extraarticular manifestations of the disease including a pale, erythematous coalescing macular rash, primarily on the trunk but also present in other areas including palms and soles. Hepatosplenomegaly, pleuritis, and pericarditis are common. Serology for RF and ANA are negative. The arthritis of systemic JRA may progress substantially, leading to joint destruction in as many as a quarter of patients.

Laboratory evaluations associated with the disease are not highly specific for JRA. Arthrocentesis is often necessary to exclude acute suppurative arthritis, particularly in pauciarticular presentations. Initially, radiographs demonstrate only soft tissue swelling and synovial effusions. The findings associated with bone and joint damage occur later.

Emergency department management focuses primarily upon excluding other diagnostic considerations, especially in children who have not previously received a confirmed diagnosis of JRA. Hospital admission is recommended for those children in whom the diagnosis is in doubt or who are to be treated empirically for suspected acute suppurative arthritis while synovial fluid cultures are pending.

Initial therapy for those with an established diagnosis includes aspirin at a dosage of 80 to 125 mg/kg/day, with careful monitoring of salicylate levels to maintain a therapeutic level between 20 and 30 mg/dL. Other nonsteroidal anti-inflammatory drugs are becoming increasingly popular.

The use of glucocorticoids should be reserved for use exclusively in those patients in whom the diagnosis is categorically certain and whose systemic JRA symptoms have proved unresponsive to aspirin. They are also utilized in the management of decompensated pericarditis or myocarditis and in the management of unresponsive iridocyclitis. Other management strategies, including intraarticular glucocorticoid injections and the use of gold or chloroquine, or cytosine, should be initiated by a pediatric rheumatologist.

133 SICKLE CELL DISEASE

Peter J. Paganussi
Thom Mayer
Maybelle Kou

Sickle cell disease (SCD) is among the most common inherited disorders worldwide. It is the most common pediatric genetic condition encountered in emergency medicine, especially in urban settings. This genetic condition is found primarily in people of African, Mediterranean, Indian, or Middle Eastern heritage.

In the United States about 8 percent of the African-American population carries the hemoglobin (HgbS) gene and about 0.15 percent (approximately 1/500) are homozygous (HgbSS). These individuals have a predominance of "sickled" hemoglobin, thus resulting in symptomatic SCD. Patients with this hemoglobinopathy have both sickle (A_2) and fetal hemoglobin. The most frequently encountered heterozygous sickle genotypes are HgbSA (sickle cell trait), Hgb-beta thalassemia (sickle beta thalassemia), and HgbSC (sickle cell–hemoglobin SCD). These less common variants of the homozygous disorder have similar, but far less severe, clinical manifestations. Patients with sickle cell trait have a normal life expectancy. However, SCD is associated with a significant mortality rate: 20 to 30 percent of all deaths from SCD occur before 5 years, with a mean age at death of 14 years of age. Current survival has been greatly improved as a result of more aggressive infection prophylaxis and advances in therapy. Nonetheless, the highest mortality occurs in children between 1 and 3 years of age, with sepsis being the leading cause of death.

The end-organ pathology created by sickle cell anemia can be found in every organ system. Clinical effects of the disorder can begin in infancy but usually are not seen until 5 to 6 months of age, because high levels of fetal hemoglobin are present following birth, and the beta-Hgb subunit is not predominant until about 3 months of age. SCD is characterized by abnormal sickle-shaped cells that are less deformable than normal red blood cells. Aggregation of these less pliant, abnormally shaped cells leads to obstruction and thrombosis of small vessels, resulting in ischemia and tissue infarction, leading to end-organ dysfunction.

PATHOPHYSIOLOGY

The genetic abnormality responsible for the sickling process is caused by a single amino acid substitution of valine for glutamic acid in the beta subunit of the hemoglobin molecule. The resultant hemolytic anemia is caused by the abnormal properties of HgbS. Affected red blood cells undergo repeated cycles of sickling and unsickling, with the HgbS strands polymerizing abnormally in response to deoxygenation. Without an attached O_2 molecule, they tend to coalesce and stretch into long monofilaments, thereby resulting in the distorted sickle shape of the red cell membrane. These irreversibly sickled cells diminish blood viscosity, causing hemolysis and obstructing the microcirculation (vasoocclusive phenomenon) of end-organ tissues. Capillary obstruction deprives tissues of oxygen and metabolic nutrition. It has long been presumed that the resultant hypoxia and ischemia cause the pathologic and clinical features of the disease. This entire process is felt to be self-perpetuating and sustains continued sickling. Others have recently proposed that plasma proteins, endothelial cells, and other genetically driven mechanisms play a major role in this complex process. A few investigators have even questioned whether vaso-occlusion exists at all, theorizing that tissue ischemia and infarction result from shunting of blood away from end-organ vascular beds rather than occlusion by deformed, sickled cells.

CLINICAL PRESENTATION

Patients with SCD classically present with signs and symptoms classified by the type of crisis they manifest (Table 133-1).

Vasoocclusive crises
  Musculoskeletal
    Long bones
    Lumbosacral
    Dactylitis
  Abdominal pain
    Generalized
    Right-upper-quadrant syndrome
  Acute chest syndrome
  Central nervous system crisis
  Renal crises
  Priapism
Hematologic crises
  Acute splenic sequestration
  Aplastic crises
  Hemolytic crises
Infectious crises

TABLE 133-1   Types of Sickle Cell Crises

Vasoocclusive crises are the classic "sickle crises" characterized by painful events, often involving the back, chest, extremities or abdomen. They are the most common reason for emergency department (ED) visits by children with SCD. These vasoocclusive events account for more of the morbidity and hospitalizations than any other set of complications. The episodes are highly variable from patient to patient, with many patients reporting no crises at all, whereas others experience them on a regular basis, varying in location, duration, and severity. Typical sickle cell patients average about four severe attacks per year; with few patients reporting crises daily.

Some of these vasoocclusive crises seem to have "triggers." Stress (emotional or physical), cold water immersion/exposure (especially as associated with shivering postexposure), dehydration, high altitudes/hypoxia, or infection (bacterial or viral, with the latter being the most common trigger in children under the age of 10).

Most vasoocclusive crises occur without any obvious cause. They result from the classic mechanism of sludging of sickled red blood cells into the microcirculation, resulting in tissue hypoxia and infarction. The associated pain may recur in the same location(s), but it can be anywhere in the body. Young children tend to have pain in the limbs, whereas adolescents more commonly complain of abdominal pain. Overall *musculoskeletal* (first) and *abdominal pain* (second) are the two most common types of vasoocclusive crises.

With *musculoskeletal pain*, the location can be anywhere but mostly involves the long bones—i.e.,the femur, tibia, and humerus. Lumbosacral pain is also commonly reported. Often there are no demonstrative physical findings but point tenderness may be found in the painful locations. Inguinal pain with difficulty in weight bearing and walking should raise the suspicion of avascular necrosis of the femoral head. Radiographs and/or a bone scan will aid in the diagnosis.

Infants may present with *sickle dactylitis*, also known as hand and foot syndrome. This occurs secondary to ischemia and infarction in the bone marrow of the extremities. Nutrient arteries that supply the metacarpals and the metatarsals become occluded and cause avascular necrosis. Clinically one sees swelling and pain of the hands and feet, often with an accompanying low-grade fever (i.e., less than 38.6°C or 101.5°F). One or all four extremities may be involved. Dactylitis is usually

seen in children under the age of 2 and is rare after the age of 5.

Abdominal pain is the next most common type of vasoocclusive crisis seen in children with SCD. It is characterized by its abrupt onset, lack of localization, and recurrence. Patients often complain of diffuse, generalized abdominal pain, typically in the absence of significant peritoneal signs. Bowel sounds usually remain present and auscultate normally during these attacks. It can be extremely difficult to differentiate whether the pain is caused by vasoocclusive crisis or by a more common type of surgically correctable condition. While peritoneal signs are often absent in crisis, abdominal guarding and rebound tenderness may be present to cloud the diagnosis. Mesenteric infarction as well as splenic and hepatic infarction are the most likely causes of the pain, but the differential also should include pancreatitis, hepatitis, appendicitis, perforated viscus, and pelvic inflammatory disease/gynecologic pathology. It is important to determine if the abdominal pain in SCD patients has substantially changed in character, quality, duration, severity, and associated symptoms. If such changes are present, infection or other related diagnoses should be explored.

Because of the rapid turnover of red blood cells bilirubin gallstones commonly form. This can result in biliary colic and/or cholecystitis with a secondary gallstone ileus ["right-upper-quadrant (RUQ) syndrome"]. Any sickle cell patient in crisis with RUQ pain should be carefully evaluated for this possibility. Approximately 75 percent of sickle patients have demonstrable bilirubin gallstones; fortunately only about 10 percent become symptomatic.

RUQ syndrome is characterized by the sudden onset of RUQ pain, anorexia, extreme hyperbilirubinemia (greater than 50 mg/dL), and progressive hepatomegaly. RUQ syndrome is usually benign and self-limiting in the pediatric patient population. It is felt to result from intrahepatic cholestasis and seems reversible with intravenous fluids and other supportive measures. However, in a small number of adult patients, this syndrome can progress to liver failure.

With all of the aforementioned conditions, ultrasound examination and/or computed tomography (CT) of the abdomen and pelvis may be useful. Prompt surgical consultation is initiated in patients in whom the diagnosis cannot be clarified.

Infections can cause vasoocclusive crises; therefore, determining the presence of an infectious process is critical. Painful crises are often associated with a low-grade fever and leukocytosis, but any temperature above 101°F/38.4°C (or an absolute band count greater than 300 cells per cubic millimeter) is more likely to represent an infectious etiology than tissue ischemia.

Other Vasoocclusive Types of Crises

ACUTE CHEST SYNDROME/PULMONARY CRISIS   Acute chest syndrome is characterized by signs and symptoms of acute lower respiratory tract disease—i.e., cough, chest pain (often pleuritic in nature), leukocytosis, tachypnea, dyspnea, and so on. All are usually accompanied by an infiltrate on chest x-ray (often the infiltrate takes 2 to 3 days to become apparent on a radiograph). The differential diagnosis includes acute chest syndrome/pulmonary infarction, pneumonia (bacterial or viral), and pulmonary thromboembolus. Pulmonary infarcted areas often become secondarily infected, leading to the acute chest syndrome. This is a major cause of mortality in sickle patients of all ages but especially in those above the age of 10. It accounts for about 15 percent of adult deaths and can be seen in about 30 percent of patients with sickle disease.

A standard chest/infiltrative disease workup is indicated with some notable variations. Arterial blood gases, complete blood count (CBC), and sputum analysis are certainly indicated. These patients should all be admitted to the hospital for supplemental oxygen therapy, pulmonary toilet, and empiric parenteral antibiotic therapy. The role and value of noninvasive pulse oximetry has been controversial. Some investigators believe that it accurately reflects arterial oxygen saturation, but others question the accuracy of the readings. It is clear, however, that some totally asymptomatic patients with sickle disease exhibit appreciable oxygen desaturation. This may be due to the abnormal sickle cell morphology of the red blood cell (RBC) and its spectrographic "reflection" on light plethysmography as measured by most standard pulse oximeters. The other issue is pulmonary angiography, which in general is to be avoided, since contrast material seems to cause more pulmonary sickling. A ventilation/perfusion ($\dot{V}/\dot{Q}$) scan may be helpful, especially if a baseline scan is available for comparison. If a significant $\dot{V}/\dot{Q}$ mismatch is discovered, heparinization may be indicated. The major concern is that multiple episodes of chest syndrome can result in pulmonary fibrosis and impair pulmonary function. Patients with multiple episodes often develop pulmonary hypertension and end-stage lung disease as young adults, hence the high morbidity and mortality rates. Any patient with significant cardiopulmonary decompensation should be considered for exchange transfusion therapy.

CEREBROVASCULAR DISEASE/CNS CRISIS   Some 5 to 10 percent of children (15 to 25 percent in all age categories) with SCD have a clinically apparent cerebrovascular event, characterized by acute onset of hemiparesis, seizures, headaches, transient ischemic attacks, dizziness/vertigo, sensory hearing loss, cranial nerve palsies, paresthesias, and inexplicable coma. These crises tend to be painless but are abrupt in onset. Cerebral infarction is more common in children, while cerebral hemorrhage is more typical in adults. The overall rate of subarachnoid hemorrhage (SAH) is increased in sickle disease patients. CT scan, lumbar puncture, and magnetic resonance imaging (MRI) are all helpful.

RENAL CRISIS   Like cerebrovascular crisis, renal vasoocclusive events are common but generally asymptomatic. Symptoms of renal infarction may include flank pain, renal colic, and costovertebral angle tenderness to percussion/palpation. Gross or microscopic hematuria may be evident, and some patients may actually pass renal tissue in their urine secondary to papillary necrosis. Monitoring of baseline renal function (i.e., BUN/creatinine) is always recommended in sickle patients.

PRIAPISM   This painful, sustained erection of the penis in the absence of sexual stimulation is the result of the accumulation of sickled cells in the corpora cavernosa. Severe and prolonged attacks can cause impotence. This occurs in up to 30 percent of males with SCD; surgical decompression is usually required. Newer approaches include oral administration of a-adrenergic agonists (terbutaline and pseudoephedrine) or intrapenile injection (usually with dilute epinephrine) of vasodilators such as hydralazine, and/or needle aspiration of the corpora cavernosa.

Hematologic Crises

The hallmarks of these crises are an acute drop in serum hemoglobin levels and clinical symptoms of generalized weakness/malaise, fatigue, shortness of breath/exertional dyspnea, progressive congestive heart failure, and/or shock. There are two types of hematologic crisis (Table 133-2).

	Sequestration Crises	Aplastic Crises	Hemolytic Crisis
Onset	Sudden	Gradual	Sudden
Pallor	Present	Present	Present
Jaundice	Normal	Normal	Increased
Abdominal pain	Present	Absent	Absent
Hemoglobin level	Very low	Low or very low	Low
Reticulocytes	Unchanged or increased	Decreased	Increased
Marrow erythroid activity	Unchanged or increased	Decreased	Increased

TABLE 133-2   Comparison of Findings in Sequestration, Aplastic, and Hemolytic Crises in Sickle Cell Disease

ACUTE SPLENIC SEQUESTRATION   This occurs primarily in infants and young children and is the second most common cause of death in children with SCD under the age of 5. The spleen will enlarge to beyond its baseline size, accompanied by a decline in hemoglobin concentration; hence patients present with splenomegaly and hypovolemic shock. These symptoms may occur suddenly or insidiously, and repeated episodes are common. It is a result of sickled cells blocking splenic outflow and drainage, thus causing pooling of both peripheral blood and sickled cells in the spleen. These crises are often preceded by a viral infection, with parvovirus B19; rhinoviruses and echoviruses have also recently been implicated.

These splenic sequestration crises are often divided into major and minor types. In major sequestration, the spleen enlarges rapidly and the serum hemoglobin levels

drop to less than 6 g/dL—or to 3 g/dL from that particular patients' baseline. A minor episode is more insidious and leads to progressive splenomegaly, with hemoglobin levels generally greater than 6 g/dL. Reticulocyte counts tend to be higher than normal, reflecting the compensatory increase in bone marrow activity.

Management includes transfusion of packed RBCs and exchange transfusions. Ultimately splenectomy may become necessary.

APLASTIC CRISIS   Among the most life-threatening of all complications related to SCD, this complication occurs when bone marrow erythropoiesis slows or completely ceases, resulting in erythroid aplasia. It is characterized by severe anemia with hematocrit levels of 10 percent or lower, hemoglobin levels of 1 to 3 g/dL or less, and reticulocyte counts of as low as 0.5 percent. White blood cell (WBC) counts and platelet counts tend to remain stable despite the lack of erythropoiesis. It is now known that these crises can be precipitated primarily by viral infections (most notably parvovirus B19), but folic acid deficiency and bone marrow suppressive/toxic drugs such as phenylbutazone have also been implicated. Fortunately these crises tend to occur only once in the lifetime of a patient with SCD and are usually self-limiting. RBC transfusions are usually necessary secondary to the severe anemia. This helps to avoid any secondary cardiopulmonary complications.

Infections/Infectious Crises

Bacterial infection poses a serious threat to the child with sickle cell anemia. In the first 10 years of life the most common infections are bacteremia, pneumonia, osteomyelitis, meningitis, and urinary tract infections. In the group under 5 years of age, it is often fatal; it occurs rapidly and can be overwhelming. The primary pathogens are usually encapsulated organisms: *Streptococcus pneumoniae, Haemophilus influenzae, Escherichia coli,* and *Staphylococcus aureus.* Other common infections include pneumonia caused by *Mycoplasma pneumoniae,* and osteomyelitis due to *Salmonella typhimurium, Staph. aureus,* and *E. coli.*

Repeated splenic infarction resulting in functional asplenia is felt to be the most likely reason for the increased risk of infection. Splenic infarction can occur as early as 5 months and is routine by 5 years of age. The susceptibility to bacterial infections results from deficient antibody formation and impaired phagocytosis. The complement activation system is impaired as well. Serum levels of IgM are also decreased.

During the first 5 years of life, the most common bacterial pathogen appears to be *Strep. pneumoniae*, and sepsis from this organism is the most common cause of death in this age group. The middle ear and the lungs tend to be the typical foci. Beyond 5 years, there tends be an increased frequency of gram-negative infections.

Children with SCD tend to become infected with *H. influenzae* at higher rates than other children. The course of these infections tends to be more insidious than that of those with *Strep. pneumoniae.*

Pneumonia of bacterial etiology is approximately 100 times more common in SCD patients than in the general population. Pneumonia generally causes hypoxia that further exacerbates the sickling. *Strep. pneumoniae* and *H. influenzae* are the two most common etiologic agents, but mycoplasmal infections are also common and should be considered when patients fail empiric (i.e., "nonmacrolide") antibiotic therapy. Viral pneumonia is also common, especially under the age of 2.

SCD patients also have an increased incidence of osteomyelitis. Often the etiologic agent is *S. typhirium* (about 50 percent). It can also be caused by *Staph. aureus* and *E. coli.* Also seen in increased frequency from the general population are meningitis and urinary tract infections. Bacterial meningitis and septicemia are approximately 600 times more common in SCD patients than in other children.

DIAGNOSIS

NEWBORN SCREENING   In the United States, most states with a sizable African-American population have implemented newborn screening programs to identify affected individuals at birth. Success in preventing early complications and assuring reliable follow-up mechanisms has had a significant effect on reducing overall mortality from the disease. Patients identified through programs such as these are then enrolled for comprehensive treatment. Cord blood can be utilized right in the delivery room.

Hemoglobin electrophoresis is the "gold standard" and most accurate diagnostic study to determine and distinguish sickle cell anemia (homozygous Ss), sickle cell trait (HgbSC), and sickle cell thalassemia. In the newborn and infant, this test is always necessary to confirm the diagnosis.

LABORATORY STUDIES   As always, prudent laboratory testing is tailored to the clinical signs and symptoms of patients as they present to the ED. The following is a list of some commonly ordered diagnostic studies.

SICKLE PREP   If the diagnosis is in question or in previously undiagnosed cases, the emergency physician will need a rapid assay for determining the presence of SCD. The sickle prep is a peripheral blood smear specially prepared so as to induce RBC sickling. These cells are then seen on routine microscopy of the smear. Tests such as the Sickledex and Metabisulfite tests have been used. While these tests can be useful in the ED, they are limited in their ability to diagnose SCD in infants under the age of 4 to 6 months, and they cannot diagnose sickle cell trait.

COMPLETE BLOOD COUNT (CBC)   All patients who present to the ED in sickle cell crisis or any other complaint referable to SCD should have a CBC performed; of paramount importance is the serum hemoglobin level. The average hemoglobin in patients with SCD is generally between 6 and 9 g/dL. Obtaining a prior baseline level is critical, because any patient with a drop of 2 to 3 g/dL in hemoglobin or a decline in the serum hematocrit by 4 to 6 percent may reflect severe hematologic crisis or hypovolemia and shock. Platelet counts are usually elevated at baseline. White blood cell (WBC) counts are also often elevated at baseline, ranging from 12,000 to 18,000 μL, usually with a normal differential. Any rise in the total WBCs or leftward shift may indicate the presence of significant underlying pathology. The peripheral smear often shows sickled cells as well as Howell-Jolly bodies, indicative of splenic dysfunction and failure.

RETICULOCYTE COUNT   Because of accelerated RBC turnover, reticulocytes appear in greater numbers on the peripheral smear. The mean reticulocyte count is approximately 12 percent (with a range of 5 to 15 percen) in SCD patients. With a reticulocyte count of 3 percent or less, aplastic crisis should be considered. An extremely high count may be indicative of hemolysis. Certainly any decrease of 2 g/dL or greater in serum hemoglobin levels warrants obtaining a reticulocyte count.

BLOOD CULTURES   Blood cultures should be obtained in any SCD patient with a temperature higher than 38.4°C (101°F) and in any patient suspected of having bacteremia or sepsis. Any child with radiographic evidence of infiltrative disease should also have blood cultures drawn.

URINALYSIS (UA)   Any patient with a fever and/or urinary symptoms (especially dysuria or hematuria) should have a UA (and appropriate culture) obtained. RBCs or tissue in the urine are seen with papillary necrosis/renal crisis. Isosthenuria, the inability to concentrate urine, is typically present, with specific gravities of about 1.010. The specific gravity can be quite low in patients with SCD even when they are dehydrated.

ELECTROLYTES   Electrolytes should be obtained in any SCD patient who appears clinically to be dehydrated. Significant imbalances can occur because of isosthenuria.

ARTERIAL BLOOD GAS (ABG)   An ABG should be obtained in all SCD patients with chest pain not typical of vasoocclusive crisis or in patients with any respiratory complaints. A large arterioalveolar (A-a) gradient suggests either pulmonary infection, infarction, or potential thromboembolus. It is helpful to have a baseline reference ABG since most adolescents and adults with SCD exhibit a mild to moderate chronic hypoxia. Generally, arterial P_{O_2} levels less than 60 mmHg in adults or 70 mmHg in children are indicative of acute pathology.

LIVER ENZYMES   Liver enzymes may be helpful in SCD patients who present with abdominal pain. However, baseline abnormalities are common, especially an elevated indirect bilirubin, which is usually secondary to the chronic hemolytic state of SCD.

CEREBROSPINAL FLUID ANALYSIS   A lumbar puncture should be performed when meningitis is a consideration.

Radiologic Studies

CHEST X-RAY   Patients with chest pain, suspected pneumonia, or dyspnea/respiratory symptoms should have chest radiographs. It is important to remember that in

acute chest syndrome, the x-ray may appear normal for the first 48 h; thus a normal-appearing radiograph does not preclude significant pulmonary pathology.

EXTREMITY X-RAYS   Extremity x-rays should be obtained in patients in whom ischemic necrosis of the femoral or humeral head is suspected or in those with localized bony tenderness. Avascular necrosis of the femoral head occurs in up to 12 percent of SCD patients. Small lytic lesions are also seen in patients with sickle dactylitis. Plain radiographs are somewhat limited in diagnosing bony infarction and/or osteomyelitis acutely. It may take 10 to 14 days for the radiographic changes to become evident. A bone scan or MRI can detect changes consistent with osteomyelitis usually within 24 h.

CT/MRI OF THE HEAD   CT or MRI of the head should be obtained in SCD patients with any lateralizing neurologic signs or acute/new neurologic deficits.

ABDOMINAL ULTRASOUND OR CT   These tests may be helpful in patients with abdominal pain, especially if a surgically correctable cause is suspected. The diagnosis of typical intraabdominal pathology (i.e., appendicitis, cholecystitis, pancreatitis, abscesses, bowel obstruction/infarction) with these imaging modalities is not affected by the presence of vasoocclusive crisis.

TREATMENT

Management of patients with SCD focuses on both acute and chronic illness. It is important to remember that progressive end-organ involvement occurs over time. Of primary importance are ocular, pulmonary, cardiac, hepatic, and renal changes. These—as well as issues of growth, development, and sexual maturation—should be routinely monitored at well-patient visits to the pediatrician/hematologist. In the ED, it is the acute illness that confronts the physician. Complications arising from SCD are managed based upon the nature of the pathology. The ED care of patients with SCD presenting in crisis is generally supportive in nature. The mainstays of therapy have been hydration/fluid replacement, analgesia, supplemental oxygen, and blood transfusion.

FLUID REPLACEMENT   All types of sickle cell crisis can be precipitated or exacerbated by dehydration. If the episode is relatively mild, oral fluid replacement may be effective. Patients with severe pain, orthostasis, or change in vital signs will likely require intravenous hydration. The rate of hydration is generally at $1\frac{1}{2}$ times maintenance (about 2250 mL/M^2 per day). Patients need to be carefully monitored to avoid fluid overload and iatrogenic cardiac failure, especially those with cardiopulmonary crisis/acute chest syndrome. Electrolytes should be checked and fluid choice adjusted appropriately.

ANALGESIA   Analgesia is of paramount importance and should always be sufficient to control the pain. "Standard doses" of narcotic medication may not be enough for the individual patient with SCD. Although narcotic dependence or enhanced narcotic-seeking behavior may be a problem for rare patients, this should never affect the decision to control severe pain. The establishment of treatment guidelines and protocols for the ED management of patients with SCD can help minimize manipulative behavior and change expectations. The approach should be consistent. With the advent of patient-controlled analgesia (PCA) pumps, narcotic usage and dosing can be carefully controlled and reviewed. In the ED, narcotics should be chosen with potential side effects, drug interactions, and serum half-lives in mind.

Oral narcotic preparations such as Tylenol #3, Vicodin, or Percocet are usually adequate for moderate types of pain. Parenteral narcotics are usually required for more severe pain. Demerol (meperidine) in often used, in combination with an antiemetic, as an intramuscular injection. This may be useful, but only in limited doses, since meperidine can lower the seizure threshold. Also, repeated intramuscular injections run the risk of forming sterile abscesses and scarring, which can further exacerbate painful crises; they are therefore to be avoided in treatment of prolonged, painful crises. Intravenous narcotic administration is preferable, and a PCA pump is ideal. Morphine (at 0.15 mg/kg per dose to a maximum of 10 mg) every 2 to 3 h and hydromorphone (Dilaudid, at 0.02 to 0.05 mg/kg per dose) are good choices. Dilaudid has a slightly more rapid onset and slightly shorter duration of action as compared with morphine. Approximately 1.3 mg of Dilaudid is considered equivalent to about 10 mg of morphine. Both medications should be adjusted to provide about 3 to 4 h of pain relief. The addition of nonsteroidal anti-inflammatory drugs has been shown to be of some benefit; however, these are to be used cautiously or not at all in patients with renal compromise.

OXYGEN   Supplemental oxygen has long been considered an important part of treating SCD crises. More recent investigations have shown that it is beneficial only if the patient has demonstrable hypoxia.

CARDIAC MONITORING   Cardiac monitoring is necessary if the patient has a history of known cardiac disease, signs and symptoms of acute chest syndrome, or cardiopulmonary compromise. When aggressive fluid replacement is warranted, cardiac monitoring also becomes important.

TRANFUSION THERAPY   Blood transfusions are often necessary in children undergoing splenic sequestration crisis and severe aplastic crisis. In addition, transfusions may be needed in the management of cerebrovascular accident (CVA), priapism, or as perioperative management prior to surgery. Naturally, transfusion carries risk: alloimmunization, HIV infection, hepatitis, volume overload, and iron toxicity (secondary to repeated transfusions). Transfusion can also markedly decrease erythropoiesis.

The decision to institute transfusion therapy can be difficult. Clearly, in splenic sequestration crisis with hypotension, blood should be transfused. A hematologist should be consulted emergently to help direct therapy. An initial transfusion of 10 mL/kg of packed RBCs can be started in the ED.

Aplastic crisis may also require a transfusion of packed RBCs. When aplastic, splenic sequestration, or hemolytic crises occur, exchange transfusion is preferable. If the serum hemoglobin is greater than 6 g/dL, transfusion is rarely indicated.

Symptom-Specific Therapy

INFECTIONS   Pneumococcal sepsis in children with SCD has a 14 percent mortality rate. Prophylactic oral penicillin, administered daily, has proven to be quite effective in decreasing the incidence of sepsis and death in children under the age of 6. This practice has not been shown to be of value in the adult population with SCD. The polyvalent pneumococcal vaccine is also recommended at 2 years of age. (*Note:* Some recommend it be given at 6 months, 2 years, and again at 6 years of age.)

Since *Strep. pneumoniae* and *H. influenzae* are the primary bacterial pathogens of SCD, patients should be vaccinated in childhood against them as well as receiving the hepatitis B vaccine. Parenteral antibiotic therapy usually begins with cephalosporins (i.e., cefuroxime or ceftriaxone), which have excellent activity against these two pathogens. Choice of intravenous antibiotic depends upon the given clinical scenario and culture results.

CNS CRISIS   Any neurologic signs or symptoms necessitate immediate stabilization and careful monitoring. Admission to an intensive care unit (ICU) setting is most appropriate. A head CT or MRI should be obtained, and—based on those results—lumbar puncture may need to be performed to rule out meningitis or subarachnoid hemorrhage. After an acute central nervous system (CNS) event, exchange transfusion may be indicated, with a goal of lowering the HgbS concentration to less than 30 percent.

PRIAPISM   All SCD patients with this condition should have a urologic consultation. Intravenous hydration and analgesic therapy should be instituted immediately. The bladder should be emptied, either by spontaneous void if possible or by catheterization. If the priapism is not relieved after 2 to 3 h, exchange transfusion becomes necessary. If this is not successful, surgical intervention will be required. This is why prompt urologic consultation in the ED for this entity is important.

LOCALIZED BONE PAIN   Localized bone pain accompanied by fever and leukocytosis strongly suggests osteomyelitis. Diagnosis can be confirmed by plain film radiographs, bone scan, and/or MRI. The site may be needle-aspirated and cultured. Empiric parenteral antibiotic therapy should begin with coverage provided to treat *Salmonella* species and *Staph. aureus.* Intravenous trimethoprim-sulfamethoxazole (2.5 mg/kg, based on the trimethoprim component, q 6 h) or, as an alternative, ceftriaxone (25 to 50 mg/kg q 12 h), which provides better *Staph.* coverage, can be used.

DISPOSITION

Disposition depends upon ED findings, observation, and response to initial therapy. The following is a list of guidelines to aid ED physicians in determining which children with SCD require hospitalization:

1. Temperature greater than or equal to 103°F/39°C, WBC counts greater than 30,000/mm^3, or left shift and/or other hematologic parameters greatly altered from

baseline values.
2. Any signs of respiratory distress, hypoxia, and/or lobar infiltrate on chest x-ray.
3. Any new CNS findings or presence of neurologic crisis.
4. Patients with splenic sequestration or aplastic crisis.
5. An acute abdomen.
6. Prolonged priapism.
7. Any type of vasooclusive crisis that does not respond to intravenous hydration and analgesia (usually after about 4 to 6 h of therapy).
8. Inability to maintain adequate oral hydration.
9. Patients in whom the diagnosis remains uncertain.
10. Follow-up (i.e., telephone contact, return visit, etc.) is uncertain or unlikely because of distance, inconvenience, or poor compliance.

If patients with vasooclusive crisis are discharged home, they should be advised to maintain adequate oral hydration, take pain medication (a 2- to 3-day supply should be provided), and return immediately if fever over 100.4°F/38°C occurs, the pattern of pain worsens or changes, or vomiting begins. All patients treated and released from the ED should be reevaluated in 24 to 48 h by their private pediatrician/physician or hematologist (generally 24 h for children and 24 to 48 h for adults).

Variants of Sickle Cell Disease

SICKLE CELL TRAIT (SCT)   This is the carrier state of SCD and the most frequently encountered sickle cell variant. It is erroneous to consider this a "mild" form of SCD. Hematologically these patients are normal. Their RBCs have a normal lifespan; therefore there is no demonstrable anemia. The peripheral smear should not reveal sickled cells except in the presence of extreme hypoxia.

Clinically these patients have minimal complications, with the kidney being the most commonly affected organ. Hematuria is found in about 1 percent of patients with SCT and is most likely due to papillary necrosis following microinfarcts in the renal medullary tissue. Severe hypoxia and/or exposure to high altitudes can cause splenic infarction and CNS complications; there is also an increased incidence of sudden death in these patients during physical exertion/training. This is thought to be secondary to increased sickling under these extreme conditions. In general, the vast majority of these patients are asymptomatic and lead normal lives with a normal life expectancy.

SICKLE CELL HEMOGLOBIN-SC DISEASE   This heterozygous variant results when the gene for HgbS is inherited from one parent and the gene for HgbC is inherited from the other parent. These patients can have a mild to moderate anemia and usually a mild reticulocytosis. Their peripheral smear reveals an abundance of target cells and a few sickle-shaped cells. Additionally HgbC may be seen precipitated as rhomboid crystals in the RBCs. Splenomegaly is the major feature of HgbSC disease and persists into adulthood in about 60 percent of patients.

Patients with HgbSC disease can have painful crises and organ infarcts; they are also at higher-than-normal risk for bacterial infections. Avascular necrosis of the femoral head, ocular complications/visual loss, and renal medullary infarcts have all been reported in these patients. Women with SC disease have an increased incidence of complications during pregnancy. Overall, while some patients have complications as profound as those with SCD, most patients with HgbSC disease have few clinical complications.

SICKLE CELL BETA-THALASSEMIA DISEASE   Also a heterozygous sickle cell variant, this occurs when the gene for sickle hemoglobin is inherited from one parent and the gene for beta thalassemia is inherited from the other. The clinical severity of the disease, frequency of complications, and the degree of the resultant anemia depends on the type of beta-thalassemia gene inherited. Approximately 80 to 90 percent of affected individuals have a beta-thalassemia gene that allows for the production of some normal beta chains; thus some normal HgbA is produced. These patients in general do quite well; they have a mild hemolytic anemia (with near normal Hgb levels), suffer few painful crises, and sustain minimal end-organ damage. The remaining 10 to 20 percent of patients inherit a beta-thalassemia gene that produces no beta chains; therefore they have no normal hemoglobin. These individuals have a severe hemolytic anemia and vasoocclusive symptoms similar to those seen with SCD. Splenomegaly is found in 70 percent of patients with this variant.

134 EVALUATING THE HANDICAPPED OR DISABLED CHILD

Cheryl H. Hack

There are about 7 million children in the United States who have conditions that impair their ability to function physically or mentally. Some disabilities and handicaps may be medically distinct and self-limited, such as limb deformities, hearing impairments, or spastic diplegia. Others are multidimensional, consisting of multiple medical problems such as meningomyelocele or severe mental impairment with associated severe cerebral palsy. Impaired neurologic functioning, orthopedic deformity, and chronic illness with multiple system involvement result in complex medical problems and greater likelihood that an individual will encounter difficulties and require emergency evaluation and treatment. Caring for handicapped or disabled children in the emergency department (ED) can be a difficult task due to complex ongoing medical problems, limited historical information, altered baseline functioning, and/or the need for the emergency physician to consider the impact of interventions on the course of the underlying disability or impairment.

Evaluating the child with handicapping or disabling conditions in the ED requires more time. Patience in obtaining a good history will assist the physician in decision making. Knowledge of specific medical problems associated with various handicapping or disabling conditions will help to focus the history and examination. Identification of management issues will allow the physician to design interventions that benefit the child and the family in both the long and short term.

Obtaining a medical history in the ED can be difficult, even with a normally healthy child. Obtaining a medical history in a disabled or handicapped child provides even more challenges. A medical condition of importance may not be reported because it is under treatment and is not currently creating any difficulty for the individual (e.g., neurogenic bowel or bladder). Information regarding the use of assistive devices such as braces, hearing aids, glasses, or prosthetics may not be offered because the family does not realize that this may give the physician information needed for making treatment decisions. Directed questioning may be necessary to avoid difficulties.

While obtaining the medical history, attempt to identify all existing medical conditions. Medications currently being used can be helpful in this task. A list of medications commonly used in cerebral palsy is given in Table 134-1. Information regarding the use of assistive devices may be important in management issues. Ask specifically about bracing, hearing aids, glasses, and use of suppositories and enemas. Hearing aids in a child with external otitis media or perforated tympanic membrane must be a consideration. Braces or night splints must be considered when lacerations or skin lesions are present. Children with complex medical problems may receive a variety of medical procedures in the home setting, including suctioning, nebulizer treatments, chest percussion and drainage, clean intermittent catheterization, and fecal disimpactions. Knowledge of these home-based procedures will help in making decisions regarding hospitalization and/or further home treatment. Associated medical conditions may have an impact on development of a differential diagnosis. By using information from the medical conditions associated with individual disorders described below, the physician can better guide questioning regarding associated medical problems.

Generic Name [Brand Name]	Most Common Side Effects
Baclofen (Lioresal)	Drowsiness, dizziness, weakness, confusion, headache, insomnia, hypotension, nausea, constipation, urinary frequency
Clonidine (Catapres)	Drowsiness, dry mouth, orthostatic hypotension, nausea and vomiting, anxiety, depression, sleep disturbance, nocturia, rash
Dantrolene (Dantrium)	Drowsiness, dizziness, weakness, diarrhea, constipation
Diazepam (Valium)	Drowsiness, ataxia, weakness, confusion, constipation, dysarthria, diplopia, rash, urinary retention

TABLE 134-1   Medications Commonly Used for Spasticity

CEREBRAL PALSY

Cerebral palsy is a disorder of movement and posture due to static, nonprogressive injury sustained by the developing brain. The brain damage must occur by 5 years of age. It occurs in 2.5 to 3 per 1000 individuals. Diagnosis before 12 to 18 months of age can be confused with transient tonal problems or progressive degenerative disorders. The movement problems manifest in a variety of forms and can affect the head, trunk, and extremities in a variety of ways. Cerebral palsy is commonly classified by type, distribution, and degree of involvement. Types include spastic, dyskinetic (choreoathetoid), hypotonic, and mixed forms. Distribution relates to the involvement of the extremities. Diplegia, hemiplegia, and quadriplegia are the most common. Rarely one sees a child with monoplegia or triplegia. Severity is rated subjectively as mild, moderate, or severe.

Children with cerebral palsy may have associated medical problems as a direct effect or complication of motor dysfunction or underlying brain damage. Seizures, oral motor dysfunction, gastroesophageal reflux, constipation, urinary tract infections, pneumonia, wheezing, hearing loss, strabismus, visual impairments, scoliosis, contractures, and hip dislocation or subluxation are all seen with increased frequency in children with cerebral palsy. Children with less severe presentations have minimal associated medical problems (i.e., the child with spastic diplegia may have only issues related to spasticity). As the severity of impairment increases to spastic quadriplegia, the incidence and severity of associated problems and need for emergency medical treatment also increase.

In managing the child with severe cerebral palsy in the ED, special attention should be given to seizures, respiratory tract problems, fluid status, nutritional status, bracing, and skin problems.

Seizures

Seizures are present in 50 percent of children with cerebral palsy. With increasing severity of cerebral palsy, there are often more frequent and complex seizures. Multiple seizure types may occur in a single individual. This may cause difficulty in eliciting a complete seizure history if the physician is unaware that different seizure presentations are documented historically. Multiple anticonvulsant medications may be required to adequately control seizures. When multiple anticonvulsants are required, the physician should be alert to the possibility of multiple seizure types, interactions of the various anticonvulsant medications, and the possible fragility of seizure control. Contact with the managing neurologist is strongly advised in such cases. The treatment of medical problems should be evaluated with regard to drug-drug interactions whenever a medication is recommended. Anticonvulsant medications may affect or be affected by many other drugs. Theophylline is known to lower seizure threshold, and erythromycin may elevate drug levels into the toxic range.

Pulmonary Problems

Respiratory tract symptoms are seen commonly in children with severe forms of cerebral palsy. They include chronic congestion, recurrent wheezing pneumonia, microaspiration, and aspiration.[1] The respiratory tract problems are generally related to oral motor dysfunction and gastroesophageal reflux.

Oral motor dyspraxia presents with exaggerated gag and retained bite reflexes, tongue thrust, and oral hypersensitivity, which can lead to choking, gagging, and aspiration.[1,2] Oropharyngeal incoordination manifests early with poor feeding and failure to thrive and contributes to aspiration. Gastroesophageal reflux is associated with aspiration of food and chemical fumes that may be damaging to pulmonary tissues and can be associated with the development of pneumonia. Lack of head control may lead to pooling of secretions in the posterior pharynx with spillage of contents into the vallecula and then into the trachea.

Pneumonia often is due to aspiration. If there is no evidence for secondary bacterial infection, the pneumonia may be chemical in nature and may resolve on its own. Pneumonia is treated early with antibiotics because of the risk of secondary bacterial infection if the aspiration is of oral contents. With mounting evidence for ongoing microaspiration in many individuals with cerebral palsy that does not result in infection, this concept will need to be reexamined, and treatment may be deferred initially. Secondary bacterial superinfection should be treated promptly. Unilateral pneumonia could involve the possibility of a foreign body retained in the respiratory system, as it would be in the normal child.

Wheezing is a difficult problem in this population. Some children with cerebral palsy have been born prematurely and have a history of respiratory problems stemming from bronchopulmonary dysplasia and reactive airways disease. A small number may have developed tracheomalacia and required tracheostomy. When these children have adventitial respiratory noises, it is important to differentiate clearly what is happening. Wheezing accompanied by impaired air movement should be treated appropriately with bronchodilators. However, the clinician must evaluate the situation carefully for evidence of stridor on inspiration as opposed to wheeze on expiration. Possible reasons for wheezing or stridor include a retained foreign body, tracheal edema, impaired vocal cord function, tracheomalacia, aspiration of gastroesophageal contents, and asthma (Table 134-2). Aspiration should be considered before instituting therapy. Children with spastic quadriplegia in particular are at risk for reactive airways triggered by microaspiration of saliva, food, or gastric fluids. The respiratory tract may be responding to a potential threat, and bronchodilatory treatments may not be effective in resolving the wheezing and would not be a desired treatment. Management of wheezing in the emergent situation should start with an assessment of the contribution of aspiration. A simple initial evaluation should investigate the effect of positioning in severely affected individuals with impaired head control. Placing the head and neck in the "sniffer" position to maximize the airway and minimize the risk of secretions pooling in the posterior pharynx may improve respiratory functioning by decreasing aspiration. Evaluations of air movement, nasal flaring, intercostal retractions, and blood gases to assess respiratory distress are indicated. If significant impairment of air movement is compromising the patient, bronchodilators may be used with caution, remembering that if the wheezing is due to aspiration, there may be little or no improvement. In such cases, reconsideration of treatment options is always warranted. Further evaluation for gastroesophageal reflux leading to aspiration will require multiple radiographic studies and should be done either in the outpatient setting or, if the respiratory distress is severe, on an inpatient basis following resolution of the immediate distress. Medications to reduce reflux or acidity such as metoclopramide, cisapride, and ranitidine may be helpful. Children will need to be hospitalized if secondary pneumonia is suspected or respiratory compromise is evident.

Stridor	Wheezing
Epiglotitis	Asthma
Foreign body aspiration	Tracheomalacia
Spasmodic croup	Gastroesophageal reflux
Allergic reaction	Foreign body aspiration
Laryngomalacia	Tracheal stenosis
Subglottic stenosis	Extrinsic tracheal compression
Vocal cord dysfunction	Microaspiration
Bacterial tracheitis	Bronchiolitis
Trauma	

TABLE 134-2 Respiratory Distress in Children

Drooling

The control of saliva may be impaired in children with severe spastic quadriplegia. Poor head control and oromotor deficits are the cause. With the head held flexed or to the side, there may be pooling of oral secretions in the anterior portion of the oral cavity. If bolus formation is not initiated, these secretions will spill over the lips and onto the face and body. Although primarily thought of as a social or cosmetic issue, drooling may lead to skin problems such as chapping on the face. Families and physicians have used a variety of techniques to stem the drooling when it persists in childhood and is perceived as a problem. As a side effect, some common medications are noted to decrease secretions. These drugs, including scopolamine, atropine, imipramine, trihexyphenidyl hydrochloride (Artane), glycopyrrolate (Robinal), benztropine mesylate (Cogentin), and antihistamines, have been used with limited success. [3] Side effects of these medications, toxicity (if the family should give multiple doses), and possible drug interactions are of concern in the emergency setting. Surgery also has been used for severe drooling. Salivary duct rerouting is the most commonly used procedure at this time.[4] Following surgery, cheek swelling and swallowing dysfunction have been noted. In a small number of patients, ranula formation was noted. In the past, xerostoma has been reported after surgical removal of salivary glands with resulting lesions of the oral mucosa and increased dental caries. None of these issues needs to be handled on an emergent basis and should be referred to the ENT service for long-term management on an outpatient

basis.

Growth Failure

Growth failure may be a problem in the child with cerebral palsy. Increased energy requirements and difficulty in handling food in the oral cavity combine to cause growth failure. Energy requirements in the young child with spastic cerebral palsy may be increased to 140 to 160 kcal/kg/day. Chronic failure to thrive decreases energy and strength to accomplish motor tasks and coordinate movement and may impair immunologic function. Children with oromotor dysfunction often have limited skills in handling foods and particularly in handling liquids. These children require high-caloric-density food and may require alternative feedings on a supplemental or primary basis.

Gastrostomy tubes with or without Nissan fundoplications may be in place. Tube feedings may be the primary caloric intake or may be used supplementally (often at night) to improve the nutritional, health, and functional status of the child. Problems with the gastrostomy tube or the skin surrounding it may bring children into the ED. Irritation of the skin site due to movement of the gastrostomy tube may occur with development of granulation tissue and/or leakage of gastric contacts. The stability of the tube needs to be checked, and bumpers holding the tube in place may need to be adjusted. If leakage of acidic contents has caused skin breakdown, the leakage needs to be eliminated, if possible, and a barrier should be used to protect the skin until it heals. Zinc oxide-based creams often are effective, but adherence to the skin can be a problem. An enterstomal therapist may be able to offer assistance in choosing products that offer the best adherence properties. Gastrostomy tubes falling out and being pulled out intentionally or unintentionally also can be an issue. The stoma should be maintained if possible to allow for replacement of an appropriate tube in a controlled manner as soon as possible. Placement of a red rubber feeding tube through the stoma and taping it in place can be effective for up to several days if necessary. If skin irritation or breakdown is a problem, then securing the tube may be a challenge. The physician should attempt to secure the tube without placing tape on macerated skin surfaces.

Dehydration

Marginal or deficient fluid balance may be present in children with severe cerebral palsy and oromotor problems, particularly if gastrostomy tube feedings are not in place. When the child with failure to thrive and a limited fluid status develops a routine gastroenteritis, dehydration and nutritional status become major difficulties. Some children dehydrate with minimal diarrhea or vomiting and have difficulty maintaining hydration until the diarrhea or vomiting resolves. Hypernatremia or hyponatremic dehydration with seizure activity may result if the sodium load is very high or low. Hospitalization decisions should be based on the history of diarrhea, hydration status of the patient in relation to the amount of diarrhea reported, and baseline nutritional status. The further below the 5th percentile for weight a child is, the greater is the concern that the child cannot be orally hydrated if diarrhea or vomiting persists. Obtaining a premorbid weight from the family will assist the physician in estimating fluid loss. Monitoring urine output also will provide information, as will the traditional signs of dry mucous membranes, tachycardia, skin tenting, and sunken eyes. When rapid dehydration occurs in the malnourished child with limited hydration as the baseline, intravenous access may be a problem. If an intravenous line cannot be placed successfully, interosseus line placement should be considered. In addition to treatment with fluid boluses, full feeds should be continued.

Constipation

Constipation occurs secondary to increased tone, impairment of sphincter relaxation, and limited fluid and fiber intake. It may be accompanied by rectal tears, overflow diarrhea, and anorexia. Getting an accurate history is important in the diagnosis of constipation. Families frequently complain of constipation if the child cries, strains, or does not have a bowel movement daily. Constipation is hard balls of stool even if this occurs on a daily basis. There is no constipation if the stools are soft, even if the child cries, appears to strain, or does not have a daily stool. Emergent management of constipation is by suppository if the problem is of brief duration or with an enema if long-standing or if fecal material can be palpated in the abdomen. Saline, Fleets, or oil-based enemas may be used. If constipation is of long duration, a home program will be needed. Contact with the treating physician or a gastroenterologist most likely will be needed.

In children with recurring constipation, avoid the routine use of Fleets enemas so as to prevent electrolyte abnormalities. Avoid chronic use of oral mineral oil in children with oromotor dysfunction because it is associated with a high risk of aspiration and may cause impaired absorption of fat-soluble essential vitamins. If a home program has been developed with frequent use of these products, electrolytes should be monitored and vitamin deficiency syndromes may need to be considered.

Enuresis

Enuresis, or incontinence, may persist due to motor and mental difficulties. In the severely impaired child, as with infants, urinary tract infections should be considered in the uncomfortable, ill-appearing child without clear evidence of other infectious sources. An increased incidence of urinary tract infections has been observed without evidence of urinary tract abnormalities. This has been ascribed to hygiene issues in the past, although a neurogenic bladder with urinary retention should be ruled out. A urinalysis should be done, with care taken to limit external contamination. Contractures of the hips and tight adductors make it difficult at times to clean the vaginal and perineal areas. Referral for radiologic studies to rule out anomalies of the urinary tract is recommended. Most urinary tract infections can be managed on an outpatient basis. If pyelonephritis is suspected, a urology consultation and hospitalization should be considered.

Sensory Problems

Problems with vision and hearing are common and do not generally cause any difficulty on an emergent basis. Hearing loss is present in 5 to 15 percent of children with hemiplegia. In addition, there may be conductive losses in children who are bottle-fed in a supine position. Visual problems include strabismus, hyperopia, cataracts (congenital infections), retinopathy of prematurity, and cortical blindness.

Spasticity Management and Contractures

Spasticity of muscles not only causes functional impairments but also is associated with the development of bony deformity in many children with cerebral palsy. Management occurs in progressive stages depending on the functional impairments. Physiotherapy, orthotics, medications, and then surgeries are used. When left untreated, the child is likely to develop contractures and positional deformities.

Oral medications have been used to treat spasticity in recent years, including benzodiazepines, dantrolene, and baclofen. Their use has been limited by the development of tolerance for dosages, narrow therapeutic ranges, hepatic toxicity, and sedation. Injections of alcohol in the form of nerve-point blocks and botulinium toxin into the muscle also have been used. These treatments are more invasive, can be painful, are of limited duration (3–6 months), and can result in loss of function for a short period of time. They also can be very effective in decreasing spasticity and improving the child's function.

Surgical treatment of spasticity comes from two different directions at this time. Orthopedic surgeons operate to correct skeletal deformities, release contractures, and rebalance muscles to improve function. Tendon lengthening, tendon releases, muscle transfers, and osteotomies are the primary procedures. Neurosurgeons operate to reduce spasticity and prevent bony deformities and functional losses. [5] Neurosurgical procedures include baclofen pumps that can dispense medication directly into the intrathecal sac to eliminate systemic side effects seen in oral medications and selective dorsal rhizotomies that provide a permanent reduction in tone.

The emergency physician may be called on to evaluate pain or loss of function and should be aware of these procedures and medications and their effects. Following injection procedures, there are occasionally muscle imbalances with muscle spasms and pain. Following injection procedures and surgery, there may be loss of function in the affected extremities, and with botulinum toxin, there have been rare cases of systemic effects of short duration (personal observation). The baclofen pump, which has an 18-mL drug reservoir, can be palpated as a circular metal disk in the abdominal wall. In the event of pump failure, there could be a drug overdose. Symptoms of baclofen overdose include drowsiness, light-headedness, dizziness, somnolence, respiratory depression, seizures, rostral progression of hypotonia, and loss of consciousness progressing to coma. See Fig. 134-1 and Fig. 134-2 for management of baclofen overdose.

**FIG. 134-1.** Management of intrathecal baclofen overdose.

FIG. 134-2. Use of an infusion pump. (With permission of Medtronic Neurological.)

Contractures of the extremities are one of the most commonly perceived difficulties of children with cerebral palsy. When spasticity is not treated, major problems can develop at the hip, ankle, wrist, and hand. In a small number of cases, elbow, shoulder girdle, and knee deformities are of concern. Adductor contractures of the hips may interfere with perineal hygiene and sitting. Hip flexion contractures may interfere with standing and independent transfers. Hip subluxation and dislocation may interfere with ambulation and may result in chronic pain syndromes and arthritis when the child becomes an adult. [6,7] The routine treatment for the pain is the same as for degenerative arthritis. Bracing is used for management of contractures and should be closely evaluated when wounds are sustained in braced areas. Bracing will hold the joint in a different position, and areas of skin tension will change with bracing. Placement of sutures or dressings may be affected by the brace or the altered position of an extremity without a brace. Friction from the brace could impair wound healing, increase the chance of infection, and create new wounds due to the pressure of the brace if proper assessment and attention to the brace is not part of the management. Removal of a brace may be required in early wound management unless a tension problem will complicate management more. Similar problems may occur with serial casting procedures.

Fractures

Osteopenia frequently develops in bones secondary to disuse and nutritional issues. [8] Fractures occur more easily in osteopenic bones. Children with limited movement and osteopenia may sustain fractures without excessive force being used. Lifting or moving an older child may cause fractures when osteopenia is present. Stretching and range-of-motion exercises used to prevent the development of contractures also can result in fractures if the person doing them is unaware of osteopenia and uses an aggressive stance for therapy. Fractures may present with discomfort and swelling of an extremity and should be considered in the irritable, severely impaired child. Fractures may be treated with casting if the child has and uses voluntary movement, but soft wraps may be used in the child with significantly limited voluntary movement. Displaced fractures are uncommon, and, when present, forceful activity is generally involved. Routine handling and therapy generally are not associated with this type of injury. Consultation with an orthopedic surgeon and hospitalization may be required.

Scoliosis

Scoliosis is present in children with quadriplegia and may contribute to respiratory tract problems due to restrictive phenomena. Skin problems also may develop under braces, requiring modification of the brace. Referral for orthopedic management may be required to evaluate the brace, particularly if it is new or very old.

MENINGOMYELOCELE (MYELOMENINGOCELE)

Meningomyelocele is the most common congenital defect of the neural tube. The spinal cord, meninges, and vertebral column are involved due to failure of the neural tube to fuse in early embryogenesis. It causes varying amounts of sensory and motor impairment based on the level of the lesion and accompanying medical problems. Incidence is 0.7 per 1000 live births in the United States. Etiology is considered to be multifactorial, although folic acid deficiency has been associated. Folic acid is currently recommended as a supplement as early as possible during pregnancy. Other neural tube defects are anencephaly, encephalocele, lipomeningocele, spina bifida occulta, sacral agenesis, and meningocele.

Children with meningomyelocele have multiple, complex medical problems due to impairment of nerves at or below the site of the lesion. There is variable impairment of sensory and motor nerves controlling voluntary and autonomic functioning. Associated medical concerns include neurogenic bowel and bladder function, contractures, scoliosis, club feet, hydrocephalus, Chiari II malformation, tethering of the spinal cord, spinal cord syrinx, vesicoureteral reflux, decubitus ulcers, constipation, encopresis, recurrent urinary tract infections, growth failure, latex allergy, gastroesophageal reflux, apnea/stridor syndrome, seizures, partial agenesis of the corpus callosum, strabismus, visual acuity impairment, precocious puberty, and osteoporosis. Individuals also may have cognitive impairments. Mild forms of cognitive impairment may affect visual motor functioning. More severe cognitive impairment has been associated with sparing of verbal skills and a "cocktail party" syndrome, in which the children may be able to carry on superficial social conversations with ease but be unable to comprehend and use specific information provided to them or respond to specific questions.

Hydrocephalus

Hydrocephalus is present in 70 to 90 percent of children with thoracic or lumbar level defects and in substantial numbers of those with sacral level defects. It is routinely treated with shunt placement early in life. Concerns regarding shunt function are common in patients presenting to the acute care setting. Signs and symptoms of shunt malfunction are lethargy, irritability, nausea, vomiting, visual problems, cognitive changes, neck pain, headache, swelling along the shunt path, or seizure.[9,10] Not all symptoms need be present to indicate malfunction of the shunt. The symptomatology is nonspecific and can easily be due to a variety of other problems such as sepsis, urinary tract infection, otitis media, gastroenteritis, sinus infection, or viral syndromes. A number of children with massive constipation and a shunt may complain of similar symptomatology, which resolves when the fecal backup is relieved. Evaluation for shunt malfunction should proceed only after infectious and other causes have been eliminated. Preliminary studies for a malfunctioning shunt include a shunt survey (radiographs of the skull, chest, and abdomen) to evaluate connections and the shunt position and head CT to assess ventricular size and position of the proximal end in the ventricle. If questions remain, a shunt tap should be used to evaluate opening pressures and assess for infection. If inconclusive, a shunt clearance study with dye or radioisotope may provide additional information regarding flow through the system. Shunt taps should be done by neurosurgical staff when they are available, unless respiratory or cardiac compromise appears to be life-threatening.

Urinary Tract Problems

Urinary tract problems were at one time a primary cause of morbidity and mortality in children with meningomyelocele. Neurogenic bladder with chronic retention from

dyssynergia, overflow incontinence, dribbling incontinence from an open bladder neck, vesicoureteral reflux, renal calculi, and urinary tract infections are common problems in this population. Children may be on prophylactic antibiotics, oxybutynin, or imipramine in an attempt to eliminate infections, minimize upper tract damage, and assist in the development of urinary continence. The side effects of the latter two are given in   Table 134-3. Urinary tract colonization has been described in 60 to 70 percent of this population, and in the absence of vesicoureteral reflux, treatment is reserved for those with symptomatic urinary tract infection. Use of nitrofurantoin, trimethoprim-sulfamethoxazole, or amoxicillin is advised until culture results are available to minimize development of resistant strains of bacteria. Prior to treating an infection, it is important to know what antibiotics are currently in use. If broad-spectrum antibiotics have been used recently, there is an increased potential for a monilial infection.

Generic Name (Brand Name)	Most Common Side Effects
Oxybutynin (Ditropan) Propantheline (Pro-Banthine)	Dry mouth, blurred vision, gastrointestinal intolerance, fever, flushing
Imipramine (Janimine, Tofranil)	Nervousness, sleep disorders, tiredness, mild GI disturbances, constipation, seizures, anxiety, syncope

TABLE 134-3 Medications Commonly Used in Meningomyelocele

Clean intermittent catheterization is used to increase continence and manage urinary retention. When used with good technique, it does not increase the incidence of urinary tract infection. On rare occasions, false channels are formed with catheterization. When this occurs, special catheters such as coudé (curved-tip) catheters may be used to facilitate catheterization and minimize the chance of further trauma. It is wise to question the family regarding catheterization, catheter size, and special types of catheters that may be used. Use of indwelling catheters with balloons is not recommended due to problems with latex allergies (see below).

Intractable incontinence may be present due to severe bladder neck or sphincter deficiency and/or a noncompliant, high-pressure, low-capacity bladder. Reconstructive surgery such as bladder augmentation, bladder neck sling, artificial urinary sphincter, or collagen injections to the bladder neck may be required to provide continence and an adequate bladder capacity. Bladder augmentation has been used widely to increase the bladder capacity of some children with small hyperreflexic bladders. Any individual with a bladder augmentation who presents with abdominal pain should be evaluated for rupture of the bladder. Symptoms of bladder rupture include abdominal pain (which may radiate to the shoulder), abdominal distention, and shock. This is a life-threatening event requiring vascular support, antibiotic prophylaxis, and immediate operation. If this is suspected, the urologist should be contacted immediately.

A small number of children may develop renal calculi. If a small stone is being passed, symptomatic treatment for severe pain is required. Larger stones and asymptomatic stones should be noted, and follow-up with the child's urologist is recommended.

Chiari II Malformation

Chiari II malformation is present in the majority of children with meningomyelocele. Chiari II malformation consists of malformation of the cerebellum, hindbrain, and brainstem. Aqueductal stenosis is commonly associated. Symptomatic Chiari malformation is characterized by apnea, vocal cord paralysis, stridor, oral motor dysfunction, visual dysfunction, and upper limb weakness and incoordination in the infant. In older children it presents with visual dysfunction, motor incoordination, headache, and hand weakness.[11] Even mild cervical hyperflexion-extension injuries may result in symptoms. Of greatest concern is the young child or infant who presents to the ED with stridor and meningomyelocele. Suspicion of a Chiari malformation should be present, and evaluation should be ordered on an expedited basis. Stridor may be associated with vocal cord paralysis and may proceed to complete airway obstruction in a small number of patients. Evaluation is by MRI of the craniocervical junction. For children with severe respiratory compromise, immediate hospitalization is required. If respiratory tract function is not severely impaired and the process is static by history, a case-by-case decision should be made regarding hospitalization based on availability of prompt outpatient services from neurosurgery, otorhinolaryngology, and radiology for MRI. When significant respiratory compromise is associated with Chiari II malformation, tracheostomy may be required. Tracheostomy should be reserved for patients in whom intubation is not possible.[12]

Individuals with myelomeningocele and Chiari II malformation may have instability of the craniocervical junction. If the Chiari malformation has been symptomatic, it may have been treated with decompression surgery. The surgery may involve removal of a posterior segment of the cranium at the foramen magnun and/or laminectomy of the cervical vertebrae. Fusion of the cervical vertebrae may be done to improve cervical stability. If the child is in a motor vehicle accident, there should be a high index of suspicion for upper cervical spine injury. Routine precautions should be instituted, and complete evaluation, including flexion and extension films of the neck, should be done if indicated.

Spinal Cord Tethering

Tethering of the spinal cord can occur as the child grows. Tethering may present as ataxia, rapid progression of scoliosis, loss of functional motor level, a change in urinary continence (new-onset incontinence in a child who had previously been dry on a bladder program), or new-onset orthopedic deformities of the lower extremities. For the child who presents with increasing urinary incontinence with no evidence of an acute urinary tract infection, a neurosurgical consult should be considered. This is generally not an emergency, although it should be evaluated promptly in an office setting.

Skin Problems

Burns and pressure sores are seen in insensate areas with increased frequency. Burns occur and can be quite severe due to a lack of protective response triggered by pain. Pressure sores are frequent due to a lack of sensation. Common areas for pressure sores are under braces and in the sacral and ischial regions. Caution should be used in evaluation of pressure sores because healthy-appearing tissue may overlie abscesses or infected tracts extending proximally toward bony structures deep to them. When infections track deep, osteomyelitis may develop, requiring hospitalization, surgical debridement, long-term intravenous antibiotic therapy, and management of the skin surface.

Open areas should be evaluated carefully for evidence of tracts. Other wounds proximate to a pressure ulcer should be documented carefully with a suspicion that they may be connected by tracts. Evaluation should include probing for tracts, looking for undermined areas, obtaining radiographs to assess bony changes of osteomyelitis, and an erythrocyte sedimentation rate (ESR) or C-reactive protein determination. If cellulitis or bone changes are identified, consider admission for institution of intravenous antibiotics and a complete evaluation of bone involvement. Simple pressure ulcers without evidence of infection or extension can be treated successfully with local measures and pressure relief. Superficial wounds can be treated with sulfadiazine or duoderm wafers. Deeper wounds require wet-to-dry or gel dressings. Sulfadiazine, wet-to-dry dressings, and gel dressings are changed two to four times daily. Duoderm wafers are left in place for up to 3 days at a time if they remain dry and intact. Ulcers below braces require discontinuation of the bracing for 3 to 6 weeks to allow healing to occur. Ulcers on the buttocks require staying in a prone or supine position, with all pressure off the wound.

Additionally, the physician should check to ensure that a pressure-relief system is intact and functioning to prevent future skin breakdown. For wheelchair users, cushions to relieve pressure are advised. Air-filled ROHO cushions, gel cushions, and foam cushions are available and used extensively for this purpose. Children are also instructed in wheelchair push-ups to change their position in the chair. Watches with alarms that can be set to go off every 15 to 20 min are advised to remind the individual to do a push-up.

Bowel Problems

Neurogenic bowel is often seen, with resulting fecal incontinence, encopresis, or constipation. Many children are on a routine bowel management program in an

attempt to achieve fecal continence. Bowel problems may present in the ED in a number of atypical ways. Children with shunted hydrocephalus often present with complaints of headache or shunt malfunction. This may be due to significant intraabdominal pressure from fecal retention, which may be transmitted via the shunt to the head. Abdominal discomfort also may be a presenting complaint, but frequently the child and family will deny any bowel problems or constipation. Even in children with daily stools, severe fecal stasis may develop due to impaired peristalsis. The child who presents with intermittent diarrhea also may have fecal stasis and buildup with overflow incontinence.

Bowel management techniques in the home include dietary manipulations, Karo syrup in feeds, Senokot, Dulcolax, glycerin suppositories, or a variety of enemas. Due to the chronic nature of this difficulty, mineral oil and Fleets enemas are not used routinely. This is to minimize the chance of families repeatedly using preparations that may cause vitamin deficiency or metabolic disturbances with frequent, ongoing use.

When constipation or fecal stasis is a consideration, a flat plate of the abdomen is helpful in clarifying the problem. Constipation of significant proportion can be handled by a high enema, suppository, or manual disimpaction. High enema is often the most effective. Difficulties may be encountered due to poor rectal tone and the inability of the child to retain an enema or suppository voluntarily. Families who routinely use enemas may have adapters to assist in the retention of an enema. When constipation or fecal stasis is the problem, there is generally no need for hospitalization. Following an initial clean-out procedure in the emergency department, the child can be discharged. Follow-up with the general pediatrician, a comprehensive spina bifida program with specialists knowledgeable about bowel management, or an enterostomal therapist to arrange an ongoing bowel management program is advised.

Sexual Abuse

Sexual abuse questions may come up on occasion in children with meningomyelocele. Care must be taken in the assessment because rectal tone is often impaired, and a patulous anus may result. Rectal tears and prolapse also may be present in the child with constipation.

Latex Allergy

Latex allergy is a concern in children and adults with meningomyelocele. It occurs in 24 to 67 percent of children with meningomyelocele. Increasingly severe allergic-type reactions are being reported related to latex and latex-containing products. Reactions vary from mild local reactions to anaphylaxis. Children may present with local or generalized swelling, hives or edema, itching, or a rash. Runny nose or eyes, coughing, sneezing, wheezing, stridor, and difficulty swallowing or breathing also may be presenting complaints. [13,14 and 15] A history of latex allergy or sensitivity should be obtained in all children with meningomyelocele prior to any examination or procedure in which latex gloves or other latex-containing supplies may be used. Many routine medical supplies contain latex, including frequently used supplies on the crash cart. (See Table 134-4 for a list of latex-containing supplies.) Many programs are recommending that identification bands be worn by children with meningomyelocele and latex allergy. If a severe allergic reaction is observed, the child should be discharged with an Epi-Pen, and formal testing for latex sensitivity should be done in the private physician's office. All surgeons providing care and the local anesthesiologist should be notified. This can be done by notifying the local physician or clinic responsible for the child's specialty care.

TABLE 134-4 Latex-Containing Supplies and Alternatives

Fractures

Fractures occur with increased frequency when the child has osteopenia. Children with fractures to the lower extremity should be evaluated for level of sensation. If the child is insensate and paraplegic, casting may not be required. Soft wrapping of the extremity and elevation are the preferred mode of treatment. [16]

Respiratory Tract Problems

Respiratory tract problems generally are not associated with meningomyelocele other than vocal cord paralysis with Chiari II malformations or with the child with severe allergy to latex. Rarely, fibrotic changes in the lung have been associated with oxybutynin use. If chronic respiratory difficulties are present in a child on oxybutynin, discontinuation of the drug should be considered along with acute management.

SPINAL CORD INJURY

Pediatric spinal cord injury is an acute traumatic lesion of the spinal cord and roots resulting in motor and/or sensory deficit occurring between birth and adolescence. About 1100 new pediatric cases occur each year secondary to motor vehicle accidents, sporting accidents, falls, gunshot wounds, and birth trauma.

Spinal cord injury may result in complete or partial loss of neurologic function below the level of the lesion. Pain, heterotopic bone ossification, hypercalcemia, renal calculi, and depression are frequent issues for all children with spinal cord injury. [17] Other associated medical problems are similar to those encountered by children with meningomyelocele. Neurogenic bowel and bladder, decubitus ulcers, spasticity or hypotonicity, gastroesophageal reflux, esophagitis, aspiration, impaired sensation, ureterovesical reflux, scoliosis, contractures, and osteoporosis are common. For children with cervical or thoracic level lesions, respiratory compromise due to impaired phrenic nerves and/or abnormal innervation of abdominal musculature may be present. Autonomic dysreflexia and oral motor dysfunction also may be present. Since many of the issues are well covered in the section on meningomyelocele, this section will cover only the issues specific to spinal cord injuries.

Autonomic Dysreflexia

Autonomic dysreflexia is dramatic paroxysmal hyperactivity of uninhibited sympathetic and parasympathetic nerves in children with spinal cord lesions proximal to thoracic level 6. It is caused by stimulation below the level of the lesion by bladder overdistention, fecal impaction, skin breakdown, or fractures. Presentation is sweating, flushing, pounding headache, hypertension, bradycardia, and piloerection above the level of the lesion. Death or cerebral vascular accident may result. [17]

Dysreflexia is managed by eliminating the stimulus. Moving the child to a sitting position to take advantage of orthostatic hypotension, discontinuation of procedures in progress, emptying the bladder, disimpaction of the bowel, and normalizing body temperature should be used as required. When disimpaction is required, an anesthetic gel or ointment should be used to minimize afferent stimulation. If positional changes and elimination of the stimulus do not suffice, treatment may require sublingual nifedipine or IM or IV hydralazine. Nitropaste in a 1-in patch also may be applied, if available, for emergency reduction of hypertension. It should be removed immediately when blood pressure returns to normal.

Pain

Chronic pain described as dysesthesia or paresthesia is common in adolescents with spinal cord injury but infrequent in younger children. Pain generally is managed with analgesic agents. Long-term use of narcotic analgesics is avoided. Heat, relaxation therapy, and hypnosis also have been useful adjuncts. Care must be taken in

the emergency room to avoid prescribing of medications that may be abused.

Heterotopic Bone Formation

Heterotopic bone formation may develop months after spinal cord injuries. It presents with heat, swelling, restricted motion, and pain. Commonly affected joints are the hip, knee, elbow, or shoulder. Ankylosis may develop and make routine activities impossible. This will need to be differentiated from fracture, infection, or other emergent conditions. Management is conservative, with analgesics for pain. Aspirin is sometimes used for prevention of recurrence. When heterotopic bone formation is present, the child and family should be prepared for problems with skin breakdown and secondary infection, which occur rarely.

Respiratory Dysfunction

Respiratory dysfunction is seen in some children with cervical-level lesions. Use of ventilators may be necessary either during the night or full time. Even in those with no need for early ventilator support, respiratory difficulty may develop due to increasing spasticity of abdominal muscles or muscular fatigue. When children present with respiratory difficulty, attention must be paid to pulmonary toilet, use of assistive devices, and the presence of previous respiratory difficulties or progression of respiratory difficulties. Impaired motor control may result in reflux and aspiration, which may contribute to the difficulties being experienced. Pulmonary consultation, if available, may allow the emergency physician to adjust the ventilator and prevent hospitalization. Children with phrenic nerve stimulators may need to be hospitalized for management.

Psychiatric and Psychological Problems

Psychiatric and psychological problems develop related to loss of independence and impairments of body image. Depression, severe uncontrolled anger, panic attacks, and temper tantrums can make care of these children difficult. Most difficulties of this type can be handled on an outpatient basis by a psychologist, social worker, or physician experienced in working with this population. For severe depression, suicidal ideation, or other emotional problems that are out of control, hospitalization and/or psychiatric evaluation may be needed.

DEVELOPMENTAL DISABILITY (MENTAL RETARDATION)

Mental retardation is a substantial limitation in present functioning associated with subaverage intellectual capabilities and limitations in two or more adaptive skill areas (communication, self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and work). It is a result of injury, disease, metabolic disorder, or other abnormality of the central nervous system occurring before the age of 18. Mental retardation occurs in 2.5 percent of the population. Etiology is known for certain syndromes associated with mental retardation, but the majority of individuals with mental retardation have no clearly identified etiology. Down syndrome, fetal alcohol syndrome, and fragile X syndrome are the most common known etiologies of mental retardation.

Dealing with the mentally retarded child in the ED is difficult because of the variety of medical problems that may be encountered and because the individual often is not able to clearly communicate the problem to the physician or the care provider. It is important to be aware that a child or care provider who cannot cooperate with questioning or physical examination may be mentally impaired.

Children with mental retardation have a wide variety of associated medical problems. With increasing severity of mental retardation, there is increased incidence of associated problems. Cerebral palsy, visual deficits, seizure disorders, failure to thrive, hypotonia, gastroesophageal reflux, aspiration, and psychiatric disorders have all been seen in the general population with mental retardation. Mental retardation associated with known syndromes may have diagnosis-specific medical problems such as in Down syndrome, the best known of these syndromes. Listings of diagnosis-specific medical problems can be found in Table 134-5.

TABLE 134-5   Medical Conditions Associated with Specific Mental Retardation Syndromes

Pulmonary Problems

Respiratory tract symptoms may be present in severely mentally impaired individuals. Chronic congestion, recurrent pneumonia, and wheezing may occur due to low tone and are similar to the problems seen in the individual with cerebral palsy. Mentally impaired individuals function at an earlier developmental age than the chronologic age. Severely impaired individuals may function at a preschool level and thus are at an increased risk of a foreign body aspiration like an average toddler.

Gastroesophageal Reflux

Gastroesophageal reflux is often present when tone is low. It may contribute to aspiration problems and can be associated with gastritis and esophagitis. Gastroesophageal reflux may present as emesis, nonspecific irritability, discomfort, or a lack of appetite and may contribute to failure to thrive. When the family complains about emesis, the physician needs to clarify their description; they may be seeing clearing of secretions from the upper airways. In the severely impaired child, "emesis" may be a stimulated gag and cough to clear secretions from the posterior pharynx. True emesis should contain stomach contents. If the child is tube fed, this will be formula. Often the parent will describe emesis that is composed of mucousy material instead of formula or food.

Evaluation for gastroesophageal reflux generally is not required on an emergent basis, but management information may be useful. Metoclopramide can be used to improve transit time through the stomach when delayed gastric emptying is found on scintigraphic studies of gastric functioning. Ranitidine and other new blocking agents have been used to decrease the acidity of the gastric contents when gastritis or esophagitis is identified. Thickened feedings, positioning, and other techniques have been used with some success but are of questionable assistance in older individuals. In some cases, Nissan fundoplication is required for management of moderate to severe reflux not responsive to medical management.

Children with cognitive impairments may have unusual behaviors such as pica. When indigestible materials are ingested on a routine basis, bezoars may develop consisting of hair, cloth, or other materials. This also may present like reflux due to outlet obstruction. A barium swallow should identify this problem. Surgical removal may be required on an emergent basis. This problem should be evaluated for admission on a case-by-case basis.

Seizures

Seizures are present in 30 percent of children with mental retardation. With increasing severity of mental retardation, there are often increasingly complex seizures. Problems associated with epilepsy are identical to those of children with cerebral palsy described earlier in the chapter. The physician should be alert to the possibility of multiple seizure types, use of multiple anticonvulsants, drug-drug interactions of anticonvulsant medications, and the possible fragility of seizure control. Contact with the managing neurologist is strongly advised in such cases.

Psychiatric and Behavioral Problems

Psychiatric and behavioral problems combined with limited understanding of what is happening to them and an unfamiliar, overstimulating situation often lead to an uncooperative and at times combative child. The prevalence of major psychiatric disorders and attention deficit disorder is two to three times that of the general population. Stereotypy and self-injurious behavior are seen almost exclusively in the mentally retarded population, with increased incidence in children with the most severe cognitive limitations. Treatment of psychiatric and behavioral disorders is similar to treatment of these disorders in the general population.

The most worrisome problem in the ED is self-injurious behaviors. Self-injurious behavior is chronic, repetitive acts that may result in serious medical consequences. Self-injurious behaviors may include head-banging, chewing, hitting, and picking at various body parts. Behavior management, protective strategies, and pharmacologic intervention have all been used with variable success. When dealing with injuries sustained secondary to self-injurious behavior, use protective strategies immediately. Referral to psychiatric, psychological, or developmental services for behavior management and possible pharmacologic intervention is advised. This may be done on an outpatient basis. For children with known problems who are currently being treated for psychiatric disorders or behavioral problems, the side effects of the medications may become an issue. See Table 134-6 for a list of pharmacologic agents and their side effects.

Generic Name (Brand Name)	Most Common Side Effects
Diazepam (Valium)	Drowsiness, ataxia, weakness, confusion, constipation, dysarthria, diplopia, rash, urinary retention
Desipramine (Norpramin, Pertofrane)	Drowsiness, incoordination, weight gain, constipation, blurred vision, dry mouth, insomnia, anxiety, confusion, nightmares, delusions, psychosis, blood dyscrasias
Fluphenazine (Permitil, Prolixin), haloperidol (Haldol), Methylphenidate (Ritalin), thioridazine (Mellaril)	Extrapyramidal movement disorders, neuroleptic malignant syndrome, drowsiness, restlessness, nausea, blurred vision, rash, dry mouth, polyuria, altered glucose regulation, weight gain or loss, anorexia, insomnia, rebound, headache, tics, agitation, rash, tachycardia, hypertension, weight loss, decreased growth rate, abdominal pain

TABLE 134-6 Medications Commonly Used in Mental Retardation

Down Syndrome

Congenital heart defects occur in 40 to 60 percent of children with Down syndrome. Atrioventricular canal defects, ventricular septal defects, atrial septal defects, tetralogy of Fallot, and patent ductus arteriosus are all reported in this population. Pulmonary hypertension may develop in these children, associated with chronic upper airway obstruction and left-to-right shunts. Congestive heart failure has been described even in children without known heart lesions. Mitral valve prolapse and aortic regurgitation are described in adults but not in children.

Gastrointestinal problems are common, including imperforate anus, pyloric stenosis, tracheoesophageal fistula, and Hirschsprung disease. Due to gastrointestinal malformations, hypotonia, and previous surgeries, partial bowel obstruction and constipation may present as problems in the emergency room.

Atlantoaxial instability and dislocation have been identified and are felt to be related to joint laxity. Spinal cord compression may develop, with neck pain, head tilt, torticollis, frequent staggering or falling, increased deep tendon reflexes, clonus, limb weakness, paresthesias, or hemi- or quadriplegia. Symptomatic children require immediate surgical stabilization.

Recurrent upper respiratory infections, chronic sinusitis, and chronic middle ear effusions are seen in many young children with Down syndrome. These can be treated using standard protocols but should be referred to an otorhinolaryngologist or pulmonologist when they occur repeatedly. Sleep apnea and obstructive apnea are described but are not generally problems in the emergency setting.

A variety of other medical problems may be seen on an emergent basis: hypothyroidism, thyroiditis, leukemia, and transient neonatal leukoproliferative disorder. Skin problems are seen including eczema, folliculitis, alopecia areata, and sun hypersensitivity.

Fragile X Syndrome

Fragile X syndrome is an X-linked condition consisting of mental retardation or learning disabilities, connective tissue disorders, and sensory integration dysfunction. It affects 1 in 1000 individuals and affects males more severely than females. There are few associated medical conditions, and generally they do not cause severe problems. Mitral valve prolapse, seizures, strabismus, frequent ear infections, allergies, self-abusive behaviors (particularly biting), and hyperextensible joints are reported in some children. The major difficulties that may be encountered may be related to autistic-like behaviors and self-abusive behaviors.

Prader-Willi Syndrome

Prader-Willi syndrome is a condition characterized by mental retardation, hypotonia, hypogonadism, and obesity. It is a sporadic multisystem disorder with an incidence of 1 in 10,000. It is due to a chromosomal deletion on the 15th chromosome. Presentation in infancy is of poor suck, hypotonia, developmental delay, and early failure to thrive. During childhood, the poor eating habits change to hyperphagia and obesity, which becomes a major problem for health and life. Consequences of obesity include somnolence, hypoventilation, cor pulmonale, and non-insulin-dependent diabetes mellitus. Associated problems are scoliosis, strabismus, and inability to vomit. Occasional problems may include decreased sensitivity to pain, seizure disorder, short stature, skin picking, easy bruisability, fractures from minor trauma, and acanthosis nigricans.

Obesity develops due to hyperphagia, inability to vomit, and decreased caloric requirements. Children become obsessed with food and eating. Abnormal behaviors are manifested with gorging, foraging for food, eating inedibles, and violent temper outbursts when eating is thwarted. Respiratory problems occur secondary to massive obesity. Pickwickian syndrome with hypoventilation, hypercapnia, hypoxia, and right-sided heart failure have been seen in older children. Impaired breathing leads to carbon dioxide retention, acidosis, constriction of the pulmonary arterioles, pulmonary hypertension, and the chance of pulmonary embolus. Non-insulin-dependent diabetes mellitus is seen in some patients related to their obesity. Most people with diabetes can be managed with oral hypoglycemics and/or weight loss. Insulin is rarely required, and response to insulin may be unpredictable. Early atherosclerosis and glomerulosclerosis may occur secondary to the diabetes.

The inability to vomit can be of concern in the ED. Hyperphagia may result in food foraging, consumption of nonfood materials, and toxic ingestions. In this patient population, ipecac should be avoided. Ipecac toxicity can result if the patient is unable to vomit. Gastric aspiration or other techniques should be used.

Respiratory insufficiency with hypoventilation is frequently not responsive to hypercapnia. Medroxyprogesterone acetate may be helpful as a respiratory stimulant in some cases. Gastric perforation as a consequence of overeating is seen in rare cases.

Williams Syndrome

Williams syndrome is a disorder of unknown etiology that presents with elfinlike facies, cardiovascular disease, infantile hypercalcemia, learning disabilities or mild to moderate mental retardation, and an outgoing personality. It appears to develop into a multisystem disease in adulthood.

Cardiovascular difficulties, endocrinologic abnormalities, urinary tract problems, gastrointestinal problems, and arthropathy are observed with increasing incidence over time. Supravalvular aortic stenosis is the most common cardiac problem. Pulmonic stenosis, coarctation of the aorta, strabismus, joint contractures, and

hypertension are also reported. Hypercalcemia is seen in infants and recurs in adults. Calcium levels should be monitored. Children who present with polydypsia, polyuria, irritability, and constipation should be evaluated for hypercalcemia. Urethral stenosis, bladder diverticuli, vesicoureteral reflux, renal artery stenosis, constipation, ulcers, diverticulitis, and arthropathy are reported in adults with the syndrome.

Rett Syndrome

Rett syndrome is a form of mental retardation occurring only in females and characterized by normal early development followed by a loss of purposeful hand use, regression in social development, progressive ataxia or spasticity, and development of mental retardation. [18] Hand stereotypies and spontaneous noncommunicative vocalizations or laughter are typical of this syndrome. Incidence is 1 in 10,000 to 15,000 females. Hyperventilation, breathholding, air swallowing, bruxism, ataxia, muscle wasting, poor circulation in the lower extremities, frequent fractures, scoliosis, seizures, and intermittent flushing have been described in association with this syndrome.

These girls may present to the ED with a variety of symptoms, including fainting due to apnea or hyperventilation or with severe abdominal distension due to air swallowing. Apnea has been known to last 30 to 40 s and may involve cyanosis. Screaming attacks may occur in puberty. Children need to be assessed for possible pain due to an acute abdomen, dental pain, kidney stones, or other medical causes. If no source of medical concern is identified, the child may be suffering from a screaming attack.

Seizures are seen often in this population and may be generalized, partial, or mixed. Atypical infantile spasms also have been described. Seizures may be refractory to drug therapy, and individuals are at times prone to adverse reactions to their anticonvulsant medications. Some "seizures" actually may be nonepileptic paroxysmal events unresponsive to antiepileptic medications. Caution is advised in adjusting dosages. Consultation with the treating neurologist or specialist managing the child is strongly advised if seizure is the presenting problem.

UROLOGIC PROBLEMS OF PREADOLESCENT AND ADOLESCENT BOYS

Disorders Involving the Foreskin

Differentiation of the genitalia occurs between the ninth and thirteenth gestational week. The prepuce of the glans penis, which forms the foreskin, is adherent to the underlying glans penis and remains so throughout gestation and during the first several years of postnatal life. The foreskin of the newborn and infant cannot easily be retracted. Doing so shears the attachments between the epithelial layers of the glans penis and the foreskin. This normal adherence of the foreskin of the infant and toddler to the underlying glans penis is referred to as physiologic phimosis and is a part of normal male child physical development and maturation. It can persist in some (3 to 6 percent) boys into the grade-school years, spontaneously resolving during early puberty in the vast majority of boys.

FORESKIN PEARLS Secretions and sloughed epithelial cells (smegma) from the surface of the glans penis accumulate under the foreskin and contribute to the gradual elevation and separation of the foreskin from the surface of the glans penis. The thin foreskin may reveal such accumulations of smegma, referred to as foreskin pearls. They ultimately will decompress at the terminus of the foreskin's attachment to the glans penis. If unassociated with evidence of cellulitis (erythema, warmth, induration, and tenderness), they do not represent an infectious complication and require no treatment beyond an explanation and reassurance for the concerned parent.

PHIMOSIS It is important to differentiate physiologic phimosis, as mentioned above, from pathologic phimosis. Phimosis is pathologic when a previously retractable foreskin is no longer retractable or when foreskin retraction is unachievable beyond puberty. Pathologic phimosis is rare in children. It may complicate circumcision or may result from repeated trauma, infections, or chemical irritation. It may be suspected if, during examination of the comfortably retracted foreskin, the foreskin appears rolled or thickened, rather than thin and effaced as the foreskin is pushed gently toward the base of the penis.

Pathologic phimosis associated with obstruction of urinary stream, recurrent urinary tract infections, or recurrent bouts of balanoposthitis represents an indication for referral to a urologist or pediatric surgeon for elective circumcision. Nonsurgical management of pathologic phimosis has been proposed. Case reports and case series reports of balloon dilatation and topical steroids suggest a limited role for these approaches.

PARAPHIMOSIS Regardless of the reasons for foreskin retraction, timely replacement of the foreskin ring distal to the glans penis is necessary. Failure to do so will result in the formation of painful edema in the foreskin and glans penis secondary to venous congestion caused by the constriction by the preputial ring. Ultimately, vascular insufficiency may threaten the viability of the glans penis and foreskin. This condition, known as paraphimosis, is an emergent urologic condition.

Differential diagnostic considerations include penile infections (balanoposthitis), idiopathic penile edema (insect bites, contact dermatitis, etc.), and, more important, a circumferentially constricting foreign body (hair, clothing, rubber band, etc.). Among the most pressing duties of the examining physician is the identification and removal of any constricting foreign body. The profound edema of the glans penis and the foreskin may make this task exceedingly difficult.

Management rests largely with the control of swelling and of pain, using systemic analgesia, dorsal penile nerve block, or both. Control of edema may be achieved by application of cool, compressive (1-in Surgical Cling) dressings, starting at the distal penis and wrapping proximally. Alternatively, the glans penis may be cooled with ice water-filled latex examination gloves. Reexamination of the penis for the presence of a constricting foreign body should then be performed.

Once the diagnosis of paraphimosis has been confirmed, it is reduced using a variety of techniques. The most commonly successful reduction technique involves the simultaneous distal traction of the foreskin using the index and third fingers of each hand while the thumbs push the swollen glans penis back through the paraphimotic ring of the foreskin. The use of a gauze sponge between the third and index fingers of each hand and the foreskin aids considerably in traction on the foreskin. If this technique is unsuccessful, a surgical release of the edematous foreskin is indicated, ideally in conjunction with urologic consultation. Either a single puncture of the foreskin using a 21-gauge needle or (more definitively) a dorsal slit of the edematous foreskin ring should restore vascular supply to the glans penis.

Discharge from the emergency department is appropriate following demonstration of spontaneous voiding of the bladder. Outpatient consultation with a urologist or a pediatric surgeon is appropriate and should be coordinated through the child's primary care physician.

BALANOPOSTHITIS Balanitis is an inflammation of the glans penis. Balanoposthitis is an inflammatory process that also involves the foreskin. The cause of balanoposthitis in preadolescent boys is usually infection but may occasionally be trauma, including chronic friction, zipper injuries, and contact dermatitis, or a fixed drug eruption (tetracycline or clotrimazole). Even rarer are plasma-cell balanitis and balanitis xerotica obliterans. As many as 3 percent of boys experience balanoposthitis, the vast majority of whom are uncircumcised.

The microbiology of infectious balanoposthitis reveals an abundance of gram-positive and gram-negative organisms. Most infections of the foreskin and glans penis represent invasion by normal flora and are usually polymicrobial. Contributing factors to the development of these infections (e.g., poor hygiene) are unproved and controversial. *Candida albicans* may be the pathogen in prepubertal children, and recurrences of balanoposthitis due to this organism should alert the physician to the possibility of immunocompromise, such as occurs with diabetes mellitus. Group A b-hemolytic streptococcus has been reported as an infectious organism, and its identification (via rapid antigen detection of associated thin, purulent discharge) warrants aggressive and specific antistreptococcal therapy. Sexually transmitted organisms are responsible for many cases of balanoposthitis in older adolescents.

Physical examination of a child with balanoposthitis reveals redness (100 percent), swelling (91 percent), discharge (up to 73 percent in one series but usually far less common), and soreness. Systemic fever and constitutional symptoms are atypical. Any urethral discharge is swabbed for detection of streptococcal antigen, and rapid antigen assays that test negative are cultured. If the rapid streptococcal antigen test result is negative, a smear of the discharge is examined using Gram stain. The presence of polymorphonuclear leukocytes on Gram stain of a urethral smear of a prepubertal boy whose rapid test for *Streptococcus pyogenes* is negative should alert the physician to the possibility of a sexually transmitted infection. The emergency physician should be cognizant of the forensic diagnostic criteria for documentation of infections due to *Neisseria gonorrhoeae* and *Chlamydia trachomatis* in his or her community and should select the appropriate culture methods, DNA probes, or other rapid diagnostic tests accordingly.

Management of the more common nonspecific balanoposthitis involves local hygiene measures, including sitz baths and gentle cleaning of the foreskin sulcus and glans penis. The soothing effect of a warm-water sitz bath also facilitates voiding in many children with voluntary urinary retention due to dysuria from a variety of causes. Some clinicians recommend the application of 0.5% hydrocortisone cream to the affected parts. Antimicrobial topical ointments that do not contain neomycin have been traditionally recommended, but their utility is unproved. Occasionally, 5 to 7 days of amoxicillin or a first-generation cephalosporin may be useful in recalcitrant cases or in cases associated with more advanced cellulitis. Circumcision is considered in cases of recurrent balanoposthitis.

Circumcision Complications

MEATAL STENOSIS   Stenosis of the urethral meatus is fairly common. It represents a condition most likely acquired as a result of prolonged exposure of the meatus to moisture from wet diapers. The inflammation from an episode of ammoniacal (diaper) dermatitis causes the tender meatal edges to slough their epithelial surfaces. The urethral meatus becomes adherent to the side-to-side fashion, starting ventrally and progressing dorsally, resulting in a pinpoint meatus at the apex of the glans penis. Meatal stenosis is quite rare in uncircumcised boys.

The clinical presentation of a child with meatal stenosis is typical. It usually comes to the attention of the family of a boy only after the age of toilet training. The family relates that the boy's urine stream is notably difficult to control. There exists a characteristic dorsal deflection of the urinary stream, and the boy may complain of intermittent dysuria, blood spotting on his underwear due to meatal inflammation, and occasionally urinary frequency or a sense of voiding urgency due to residual urethral urine following voiding. Prolonged voiding times are not unusual, and some boys condition themselves to sit while voiding in their efforts to cope with these symptoms.

Management of a symptomatic boy with urethral stenosis usually involves urethral meatotomy, an office procedure in the hands of most pediatric urologists. Subsequently, a regimen designed to maintain separation of the recently divided urethral meatus edges is necessary for up to 6 weeks in order to prevent restenosis.

POSTCIRCUMCISION PHIMOSIS   Improper seating of a circumcision bell clamp at the time of foreskin removal may result in excess residual foreskin following the procedure. Since the circumcision site is circumferential in nature, the inevitable contraction of the scar may yield a progressive narrowing of the foreskin orifice. At some point, the narrowed foreskin orifice slides distally over the glans penis, entrapping it. Further contraction of the circumcision scar may result in such a degree of phimosis that urine flow is obstructed. This phenomenon is more common in boys with prominent peripenile fat pads, particularly in boys with a retracted-appearing penis.

Diagnosis rests with the identification of a tight phimotic ring in a boy who has prevously undergone circumcision. Occasionally, early detection of progressive narrowing of the foreskin orifice may afford an opportunity for stretching the foreskin orifice either through aggressive foreskin retraction or the use of a hemostat. More commonly, the child requires a circumcision revision.

SURGICAL PENILE GLANS ADHESIONS   Contact of a postcircumcision scar with the recently denuded glans penis may result in a very thick adhesion between the epithelial surface of the glans penis and the circumcision scar. These adhesions cannot be separated by blunt dissection, requiring surgical separation instead. They are prevented by repeated application of antimicrobial ointment to the glans penis for 7 to 10 days following circumcision.

Disorders of the Penile Shaft

HYPOSPADIAS   The incidence of hypospadias approximates 1 in 300 live male births in the United States. If the most minor degrees of hypospadias are included in incidence studies, the rate climbs to as high as 1 in 125 live male births. The condition is more common in white boys than in black boys and internationally is most common in Italians and in those of Jewish ancestry. Hypospadias exhibits a polygenic inheritance pattern.

Hypospadias is a congenital defect characterized by an incomplete development of the anterior urethra. The urethral meatus may be located anywhere along the ventral shaft of the penis or may open to the scrotum or perineum. More proximal locations of the urethral meatus are associated with a greater likelihood of ventral shortening and curvature of the penis during erection (i.e., chordee). Hypospadias occurs as a result of varying defects of the urethra, corpus spongiosum, and corpus cavernosa. The ventral skin of the penis is usually thin, and the foreskin is insufficient on its ventral surface.

Several classification systems have been proposed for hypospadias, the most useful of which relate the location of the urethral meatus after any associated ventral curvature has been released. Such a classification system allows boys with hypospadias to be grouped into three categories:

1. *Anterior hypospadias* (50 percent of cases) refers to a urethral meatus position on the inferior surface of the glans penis, on the ventral corona or subcoronal furrow, or somewhere along the distal third of the ventral shaft.
2. *Middle hypospadias* (20 percent of cases) refers to a urethral meatus position along the middle third of the ventral shaft.
3. *Posterior hypospadias* (30 percent of cases) refers to a urethral meatus position along the posterior third of the ventral shaft, at the base of the shaft in front of the scrotum, on the scrotum between the genital swellings, or behind the scrotum or genital swellings.

Hypospadias and chordee are associated with several other anomalies. Undescended testes and inguinal hernia are the most common associated anomalies, ranging from a 9 percent incidence with anterior and middle hypospadias to a 17 percent incidence with posterior hypospadias. A utricle masculinus (a membranous urethral sac) is more frequently associated with more severe and posterior forms of hypospadias. Abnormalities of the higher urinary tract are infrequent in boys with hypospadias, and routine evaluation of the urinary tract is not recommended in boys solely because of the presence of hypospadias.

The treatment of hypospadias and chordee is designed to provide a straight penis with a urethral meatus as close as possible to the glanular tip so as to afford a directionally forward urinary stream and normal coitus. A boy whose urethral meatus is located very anteriorly on the ventral surface of the glans penis and who does not manifest ventral penile curvature probably will be capable of directionally forward urine stream and probably does not require urologic consultation. The identification of any more significant degree of hypospadias suggests an indication for urologic consultation in cooperation with the child's primary care physician. Experienced pediatric urologists can perform a variety of single-staged and multistaged operative procedures to accomplish the goals of treatment outlined above.

PRIAPISM   Priapism is a persistent and usually painful engorgement of the paired dorsal corpora cavernosa, resulting in a dorsal penile erection, while the glans penis and the ventral surface remain flaccid. The resultant erection is not necessarily associated with sexual stimulation or desire, and it is not relieved by ejaculation.

In children, the disorder most commonly has a hematologic basis. Sickle cell hemoglobinopathies account for about two-thirds of cases in children. Priapism affects 2 to 6 percent of prepubertal children with sickle cell disease, and the frequency increases upon completion of puberty to as high as 40 percent of adult patients with sickle cell disease. Leukemia is the underlying hematologic disorder in about 11 percent of children with priapism. Other causes include blunt trauma, anticoagulation therapy, diabetes mellitus, and idiopathic causes.

The etiology of the painful engorgement of the corpora cavernosa elements in priapism is thought to center on the autonomic control of blood flow *out of* the emissary venous system of the penis versus the rate of blood flow *into* the arterioles and sinusoids of the corpora cavernosa. The flow of blood into the arterioles and sinusoids of the corporal elements may be characterized as either high flow or low flow, reflected in ^{99m}Tc penile scan flow studies. The mechanism of high-flow priapism was initially described as a consequence of blunt trauma, whereas the priapism associated with sickle cell disease in adults is usually referred to as low-flow, or ischemic, priapism. Some children with sickle cell-mediated priapism have been identified with high-flow ^{99m}Tc penile scans, giving rise to optimism that the penile scans would prove useful in predicting impotence risks. However, the ^{99m}Tc penile scan data on children with sickle cell priapism remain inconclusive in predicting long-term sequelae.

Priapism differs from a normal penile erection in that the glans penis and the ventral surface of the penis remain flaccid. Its onset is most frequently at night or in early morning. While the priapism of sickle cell anemia may represent an isolated finding, associated complications of sickle cell disease, including sequestration, aplastic crisis, infection, and vasoocclusive crisis, should be investigated. The most frequently encountered acute complication is acute urinary retention, which may represent a voluntary effort to avoid pain or may be mechanical in nature. The long-term complication is impotence. Factors contributing to the development of impotence are variable among patients: multiple episodes, prolonged duration, and onset of priapism in older patients have all been associated with development of impotence.

The diagnosis of priapism is strictly clinical. Laboratory data serve to illustrate comorbid conditions or metabolic status. Differential diagnostic considerations include phimosis with erection and paraphimosis, each distinguished from priapism by engorgement of the glans penis. Peyronie's disease results in tissue fibrosis that yields plaques, which may create a painful erection of the penis. A history of anticoagulant use usually indicates anticoagulant-induced priapism. Cervical or thoracic spinal cord lesions may produce an erection due to sympathectomy, but the erection will involve the corpora cavernosa as well as the glans penis and ventral portion of the penis. The use of ^{99m}Tc penile scans is currently limited to research.

Management of priapism centers on pain relief, adequate hydration, and monitoring for urinary retention. All children with priapism are admitted to the hospital. A child whose priapism is associated with an underlying hematologic disorder receives a hematologic-oncologic consultation. The aggressiveness of fluid administration, the

indications for and administration of blood transfusions, and the timing of surgical consultation are all matters of debate.

Scrotal Swelling and Scrotal Masses of Childhood

This section reviews diagnostic entities and management specific to prepubertal boys. In particular, painless scrotal masses and swelling are reviewed. The most common causes of painless *cystic* scrotal masses in prepubertal boys are inguinal hernias, hydroceles, varicoceles, and spermatoceles. Less frequently encountered entities include various painless *solic* scrotal masses, such as acute idiopathic scrotal edema, testicular tumors, and soft-tissue tumors of the spermatic cord.

PAINLESS CYSTIC SCROTAL MASSES **Inguinal Hernias and Hydroceles** Inguinal hernias and hydroceles, caused by incomplete or abnormal obliteration of the processus vaginalis, are the most common cause of inguinal and scrotal masses in childhood. The incidence of pediatric inguinal hernias is 10 to 20 per 1000 live births and is much higher in premature and low-birth-weight infants. Inguinal hernias are more common on the right side (60 percent) than on the left (30 percent), and 10 percent are bilateral. They are more common in boys (male-to-female ratio, 4:1). In addition to prematurity and low birth weight, many other conditions are associated with increased incidence of inguinal hernias and hydroceles, including (1) all forms of ascites and increased quantities of peritoneal fluid, (2) a positive family history, (3) hypospadias and epispadias, (4) cryptorchidism, (5) cystic fibrosis, (6) various connective tissue diseases, and (7) the mucopolysaccharidoses.

Hydroceles exist when fluid surrounds the testes, with or without direct communication with the abdominal cavity through the processus vaginalis. Their natural course is distinctly different from that of inguinal hernias. Isolated hydroceles manifest a substantially lower risk of incarceration than inguinal hernias. Most noncommunicating hydroceles are painless, are apparent in the immediate neonatal period, and disappear spontaneously by 1 year of age.

Clinically, a child with an inguinal hernia has a bulge or swelling in the scrotum or groin that is most apparent when the child is crying. At times the parent remarks on symptoms of fussiness, vomiting, or other feeding problems. Examination of the child reveals a smooth mass arising from the external ring, perhaps accompanied by swelling in the ipsilateral hemiscrotum. Unincarcerated hernias are easily reducible. Palpation of the spermatic cord reveals a thickening or the "silk-sleeve" sign.

Examination of a child with suspected hydrocele reveals a scrotal fullness that transilluminates. However, the presence of transillumination of the scrotal mass fails to exclude reliably the possibility of coexisting hernia or another pathologic condition. Palpation of the testis confirms descent and is necessary in order to exclude accompanying testicular tumor. If palpation fails to adequately demonstrate a normal-sized and -shaped testis, sonography is indicated to rule out the possibility of an accompanying intratesticular tumor.

A noncompressible, painless cystic mass in a newborn that is unassociated with abnormalities of the testis suggests a diagnosis of noncommunicating hydrocele. Observation of such a child is appropriate, since the majority of cases resolve spontaneously within the first year of life.

Compressibility of the mass suggests a hydrocele communicating with the abdominal cavity through the processus vaginalis. In such a situation and in cases of suspected inguinal hernia, surgical consultation is indicated for the purpose of scheduling surgical repair. Meanwhile, the family is educated about the signs and symptoms of incarceration of an inguinal hernia, including (1) increase in the size of the hernia mass or persistence of a mass, (2) systemic toxicity, (3) abdominal distention, or (4) vomiting, especially bilious vomiting. In cases where a clear clinical diagnosis is not possible, surgical consultation and elective exploration are warranted.

A clinical challenge exists when a child with a hydrocele presents with a coexisting condition that leads to scrotal pain and/or increased scrotal swelling. Inguinal hernia incarceration, testicular torsion, epididymitis, intrascrotal tumors, and acute intraabdominal pathologic conditions may occur in a child with a hydrocele. Careful and gentle examination is usually sufficient to diagnose an incarcerated inguinal hernia or coexistent testicular pathologic condition.

The safest and one of the more effective maneuvers for reducing incarcerated inguinal hernias involves relaxation of the abdominal wall, using sedation if necessary, and subsequent placement of the child in the Trendelenburg position. This results in successful reduction of the incarceration more than 70 percent of the time. Failure of this technique represents an indication for immediate surgical consultation and exploration.

Varicoceles A varicocele is a dilated and elongated network of veins of the pampiniform plexus and apparently is a consequence of spermatic venous valvular incompetence. Found predominantly on the left side (85 to 90 percent), varicoceles are rare in children under 10 years of age, but the incidence increases through early puberty to include 15 percent of adolescents.

Physical examination is best performed in the upright position and reveals a mass posterior, lateral, and superior to the testis extending up the spermatic cord. The mass as been described as feeling like a bag of worms. While usually painless, some boys report a dull ache in their scrotum associated with the varicocele.

The clinical significance of varicocele rests primarily with the association between this condition and adult male infertility. While infrequently an immediate concern of the adolescent, there is ample evidence that the risks of testicular hypotrophy, declining semen parameters, and infertility progress the longer the varicocele remains untreated. Therefore, the identification of a varicocele represents an indication for urologic referral in conjunction with the boy's primary care physician. Urologists recommend surgical repair of varicoceles that are (1) bilateral, (2) painful, or (3) associated with a significant disparity in testicular size of greater than 2 cm ^{3}. Rarely, a varicocele may develop as a consequence of an acute increase in inferior vena caval pressure, in turn the consequence of an intra-abdominal tumor or vena caval thrombosis.

Spermatoceles and Epididymal Cysts Sperm-containing cysts of the rete testis or efferent ducts (spermatoceles), or of the epididymis (epididymal cysts) are the next most common cause of painless scrotal masses in children after hernias, hydroceles, and varicoceles. Located superior and posterior to the testis, they usually transilluminate well. Ultrasound studies confirm the location of the mass, demonstrating a nearly echo-free zone without disorganization of the surrounding parenchyma. Spermatoceles and epididymal cysts are unassociated with infertility and are usually painless. Management consists of confirming the diagnosis with sonographic study if necessary and subsequent parental and patient education. Surgical excision is reserved for enlarging spermatoceles, particularly those associated with discomfort unresponsive to nonsteroidal anti-inflammatory medications.

PAINLESS SOLID SCROTAL MASSES **Idiopathic Scrotal Edema** Idiopathic scrotal edema results in painless scrotal erythema and induration in boys from age 2 to 11 years. Two-thirds of cases are unilateral. The etiology remains obscure. No specific allergen has been identified.

The child has no complaint of pain but may note minimal pruritis and may exhibit a waddling gait. Erythema and swelling may extend to portions of the phallus, abdomen, and groin. Examination reveals a thickened and edematous scrotal skin and underlying tunics, but the boy has little or no tenderness to palpation of the affected areas. There is no fever. The testes, epididymis, and tunica vaginalis are normal, although the degree of swelling of the scrotal skin may preclude adequate examination by palpation. In sonographic studies done in such extreme cases, the underlying scrotal structures and vascular flow appear normal. The urinalysis results and peripheral white blood cell count are normal.

The scrotal edema and erythema resolve in 1 to 4 days, although recurrence rates approach 21 percent. Management involves reassurance of the child and parents. No benefit has been observed from use of steroids, antihistamines, and antibiotics.

Solid Painless Extratesticular Masses Of greatest concern upon identifying a painless solid paratesticular mass in childhood is the diagnosis of paratesticular rhabdomyosarcoma, the most common paratesticular malignancy in childhood. Rhabdomyosarcoma is one of the most common malignant solid tumors of childhood, along with the lymphomas, Wilms tumor, and neuroblastoma. The paratesticular site is the primary location in 10 percent of children with rhabdomyosarcoma. Rhabdomyosarcoma has two peak incidences: one between 2 and 6 years of age, and the other between 14 and 18 years of age.

The clinical presentation is that of a painless, unilateral, solid scrotal mass that initially is distinct from the testis, characteristics that are confirmed by sonographic evaluation. Immediate referral to a pediatric hematologist-oncologist, who will coordinate a multidisciplinary surgical–diagnostic staging and management approach, is mandatory.

There exist a variety of other painless malignant and benign solid tumors of the extratesticular scrotum, but the diagnosis and subsequent management of all of them rest with histologic methods following surgical exploration through an inguinal incision.

Solid Painless Intratesticular Masses Testicular tumors account for less than 1 percent of solid tumors in infants and children. The peak incidence of testicular tumors occurs at 2 years of age. Their significance lies, not in their frequency, but in the relatively frequent development of a secondary hydrocele in 7 to 25 percent of affected patients. This association leads to misdiagnoses and delays initiation of definitive treatment of the underlying tumor. As stated previously, the association of testicular tumors and secondary hydrocele mandates sonographic visualization of the testis if the size or position of the hydrocele precludes an adequate palpation examination of the testis.

Demonstration of a painless intratesticular mass mandates immediate referral to a pediatric hematologist-oncologist, who will coordinate obtaining a surgical diagnosis and determine treatment based on histologic analysis and staging of the tumor.

GYNECOLOGIC PROBLEMS OF PREADOLESCENT GIRLS

Disorders of the Labia

LABIAL AND VULVAR AGGLUTINATION (ADHESIONS)   Agglutination (adhesion) of the labia minora or vulva is usually seen in girls 3 months to 6 years of age, although it is occasionally seen in girls who are approaching puberty. This condition is also called vulvar synechiae, gynatresia, vulvar or labial fusion, and labial coalescence. This disorder accounts for about 50 percent of prepubertal gynecologic complaints seen in an outpatient setting.

Prepubertal labia minora, covered by a very thin hypoestrogenized epithelium, are easily inflamed and denuded following infection, local trauma, or irritation. Often, the source of irritation is an environmental source previously tolerated during the diapered neonatal period and during earlier infancy (e.g., bubble bath, baby shampoos, and soaps). In addition, the anterior progression of labial agglutination from its origins at the posterior fourchette may lead to a significant "pocketing" of voided urine behind the agglutinated tissues, serving as a nearly constant source of additional irritation.

The girl with labial agglutination is most often asymptomatic, and the diagnosis comes to the physician's attention through parental concern or during routine examination. Some children have symptoms of urethritis; others have difficulties in toilet training due to the tendency for the perineum to remain moist from pocketed urine. Urinary tract infections are common.

The physical examination of a girl with labial agglutination is sufficient to distinguish this condition from its differential diagnostic considerations: ambiguous genitalia and imperforate hymen. The site of midline fusion of the labioscrotal folds seen in ambiguous genitalia, known as the median raphe, is a thick, raised, linear structure. In contrast, the site of midline labial agglutination is very characteristically thin, demonstrating agglutination of medial surfaces of the labia, not fusion of the labioscrotal folds. In addition, the agglutinated labia minora are distinct from and fused in the midline under the clitoral hood, while in ambiguous genitalia the labia minora are incorporated into the clitoral hood. Differentiation of labial agglutination from imperforate hymen is easily accomplished by noting that the hymen is located at the vaginal orifice, which is on the same plane as the urethra, as compared to the more exterior position of and posterior-to-anterior extension of labial agglutination. Occasionally, the presence of labial agglutination may give rise to parental concerns about sexual abuse if the adhesions are forcibly disrupted during straddle activity, resulting in a larger than previously recognized "opening," perhaps with a small amount of oozing blood.

Most girls exhibiting labial agglutination require no treatment, since the adhesions resolve spontaneously during puberty. Girls whose labial agglutination results in recurrent urinary tract infections, toileting difficulties, or difficulties in visualizing the urethra should probably be treated. Almost always, the agglutination responds to removal of the source of the caustic irritation coupled with careful application of topical estrogen cream (0.1% conjugated estrogen vaginal cream) twice daily for 2 to 4 weeks.

LICHEN SCLEROSIS ATROPHICA   Although uncommon in prepubertal girls, lichen sclerosis is being increasingly recognized by emergency physicians and pediatricians. This increased recognition is in some measure a reflection of increased concern about and awareness of sexual abuse and the subsequently increased frequency of perineal examination of prepubertal girls. The affected girl complains of itch, irritation, dysuria, perineal and/or perianal pain, and bleeding. There may be a coexistent vaginal discharge. As perianal pain persists, the girl may develop problems with painful defecation, stool retention, constipation, and encopresis.

The characteristic appearance of the vulva is white, atrophic, and finely wrinkled. Ulcerations, blisters, excoriations, and inflammation are seen over the vulva, perineum, and perianal area, often giving rise to the terms *hourglass* or *figure-eight* to describe the pattern of skin involvement. Secondary infection is possible. Progression of the disease leads to distortion, thickening, and scarring of vulvar and perineal architecture. The condition is differentiated from vitiligo by absence of inflammation or atrophy in the latter. The diagnosis of lichen sclerosis atrophica is made on clinical grounds and may be confirmed histologically from biopsy specimen in atypical cases.

The friability of the affected tissues leads to an increased risk of bleeding, even as a consequence of very minor trauma (e.g., the friction associated with bicycling). This has given rise to concerns in some parents about possible sexual abuse. Typically, the child denies such contact. There is no evidence linking lichen sclerosis atrophica to sexual abuse.

Management involves removal of all perineal irritants accompanied by the use of systemic antipruritics and the local application of an emollient ointment, such as A & D ointment. A 2- to 3-month course of treatment with a low-potency topical steroid cream, such as 2.5% hydrocortisone cream, applied two to three times daily, is often useful. Topical antifungal creams and systemic antibiotics are indicated for treatment of yeast and dermatophyte infections, and bacterial superinfections, respectively.

Interlabial Masses

URETHRAL PROLAPSE   Urethral prolapse is an uncommon disorder affecting prepubertal girls from the immediate newborn period to 11 years of age in which there is a circular eversion of urethral mucosa through the urethral meatus. It has been estimated to have an incidence of about 1:2880 girls, and almost all (90 to 100 percent) cases occur in black girls.

The etiology of urethral prolapse is not clearly understood. Many hypotheses have been proposed to explain the disorder, most of which center on lax periurethral fascia, vaginal mucosal atrophy, urethral mucosal redundancy or increased urethral width, repeated episodes of increased intraabdominal pressure, and estrogen deficiency of the prepubertal girl. The specific contributions of any of these phenomena to the development of urethral prolapse are conjectural.

Urethral prolapse typically presents with painless "vaginal" bleeding. The diagnosis is made with the observation of a doughnut-shaped mass originating from and encircling the urethral meatus that protrudes through the vulva. The prolapsed tissue is edematous and friable, often ulcerated, and apparently infected. Urethral prolapse is the only diagnosis in which a circular mass surrounds the urethral meatus. It is necessary to identify the urethral meatus with certainty, either by observing the child voiding her bladder or by catheterization if necessary.

While painless vaginal bleeding is the most common complaint at presentation, dysuria, perineal discomfort, and the sensation of a vulvar mass have been reported as isolated symptoms. The often dark, cyanotic, hemorrhagic appearance of the mass and its associated blood clots have been misinterpreted by families and physicians as evidence of sexual abuse. In fact, the correct diagnosis is not commonly made by the physician initially examining the child. The differential diagnostic considerations include prolapsed ectopic ureterocele, prolapsed bladder, prolapsed urethral polyp, ectopic ureter, urethral cysts, hydrocolpos, condyloma acuminatum, periurethral abscess, and sarcoma botryoides. Identifying a round mass encircling the urethral meatus eliminates each of these diagnostic considerations.

A wide range of treatment options have been recommended for urethral prolapse. Conservative therapy appears warranted for a mild degree of prolapse and include sitz baths, application of topical estrogen cream (0.1% conjugated estrogen cream), and serial observations over several months. Surgical treatment options include primary excision of the prolapse (associated with the highest success rate and lowest rates of recurrence), manual reduction under anesthesia, suture ligation of the prolapse over a Foley catheter, and cryosurgery. Failure of conservative therapy serves as an indication for consultation with a urologist, pediatric surgeon, or gynecologist.

HYDROCOLPOS   If an imperforate hymen, transverse vaginal septum, or atretic vagina completely prevents the egress of secretions from the uterus and cervical

glands, a hydrocolpos results (hydrometrocolpos if the uterus is also distended).

A bulging, shiny, pearly gray "mass" is seen covering the introitus. The mass is actually the remarkably distended hymenal membrane, stretched thin. The urethral meatus is observed to be distinct from the "mass" and is located anterior to it. Examination may reveal an abdominal mass palpable externally as well as a palpable rectal mass. The child may experience urinary retention.

A sonogram reveals a nonmobile, midline, cystic mass behind the bladder. The superior wall of the bladder may exhibit compression by the mass. In the presence of urinary retention or ureteral compression by the mass, the sonogram may reveal hydronephrosis. Treatment consists of aspiration and surgical drainage of the cyst's contents, a grayish-white mucoid material.

PARAURETHRAL CYSTS   Paraurethral cysts occur uncommonly in children but are seen occasionally in the neonatal period. Cystic degeneration of the paraurethral glands, Gartner's ducts, müllerian ducts, or Skene's ducts may result in the appearance of a cystic paravaginal or introital mass. Following a careful history and physical examination, the infant with a suspected paraurethral cyst should undergo imaging studies necessary to evaluate the relationship between the cystic mass and the urethra, bladder, ureters, and kidneys. These studies usually begin with a sonogram and may include a voiding cystourethrogram, contrast injection of the cyst itself, and occasionally cystourethroscopy.

SARCOMA BOTRYOIDES   Sarcoma botryoides is an embryonal rhabdomyosarcoma arising from a hollow viscous, such as the bladder or the vagina. The name refers to the grapelike configuration of the mass. The peak incidence is at 2 years of age, and over 90 percent of cases occur before 5 years of age.

The tumor arises in the distal vagina in younger girls, whereas in older children it originates more commonly on the anterior wall of the vagina near the cervix. Tumor growth fills the vagina with a mass that assumes the shape of a cluster of grapes, often prolapsing through the urethra or vaginal introitus. All growths with such an appearance should be presumed malignant until proved otherwise. Other symptoms may include vaginal bleeding, abdominal pain, or a palpable abdominal mass.

Early diagnosis is critically important to prognosis. Upon observing a suspicious lesion, immediate referral to a pediatric hematologist-oncologist is indicated.

136 PEDIATRIC URINARY TRACT INFECTIONS

Michael F. Altieri
Mary Camarca
Thom A. Mayer

EPIDEMIOLOGY

Urinary tract infections (UTIs) are an important cause of febrile illnesses in infants and children in the United States. UTI occurs in 4 to 7 percent of febrile infants. [1] Symptomatic UTIs occur in approximately 2 percent of children from 1 to 5 years of age and in up to 3 to 5 percent of school-aged girls. [2] Since the presenting signs and symptoms are often nonspecific, especially in younger infants, the diagnosis of UTI is often presumptive rather than definitive. The incidence of UTI varies greatly with age, gender, historical factors, such as prematurity, and history of previous UTI. Proper initial evaluation, interpretation of laboratory data, treatment, and follow-up are essential to avoid the long- term complications of renal scarring. The American Academy of Pediatrics has published a practice parameter on this subject, the recommendations from which are reflected in this chapter. [3]

PATHOPHYSIOLOGY

In the neonatal period, UTI originates via hematogenous spread resulting in bacterial seeding of the renal parenchyma. After the neonatal period, bacteria gain access to the urinary tract via perineal and periurethral colonization, with subsequent retrograde contamination of the lower urinary tract structures. Virulence of the pathogen, host immunity, and structural and functional aspects of the urinary tract all play important roles in the development of UTI. Much is known about structural and functional factors contributing to the risk of UTI. Congenital urinary tract anomalies, vesicoureteral reflux, and urolithiasis are associated with a higher incidence of UTI. [3,4,5 and 6] However, it is now clear that pyelonephritis in the absence of vesicoureteral reflux is far more common than previously thought. Behavioral and functional factors, such as poor hygiene, voluntary urinary retention, and constipation, have been associated with increased risk of UTI. [7,8]

CLINICAL FEATURES

Other than fever, few symptoms are consistently found in infants and children diagnosed with UTI. Neonates may present with jaundice, poor feeding, irritability, and lethargy. Older infants and young children commonly present with gastrointestinal complaints, such as abdominal pain, vomiting, and change in appetite. The classic signs of dysuria, urinary frequency, urgency, or hesitancy are more likely to be present in older children and adolescents. The clinical signs and symptoms of UTI also vary with the primary site of infection along the urinary tract. The symptoms of dysuria, frequency, and urgency are more often associated with lower tract (uncomplicated) infections, such as cystitis, and urethritis. More systemic symptoms, such as fever, chills, vomiting, and dehydration, suggest upper tract (complicated) infection. However, recent studies clearly indicate that pyelonephritis often occurs in the absence of such symptoms. [9,10] Unfortunately, the signs and symptoms of infection anywhere along the urinary tract may be nonspecific and overlapping. For these reasons, UTI should be considered in all febrile children, regardless of symptoms or lack thereof. Furthermore, upper tract infection should be considered as well, particularly in febrile children. The utility to distinguish between lower and upper tract disease is relevant when considering treatment options, long-term sequelae, and recommendations for follow-up.

DIAGNOSIS

Gram-negative enteric bacteria are the most commonly isolated organisms in UTI. While P-fimbriated *Escherichia coli* accounts for the vast majority of infections, *Klebsiella, Proteus,* and *Enterobacter* species are also important pathogens. *Enterococcus* species, *Staphylococcus aureus,* and group B streptococci are the most frequently isolated gram-positive organisms and are more likely to be causative organisms in the neonatal period. Coagulase-negative staphylococcal UTI occurs in teens and young adults. Adenovirus may cause acute cystitis, occurs more commonly in young boys, and is clinically indistinguishable in many cases from bacterial disease.

While urine culture is the gold standard in the diagnosis of UTIs in children, culture results are rarely, if ever, available to physicians in the emergency department. Therefore, emergency physicians must rely on clinical data and other laboratory tests while obtaining a urine culture to subsequently confirm the diagnosis.

With an incontinent child, a specimen for urinalysis and culture should be obtained through direct bladder sampling (catheterization or suprapubic sampling) or through a cleanly voided specimen in boys and older girls. *Bagged urine specimens are not acceptable because of the high degree of contamination.* Urine specimens from older children with voiding control should be obtained from a cleanly voided midstream clean catch. [5] Parents should be instructed on the proper technique for avoiding contamination of specimens. Periurethral contamination of specimens can be avoided by having girls sit backward (facing the rear of the toilet). This position favors labial retraction and better exposure of the urethral meatus. Because bacterial contaminants grow rapidly at room temperature, a urine specimen that cannot be cultured immediately should be kept on ice or at a temperature of 4°C (39.2°F) until culturing can be accomplished.

While urinalysis is the most common adjunctive diagnostic test for a possible UTI, urine chemical test strips are also a quick means of initial urine screening for the detection of leukocyte esterase and urinary nitrates. Esterases are released into the urine after the breakdown of white blood cells, providing presumptive evidence of infection. Occasionally, false-negative urine test strip results are obtained for very young infants because their leukocyte response may be limited. Nitrates are converted to nitrites by gram-negative urinary pathogens, and urine test strips may also provide indirect evidence of bacteriuria. Hematuria, proteinuria, and pyuria are commonly associated with UTIs but are nonspecific and can occur in the absence of infection. The presence of bacteria in catheterized urinary sediment also lends support to the presence of a UTI. In most studies, the sensitivities of a positive test result for urinary leukocyte esterase or nitrite or a positive urine culture result are less than 50 percent. The combined presence of pyuria (more than five white blood cells per high-power field) and bacteriuria on urine microanalysis improves the sensitivity to approximately 65 percent. The positive predictive value of a urinalysis is 81 percent.

Peripheral white blood cell counts and erythrocyte sedimentation rates are also nonspecific indicators that should only be interpreted in conjunction with the results of the urinalysis and urine culture. A guide to interpreting urine culture results based on the various methods of obtaining urine samples is contained in Table 136-1.

Method of Collection	Quantitative Culture: UTI Present
Suprapubic aspiration	Growth of urinary pathogens in any number (exception of up to 2–3 × 10³ coagulase-negative staphylococci)
Catheterization	Febrile infants or children with ≥5 × 10⁴ CFU/mL of single pathogen*
Midstream clean void	Symptomatic patients with ≥10⁵ CFU/mL of a single urinary pathogen
Midstream clean void	Asymptomatic patient with two specimens on different days with >10⁵ CFU/mL of the same organism

*Infection may be present with counts as low as 10–50 × 10³ CFU/mL.
Abbreviation: CFU, cell-forming units.

TABLE 136-1   Interpretation of Positive Urine Culture Results

TREATMENT

As mentioned before, early treatment of UTIs, especially in infants and young children, decreases the risk of kidney damage. Table 136-2 summarizes the approach to management of children with UTI. Inpatient management should be instituted for any child less than 3 months of age with a febrile UTI; children who have significant dehydration or appear toxic; those with pyelonephritis, urinary stents or other urinary foreign bodies, or renal insufficiency; or those who are immunocompromised. In addition, if a child's compliance and follow-up is questionable, inpatient or pediatric short-stay unit treatment should be considered.

TABLE 136-2   Management of Urinary Tract Infections

Children older than 3 months with febrile UTIs who appear nontoxic and only mildly dehydrated and who do not have persistent vomiting may be rehydrated in the emergency department. These children may initially receive intravenous antibiotic therapy and may then be discharged home on a course of oral antibiotics. Prior to discharge, they should demonstrate adequate oral intake and retention of fluids and have arrangements made for follow-up care within several days either with the primary care physician or the emergency department. Specific antibiotics and their dosing for both inpatient and outpatient therapy are contained in Table 136-3, but therapy should be guided with an understanding of the antibiotic resistance patterns in the hospital and community. Instructions should be given to the caregiver regarding follow-up on culture results.

TABLE 136-3   Common Antimicrobial Drugs Used in Pediatric Urinary Tract Infections

DISPOSITION

Numerous clinical investigators and clinicians have discussed and debated in recent years the most appropriate radiologic studies for the follow-up of children with UTIs, and various algorithms have been proposed.[9,10,11 and 12] Although imaging studies for UTIs are rarely indicated as part of the diagnostic workup in the emergency department (except in cases where there is a palpable mass), it is important to arrange follow-up for all children with febrile UTIs. A recent evidence-based study of the existing literature suggested that large multicenter studies are needed to more carefully delineate a definitive approach to imaging the genitourinary system in children with UTI.[11] However, until such studies are completed, the following is a reasonable diagnostic approach to imaging. First, the goals of radiologic imaging are to (1) identify existing upper tract disease capable of causing cortical scaring so that appropriate antibiotic therapy can be instituted, (2) identify treatable lesions of the genitourinary system, and (3) guide an approach to prevent further renal scarring and subsequent impairment of renal function.

In the past, indications for imaging of pediatric patients with UTI included neonates, females with recurrent UTI (two or more episodes), and males of any age with UTI. However, more recent studies support the approach outlined in Fig. 136-1, which some institutions utilize even for patients with a first episode of UTI.[12] Acutely febrile and/or toxic children with UTI as the documented or presumed source of fever should have a renal cortical scan (RCS) to assess for renal involvement. If renal scarring and/or active infection is present, the patient should have intravenous antibiotic therapy to reduce scarring and eliminate infection. If the RCS results are negative, males should have a voiding cystourethrogram (VCUG) and females an isotope cystogram (IC) to assess for vesicoureteral reflux. In afebrile children, the VCUG for males and IC for females should initially be assessed, followed by RCS if the results are positive. Renal sonography may be done at the time of RCS, VCUG, or IC to assess for dilatation of the collection system.

FIG. 136-1. Algorithm for radiographic evaluation of children with their first UTI. (Adapted from Gausche M, in Strange GR, ed: *Pediatric Emergency Medicine: A Comprehensive Study Guide.* New York, McGraw-Hill, with permission.)

While such radiologic imaging is not necessarily coordinated by the emergency department, it is important for emergency physicians to be aware of the necessity of follow-up and the reasons for imaging so that it can be coordinated with the patient's inpatient physician or primary care provider.

137 SEXUALLY TRANSMITTED DISEASES

Dexter L. Morris

Sexually transmitted diseases (STDs) are commonly encountered in emergency and urgent care settings. It is important to diagnose and treat them to protect the health and future fertility of the patient as well as the health of the patient's sexual contacts. Furthermore, individuals with STDs are more likely to acquire human immunodeficiency virus (HIV) infection than the general population. Thus diagnosis of an STD suggests the need for HIV counseling and testing. This chapter discusses the major STDs with the exception of HIV infection, which is discussed in Chap. 139, and hepatitis B infection, which is discussed in Chap. 82. Vaginosis and pelvic inflammatory disease (PID) are also discussed elsewhere (Chap. 104 and Chap. 105, respectively). In addition to specific antimicrobial treatment for STD patients, the end of this chapter contains important guidelines for follow-up and reporting of STDs. Treatment guidelines for STDs change frequently. *The Morbidity and Mortality Weekly Report* of the Centers for Disease Control and Prevention (CDC) is an excellent source of updates.

DIAGNOSIS

The most important aspect of the diagnosis of STDs is to maintain a high level of awareness. While many patients may present with an obvious STD (lesion on the penis), more commonly the chief complaint may be as vague as dysuria or lower abdominal pain. For example, a study at an inner-city ED suggested that half the patients who were discharged with a diagnosis of urinary tract infection (UTI) had one or more positive STD cultures.

Once a physician suspects an STD, obtaining a history of sexual activity and previous STDs is important. This may clue the physician into examining or culturing oral or anal areas, help differentiate mechanical from infectious lesions, and predict risk for hepatitis and HIV infections. Questions about pregnancy and sexual assault should asked, if appropriate. These questions can be asked in a nonconfrontational manner by explaining to the patient their rationale.

Careful examination of the genital areas (and pelvic examination in women) is important. The foreskin should be retracted, if present, and the physician should be sure to look in skin folds and other areas that may not be readily viewable, particularly in obese persons. Cultures for gonorrhea and chlamydia should be taken if there is a suspicion of STDs to document the infection. Other tests may be appropriate for specific lesions.

STDs without Lesions

CHLAMYDIAL INFECTIONS   *Chlamydia trachomatis* is an obligate intracellular bacterium that has a growth cycle that alternates between two morphologic forms. Chlamydial infections present with a wide spectrum of clinical manifestations. In men, infection causes urethritis, epididymitis, and proctitis. In women, urethritis, cervicitis, and PID are common. In both sexes, the prevalence of asymptomatic infection is high, ranging from 3 to 5 percent in the general population to 15 to 20 percent among individuals attending STD clinics. Patients with gonorrhea have an even higher incidence of concomitant chlamydial infection. Untreated chlamydial infections are thought to be an important cause of infertility in women. The incubation period is 1 to 3 weeks, and symptoms, if present, can range from mild vaginal burning or irritation to peritonitis.

Diagnosis   Although the organism can be cultured, this has a relatively low yield. Indirect methods using direct immunofluorescence, enzyme-linked immunosorbent assay (ELISA)-type assays, and DNA probes are available.

Treatment   Treatment is with azithromycin 1 g PO in a single dose or doxycycline 100 mg PO bid for 7 days. Table 137-1 lists alternative treatment options.

TABLE 137-1   Antimicrobial Therapy for STDs

GONOCOCCAL INFECTIONS   *Neisseria gonorrhoeae* are gram-negative diplococci that remain sensitive to antibiotics, although recent years have seen the emergence of strains resistant to penicillin (up to 25 percent) and, less commonly, tetracycline. Gonococcal infection presents usually as urethritis in men and cervicitis or PID in women. Epididymitis and prostatitis also can occur in men. Rectal infection occurs in 30 to 50 percent of women with gonococcal cervicitis and can be the only site of infection in homosexual men. *N. gonorrhoeae* also can be isolated from the pharynx, but rarely does it cause a pharyngitis. The incubation period ranges from 3 to 21 days. Disseminated infection also occurs in approximately 2 percent of untreated primary gonorrhea. This manifestation is characterized by skin lesions (tender pustules on an erythematous base, 50 to 70 percent), arthralgias, tenosynovitis, or arthritis (30 to 40 percent), and fever or general malaise (80 percent). Gonococcal infections can decrease fertility in women, presumably by scarring the fallopian tubes. They also increase the chance of ectopic pregnancy by the same mechanism.

Diagnosis   Cervical or urethral culture on a selective medium is the standard for diagnosis, having a sensitivity of 80 to 90 percent. A Gram stain of a urethral smear showing intracellular gram-negative diplococci is sensitive and specific in men but much less useful in women. Diagnosis of disseminated gonococcal infection is more difficult with only 20 to 50 percent of blood, lesion, or joint cultures being positive. Obtaining cervical, rectal, and pharyngeal samples may improve the chance of a culture diagnosis.

Treatment   Cefixime 400 mg PO, ceftriaxone 125 mg IM or ciprofloxacin 500 mg PO, or ofloxacin 400 mg PO all in single doses are recommended. Patients also should be treated for presumed chlamydial infection. PID or disseminated disease is usually treated with higher doses of ceftriaxone. Decisions to admit patients with symptomatic disease are based on their overall clinical picture as well as their ability to follow up on an outpatient basis.

TRICHOMONAL INFECTIONS   *Trichomonas vaginalis* is a flagellated protozoan that causes urogenital infections in men and women. The prevalence is less than 1 percent in women overall but up to 15 percent in those attending STD clinics. Disease is most commonly characterized by vaginosis with discharge. Abdominal pain also can be present. In men, the disease is often asymptomatic, but it can cause urethritis. Incubation ranges from 3 to 28 days.

Diagnosis   Microscopic examination of wet preparations of cervical smears or spun urine samples that reveal the classic motile parasites is diagnostic.

Treatment   Metronidazole 2 g PO in a single dose is the usual treatment.

STDs with Lesions

The diseases discussed in this section often present with genital lesions that may be difficult to distinguish from one another. Characteristics of the lesions and their accompanying signs and symptoms are provided in . Granuloma inguinale (donovanosis) rarely occurs in the United States, and readers are referred to the Bibliography for more information.

Disease	Nature of Genital Ulcer	Incubation Period (Range)	Painful	Inguinal Adenopathy
Syphilis	Indurated, relatively clean base, heals spontaneously	2 weeks or longer	No	Firm, rubbery nodes; tender
Herpes simplex infection	Multiple, small, grouped vesicles; coalesce and form shallow ulcers; vulvovaginitis	2–7 d	Yes	Tender bilateral adenopathy
Chancroid	Irregular, purulent, undermined edges; not indurated; multiple ulcers	3–12 d	Yes	Present in 50%; usually unilocular, if fluctuant, very painful; may form crater
Lymphogranuloma venereum	Usually not observed; small and shallow; rapid spontaneous healing	5–21 d	No	More common in males; nodes in matted cluster; unilateral or bilateral multi-located

TABLE 137-2   Clinical Features of Genital Ulcers

GENITAL WARTS   Human papillomaviruses (HPVs) are DNA viruses that cause genital warts by direct transmission. Different genotypes also have been implicated in cervical cancer, but the relationship is far from clear. The warts usually appear after an incubation period of 3 to 4 months and may coalesce to form condylomata acuminata. Although painless, their location or size may cause discomfort.

Diagnosis   Diagnosis is clinical, with care to exclude other STDs.

Treatment   Treatment decisions are based on the size and number of lesions, the amount of discomfort they are causing, and patient preferences. Recommended treatment is podofilox 0.5% solution or gel applied with a cotton swab or a finger to the visible warts twice a day for 3 days, followed by 4 days of no therapy, with the cycle repeated up to 4 times. Also recommended is imiquimod 5% cream applied at bedtime 3 times a week for up to 16 weeks. The treatment area should be washed 6 to 10 h after treatment with Imiquimod. Cryotherapy in a physician's office is also a common therapy.

SYPHILIS INFECTIONS   *Treponema pallidum,* a spirochete, is the causative agent of syphilis as well as yaws and pinta. It enters the body through mucous membranes or nonintact skin. It remains very sensitive to penicillin; thus diagnosis rather than treatment is the main difficulty in controlling this disease. The last 7 years has seen a marked increase in syphilis thought to be secondary to behavior associated with drug use. Syphilis occurs in three stages.

1. *Primary.* The initial stage of infection is characterized by a painless chancre with indurated borders on the penis, vulva, or other areas with sexual contact. The incubation period is about 21 days, with lesions then disappearing after 3 to 6 weeks. There are no constitutional symptoms, and a lesion may even be absent with primary disease.
2. *Secondary.* This stage, which occurs 3 to 6 weeks after the end of the primary stage, includes nonspecific symptoms such as sore throat, malaise, fever, and headaches. Rash and lymphadenopathy are the most common symptoms. The rash often starts on the trunk and flexor surfaces, spreading to the palms and soles. It takes on many forms but is often dull red and papular. This stage also resolves spontaneously.
3. *Tertiary (latent).* Involvement of the nervous and cardiovascular systems is characteristic of this stage, which may occur years after the initial infection. Specific manifestations range from acute meningitis, dementia, and neuropathy (tabes dorsalis) to thoracic aneurysm. Tertiary syphilis is uncommon.

Diagnosis   Dark-field microscopy can be used to identify treponemes from primary lesions as well as from secondary lesions. Several serologic tests are available, including nontreponemal tests (rapid plasma reagin, VDRL) and specific treponemal antibody tests (fluorescent treponemal antibody absorption, or FTA-ABS). Nontreponemal tests are positive about 14 days after the appearance of the chancre and false positive in 1 to 2 percent of the population. FTA-ABS tests are slightly more sensitive and specific but more difficult to perform.

Treatment   Given the multiple stages and manifestations of syphilis, considering the diagnosis is the most crucial part of treatment. Benzathine penicillin G 2.4 million units IM in a single dose has remained the standard of care. Doxycycline 100 mg PO bid for 2 weeks may be used for allergic individuals. Treatment of latent syphilis is usually three doses of penicillin as above, given 1 week apart.

HERPES SIMPLEX INFECTIONS   Herpes simplex virus type 2 (HSV-2) or HSV-1 can cause genital herpes infections by infection of mucosal surfaces or nonintact skin. Primary infections are characterized by painful pustular or ulcerative lesions occurring 8 to 16 days after contact with an infected individual (although infections can be asymptomatic). Systemic symptoms are common and include fever, headache, and myalgias. Dysuria is common, whereas urinary retention secondary to swelling and pain is not uncommon. Approximately 80 percent of patients also have lymphadenopathy, and aseptic meningitis can occur. The untreated illness lasts 2 to 3 weeks to complete healing. Unfortunately, the virus remains latent, and recurrent infections occur in 60 to 90 percent of patients. These are usually milder and of shorter duration.

Diagnosis   Clinical diagnosis of the painful vesiculopustular lesions is often possible. A smear may be taken of the lesions and stained to demonstrate large intranuclear inclusions, although this is less sensitive than direct culture. Viral cultures can be done and are positive in 1 to 4 days. New assays using ELISA and polymerase chain reactions are being developed.

Treatment   For a first clinical episode, treatment is with acyclovir 400 mg PO tid for 7 to 10 days, acyclovir 200 mg PO 5 times a day for 7 to 10 days, famciclovir 250 mg PO tid for 7 to 10 days, or valacyclovir 1 g PO bid for 7 to 10 days. Treatment duration can be extended if the lesions persist. For treatment of proctitis or oral infections, higher doses are used (acyclovir 400 mg five times a day for 7 to 10 days). Acyclovir at 5 to 10 mg/kg of body weight may be given IV every 8 h for 5 to 7 days to patients requiring hospitalization.

Episodic recurrent infection should be treated for 5 days with acyclovir 400 mg PO tid, acyclovir 800 mg PO bid, famciclovir 125 mg PO bid, or valacyclovir 500 mg PO bid.

CHANCROID   *Hemophilus ducreyi* is a pleomorphic gram-negative bacillus that causes genital ulcers and lymphadenitis. It is much more common in developing countries but has seen a resurgence in recent years in the United States. After an incubation period of 3 to 10 days, a tender papule appears at the site of infection, followed by ulceration of the lesion. Multiple lesions may be present in up to 50 percent of patients and may include bubo formation and spontaneous rupture. There are few constitutional symptoms.

Diagnosis   Diagnosis can be made on clinical grounds, but other diseases such as syphilis need to be excluded. A swab of a lesion or pus from a bubo can be cultured but only with limited success.

Treatment   Azithromycin 1 g PO in a single dose, ceftriaxone 250 mg IM in a single dose, ciprofloxacin 500 mg PO bid for 3 days, and erythromycin base 500 mg PO

qid for 7 days are all recommended treatments.

LYMPHOGRANULOMA VENEREUM   Specific serotypes of *C. trachomatis* cause this disease, which although endemic in other parts of the world is seen only sporadically in the United States. The primary lesion can take on many forms and be confused with other STDs (see Table 137-2). Ten days to 6 months following the initial lesion, an inguinal bubo forms (unilateral in 60 percent). The buboes continue to grow, either rupturing or forming firm inguinal masses.

Diagnosis   Serologic tests and culture are the mainstays of diagnosis.

Treatment   Doxycycline 100 mg PO bid for 21 days is the usual regimen. Table 137-1 gives alternative treatments.

TREATMENT DURING PREGNANCY

Pregnant patients with STDs should be referred to the physician providing their prenatal care. In general, penicillin, ceftriaxone, azithromycin, cefixime, metronidazole, and acyclovir are felt to be safe for use during pregnancy. If the safety of treatment is in doubt, an obstetrician should be consulted.

PROPHYLAXIS FOR EXPOSED PATIENTS

Patients who have been sexually exposed to a person known to have an STD should be treated presumptively for gonorrhea and chlamydial infections with one of the regimens described earlier. Cultures are usually taken for documentation purposes. Prophylaxis also should be given for victims of sexual assault. HIV prophylaxis is discussed in Chap. 149, and prophylaxis for herpes simplex infection has not been fully studied.

GENERAL RECOMMENDATIONS FOR TREATMENT AND FOLLOW-UP

When treating patients for STDs in the ED, it is important to remember that many STDs occur together; follow-up and compliance for many ED patients are poor, and lack of treatment can contribute to infertility. For these reasons, a standardized approach is suggested for patients with suspected STDs. This should include

1. Treating even when an STD is only suspected, especially for gonorrhea and chlamydia, with emphasis on single-dose treatments
2. Obtaining a serologic test for syphilis
3. Ascertaining pregnancy status and consulting obstetrics if the patient is pregnant
4. Reporting appropriate diseases to the state health department
5. Counseling patients about prevention of STDs
6. Counseling patients about the advisability of HIV testing
7. Counseling patients about advising partner(s) to seek treatment
8. Arranging for appropriate follow-up
9. Documenting all the preceding on the medical record

138 TOXIC SHOCK SYNDROME AND STREPTOCOCCAL TOXIC SHOCK SYNDROME

Shawna J. Perry
Ann L. Harwood-Nuss

TOXIC SHOCK SYNDROME

Toxic shock syndrome (TSS) is a severe, life-threatening syndrome characterized by high fever, profound hypotension, diffuse erythroderma, mucous membrane hyperemia, pharyngitis, diarrhea, and constitutional symptoms. It can rapidly progress to multisystem dysfunction with severe electrolyte disturbances, renal failure, and shock. Although first described in 1978 by Todd in seven children with *Staphylococcus aureus* infections, TSS has been associated primarily with tampon use. [1] In 1981, a nationwide epidemic of TSS associated with extended tampon use was widely recognized among otherwise healthy young women.

The TSS case definition is given in Table 138-1. This definition was formulated in 1980 and revised in 1997, by the Centers for Disease Control and Prevention (CDC) to ensure that cases included in various surveillance studies were the same clinical entity as TSS. In the absence of a definitive laboratory marker, the strict application of the case definition is warranted but undoubtedly excludes the less severe (subclinical) cases. [2]

TABLE 138-1   Case Definition of Toxic Shock Syndrome

The incidence of TSS has dropped precipitously over the past 20 years, with the majority of cases unrelated to menses and crossing all segments of society. A similar, but more menacing TSS-like syndrome, streptococcal toxic shock syndrome (STSS), has emerged over the last decade. It is associated with invasive and noninvasive streptococcal infections, has a rapidly progressive course, and a very high case-fatality rate.

Pathophysiology

ETIOLOGY AND PATHOGENESIS   Most cases of TSS have been directly associated with colonization or infection with *S. aureus.* An exotoxin, toxic shock syndrome toxin (TSST-1) has been implicated as a significant factor in the production of symptoms associated with TSS, either through direct toxic effects on the host or through stimulation of secondary mediators in response to TSST-1. The biologic properties of TSST-1 include the ability to (1) induce fever directly on the hypothalamus or indirectly via interleukin 1 (IL-1) and tumor necrosis factor (TNF) production, (2) promote T-lymphocyte "superantigenization" and overstimulation, (3) induce interferon production, (4) enhance delayed hypersensitivity, (5) suppress neutrophil migration and immunoglobulin secretion, and (6) enhance host susceptibility to endotoxins.

Ninety percent of menstrual-related cases of TSS (MRTSS) are caused by *S. aureus* strains that produce TSST-1, which is present in less than half of nonmenstrual-related TSS (NMTSS) cases. Enterotoxins B and C have been identified from isolates of NMTSS and have a biochemical structure almost identical to that of TSST-1. This explains the similarity in clinical manifestations of MRTSS and NMTSS. NMTSS may be mediated by unidentified precursors and toxins or by-products of TSST-1. [3]

The amount of TSST-1 produced by toxigenic strains of *S. aureus* in MRTSS is enhanced by certain vaginal conditions: temperature of 39 to 40°C (102.2 to 104°F), a neutral pH, a P_{O_2} of greater than 5 percent, and supplemental CO_2. These conditions can be met with the change in vaginal pH from acidic to neutral during menses and an increase in O_2 and CO_2 content of the vagina with the introduction of tampons or intravaginal devices. Other influences include synthetic fibers in tampon composition and a synergistic relationship between *S. aureus* and *Escherichia coli.* [4]

The most impressive aspect of the pathophysiology is the massive vasodilatation and rapid movement of the serum proteins and fluids from the intravascular to the extravascular space. Hypotension is accounted for by (1) decreased vasomotor tone, causing pooling of blood in the periphery and therein decreased central venous pressure and pulmonary capillary wedge pressure; (2) nonhydrostatic leakage of fluid into the interstitium, causing decreased intravascular volume and generalized nonpitting edema, primarily of the head and neck; (3) depressed cardiac function, including decreased wall motion and decreased shortening fraction; and (4) total body-water deficits secondary to vomiting, diarrhea, and fever.

Hypoalbuminemia, hypoferrinemia, and proteolysis caused by IL-1 are consistent with the peripheral edema, anemia, and rhabdomyolysis seen in TSS. TNF induces profound acidosis, shock, and multisystem organ failure in animal models similar to the effects of TSS. The multisystem organ failure may be a reflection of either a direct effect of the toxin on tissues or the rapid onset of hypotension and decreased perfusion.

The immunologic status of an individual plays a role in the pathogenesis of TSS, especially in cases of recurrence. Low convalescent titers to TSST-1 and enterotoxins B and C are found in the majority of patients with TSS for up to 1 year after infection. [3]

EPIDEMIOLOGY   CDC surveillance of TSS from 1979 through 1996 reported 5296 definite and probable cases (Fig. 138-1). From 1981 through 1987, there was a dramatic decrease in the number of reported cases. In 1992, only 44 definite cases, 51 probable cases, and 3 deaths occurred from TSS. Of the 44 definite cases, 20 occurred during menstruation. The decrease in cases is presumably due to changes in the composition of tampons, general public awareness of the risks of tampon use, and increased medical awareness and detection. Although the use of contraceptive sponges and diaphragms places the individual at risk, their exact contribution to the development of TSS is unclear.
FIG. 138-1. Toxic shock syndrome by quarter in the United States, 1981 to 1996.

TSS was initially a disease of young, healthy, menstruating women; 50 percent of cases reported in 1986 and 1987 were found in this group. Tampon use increased the risk of TSS in susceptible females by 33 times. *S. aureus* has been isolated from the vaginas of 98 percent of women with TSS, compared to an 8 to 10 percent carrier rate in control subjects. It is presumed that women who develop menstrual TSS are colonized with *S. aureus* before the onset of menstruation.

The proportion of NMTSS cases has increased since 1980 (59 percent), primarily because of the decrease in the number of menstruation-related cases. The absolute number of cases of NMTSS has remained relatively constant, however. Nearly 25 percent of NMTSS cases are associated with postpartum and *S. aureus* vaginal infections.[5] There is an increasing incidence of NMTSS in males. Men constitute one-third of patients with TSS, with a mortality rate 3.3 times that of MRTSS in women. A 50 percent mortality rate has been reported in non-TSST-1 *S. aureus* infections (i.e., enterotoxin B or C), while a 10 percent rate has been reported in TSST-1–producing *S. aureus* infections.

The means by which *S. aureus* enters the host in TSS are numerous and have been well documented in a wide variety of clinical settings. TSS has also been reported following influenza and influenza-like illnesses and is associated with a significant mortality rate (43 percent). Nasal packing (nasal tampons) is also associated with TSS, with 20 to 40 percent of the adult population carrying *S. aureus* in the nasal vestibule.

Clinical Features

TSS should be considered in any unexplained febrile illness associated with erythroderma, hypotension, and diffuse organ pathology. Diagnostic criteria for TSS are listed in Table 138-1. Patients with MRTSS usually present between the third and fifth day of menses. The median time to onset of illness in postsurgical NMTSS is two postoperative days. There appears to be a spectrum of severity of TSS. Mild cases of TSS may be excluded from the CDC case definition. Mild TSS is generally characterized by fever and chills, myalgias, abdominal pain, sore throat, nausea, vomiting, and diarrhea. Hypotension is usually not present, and the illness is self-limited. Severe TSS is an acute-onset, multisystem disease with symptoms, signs, and laboratory abnormalities reflecting multiple-organ involvement. Headache is the most common complaint. Some patients may experience a prodrome consisting of malaise, myalgias, headache, nausea, vomiting, and diarrhea. Sudden onset of fever and chills occurs approximately 1 to 4 days prior to presentation. Diffuse myalgias, particularly in the proximal aspects of the extremities, abdomen, and back, are reported by virtually all patients; arthralgias are also common. Profuse, watery diarrhea and repeated vomiting are reported by 90 to 98 percent of patients. Orthostatic lightheadedness or syncope may be present. Patients also complain of sore throat, headache, paresthesias, and photophobia. The patient may complain of abdominal pain, cough, or sore throat.

Physical examination reveals hypotension or an orthostatic decrease in systolic pressure of 15 mmHg in all cases. In general, victims of TSS appear acutely ill. The initial state usually lasts about 24 to 48 h; the patient may be obtunded, disoriented, oliguric, and hypotensive. There is an overall body-fluid deficit due to losses from fever, vomiting, diarrhea, and decreased systemic vascular resistance. Depressed cardiac function may also be present. Patients may show nonpitting edema of the face and extremities secondary to nonhydrostatic leakage of intravascular fluid into the interstitium. Other prominent signs may include profound muscle weakness and tenderness or abdominal tenderness. The diarrhea is usually watery and profuse, frequently with associated incontinence. One-half to three-quarters of patients have pharyngitis, with a strawberry-red tongue; conjunctival hyperemia and vaginitis are also seen. Tender, edematous external genitalia, diffuse vaginal hyperemia, "strawberry" cervix, scant purulent cervical discharge, and bilateral adnexal tenderness are seen in 25 to 35 percent of patients with menstruation-related TSS.

The rash of TSS is a diffuse, blanching erythroderma, classically described as painless "sunburn," which fades within 3 days of its appearance and is followed by full-thickness desquamation, especially of the palms and soles, during convalescence. This CDC criterion is most often missed, since it may be subtle or difficult to detect in darkly pigmented patients. Variations include patchy erythroderma and localized maculopustular eruptions. In all cases, a fine, generalized desquamation of the skin, with peeling over the soles, fingers, toes, and palms, occurs from 6 to 14 days after the onset of illness. Most severely ill patients experience loss of hair and nails 2 to 3 months later.

Specific focal neurologic findings rarely occur. Patients present with varying degrees of altered consciousness. Approximately 75 percent of patients have nonfocal neurologic abnormalities without signs of meningeal irritation. Confusion, disorientation, agitation, hysteria, somnolence, and seizures have been reported, consistent with a toxic encephalopathy from cerebral edema. If the clinical picture is unclear, a computed tomography scan and lumbar puncture should be performed. Figure 138-2 illustrates the temporal relationships of the major manifestations of TSS.
FIG. 138-2. Composite drawing of major systemic, skin, and mucous membrane manifestations of toxic shock syndrome. (From Chesney PJ, David JP, Purdy WK, et al: Clinical manifestations of toxic shock syndrome. *JAMA* 246:741, 1981, with permission.)

Abnormal laboratory values reflect the multisystem involvement in TSS. Leukocytosis, with an increase in immature forms, is frequently seen; lymphocytopenia has also been reported. A mild anemia with acute hypoferrinemia and abnormal peripheral smears consistent with microangiopathic hemolytic anemia or disseminated intravascular coagulation may be found. Azotemia, myoglobinuria, and abnormal urinary sediment (sterile pyuria and red blood cell casts) are seen as acute renal failure develops. Liver function abnormalities and hyperbilirubinemia are seen in approximately 3 percent of patients with clinical evidence of coagulopathy. Metabolic acidosis secondary to hypotension is also seen. Electrolyte abnormalities, including hypocalcemia, hypophosphatemia, hyponatremia, and hypokalemia, are common. Hypocalcemia is out of proportion to the degree of hypoalbuminemia and may be difficult to correct if there is a concomitant decrease in the serum magnesium level.

Acute renal failure secondary to acute tubular necrosis is a complication of TSS. It appears to be secondary to prerenal deficits, renal ischemia caused by hypotension, rhabdomyolysis, and possibly direct damage from TSST-1 mediators. Ventricular arrhythmias, bundle branch block, first-degree heart block, and T-wave and ST-T-wave changes have been reported. Echocardiography of patients with TSS shows wall motion abnormalities and decreased shortening fraction, suggestive

of toxic cardiomyopathy. Adult respiratory distress syndrome (ARDS) with refractory hypotension represents the ultimate end-organ damage secondary to TSS.

Diagnosis

Other systemic illnesses characterized by fever, rash, diarrhea, myalgias, and multisystem involvement resemble TSS (Table 138-2). Kawasaki disease (mucocutaneous lymph node syndrome) is characterized by fever, conjunctival hyperemia, and erythema of the mucous membranes with desquamation. Although the exanthems may be quite similar. Kawasaki disease may present with target lesions resembling erythema multiforme, and the bright-red appearance of the vermillion border is not common in TSS. Furthermore, over 80 percent of those afflicted with Kawasaki disease are under 5 years of age, and Kawasaki disease is not characterized by hypotension, renal failure, or thrombocytopenia.

Acute pyelonephritis	Acute viral syndrome
Septic shock	Leptospirosis
Acute rheumatic fever	Systemic lupus erythematosus
Streptococcal scarlet fever	Rocky Mountain spotted fever
Staphylococcal scarlet fever	Tick typhus
Staphylococcal scalded skin syndrome	Gastroenteritis
Legionnaire disease	Kawasaki disease
Pelvic inflammatory disease	Reye syndrome
Hemolytic uremic syndrome	Toxic epidermal necrolysis
	Erythema multiforme

TABLE 138-2   Differential Diagnosis of Toxic Shock Syndrome

Staphylococcal scalded skin syndrome (SSSS) is most commonly seen in children less than 5 years of age and is characterized by fever, generalized painful erythroderma, and conjunctivitis. SSSS may be distinguished from TSS by its lack of multisystem involvement. In contrast, staphylococcal scarlet fever is so similar to TSS, with full-thickness desquamation, that only pathologic specimens or serologic evidence of the exfoliatin toxin will differentiate the two entities. In streptococcal scarlet fever, the "sandpaper" rash is distinct from the macular "sunburn" rash of TSS.

Rocky Mountain spotted fever, a rickettsial infection acquired from tick bites, has a presentation similar to that of TSS, but the rash is usually petechial and delayed in onset. Toxic epidermal necrolysis resembles SSSS and occurs primarily in adults. Non-toxin-mediated, it is related to drug exposure and has a bullous component. Erythema multiforme can be associated with fever, pharyngeal erythema, and toxemia. The rash is multiform, with symmetric involvement of the lower extremities. Immunologically mediated from a drug exposure or infectious agent, it can progress to Stevens-Johnson syndrome.

Septic shock must always be considered in the differential diagnosis of TSS. In general, the appearance of a rash and the laboratory abnormalities associated with TSS will aid in distinguishing these two entities.

Treatment

Management of TSS depends on its severity. The most important aspect of initial treatment is the aggressive management of circulatory shock. Continuous monitoring of the heart rate, respiratory rate, blood pressure, oxygen saturation, urinary output, and central venous pressure is essential. Pulmonary capillary wedge pressure monitoring may also be needed in severe cases. During the first 24 h, patients may require 4 to 20 L of crystalloid and fresh-frozen plasma. There have been reports of patients requiring up to 20 L of fluid in the first 24 h of hospitalization. A dopamine infusion beginning at 5 to 20 (µg/kg)/min may be used if volume correction fails to restore normal arterial pressure. Large amounts of intravenous fluid and pressors to treat refractory hypotension can result in the rapid onset of pulmonary edema. ARDS may then complicate TSS and require mechanical ventilation with positive end-expiratory pressure.

Evaluation must include arterial blood gas analysis, complete blood count screen with peripheral smear, serum electrolyte determinations including Mg^{2+} and Ca^{2+}, coagulation studies, urinalysis, and chest radiograph. Patients with abnormal coagulation profiles and evidence of bleeding require colloid replacement, fresh-frozen plasma, or transfusions. Thrombocytopenia may require platelet transfusions. An electrocardiogram and echocardiogram may also be indicated.

A focus of infection should be aggressively sought and promptly treated. Cultures of all potentially infected sites should be obtained, including blood cultures, prior to initiating antibiotic therapy. Women with tampon-related TSS should have the tampon removed. Some authors recommend irrigation of the vagina with saline or povidoneiodine solution. Early consultation with a surgeon or a gynecologist is recommended if drainage or debridement of infectious sites is warranted.

Although antimicrobial agents have not been shown to affect the outcome of the acute illness, they are recommended and have been given to most patients to eradicate the focus of toxin-producing staphylococci as well as to decrease the recurrence rate. Antibiotic selection should include an antistaphylococcal penicillin or cephalosporin with b-lactamase stability. Nafcillin or oxacillin in doses of 1 to 2 g every 4 h provides adequate antimicrobial coverage. Cefazolin, 2 g every 6 h, also provides adequate coverage, but the first-generation cephalosporins are less b-lactamase-stable than the antistaphylococcal penicillins. In penicillin-allergic patients, clindamycin, vancomycin, and first-generation cephalosporins can be used. Vancomycin or trimethoprim-sulfamethoxazole may be used if methicillin-resistant strains are encountered. Although data on the optimum duration of antimicrobial therapy are not available, it seems prudent to administer parenteral antibiotics for at least 3 days or until the patient clinically improves. Oral antistaphylococcal antibiotics (dicloxacillin or clindamycin in penicillin-allergic patients) should then be administered for an additional 10 to 14 days. Methylprednisolone and intravenous immunoglobulin have shown improvement in some cases of TSS. [6]

Most patients become afebrile and normotensive within 48 h of hospitalization. Initial laboratory abnormalities resolve within 1 to 2 weeks, although full anemia correction occurs in 4 to 6 weeks.

Numerous sequelae of TSS have been reported and include late onset of maculopapular rash, decreased renal function, reversible loss of hair and nails, prolonged neuromuscular abnormalities, and cyanotic extremities. Neurologic deficits are common, with 50 percent of patients exhibiting residual memory deficits, decreased ability to concentrate, and diffuse electroencephalographic abnormalities.

The mechanism responsible for these sequelae is not yet clear; it has been suggested that they are due to either the delayed effects of the toxin or circulating immune complexes or are drug-mediated.

Patients not treated with b-lactamase-stable antimicrobial drugs have recurrence of the disease. [7] Most recurrent episodes of MRTSS occur by the second month following the initial episode and happen on the same day of menses as the prior attack, although some have recurred in less than 1 month and some more than 1 year later. In the majority of patients having recurrence, convalescent antibody titers are low and nonprotective. The initial episode is the most severe, although deaths have resulted from recurrences of initially mild cases of TSS.

The risk of MRTSS has decreased as a result of changes in tampon components and public education about correct tampon usage. During the outbreak of the 1980s, some tampons were composed of polyester foam and cross-linked carboxymethcellulose (polyacrylate), which provided increased absorbency and encouraged longer periods of use. Tampons are now composed of cotton and rayon. Since 1990, the US Food and Drug Administration has required a limit on tampon absorbency into one of four ranges (junior, regular, super, and super-plus) corresponding to the level of flow. Tampons should be changed every 4 to 8 h, and patients with a history of MRTSS are discouraged from their use.

STREPTOCOCCAL TOXIC SHOCK SYNDROME

The decline in the incidence of TSS in the late 1980s was closely followed by the emergence of an even more serious illness. Initially classified as streptococcal toxic

shock-like syndromes (TSLS) by the CDC, a consensus definition was formulated in 1993. It was identical to the case definition for TSS except that TSLS develops in association with a severe soft-tissue infection and culture results from a normally sterile site must be positive for *Streptococcus pyogenes* [group A streptococcus (GAS)]. In 1995, the CDC published a new case definition for streptococcal toxic shock syndrome (STSS); the current case definition, as published in 1997, is shown in Table 138-3.[8,9]

TABLE 138-3   Case Definition of Streptococcal Toxic Shock Syndrome

STSS is defined as any group A streptococcal infection associated with invasive soft tissue infection, the early onset of shock, and organ failure. Similar in presentation to TSS, STSS is associated with a higher mortality rate, may occur in patients of all ages, and may occur in most countries of the world. Labeled the "flesh-eating bacteria," the most serious GAS soft tissue infections associated with STSS are streptococcal necrotizing fasciitis and streptococcal myositis.

STSS associated with GAS invasive infections, in contrast to previous reports of GAS bacteremia, most commonly affects individuals between the ages of 20 and 50 *without* predisposing illnesses.[16] There is regional variability in populations at risk for developing STSS and necrotizing fasciitis from GAS infections. Extremes of age, diabetes, alcoholism, drug abuse, and immunodeficiency appear to be risk factors for GAS invasive infections. [11,12]

It is estimated that in the United States each year there are 2000 to 3000 cases of STSS and 500 to 1500 cases of necrotizing fasciitis. [9] The mortality rate is very high for STSS, at 30 to 80 percent.[12] In patients with STSS, 70 percent of the soft tissue infections progress to necrotizing fasciitis or myositis requiring surgical intervention. The morbidity rate of STSS is 65 to 80 percent, associated with surgical intervention to control the infection. [11,12,13] The mortality rate for streptococcal myositis is 85 percent, and that for necrotizing fasciitis is 20 to 50 percent. [12] The rate of recurrence is unknown.

Epidemiology

Although severe invasive infections caused by *S. pyogenes* (GAS) have been reported with increasing frequency during the past decade, it is not entirely clear whether these reports reflect an actual increase in the incidence of disease or increased awareness. The latter is likely, due to the dramatic nature of the infections and the coining of the phrase "flesh-eating bacteria" by the tabloid press to describe invasive necrotizing infections caused by GAS. It is believed that there has been a true, recent increase in the GAS virulence properties that may account for the changes in clinical diseases caused by GAS. Few population-based studies exist on its prevalence. Reports on the incidence range from 1.5/100,000 population in Canada to 4.4 /100,000 in the Arizona. [11,13] STSS may be underdiagnosed when associated with GAS invasive infections, since 90 percent of patients are in shock or develop shock within 4 to 6 h of admission. Prospective population-based surveillance studies from Canada from 1991 through 1995 demonstrated an incidence of STSS associated with necrotizing fasciitis to be 13 to 46 percent. [11,13] There have also been recent reports of toxic shock-like syndrome caused by non-group A streptococcal infection, specifically groups B, C, and G. In 1998, a documented group B streptococcal necrotizing fasciitis and STS-like syndrome was reported in three patients with significant underlying disease; the authors postulate that group B streptococcus has acquired an increased ability to cause fasciitis and may be the cause of a new clinical syndrome in adults. [14,15,16]

Pathophysiology

The resurgence of GAS invasive infections appears to be the result of the production of more virulent exotoxins from the M-type isolates of GAS. Streptococcal pyogenic exotoxins (SPEs) are produced by 90 percent of GAS isolates. [16] Three distinct exotoxins (SPEs A, B, C) have been identified. SPE A, also known as the scarlet fever toxin, is the most powerful and most frequently found SPE in STSS. It has a molecular structure similar to that of enterotoxin B of NMTSS. The SPEs A and B display features similar to those of TSS-mediated exotoxins, including pyrogenicity, superactivation of T cells, and synthesis of TNF, IL-1, and IL-6. [16] These powerful cytokines can induce severe acidosis, shock, and multisystem organ failure, as in TSS. The effects of the "superantigens" SPE A and SPE B are hypothesized to be similar to yet more profound than those of TSST-1, with greater induction of TNF, IL-1, IL-6, and other cytokines, thereby causing more severe signs and symptoms.[16] The patients suspected of being most at risk for developing STSS are those without immunity to M-type 1 SPE A- or B-producing strains of GAS. The SPE C has been found in fewer GAS isolates, and its role in STSS is not clear.

The portal of entry of streptococci cannot be proven in about 50 percent of cases and can only be presumed in many others. [12] Most commonly, infection begins at a site of minor local trauma, usually without disruption of the skin. Cases have developed from burns, lacerations, abrasions, hematomas, minor nonpenetrating muscle injuries, surgical procedures, and recent infections with varicella or influenza. [12]

Clinical Features

Pain is the most common initial symptom of STSS, usually of abrupt onset, severe, and preceding tenderness or physical findings. [12] Eighty percent of patients have signs of soft tissue infection; this progresses to necrotizing fasciitis or myositis in 70 percent of patients. Although most commonly affecting the extremities, the location of the pain may suggest an intraabdominal process, such as peritonitis or pelvic inflammatory disease, or other conditions, such as pneumonia or pericarditis. Up to 20 percent of patients may experience a prodromal influenza-like episode including fever, chills, myalgias, and diarrhea. Fever is the most common early sign. Confusion is present in 55 percent of patients, and coma or combativeness may also occur. Other early signs and symptoms of STSS may include dizziness, diffuse rash, and abdominal pain. The initial diagnosis of STSS may be difficult, if not impossible, to distinguish from TSS. If necrotizing fasciitis is present, fever, severe pain, swelling, and redness at the site of the wound are seen. Myositis is an uncommon complication of invasive GAS infection, with a very high fatality rate. The most common symptom is severe pain; swelling and erythema may be the only early physical findings. Muscle compartment syndromes may develop rapidly.

On physical examination, fever is the most common presenting sign, followed closely by shock. Shock is apparent at presentation or develops within 4 to 8 h of admission in virtually all patients with STSS. It may be refractory to treatment or require massive volume replacement. The development at the site of the soft tissue infection of vesicles and bullae with progression to violaceous or blue discoloration is considered an ominous sign of necrotizing fasciitis or myositis. ARDS develops in 55 percent of patients, usually following the onset of hypotension; intubation is required in the majority of cases. A diffuse erythematous rash is much less prevalent in STSS (10 percent), but if it does occur, there is desquamation.

Laboratory evaluation shows mild elevation in the white blood cell count (13,000) with a profound bandemia as high as 40 to 50 percent. Liver function test values may be two times normal; decreased platelet levels and disseminated intravascular coagulopathy may be seen. Renal dysfunction persists or progresses in all patients; dialysis is commonly required. Creatinine kinase levels become elevated if the soft tissue infection becomes necrotizing. Blood cultures are positive for GAS in 60 percent of patients, and more than 90 percent of patients with STSS have positive tissue culture results with a known site of infection. [11] One recent report suggests that magnetic resonance imaging may be useful in the early diagnosis of GAS necrotizing fasciitis. [17] Definitive diagnosis of STSS is made by positive GAS culture results from a normally sterile site in addition to the clinical and laboratory parameters defined in the case definition (Table 138-3).

Diagnosis

The differential diagnosis is the same as for TSS (see Table 138-2) with the significant addition of invasive and noninvasive GAS infections, necrotizing fasciitis, myositis, and serious infections caused by *Clostridium perfringens, Clostridium septicum,* and mixed organisms, such as anaerobic and aerobic bacteria.

Treatment

The initial treatment of STSS is similar to that of TSS, with aggressive management of shock and early use of vasopressors (see "Treatment" under "Toxic Shock Syndrome"). Antibiotic therapy should be initiated immediately in the emergency department to treat STSS and the associated infection, if present; intravenous penicillin G, 24 million U/day in divided doses, and intravenous clindamycin, 900 mg every 8 h.[12] Erythromycin should be used in penicillin-allergic patients. Intravenous immunoglobulin may be useful in the treatment of invasive GAS infections associated with STSS.[18] Although antibiotics are important, prompt and aggressive exploration and débridement of suspected deep-seated *S. pyogenes* infection are mandatory. If STSS is suspected, immediate surgical consultation is indicated, since 70 percent of patients with STSS require débridement, fasciotomy, or amputation.

Disposition

All patients suspected of having STSS should be admitted to an intensive care unit.

139 HIV INFECTION AND AIDS

Richard E. Rothman
Gabor D. Kelen

HIV causes a wide spectrum of diseases ranging from asymptomatic infection to life-threatening illnesses and may involve virtually any organ system. The signs and symptoms associated with complications are frequently nonspecific, and the social problems faced by this population are unusually complex. While the development of antiretroviral therapies has been found to slow the progression of opportunistic infections, an increasing array of therapeutic complications has emerged.

EPIDEMIOLOGY

The first reported cases of AIDS were described in 1981 when individuals with *Pneumocystis carini* pneumonia and Kaposi sarcoma were discovered among previously healthy homosexual men. The principal pathologic characteristic of AIDS was subsequently determined to be a defect in cell-mediated immunity. In 1983, isolation of a retrovirus (HIV) established the etiologic basis of AIDS. The development of an antibody assay for HIV in 1985 allowed for serologic diagnosis of infected individuals and led to an appreciation of the major modes and principal risk factors for HIV transmission.

The diagnosis of AIDS is most commonly made with laboratory evidence of HIV infection and the presence of one or more "indicator conditions." The most recent Centers for Disease Control and Prevention (CDC) definition of AIDS for reporting purposes was published in 1993 (Table 139-1).[1] The case definition of AIDS includes either the presence of one or more indicator conditions (now including pulmonary tuberculosis, recurrent bacterial pneumonia, or invasive cervical cancer), or a laboratory measure of severe immunosuppression (CD4 T-lymphocyte count <200 cells/µL).

TABLE 139-1   Indicator Conditions for Case Definitions of AIDS

Worldwide, the number of patients with HIV is continuing to grow dramatically, with current estimates of 30.6 million people living with HIV or AIDS. Since the beginning of the epidemic, 11.7 million people are reported to have died from HIV-related illnesses. If current trends continue, 60 to 70 million people will be infected with HIV by the year 2000. Developing countries, the least equipped to deal with the epidemic, have been hit particularly hard.

In the United States, HIV surveillance has improved as a result of new laws requiring mandatory reporting of HIV seropositivity in over 20 states. As of December 31, 1997, there were an estimated 1.1 million people infected with HIV (approximately 1 in every 250 Americans). Reported cases of AIDS number 641,086, and 390,692 patients with HIV-related deaths have been described.[2] AIDS is now the leading cause of death among American men 25 to 44 years old and the third leading cause of death among women in the same age group. Regional trends have changed markedly over the past decade. While more than 50 percent of AIDS cases occurred in five urban centers through 1987 (New York, San Francisco, Los Angeles, Newark, and Miami), the majority of new HIV cases now occur outside these centers, with the most significant increases seen in smaller metropolitan areas.

Risk factors commonly associated with HIV infection include homosexuality or bisexuality, injected drug use, heterosexual exposure, receipt of a blood transfusion prior to 1985, and vertical and horizontal maternal-neonatal transmission. The change in the distribution of AIDS cases by mechanism of transmission since the start of the HIV epidemic is shown in Table 139-2.[3]

Primary Risk Factor	1981–1987	1988–1992	1993–1995
Male homosexual contact	64.0	54.6	50.8
Injected drug use	17.2	24.2	27.3
Male homosexuality plus injected drug use	8.3	7.0	5.6
Heterosexual contact	2.5	6.1	10.1
Transfusion recipient	2.6	1.9	1.0
Perinatal transmission	1.2	1.5	1.0
Hemophilia	1.3	0.9	0.8
No risk reported	3.2	3.9	9.2

TABLE 139-2   Distribution of AIDS Cases by Mechanism of Transmission, % Cases

Increasing use of emergency department services by HIV-infected persons is due in part to changes in the demographic distribution of HIV cases and AIDS-related illnesses.[4] In homosexual and bisexual men, rates of newly acquired HIV, HIV progression to AIDS, and AIDS-related deaths have all declined (largely due to access to antiretroviral therapy and, in part, to effective prevention strategies). Meanwhile, rates of new HIV infection have continued to rise among young, disadvantaged, minority populations who utilize the emergency department for both primary and emergency care. During the past several years, the highest percentages of increase in reported AIDS cases have occurred among women, minority populations, and children. These changes are principally due to an increase in HIV prevalence among injected drug users and their women partners. Seroprevalence studies in one inner-city emergency department reflect these trends, with rates of HIV infection among unselected adult patients rising from 6 to 11.4 percent over a 4-year period. [4]

PATHOPHYSIOLOGY

HIV is a cytopathic retrovirus that kills infected cells. The viral genes are carried as a single-stranded RNA molecule within the viral particle. Following infection, the virus selectively attacks host cells involved in immune function, primarily CD4 T lymphocytes. Within the host cell, the RNA template is reverse-transcribed into DNA (using the enzyme reverse transcriptase), which then becomes permanently integrated into the host's genome. Once integrated, retroviral DNA may lie dormant or be activity-transcribed and translated to produce virally encoded proteins and new HIV virions. Activation of viral protein precursors into the functional enzymes required for virion infectivity is carried out by HIV protease.

The HIV virion is composed of a central RNA molecule and reverse transcriptase protein surrounded by a core protein encased by a lipid bilayer envelope. Two virally encoded transmembrane proteins, gp41 and gp120, play a critical role in the recognition and attachment of HIV virions to receptors on host CD4 lymphocytes. As a result of infection, immunologic abnormalities eventually occur, including lymphopenia, qualitative CD4 T-lymphocyte function defects, and autoimmune phenomena. Profound defects in cellular immunity ultimately result in a variety of opportunistic infections and neoplasms.

Antiretroviral therapy is directed at reducing levels of HIV RNA by interfering with the activity of the enzyme's reverse transcriptase (nucleoside and nonnucleoside reverse transcriptase inhibitors), and HIV protease (protease inhibitors). Although use of antiretroviral agents has had a significant impact on progression of disease, long-term inhibition of viral replication has remained elusive, due to a combination of factors including drug toxicity and the emergence of mutant, drug resistant strains of HIV.

Transmission of HIV has been shown to occur via semen, vaginal secretions, blood or blood products, breast milk, and transplacental transmission in utero. HIV has also been isolated from saliva, urine, cerebrospinal fluid, brain, tears, alveolar fluid, synovial fluid, and amniotic fluid. Transmission has never been documented to occur by casual contact, although there is one reported case of possible salivary transmission by deep kissing from an HIV-infected male with bleeding gums to a female partner. HIV is a very labile virus and is easily neutralized by heat or common disinfecting agents, such as Lysol, a 1:10 solution of household bleach, 0.3% hydrogen peroxide, 35% isopropyl alcohol, or 50 percent ethanol.

CLINICAL STAGES OF HIV INFECTION

The stages of HIV infection from initial acquisition to end-stage AIDS are described in Table 139-3. Acute HIV infection, essentially indistinguishable from a "flulike" illness, usually goes unrecognized but is reported to occur in 50 to 90 percent of patients. [5] The time from exposure to onset of symptoms is usually 2 to 4 weeks, and the most common symptoms include fever, sore throat, fatigue, myalgias, and weight loss. Many experts now argue that it is beneficial to identify patients at this early stage because it may be the optimal time to begin antiretroviral therapy. The best method of establishing a diagnosis during this window (when HIV antibody serologic test results are usually negative or indeterminant) is by quantitative analysis of plasma HIV RNA. Acute infection is associated with high-level HIV RNA viremia and a precipitous decline in CD4 cell counts, reflecting ongoing destruction of the host immune response. Acute symptoms last an average of 2 weeks, with clinical recovery accompanied by a significant reduction in HIV RNA levels and a moderate increase in CD4 counts.

TABLE 139-3   Stages of HIV Infection

Seroconversion, reflecting detectable antibody response to HIV, usually occurs 3 to12 weeks after infection, although delays of up to 11 months have been reported. This is followed by a long period of asymptomatic infection during which patients generally have no findings on physical examination except for possible persistent generalized lymphadenopathy, characterized by enlarged lymph nodes involving at least two noncontinuous sites other than inguinal nodes. The mean incubation time from exposure to the development of AIDS is estimated at 8.23 years for adults, and 1.97 years for children under age 5. Virologic studies of patients during this period suggest that a steady state of HIV replication and CD4 cell death and replacement exists until increased levels of HIV replication occur. Variables most predictive of disease stage are viral burden and CD4 counts, with a steeper decline in CD4 count and a higher viral burden associated with rapid progression and poor outcome.[6] Other, indirect risk factors for progression include b_2 microglobulin concentration, low levels of HIV antibody, and low hemoglobin concentration.

Early symptomatic infection is characterized by conditions that are more common and more severe in the presence of HIV infection but, by definition, are not AIDS indicator conditions. Examples include thrush, persistent vulvovaginal candidiasis, peripheral neuropathy, cervical dysplasia, recurrent herpes zoster infection, and idiopathic thrombocytopenic purpura. These conditions occur with increased frequency as the CD4 cell count drops below 500 cells/μL.

As the CD4 count drops below 200 cells/μL, the frequency of opportunistic infections dramatically increases. AIDS is defined by the appearance of any indicator condition (Table 139-1) or a CD4 count of less than 200 cells/μL. The average survival time following a diagnosis of AIDS has been estimated to be between 16 to 24 months.[7] Antiretroviral therapy and prophylaxis and treatment of opportunistic infections have been shown to delay the time to onset of complications and death in this group of patients.[8]

Advanced HIV infection exists in patients with a CD4 count of less than 50 cells/μL or clinical evidence of end-stage disease, including disseminated *Mycobacterium avium* complex or disseminated cytomegalovirus (CMV). Patients in this group have a median survival of 12 to 18 months. [7]

DIAGNOSIS

Infection with HIV may be diagnosed by several methods: detection of viral-specific antigen, assays for HIV nucleic acid, isolation of the virus by culture, and detection of antibodies to HIV. The most common assay used to detect viral antibody is an enzyme-linked immunoassay (EIA) and a confirming Western blot test on EIA-positive specimens. EIA is approximately 99 percent specific and 98.5 percent sensitive; the Western blot test is nearly 100 percent sensitive and specific if performed under ideal laboratory circumstances.

Currently, diagnostic HIV testing has no utility in emergency department evaluation or management of patients. A few limited exceptions may exist, such as when health care providers are exposed to patients' blood or in cases of sexual assault. [9,10] Given the narrow window of opportunity for initiating therapy at the earliest

stages of infection, the emergency department may yet prove to be an ideal setting for both diagnostic testing and screening. [10,11]

Knowledge of recent CD4 cell counts and HIV viremia load is frequently helpful in placing patients' emergency department presentation in an appropriate context (Table 139-3). When this information is unavailable or the stage of disease is unknown, the total lymphocyte count may be used to approximate the CD4 cell count, since a total lymphocyte count of less than 1000 cells/µL has been shown to be strongly predictive of a CD4 count of less than 200 cells/µL.

CLINICAL FEATURES AND TREATMENT

The spectrum of disease caused by HIV infection varies greatly. Many patients with asymptomatic infection may come to the emergency department for complaints unrelated to HIV disease. [12] Others may have involvement of virtually any organ system, commonly with multiple interrelated problems. Because of the complexity of HIV infection and related opportunistic infections or malignancies, specific diagnoses often cannot be made in the emergency department.

Evaluation of HIV-infected patients should be carried out with the same priority-based logical approach used for all emergency department patients, with attention to concerns particular to this population. Patients with unstable vital signs require attention to the "ABCs" and rapid stabilization. Universal precautions (in some hospitals termed standard precautions) must be used in all cases. The history and physical examination should focus on identifying the clinical stage of disease in order to direct attention to the most likely complications. History gathering must include a thorough review of past and current medications, previous infections, and attention to activities of daily living. Physical findings that might assist with staging (Table 139-3) include the presence of thrush, evidence of temporal wasting, or dementia. Diagnostic and therapeutic maneuvers are directed toward recognition of organ system involvement, assessment of the severity of disease, and institution of symptomatic and specific therapy. Table 139-4 lists some of the common pathogens causing organ system involvement in HIV-infected patients. While it is unlikely in most cases that specific therapy will be initiated by the emergency department physician, familiarity with therapeutic approaches and related complications is important. Table 139-5 contains a summary of common infections and current recommendations for therapy.

TABLE 139-4 Common Conditions Causing Organ System Involvement in AIDS Patients

TABLE 139-5 Treatment Recommendations for Common HIV-Related Infections

Pulmonary Complications

Pulmonary presentations are among the most common reasons for emergency department visits by HIV-infected patients. [10,12] Presenting complaints frequently are nonspecific and include cough, hemoptysis, shortness of breath, and chest pain. Emergency department evaluation should be directed toward determining the likely diagnosis, since early treatment may have a significant impact on morbidity and mortality rates. Appreciation of the epidemiologic characteristics and common findings associated with various pathogens can assist the emergency physician in arriving at an appropriate differential and working diagnosis, leading to sound treatment and disposition decisions.

The most common causes of pulmonary abnormalities in HIV-infected patients include community-acquired bacterial pneumonia, PCP, *Mycobacterium tuberculosis* (MTB), CMV, *Cryptococcus neoformans, Histoplasma capsulatum,* and neoplasms.

In addition to the history and physical examination, evaluation of patients with pulmonary complaints may be assisted by pulse oximetric analysis, arterial blood-gas determination, sputum culture, Gram staining, acid-fast staining, blood culture, and chest x-ray. Pulmonary radiographic findings are helpful in determining likely causes (Table 139-6). Admission should be considered for patients with new-onset pulmonary symptoms, especially those with hypoxia. Decisions regarding patients with known pulmonary involvement are based on comparison to baseline status, the effectiveness of ongoing or previous treatment, and the individual's ability to obtain outpatient follow-up. Specific symptoms are discussed below with selected common causes.

TABLE 139-6 Chest Radiographic Abnormalities: Differential Diagnosis in AIDS Patients

Despite substantial decreases in the incidence of PCP due to effective prophylaxis, it continues to be the most common opportunistic infection among AIDS patients.

Approximately 70 percent of HIV-infected patients will acquire PCP at some time during their illness, and PCP is often the initial opportunistic infection that establishes the diagnosis of AIDS. This disease is the most frequent serious complication of HIV infection in the United States and the most common identifiable cause of death in patients with AIDS. The classic presenting symptoms of PCP are fever, cough (typically nonproductive), and shortness of breath (progressing from being present only with exertion to being present at rest).

Symptoms are often insidious and accompanied by fatigue. Chest x-rays most often show diffuse interstitial infiltrates (Table 139-6). Although typical radiographic findings occur in up to 80 percent of cases, negative x-rays are reported in 15 to 20 percent of patients with PCP. [13] In patients with nondiagnostic x-ray findings and signs and symptoms suggestive of PCP, further testing should be pursued. The lactate dehydrogenase (LDH) level is elevated in patients with PCP, but the test for LDH has relatively low sensitivity and specificity, making its use in the emergency department impractical. Arterial blood-gas analysis usually demonstrates hypoxemia and an increase in the alveolar-arterial (A-a) gradient. (Early PCP should be suspected if a patient demonstrates a decrease in pulse oximetric values with exercise.) Presumptive diagnosis of PCP is often assumed in the emergency department if there is hypoxia without any other explanation. Inpatient diagnostic testing may include bronchoscopy with lavage, biopsy, and culture or examination of induced sputum by indirect immunofluorescence using monoclonal antibodies.

Initial therapy for PCP is trimethoprim-sulfamethoxazole (TMP-SMX) TMP 15 mg/kg/day and SMX 75 mg/kg/day) either orally or intravenously for 3 weeks in two or three divided doses [typical oral dosage 2 double strength (DS) tid]. Adverse reactions (most commonly rash, fever, and neutropenia) occur in up to 65 percent of AIDS patients. Pentamidine isothionate 4 mg/kg/day is one of a number of effective alternative agents. Steroid therapy should be instituted for patients with a Pa o_2 less than 70 mmHg or an alveolar-arterial gradient greater than 35. [14] The usual regimen is oral prednisone 40 mg bid for 5 days, then 40 mg qd for 5 days, and then 20 mg qd for an additional 11 days. Seventy percent of patients will have reinfection within 18 months. Prophylactic therapy is an important step in preventing reinfection and has also been shown to reduce the risk of developing bacterial pneumonia; oral TMP-SMX 1 DS qd is the preferred agent. Prophylaxis is also recommended in all patients with CD4 counts below 200 cells/µL. Repeat infections may be less responsive to therapy.

The incidence of Mtb is increasing, particularly among the homeless, institutionalized, immigrant, and intravenous-drug-using populations. Reactivation of prior infection is common, and there is a much greater risk of direct progression of disease from recently acquired infection. The incidence of tuberculosis (TB) in the AIDS population is estimated to be 200 to 500 times that in the general population. [15] Prevalence studies demonstrate significant regional variations, attributed to both the demographic characteristics of the populations and the efficacy of local public health control measures.

Clinical manifestations of TB in HIV infection vary significantly according to the severity of immunosuppression. Whereas PCP does not occur until the CD4 count is approximately 200 cells/µL, TB frequently occurs in patients with CD4 counts of 200 to 500 cells/µL. Classic pulmonary manifestations include cough with hemoptysis, night sweats, prolonged fevers, weight loss, and anorexia. With worsening immunosuppression, atypical and extrapulmonary manifestations are more common. Frequent sites of dissemination are peripheral lymph nodes, bone marrow, and the urogenital system. Classic upper lobe involvement and cavitary lesions are less common, particularly among late-stage AIDS patients. [13] Negative purified protein derivative (PPD) TB test results are frequent among AIDS patients due to immunosuppression. Definitive diagnosis may be made by stain and culture of sputum, although in some cases bronchoscopy with biopsy may be required.

In the emergency department, physicians should maintain a high index of suspicion for TB among HIV-infected patients with pulmonary symptoms due to the high rates of person-to-person transmission. Immediate isolation should be instituted until the diagnosis is ruled out. Specific procedures for ruling out TB vary by region and site and have been found to be inadequate in some emergency departments. [16] Any patient identified as high risk based on clinical presentation should be placed in isolation, with the decision for further isolation based on results of chest x-ray and detailed historical and clinical information. Current treatment guidelines recommend a four-drug initial empiric therapy (Table 139-5). Multidrug-resistant TB remains an issue of concern and should increase the awareness of the need for early isolation. All HIV-infected patients with positive PPD test results should receive prophylaxis with isoniazid for 1 year.

Nonopportunistic bacterial pneumonias are the most common pulmonary infections in HIV-infected patients. Common pathogens include *Streptococcus pneumoniae, Haemophilus influenzae,* and *Staphylococcus aureus.* Productive cough, leukocytosis, and the presence of a focal infiltrate suggest bacterial pneumonia, especially in those with earlier-stage disease. The response to empiric therapy tends to be good; a specific diagnosis can be established by Gram staining and culture.

Patients with severe immunosuppression are predisposed to disseminated fungal infections, such as *C. neoformans* and *Aspergillus fumigatus.* Other noninfectious disorders of the lung seen in HIV-infected patients include neoplasms (e.g., Kaposi's sarcoma) and lymphocytic interstitial pneumonitis. CMV or *Mycobacterium avium* complex are unlikely unless the CD4 count drops below 50 cells/µL.

Neurologic Complications

Central nervous system (CNS) disease occurs in 90 percent of patients with AIDS, and 10 to 20 percent of HIV-infected patients initially present with CNS symptoms.[17] Neurologic disease is caused by a variety of opportunistic infections and neoplasms as well as the direct and indirect effects of HIV infection on the CNS. Common presenting symptoms indicative of CNS pathology include seizures, altered mental status, headache, meningismus, and focal neurologic deficits. [17] Emergency department evaluation should include a complete neurologic examination and, when appropriate, computed tomography and lumbar puncture. Specific CSF studies that may be of value include opening and closing pressures, cell count, glucose, protein, Gram stain, India ink stain, bacterial culture, viral culture, fungal culture, toxoplasmosis and cryptococcus antigen, and coccidioidomycosis titer. Even if the emergency department evaluation is unrevealing, all patients with new or changed neurologic signs or symptoms should be admitted to the hospital for further workup. The most common causes of neurologic symptoms include AIDS dementia, *Toxoplasma gondii,* and *C. neoformans.*

AIDS DEMENTIA   AIDS dementia complex (also referred to as HIV encephalopathy or subacute encephalitis) is a progressive process commonly heralded by subtle impairment of recent memory and other cognitive deficits caused by direct HIV infection. In the early stages, diagnosis can be confused with depression, anxiety disorders, or substance abuse. Later phases of the illness are characterized by obvious changes in mental status and more severe disturbances, including aphasia and motor abnormalities. When a patient presents to the emergency department with an established diagnosis of AIDS dementia, with progressive signs or symptoms, it is important to rule out other CNS processes. A computed tomography (CT) scan in AIDS dementia typically shows cortical atrophy and ventricular enlargement.

TOXOPLASMOSIS   Toxoplasmosis is the most common cause of focal encephalitis in patients with AIDS. Symptoms may include headache, fever, focal neurologic deficits, altered mental status, or seizures. Serologic tests are not useful in making or excluding the diagnosis because antibody to *T. gondii* is prevalent in the general population. The presence of antibody to *T. gondii* in the cerebrospinal fluid is helpful, although there is a high rate of false-negative results. On a noncontrast scan, toxoplasmosis typically appears as multiple subcortical lesions with a predilection for the basal ganglia.

Noncontrast CT scanning is often used as an initial imaging study in the emergency department in HIV-infected patients with neurologic deficits, since the addition of contrast has been shown to be of marginal value in patients with completely normal noncontrast CT scans. In cases in which clinical suspicion for CNS pathology is high but the CT scan is equivocal or negative, contrast enhanced CT scanning should be arranged in the emergency department. With contrast enhancement, toxoplasmosis lesions are ring-enhancing, with surrounding areas of edema. Magnetic resonance imaging is slightly more sensitive than contrast CT in detecting the extent and number of lesions with toxoplasmosis but is usually not indicated in the emergency department.

Other causes in the differential diagnosis of ring-enhancing lesions on contrast CT include lymphoma, fungal infection, and cerebral tuberculosis. In the emergency department, it is often not possible to differentiate these causes based on initial imaging studies, but general patterns in the appearance of lesions, based on underlying pathology, have been described. Toxoplasmosis tends to have a greater number of lesions with a predilection for the basal ganglia and corticomedullary regions, while lymphoma is more often characterized by singular lesions, typically in the periventricular white matter or corpus callosum. TB is distinguished by a characteristic inflammatory appearance on CT, with a thick, isodense exudate filling the basal cisterns.

Patients with suspected toxoplasmosis should be admitted and treated with pyrimethamine (100- to 200-mg load, then 50 to 100 mg/day) and sulfadiazine (4 to 8 g/day), with folinic acid added (10 mg/day) to reduce hematologic toxicity. Steroids are beneficial for significant edema or mass effect. Failure to improve suggests an alternative diagnosis, which may require biopsy. For patients responsive to toxoplamosis therapy, chronic suppressive therapy with pyrimethamine, sulfadiazine, and folinic acid is usually indicated after initial treatment. Oral TMP-SMX (1 DS qd) is recommended for prophylaxis in patients with positive toxoplasmosis serologic test results and CD4 cell counts less than 100 cells/µL.

CRYPTOCOCCOSIS   Cryptococcal CNS infection may be seen in up to 10 percent of AIDS patients and may cause either focal cerebral lesions or diffuse meningoencephalitis. The most common presenting signs are fever and headache, followed by nausea, altered mentation, and focal neurologic deficits. Presentation may be subtle. Diagnosis relies on identifying organisms in cerebrospinal fluid by cryptococcal antigen (nearly 100 percent sensitive and specific), culture (95 to 100

percent sensitive), or staining with India ink (60 to 80 percent sensitive); serum cryptococcal antigen is also useful but has slightly lower sensitivity (approximately 95 percent). Patients with CNS cryptococcus shall be admitted for antibiotic therapy; preferred treatment is intravenous amphotericin B 0.7 mg/kg/day for 10 to 14 days. Oral flucytosine 100 mg/kg/day may be added to this therapy. Sixty percent of patients may be expected to respond to therapy, and side effects are frequent, most notably bone marrow suppression. Initial therapy should be followed by 8 to 10 weeks of oral fluconazole. Lifelong maintenance therapy with lower doses of fluconazole is indicated for all patients.

OTHER NEUROLOGIC DISORDERS   Other, less common CNS infections that should be considered in the presence of neurologic symptoms include bacterial meningitis, histoplasmosis (usually disseminated), CMV, progressive multifocal leukoencephalopathy, herpes simplex virus, neurosyphilis, and TB. Noninfectious CNS processes include CNS lymphoma (occurring in 5 percent of AIDS patients and typically manifested as a subacute neurologic deterioration over several months), cerebrovascular accidents, and metabolic encephalopathies.

HIV infection is associated with a variety of disorders of the peripheral nervous system. The most common of these is HIV neuropathy characterized by painful sensory symptoms in the feet. Symptomatic relief with pain-modifying agents, such as amitriptyline or phenytoin, should be used judiciously because of their potential for causing delirium in patients with concurrent HIV dementia. Narcotic analgesia may be helpful in severe cases.

Gastrointestinal Complications

Gastrointestinal manifestations of HIV infection are common. Approximately 50 percent of AIDS patients will present with gastrointestinal complaints at some time during their illness. The most frequent presenting symptoms include odonophagia, abdominal pain, bleeding, and diarrhea. Organisms commonly associated with gastrointestinal infection in AIDS patients are shown in Table 139-4. Emergency department evaluation should focus on recognizing the severity of symptoms and obtaining appropriate initial diagnostic studies. Therapy should include volume and electrolyte repletion and initiation of antibiotic therapy when appropriate. Disposition should be based on the duration of symptoms, the clinical appearance of the patient, and the response to emergency department therapy.

Diarrhea is the most frequent gastrointestinal complaint and is estimated to occur in 50 to 90 percent of AIDS patients. It is caused by a wide variety of enteric pathogens that affect the general population as well as other, less virulent organisms that are more common in the immunocompromised population. Emergency department evaluation of patients with diarrhea should include microscopic examination of stool for leukocytes, ova, and parasites; acid-fast staining; and bacterial culture of stool. Common causes include bacterial organisms, such as *Shigella, Salmonella,* enteroadherent *Escherichia coli,* and *Campylobacter;* parasitic organisms, such as *Giardia, Cryptosporidium,* and *Isospora belli;* CMV; *M. avium intracellulare;* and antibiotic therapy.[17]

Clinical clues regarding the cause of diarrheal illnesses may be provided by the patient's history and confirmed by supplementary testing; however, results are usually not available during the emergency department visit. Bacterial pathogens generally follow a more acute and fulminant course, while parasitic infections are more frequently indolent. If bacterial infection is suspected, empiric treatment with ciprofloxacin, which covers the common bacterial pathogens, can be started. *Cryptosporidium* and *Isospora* infection are common parasitic causes and are associated with profuse watery diarrhea. Both can be identified by a modified acid-fast stain. *Isospora belli* is usually responsive to TMP-SMZ, but relapse is common. Cryptosporidiosis tends to be difficult to treat. In patients with end-stage disease, the most common pathogens are CMV and *M. avium intracellulare;* both diagnoses usually require biopsy. Prolonged antimicrobial therapy is indicated for treatment, and resistance and relapse are frequent for both entities. About 15 percent of patients with late-stage AIDS suffer from severe, high-volume, watery diarrhea with no pathogen identified even after thorough investigation. The presumed diagnosis is AIDS-related enteropathy. Patients often require admission for correction of electrolyte abnormalities and rehydration. Octreotide, the somatostatin analogue, may be helpful in some cases.

Emergency department management should be directed toward repletion of fluid and electrolytes. Patients who are nontoxic appearing and can tolerate liquids can be referred for outpatient follow-up of test results. Patients with severe diarrhea who do not require antibiotics may benefit from symptomatic therapy, such as attapulgite (Kaopectate), psyllium (Metamucil) and, if necessary, diphenoxylate hydrochloride with atropine (Lomotil).

Oral lesions are common in HIV-infected patients and frequently contribute to malnutrition. Oral candidiasis or thrush affects more than 80 percent of AIDS patients. The tongue and buccal mucosa are commonly involved, and the plaques characteristically can be easily scraped from an erythematous base. Differentiation from hairy leukoplakia (usually manifested as adherent, white, thickened lesions on the lateral tongue borders) may be challenging for the inexperienced, but microscopic examination on potassium hydroxide smear confirms the diagnosis. The development of oral candidiasis is a poor prognostic sign and is predictive of progression to AIDS. Most oral lesions can be managed symptomatically on an outpatient basis. Clotrimazole or nystatin suspension or troches (five times daily) are the preferred treatment. Refractory or recurrent disease can be managed with oral fluconazole. Amphotericin B is reserved for severe cases.

Other causes of painful oral and perioral lesions include oral hairy leukoplakia, herpes simplex virus, and Kaposi's sarcoma. Herpes simplex can usually be recognized by typical vesicular lesions, with diagnosis confirmed by identifying multinucleated giant cells from scrapings or by culture. Both herpes simplex and hairy leukoplakia are responsive to oral acyclovir. Oral Kaposi's sarcoma appears as a nontender, well-circumscribed, slightly raised violaceous lesion. Diagnosis requires biopsy; topical treatments may be palliative.

Esophageal involvement may occur with *Candida,* herpes simplex, and CMV. Complaints of odonophagia or dysphagia are usually indicative of esophagitis and may be extremely debilitating. Disease typically occurs in patients who have oral thrush and CD4 counts of less than 100 cells/μL. Treatment of esophagitis in the emergency department is usually presumptive. Endoscopy, histologic staining, culture, and biopsy are reserved for patients who fail to respond or have atypical presentations. Presumptive treatment for *Candida,* which accounts for 50 to 70 percent of cases, is with oral fluconazole (200 to 400 mg qd for 2 to 3 weeks) or oral ketoconazole (100 to 200 mg qd for 2 to 3 weeks). Relapses are common, and intravenous amphotericin B may occasionally be required. Treatment failures endoscopically discovered to be caused by CMV and herpes simplex are treated with acyclovir and gancyclovir, respectively.

Hepatomegaly occurs in approximately 50 percent of AIDS patients. Elevation of alkaline phosphatase levels is frequently seen. Jaundice is rare. Coinfection with hepatitis B and hepatitis C is common, especially among injected drug users. Opportunistic infection with CMV, *Cryptosporidium, M. avium intracellulare,* and MTB may also cause signs of hepatitis.

Anorectal disease is common in AIDS patients. Proctitis is characterized by painful defecation, rectal discharge, and tenesmus. Common causative organisms include *Neisseria gonorrhoeae, Chlamydia trachomatis,* syphilis, and herpes simplex. Proctocolitis includes the same symptoms in the presence of diarrhea, and multiple bacterial organisms may be responsible (most commonly *Shigella, Campylobacter,* and *Entamoeba histolytica*). Diagnostic evaluation should include anoscopy, with microscopic examination, Gram stain, and culture of pus and/or stool.

Cutaneous Manifestations

Generalized cutaneous conditions, such as xerosis (dry skin), seborrheic eczema, and pruritus, are common and may be manifested prior to development of opportunistic infections. Treatment is with emollients and, if necessary, mild topical steroids. Pruritus may respond to oatmeal baths and antihistamines. Other infections, including *S. aureus* (manifested as bullous impetigo, ecthyma, or folliculitis), *Pseudomonas aeruginosa* (which may present with chronic ulcerations and macerations), and syphilis are frequently seen and should be treated with standard therapies. Several specific dermatologic conditions are discussed in more detail below.

Kaposi's sarcoma appears more often in homosexual men than in other risk groups. Clinically, it consists of painless, raised brown-black or purple papules and nodules that do not blanch. Common sites are the face, chest, genitals, and oral cavity; however, widespread dissemination involving internal organs may occur. Since cutaneous Kaposi's sarcoma is not generally associated with significant rates of morbidity or mortality, therapy is indicated only for extensive, painful, or cosmetically disfiguring lesions. Cryotherapy or radiation can be used for localized disease; widespread disease may be responsive to chemotherapy with vincristine, vinblastine, or doxyrubicin.

Herpes simplex infections are common and may be localized or systemic. In patients with significant immunosuppression, infection may become progressive, manifested as chronic ulcerative mucocutaneous lesions. Diagnosis and treatment are the same as for other patients with herpes simplex (see Chap. 150, "Common Viral Infections"). Intravenous acyclovir therapy 5 to 10 mg/kg/day is needed for extensive disease.

Reactivation of varicella zoster virus is more common in patients with HIV infection and AIDS than in the general population.[18] The clinical course is prolonged, and complications are more frequent. In HIV-positive patients with oral acyclovir 800 mg five times a day or oral famciclovir 500 mg tid for 7 days is usually sufficient.

However, in patients with disseminated disease or ophthalmic zoster, admission is indicated for intravenous acyclovir.

Intertriginous infections with either *Candida* or *Trichophyton* are often seen in patients with HIV and can be diagnosed by microscopic examination of potassium hydroxide preparations of lesion scrapings. Treatment includes topical imidazole creams, such as clotrimazole, miconazole, or ketoconazole. Scabies occurs in about 20 percent of HIV-infected patients, but classic intertriginous lesions are less common. Any patient with a scaly, persistent pruritic eruption should have lesions scraped and examined histologically for scabies mites. Treatment is with permethrin 5% cream or lindane lotion. Human papillomavirus infections occur with increased frequency in immunocompromised patients. Treatment is cosmetic or symptomatic and may include cryotherapy, topical therapy, or laser therapy. Other dermatologic conditions that occur with increased frequency among HIV-infected patients include psoriasis, atopic dermatitis, and alopecia. Referral for dermatologic consultation is appropriate.

Constitutional Symptoms and Febrile Illnesses

OVERVIEW   Systemic symptoms, such as fever, weight loss, and malaise, are common in HIV-infected patients and account for the majority of HIV-related emergency department presentations.[12] In the emergency department, systemic infection and malignancy must be excluded. Appropriate laboratory investigation may include electrolyte determinations, complete blood count, blood cultures (aerobic, anaerobic, and fungal), urinalysis and culture, liver function tests, chest radiograph, and serologic testing for syphilis, cryptococcous, toxoplasmosis, and coccidioidomycosis. Lumbar puncture may also be considered if there are neurologic signs or symptoms or unexplained fever.

When evaluating fever in patients with late-stage HIV and AIDS, it is important to remember that this population may not manifest the typical signs and laboratory findings associated with systemic infection. Clinical impression is therefore critical for determining appropriate disposition; ill-appearing patients should receive fluid resuscitation and empiric antibiotics in the emergency department and then be admitted for further evaluation and management. Outpatient evaluation and treatment may be attempted only when all of the following conditions are met: the source of the fever does not dictate admission, appropriate laboratory studies have been initiated, the patient is able to function adequately at home (e.g., can maintain sufficient oral intake, etc.), and appropriate and timely medical follow-up can be arranged.

COMMON CAUSES OF SYSTEMIC ILLNESS AND FEVER   Although fever may indicate any of a variety of infections (including bacterial, fungal, viral, and protozoal pathogens), the most common causes in the HIV-infected population are HIV-related fever, non-Hodgkin's lymphoma, and systemic infections, such as *M. avium* complex, CMV, and infective endocarditis. Fever caused by HIV infection alone tends to occur in the afternoon or evening and is generally responsive to antipyretics.

Most non-Hodgkin's lymphomas in the HIV-infected population are high-grade B-cell tumors that present with a rapidly growing mass lesion. New CNS symptoms, particularly a change in mental status in the presence of fever, should be evaluated with neuroimaging. Definitive diagnosis requires biopsy. Radiotherapy and chemotherapy are effective treatment regimens.

Disseminated *M. avium* complex is the most common opportunistic bacterial infection in AIDS patients, causing disseminated disease in up to 50 percent of patients at some time during their illness. Infection occurs predominantly in patients with CD4 counts of 100 cells/μL or less. Persistent fever and night sweats are typical. Associated symptoms include weight loss, diarrhea, malaise, and anorexia. Dissemination to the bone marrow, liver, and spleen result in the common associated laboratory findings of anemia and elevated alkaline phosphatase levels. Diagnosis may be made by acid-fast stain of stool or other body fluids, or by blood culture. *Mycobacterium avium* complex cannot be eradicated, but clarithromycin combined with ethambutol and rifabutin have been shown to significantly reduce bacteremia and improve symptoms.

CMV is the most common cause of serious opportunistic viral disease in HIV-infected patients. Disseminated disease commonly involves the gastrointestinal or pulmonary systems. The most important manifestation is retinitis (see below). Treatment is with foscarnet or ganciclovir; oral ganciclovir can be used for prophylaxis.

Fever in injected drug users should always raise concern for infective endocarditis. Previous studies have failed to identify reliable clinical or laboratory predictors of this disease. The current standard of care, therefore, is to admit all febrile injected drug users and await the results of blood cultures, due to the significant morbidity and mortality rates of missed endocarditis and the difficulties associated with outpatient follow-up in the population.

Psychiatric Disorders

Epidemiologic studies of patients infected with HIV and AIDS show a high lifetime prevalence of psychiatric disorders compared to the general population. Persons at highest risk for HIV infection (i.e., injected drug users and homosexual men) frequently suffer from mood disturbances prior to contracting HIV. Infection with HIV produces brain injury and is associated with a variety of CNS and metabolic disturbances that can produce psychiatric symptoms. HIV infection is also a significant psychosocial stressor, leading to social isolation, poverty, and hopelessness.

Evaluation of psychiatric symptoms in the emergency department should focus on an aggressive search for underlying organic causes of the acute presentation. [19] Delirium suggests the presence of a primary physiologic disease; the workup should include laboratory studies, neuroimaging, and lumbar puncture. The differential diagnosis includes CNS and toxic-metabolic derangements. Frequently, a period of observation may be required if a patient is found to be intoxicated or experiencing withdrawal symptoms.

AIDS psychosis is poorly understood. Patients may present with psychiatric symptoms, such as hallucinations, delusions, or other abnormal behavioral changes. The cause is unclear, and treatment has been identical to that for other psychoses. Acute episodes require admission.

Depression occurs in 20 percent of patients, most commonly in those with lower CD4 counts.[20] Depressive illnesses are often responsive to hospitalization and psychosocial intervention. Antidepressant therapy may be considered if symptoms of depression continue longer than 2 weeks. However, due to the increased propensity to develop medication side effects, close patient monitoring is required. Patients with suicidal ideation usually require inpatient psychiatric management.

An increased incidence of mania is observed in both the early and late stages of HIV. Late-stage mania is closely associated with dementia and carries a poor prognosis.

Management of HIV-positive patients with psychiatric complaints must include attention to violent behavior and suicidality. Assessment and stabilization may require physical restraints and acute pharmacologic intervention. Neuroleptics and benzodiazepines may be used in combination. Haloperidol and diazepam are often used; alternatives include droperidol (which has a rapid onset and short half-life) and lorazepam (which offers improved intramuscular absorption). [21]

Ophthalmologic Manifestations

Seventy-five percent of patients with AIDS develop ocular complications. Although a wide range of ophthalmic diseases occur, recognition of a few is most critical. [22]

The most common ophthalmic finding in patients with AIDS is retinal microvasculopathy, which is characterized by retinal cotton-wool spots identical in appearance to those of diabetes or hypertension. Retinal microaneurysms are also seen, primarily in the periphery. These lesions are believed to be incidental and do not cause visual disturbances. The diagnostic dilemma is to distinguish these findings from early CMV infection, and ophthalmologic consultation is recommended.

CMV retinitis is the most frequent and serious ocular opportunistic infection and the leading cause of blindness in AIDS patients. The prevalence is estimated to be up to 40 percent. Visual loss and blindness occur in all cases without early detection and prompt treatment. [23] The presentation of CMV retinitis is variable. It may be asymptomatic early on but later causes changes in visual acuity, visual field cuts, photophobia, scotoma, or eye redness or pain. Findings on indirect ophthalmoscopy are characteristic, with fluffy white perivascular lesions and areas of hemorrhage within them. First-line treatment (5 mg/kg q8h for 14 to 21 days and then 6 mg/kg/day either oral or intravenous). Even with treatment, there are frequent relapse and progression of disease, with 10 percent of affected patients ultimately going blind. [22]

Herpes zoster ophthalmicus usually presents with paresthesia and discomfort in the distribution of cranial nerve V $_1$, followed by the appearance of the typical zoster skin rash. Ocular complications include conjunctivitis, episcleritis, iritis, keratitis, secondary glaucoma, and, rarely, retinitis. Early recognition and treatment is essential to prevent ocular damage. In immunocompetent patients, oral acyclovir may be used in consultation with an ophthalmologist. Immunocompromised patients

should receive intravenous therapy. Close follow-up with reexamination should be arranged for all outpatients.

A variety of lesions can affect the areas around the eye in HIV patients, most notably Kaposi's sarcoma and molluscum contagiosum. Patients with such lesions may be referred to an ophthalmologist for local excision or cryotherapy.

Cardiovascular Manifestations

Clinically significant cardiac disease among AIDS patients is uncommon. Findings such as pericardial effusion, cardiomyopathy, and congestive heart failure are frequently reported at autopsy but are often clinically silent.

Renal Manifestations

Renal insufficiency among AIDS patients may be secondary to prerenal azotemia, drug nephrotoxicity, or HIV-associated nephropathy, which may cause chronic renal insufficiency due to focal and segmental glomerulosclerosis. Renal tubular acidosis is common and may explain a finding of hyperchloremic metabolic acidosis. Management decisions should be made in conjunction.

Sexually Transmitted Diseases

Sexually transmitted diseases are epidemiologically associated with HIV infection. Diseases that cause genital ulcers, such as herpes, chancroid, and syphilis, are believed to provide vascular portals of entry for HIV. Prevalence studies demonstrate a three- to fivefold increased odds ratio of HIV seropositivity in patients with genital ulcers.[24] A similarly increased risk of HIV infection has recently been found among patients with gonorrhea and chlamydial infections. These studies, along with recent emergency-department-based prevalence surveys, have led to a recommendation for increased surveillance of sexually transmitted diseases as a means of controlling HIV transmission.[25,26] All patients with symptoms suggestive of sexually transmitted disease should be tested for gonorrhea, chlamydia, and syphilis. Primary (chancre) and secondary (rash, mucocutaneous lesions, and adenopathy) syphilis should be treated with a single intramuscular dose of benzathine penicillin, 2.4 million units. For latent syphilis or unknown duration of secondary syphilis, three weekly injections are recommended. Any patient with known or suspected syphilis should be evaluated for the possibility of neurosyphilis, which is known to have an increased incidence in the HIV-infected population. Therapy for other sexually transmitted diseases is based on current CDC guidelines (see Chap. 137, "Sexually Transmitted Diseases").

Drug Reactions

A recent series found that 3 to 5 percent of emergency department visits by symptomatic HIV-positive patients were related to complications of pharmacologic therapy.[12] That incidence is likely to increase as the number of new antiretroviral drugs and various combination therapies being prescribed continues to increase.

Table 139-7 illustrates common side effects of medications frequently prescribed for HIV-infected patients. Review of current reference sources and consultation with a hospital pharmacologist and an infectious disease specialist are indicated when drug reactions are suspected.

TABLE 139-7   Common Drug Reactions Seen in HIV-Infected Patients

Immunizations of HIV-Infected Patients

According to the US Public Health Service Immunizations Practices Advisory Committee, HIV-infected persons should not receive live virus or live bacteria vaccines. Killed vaccines pose no danger to immunosuppressed patients.[27] Since symptomatic HIV-infected persons have a suboptimal response to vaccines, all single-dose vaccines are advised to be given as early as possible in the course of HIV infection.[27]

Table 139-8 summarizes the CDC recommendations for common immunizations. Pneumococcal vaccine is recommended for all patients over 2 years of age. Tetanus-diphtheria vaccine is recommended as a booster every 10 years for those who have completed primary series. The measles-mumps-rubella vaccine is contraindicated because measles is a live vaccine with reported serious reactions in HIV-infected patients. Hepatitis B vaccine is recommended for all high-risk individuals, including injected drug users, sexually active homosexual men, and sexually active men and women with sexually transmitted diseases or more than one sexual partner in the past 6 months. Patients should be referred to a primary care provider for routine immunization.

Vaccine	Asymptomatic	Symptomatic
Diphtheria-pertussis-tetanus (to age 7)	Yes	Yes
Tetanus-diphtheria	Yes	Yes
Oral poliovirus	No	No
Inactivated polio vaccine	Yes	Yes
Measles-mumps-rubella	No	No
Haemophilus influenzae B conjugate	No (but not contraindicated)	No (but not contraindicated)
Pneumococcal	Yes	Yes
Influenza (inactivated)	No (but not contraindicated)	No (but not contraindicated)

TABLE 139-8   Immunization Recommendations for HIV-Infected Patients

Antiretroviral Therapy

Treatment of patients with HIV has changed substantially in the past several years due to the introduction of potent antiretroviral agents. In 1996, a decline in the number of new AIDS cases and AIDS-related deaths was seen for the first time since the beginning of the epidemic, attributed in large part to the use of these new medications.[2] Extended survival has been linked to dramatic decreases in the incidence of new opportunistic events.

The first antiretroviral agent discovered to have clinical efficacy was zidovudine (AZT) (Retrovir). AZT is a thymidine analog that inhibits HIV replication by interfering with the action of viral RNA-dependent DNA polymerase (reverse transcriptase). This agent is effective in delaying progression to AIDS and decreasing mortality rates

for patients with AIDS. These trends are associated with changes in the host immune response demonstrated by increased CD4 cell counts and reduced risks of opportunistic infections. Combination therapy with two nucleoside reverse transcriptase inhibitors and a protease inhibitor results in maximal response of the immune system.[28] Eleven antiretroviral agents are currently licensed for use in HIV infection, and this number is likely to increase in the near future.

The goal of antiretroviral therapy is to reduce HIV viremia as much as possible for as long as possible. The best time to start therapy and the best drugs to use are not known with certainty, and treatment strategies will continue to evolve. General guidelines include initiation of antiretroviral therapy in persons with CD4 cell counts of less than 500 cells/μL. However, therapy must be tailored to individual patients with attention to suppression of viral replication, preservation of immune function, drug side effects, drug interactions, and the patient's preference. Education and counseling also constitute an integral part of antiretroviral therapy. For these reasons, decisions regarding initiation of and changes in antiretroviral therapy should always be made in consultation with the primary care physician and an infectious disease consultant.

ETHICAL CONSIDERATIONS

Many ethical considerations are involved in testing and treatment of HIV-infected patients. While emotionally driven sentiment has advocated on-site emergency department HIV testing, there is no rationale at this time for widespread emergency-department-based testing. Many departments have adopted strict policies against such testing due to the difficulties of ensuring adequate confidentiality, follow-up, and counseling. However, emergency-department-based voluntary HIV screening and counseling programs may play an important role in the national strategies of early HIV detection in the future, due to limitations of health care access for many at risk.[29] At present, recommendations for testing and referral to designated test sites should be made when indicated.

Confidentiality regarding HIV-related diagnoses is paramount in providing appropriate care. Treatment without discrimination, as with all disease states, should be initiated in all patients unless they specifically request otherwise.

Resuscitation of patients with advanced AIDS is a controversial subject, but in reality, decision making is no different than for other debilitating conditions. Since emergency department physicians often have limited information about individual patients, their wishes, and the state of their disease, it is recommended that appropriate therapy and resuscitative measures be undertaken unless advance directives are available. There is, however, a growing consensus not to undertake "futile" resuscitation. Care should be taken that the label *HIV* or *AIDS* does not bias the judgment that resuscitation is futile. Contact with a patient's primary care physician and family early during the emergency department stay helps in decision making about care.

Management of patients with possible sexual, injected drug use, or other nonoccupational exposure to HIV has become relevant since the US Public Health Service issued a recommendation for the use of antiretroviral drugs to reduce the risk of acquisition of HIV following occupational exposure (see below). [30] The CDC has withheld making definitive statements regarding postexposure prophylaxis (PEP) for nonoccupational exposures because of the lack of data available regarding the use of antiretroviral agents in this setting. PEP must therefore be considered on a case-by-case basis and should generally be restricted to situations in which the risk of infection is high, the intervention can be initiated promptly (<36 h), adherence to the regimen is likely, and the individual is most likely to maintain risk-reduction behavior over time.[31] Advantages of therapy must also be carefully balanced with the risk of medication side effects. In the emergency department, when the physician is faced with a case in which PEP is being considered, the assistance of experts should be sought. Risks and benefits of therapy should be considered in consultation with an infectious disease specialist and the patient's primary care provider. The CDC has a 24-h telephone hotline for physicians designed to assist with appropriate initiation of PEP (PEP Hotline 1-888-448-4911).

PRECAUTIONS FOR HEALTH CARE WORKERS

Health care workers are often exposed to the blood and body fluids of HIV-infected patients or patients at high risk of harboring the HIV virus. Emergency-department-based studies have demonstrated that substantial numbers of patients continue to have unsuspected HIV infection and that HIV seropositivity cannot be accurately predicted, even with the aid of risk factors assessment.[9] Universal precautions should be practiced, and all contacts with blood or body fluids should be considered potentially infectious. Universal precautions include gloves, gown, mask, and eye protection for any situation with the potential for exposure by splash, spray, touch, puncture, or immersion. These measures are also indicated for all emergency department procedures, including examination of bleeding patients, chest tube placement, central line placement, suturing, wound care, and lumbar puncture.[32]

The risk of acquiring HIV through occupational exposure is low. The likelihood of contracting AIDS after a parenteral exposure has been estimated at 0.32 percent; for mucocutaneous exposure, risk is considered to be at least one-tenth of that. Approximately 80 percent of documented occupational exposure cases have resulted from hollow-bore needle-stick injuries. As of December 1997, the CDC had documented 54 cases of HIV seroconversion following occupational exposure.

Guidelines for PEP of health care workers following an occupational exposure are based on a recent case-control study of needle-stick injuries from an HIV-infected source (which included 33 cases who seroconverted and 739 control subjects). This study reported that AZT prophylaxis was associated with a 79 percent reduction in disease transmission.[33] PEP recommendations for health workers are based on exposure category, and PEP should be administered in consultation with an infectious disease specialist. The highest-risk injuries are deep punctures and injuries caused by large-bore hollow needles. PEP should be initiated as quickly as possible, preferably within 1 to 2 h. The interval after which there is no benefit for starting PEP is not known, although animal studies suggest little benefit if started 24–36 hours after exposure. Antiretroviral therapy can be given for patients presenting more than 36 h after exposure, depending on the risk of transmission. Treatment regimens vary by type of exposure. All include AZT and lamivudine (3TC); indinavir (Crixivan) or nelfinavir (Viracept) is added for high-risk exposures. PEP should probably be given for 4 weeks. However, GI and constitutional side effects can be considerable.

DISPOSITION

Consultation with an infectious disease specialist and sometimes others with expertise in HIV is often necessary to provide proper therapy and disposition. Disposition decisions, as for all patients, are based on the need for definite inpatient evaluation or management and determination of the patient's ability to function as an outpatient (with special consideration regarding oral intake, ambulation, and availability of appropriate medical follow-up). General considerations for admission and discharge are given in Table 139-9.

Conditions Suggesting Admission	Conditions Suggesting Discharge
New presentation of fever of unknown origin	Normal or baseline vital signs
Hypoxemia (worse than baseline, Pₐₒ₂ < 60)	Stable medical condition
Suspected PCP	Able to take PO/not antiemetic
Suspected tuberculosis	Follow-up and referral arranged
New CNS symptoms	Patient or care giver understands instructions
Intractable diarrhea	Patient, home care giver, or hospice able to care for patient
Suicidal ideation	
Suspected CMV retinitis	
Herpes zoster ophthalmicus	
Cachexia, weakness	
Unable to care for self or receive adequate care	
Unable to attain appropriate follow-up

140 TETANUS

Donna L. Carden

EPIDEMIOLOGY

Tetanus is an uncommon disease in the United States but remains a major health problem worldwide and an important cause of infant mortality in developing countries.[1] The institution of effective and widespread immunization programs for children and routine boosters in adults has resulted in a decline in the average annual incidence of tetanus in the United States from 0.39 per 100,000 persons in 1947 to the current annual incidence of 0.02 per 100,000. [2] Although tetanus is probably underreported in the United States,[3] the incidence of the disease in this country remains considerably less than the global incidence of 18 per 100,000. [1] In the United States, the majority of tetanus occurs in temperate areas, with the states of Texas, California, and Florida responsible for the greatest number of reported cases (34, 20, and 13, respectively).[4] The overall case-fatality rate for tetanus in the United States is about 11 percent where the outcome is known, 2.3 percent among those aged 20 to 39 years; 16 percent among those aged 40 to 59, and 18 percent among those aged 60 years or older. [4] From 1995 to 1997, among the 124 cases reported in the United States, only 13 percent of patients had received a primary series of tetanus toxoid, and only half of those who sought medical care were given toxoid.[4] Intravenous drug users, especially Hispanics in California, are at disproportionate risk of contracting the disease. [4]

PATHOPHYSIOLOGY

Tetanus is an acute, often fatal disease caused by wound contamination with *Clostridium tetani,* a motile, nonencapsulated anaerobic gram-positive rod. *Clostridium tetani* exists in either a vegetative or a spore-forming state. The spores of this organism are ubiquitous and extremely resistant to destruction, surviving in soil or on environmental surfaces for years. *Clostridium tetani* is usually introduced into a wound in the spore-forming, noninvasive state but can germinate into a toxin-producing, vegetative form if tissue is compromised and tissue oxygen tension is reduced. Any factor that lowers the local oxidation-reduction potential, such as the presence of crushed, devitalized tissue, a foreign body, or the development of suppuration, favors the development of the vegetative, toxin-producing form of *C. tetani.*[5]

Once converted into the vegetative form, *C. tetani* produces two exotoxins: tetanolysin, which appears to be clinically insignificant; and tetanospasmin, a potent neurotoxin that is responsible for all the clinical manifestations of tetanus. Although the infection caused by *C. tetani* remains localized at the site of injury, tetanospasmin reaches the nervous system by hematogenous spread of the exotoxin to peripheral nerves and by retrograde intraneuronal transport. Bloodborne tetanospasmin does not cross the blood-brain barrier, but retrograde intraneuronal transport of the exotoxin enables tetanospasmin to gain access to the central nervous system.[1]

Tetanospasmin acts on the motor end plates of skeletal muscle, in the spinal cord, in the brain, and in the sympathetic nervous system. This extremely potent exotoxin prevents the release of the inhibitory neurotransmitters glycine and g-aminobutyric acid (GABA) from presynaptic nerve terminals, releasing the nervous system from its normal inhibitory control. [6]

CLINICAL FEATURES

With the advent of routine immunization of children in the United States, tetanus has become a disease of the elderly, who are particularly susceptible to tetanus due to failure to receive primary immunization or the recommended decennial immunizations. In fact, the majority of Americans over age 70 lack adequate immunity to tetanus.[7,8]

The exotoxin tetanospasmin is responsible for the clinical manifestations of tetanus, which consist of generalized muscular rigidity, violent muscular contractions, and instability of the autonomic nervous system. Wounds that become infected with toxin-producing *C. tetani* are most often puncture wounds[2] but vary in severity from deep lacerations to minor abrasions. [2,5] Tetanus can also develop after surgical procedures, otitis media, and abortion and can develop in neonates through infection of the umbilical cord and in intravenous drug users.

The incubation period of tetanus, that is, the period from initial inoculation to the onset of symptoms, can range from less than 24 h to longer that 1 month. The shorter the incubation period, the more severe is the disease and the worse is the prognosis for recovery. [1]

Clinical tetanus can be categorized into four forms: local, generalized, cephalic, and neonatal. The different categories of clinical tetanus depend on what population of neurons are involved.

Local tetanus is manifested by persistent rigidity of the muscles in close proximity to the site of injury and usually resolves after weeks to months without sequelae. Local tetanus may progress to the generalized form of the disease.

Generalized tetanus is the most common form of the disease and frequently follows a puncture wound to the foot from a nail.[2] Of those patients who seek medical care for their initial injury, the majority (more than 90 percent) do not receive appropriate tetanus prophylaxis. [2]

The most frequent presenting complaints of patients with generalized tetanus are pain and stiffness in the masseter muscles (lockjaw). [9] Nerves with short axons are affected initially; therefore, symptoms appear first in the facial muscles, with progression to the neck, trunk, and extremities. [9] The transition from muscle stiffness to rigidity leads to the development of trismus and the resultant characteristic facial expression: *risus sardonicus* (sardonic smile) (Fig. 140-1). Reflex convulsive spasms and tonic contractions of muscle groups are responsible for the development of dysphasia, opisthotonos (Fig. 140-2), flexing of the arms, clenching of the fists, and extension of the lower extremities. Patients are completely conscious and alert unless laryngospasm and tonic contraction of the respiratory muscles result in respiratory compromise.

FIG. 140-1. *Risus sardonicus* (sardonic smile) of tetanus. (From photograph reproduced with permission from the Immunization Action Coalition.)

FIG. 140-2. *Opisthotonos* of tetanus. (From photograph reproduced with permission from the Immunization Action Coalition.)

Disturbances of the autonomic nervous system, generally a hypersympathetic state, occur during the second week of clinical tetanus and present as tachycardia, labile hypertension, profuse sweating, hyperpyrexia, and increased urinary excretion of catecholamines. [10] The autonomic complications of generalized tetanus are particularly difficult to manage and contribute significantly to the morbidity and mortality of the disease.

Cephalic tetanus follows injuries to the head or occasionally otitis media and results in dysfunction of the cranial nerves, most commonly the seventh. This form of tetanus has a particularly poor prognosis.

Neonatal tetanus is an important cause of infant mortality in developing countries and carries an extremely high mortality rate (greater than 90 percent). [9] Because passive immunity from maternal antibodies protects an infant from tetanus, neonatal tetanus occurs only if the mother is inadequately immunized. Most cases of neonatal tetanus arise from unsterile handling of the umbilical stump.

Infants with neonatal tetanus present with weakness, irritability, and an inability to suck in week 2 of life. [1] Tetanic spasms, rigidity, opisthotonic posturing, and a hypersympathetic state develop later. [1]

DIAGNOSIS

Tetanus is diagnosed solely on the basis of clinical evidence. Most patients who develop the disease either have an unknown or inadequate immunization history. [2] Tetanus should be immediately suspected in older patients with a puncture wound who present with pain or stiffness in the masseter muscles.

There are no laboratory tests to diagnose tetanus, although serum antitoxin titers of ³0.01 IU/mL are usually protective and may be helpful retrospectively. Wound culture is of limited value, since *C. tetani* may be present in the absence of clinical signs or symptoms of tetanus and cultures are positive in fewer than 50 percent of patients with documented disease. [5,11]

The differential diagnosis of tetanus is presented in Table 140-1. Strychnine poisoning most closely mimics the clinical picture of generalized tetanus.

Strychnine poisoning
Dystonic reaction (phenothiazines, metoclopramide)
Hypocalcemic tetany
Peritonsillar abscess
Peritonitis
Meningeal irritation (bacterial meningitis, subarachnoid hemorrhage)
Rabies
Temporomandibular joint disease

TABLE 140-1   Differential Diagnosis of Tetanus

TREATMENT

Patients with tetanus should be managed in an intensive care unit. Respiratory compromise may require immediate neuromuscular blockade and orotracheal intubation, but tracheostomy provides the best method of prolonged ventilatory control. Environmental stimuli must be minimized to prevent the precipitation of reflex convulsive spasms.

Identification and debridement of the wound through which the clostridial spores were introduced are necessary to minimize further toxin production and to improve the oxidation-reduction potential of the infected tissue. A wound may not be identified in up to 10 percent of patients with tetanus.

Tetanus Immune Globulin

Human tetanus immune globulin (TIG) neutralizes circulating tetanospasmin and toxin in the wound but not toxin that is already fixed in the nervous system. Even though TIG does not ameliorate the clinical symptoms of tetanus, there is evidence that its administration significantly reduces mortality. [12] In a study of 545 cases of tetanus, Blake and colleagues reported that 500 IU was as effective as larger doses of TIG in reducing tetanus-induced mortality. [12] TIG should be administered intramuscularly opposite the site of tetanus toxoid administration. It should be given before wound debridement, since exotoxin may be released during wound

manipulation.[11] Repeated doses of TIG are unnecessary, since the half-life of the antitoxin is 28 days. [9]

Antibiotics

Antibiotics, although of questionable utility in the treatment of tetanus, have traditionally been administered. *Clostridium tetani* is sensitive to a number of antibiotics (e.g., penicillins, cephalosporins, tetracycline, and erythromycin), but parenterally administered metronidazole should be considered the antibiotic of choice. [13] Penicillin, a centrally acting GABA$_A$ antagonist may potentiate the effects of tetanospasmin, and therefore its use should be avoided. [1]

Muscle Relaxants

As already noted, tetanospasmin prevents neurotransmitter release at inhibitory interneurons, and therapy of tetanus is aimed at restoring normal inhibition. The benzodiazepines are centrally acting inhibitory agents that have been used for this purpose. Diazepam has been extensively utilized and results in a desirable degree of sedation as well as amnesia. However, the large intravenous doses of benzodiazepines required in tetanus may result in metabolic acidosis secondary to the propylene glycol vehicle. Thus, the water-soluble agent, midazolam, is currently the preferred agent for producing muscle relaxation in patients with tetanus. [9] Other drugs have been used less frequently but are effective muscle relaxants in the treatment of tetanus. Baclofen is a specific GABA$_B$ agonist that restores central inhibition and muscle relaxation when administered intrathecally in patients with tetanus. [14] Dantrolene blocks the release of calcium from sarcoplasmic reticulum and has been used to treat tetanus-induced muscle spasms.[15] However, prolonged use (i.e., use for longer than 60 days) is associated with hepatoxicity.

Neuromuscular Blockade

To control ventilation and muscular spasms as well as to prevent fractures and rhabdomyolysis, prolonged neuromuscular blockade may be required in the treatment of tetanus. Succinylcholine is recommended for emergency airway control, while vecuronium is the neuromuscular blocking agent of choice for prolonged blockade because of its minimal cardiovascular side effects. [16] Concomitant sedation with barbiturates or benzodiazepines is mandatory.

Treatment of Autonomic Dysfunction

The combined a- and b-adrenergic blocking agent labetalol has been successfully used to treat the manifestations of sympathetic hyperactivity in tetanus. However, several investigators have reported fatal cardiovascular complications in patients treated with b-adrenergic blocking agents alone. [17,18] Adrenergic blocking drugs, although effective in the treatment of the autonomic dysfunction of tetanus, may precipitate dangerous myocardial depression if sympathetic activity transiently diminishes.

Magnesium sulfate inhibits the release of epinephrine and norepinephrine from the adrenal glands and adrenergic nerve terminals, eliminating the source of catecholamine excess in tetanus[19] and providing a rationale for its clinical use. [10] Morphine sulfate has also been demonstrated to be effective in treating the autonomic dysfunction in tetanus[16] by reducing sympathetic a-adrenergic tone and central sympathetic efferent discharge, and by producing peripheral arteriolar and venous dilatation.[9]

Continuous epidural block with bupivacaine provides sympathetic nervous system blockade, muscular relaxation, and analgesia in generalized tetanus. [20] The central a-receptor agonist, clonidine, decreases central sympathetic and peripheral arteriolar tone [21] and has also been used to manage tetanus-induced cardiovascular instability. Finally, it has been suggested that overactivity of the parasympathetic nervous system may contribute to the autonomic instability in patients with tetanus, since many of the clinical manifestations of the disease mimic cholinergic crisis. Evidence supporting this concept is provided by a report that atropine provides cardiac stabilization in patients with severe tetanus. [22]

Active Immunization

Patients who have recovered from tetanus must undergo active immunization, since the disease does not confer immunity. Adsorbed tetanus toxoid (0.5 mL) should be administered intramuscularly at the time of presentation and at 6 weeks and 6 months after injury. Tetanus-diphtheria (Td) should be administered to patients older than 7 years of age,[23] and diphtheria-pertussis-tetanus (DPT) to patients younger than 7 years of age. [24] A summary of the guidelines for active tetanus immunization is presented in Table 140-2. A summary of the management of tetanus is presented in Table 140-3.

141 RABIES

David J. Weber
David A. Wohl
William A. Rutala

Currently, rabies causes an estimated 40,000 to 100,000 deaths each year worldwide.[1] In addition, millions of persons, primarily in developing countries, undergo costly postexposure treatment. In the United States, rabies continues to be endemic in many wild animals. Although human rabies is rare in the United States, postexposure rabies prophylaxis is likely provided to more than 35,000 persons per year.[2] Prevention efforts in the United States are estimated to cost between $230 million and $1 billion dollars.[1]

This chapter briefly reviews the microbiology, epidemiology, clinical presentation, and treatment of rabies. Because animal bites and scratches are commonly seen by primary care and emergency medical physicians, the postexposure management of persons potentially exposed to a rabid animal is reviewed in detail. Comprehensive reviews of rabies have been published in the medical literature [3,4,5,6 and 7] and in standard infectious disease or microbiology textbooks. [8,9,10,11,12 and 13] Current information is available on the "rabies homepage" produced by the Centers for Disease Control and Prevention. [14]

MICROBIOLOGY

Rabies virus is the prototype member of the genus *Lyssavirus,* of the family *Rhabdoviridae,* order *Mononegavirales.*[6] Members of this order have a nonsegmented, negative-stranded RNA genome that is tightly encapsulated into ribonucleocapsid structures. Members of the family *Rhabdoviridae* are grouped on the basis of their conical or bullet shape as visualized by electron microscopy. Their host range includes vertebrates (primarily mammals and fish), invertebrates (primarily arthropods), and plants. The *Rhabdoviridae* that infect animals and humans are divided into two genera, the *Lyssavirus* (Greek *Lyssa,* frenzy) and *Vesiculovirus* (Latin *vesicula,* little bladder).[3] Vesiculoviruses (e.g., vesicular stomatitis virus) cause disease in cattle, swine, horses, and a variety of other vertebrates. [3] Humans occasionally develop infection, which is most commonly characterized by a nonfatal, nonspecific influenza-like viral syndrome.

The rabies group of *Lyssavirus* is comprised of six serotypes, or genotypes, and includes classic rabies virus, Lagos bat virus, Mokola virus, Duvenhage virus, European bat lyssavirus 1, and European bat lyssavirus 2.[6] Rarely have lyssaviruses other than rabies caused human disease (<10 total cases described worldwide).

PATHOPHYSIOLOGY

Once introduced, the initial infection and multiplication occur with local monocytes for the first 48 to 96 h. Subsequently, the virus spreads across the motor end-plate, and ascends and replicates along peripheral nervous axoplasm to the dorsal root ganglia, the spinal cord, and the central nervous system (CNS). Following CNS replication in the gray matter, the virus spreads outward by peripheral nerves to virtually all tissues and organ systems. Viral infection of the salivary glands engenders infectivity of saliva; the infectivity of other body fluids is less well established.

Histologically, rabies is similar to other forms of encephalitis: diffuse and extensive monocellular infiltration with focal hemorrhage and demyelination, predominantly in perivascular areas in the gray matter of the CNS, basal ganglia, and the spinal cord. Negri bodies are the characteristic histologic finding for rabies, which is the site of CNS viral replication. They are eosinophilic intracellular lesions found within cerebral neurons and are highly specific for rabies. Negri bodies are encountered in about 75 percent of proven animal rabies; thus, although their presence is pathognomonic for rabies, their absence does not exclude rabies as a diagnostic possibility.

EPIDEMIOLOGY

Rabies is primarily a disease of animals.[5] The epidemiology of human rabies is a reflection of both the distribution of the disease in animals and the degree of human contact with these animals.[5] In those parts of the world where canine rabies has been controlled (i.e., the United States, Canada, and Europe), dogs account for less than 5 percent of the cases in animals. Where canine rabies has not been controlled (i.e., most developing countries of Asia, Africa, Latin America, and South America), dogs account for 90 percent or more of reported cases in animals. The major wildlife vectors of rabies are: dogs (major vector of rabies throughout the world, particularly Asia, Latin America, and Africa); foxes (Europe, Arctic, and North America); raccoons (eastern United States); skunks (midwestern United States, western Canada); coyotes (Asia, Africa, and North America); mongooses (yellow mongoose in Asia and Africa; Indian mongoose in the Caribbean Islands); and bats (vampire bats from Northern Mexico to Argentina, insectivorous bats in North America and Europe). In 1996, 49 states, the District of Columbia, and Puerto Rico reported 7124 cases of rabies in animals.[15] Wild animals accounted for almost 92 percent of the reported cases: raccoons (50.4 percent); skunks (23.2 percent); bats (10.4 percent); foxes (5.8 percent); and other wild animals including rodents and lagomorphs (2.1 percent). Rabid domestic animals included cats (3.7 percent); cattle (1.8 percent); dogs (1.6 percent); horses and mules (0.65 percent); sheep and goats (0.22 percent); and other animals such as ferrets (0.06 percent).

Animal reservoirs for rabies are found worldwide with the exception of some islands (e.g., Hawaii, Great Britain), Australia, and Antarctica. Rabies infections of mammalian species occur in geographically discrete outbreaks. Disease transmission within an outbreak is primarily intraspecific and involves a single, distinctive rabies variant. The geographic boundaries of current North America reservoirs for rabies are: [6]

1. An expanding reservoir for raccoon rabies that now encompasses the southeastern, mid-Atlantic, and northeastern United States (>3000 cases in 1996).
2. A long-standing reservoir in red and arctic foxes in Alaska, that has spread to include foxes across Canada as far east as Ontario, Quebec, and the upper parts of the northern New England states (usually <100 cases reported each year).
3. Three separate variants that infect striped skunks in long-standing reservoirs in California, the north central states, and the south central states (several thousand cases per year).
4. Two different variants in gray foxes in small but long-standing reservoirs in Arizona and Texas (~10 to 20 cases per year).
5. A recently recognized outbreak of rabies in coyotes in south Texas as a result of spillover infection from domestic dogs in a long-standing reservoir at the Texas-Mexico border.

Transmission of rabies virus usually begins when the contaminated saliva of an infected host is passed to a susceptible host. The most common mode of rabies viral transmission is through the bite of a rabid animal. Other routes of documented transmission have included contamination of mucous membranes (i.e., eyes, nose, mouth), aerosol transmission during spelunking in bat-infested caves or while working in the laboratory with rabies virus, corneal transplants, and iatrogenic infection through improperly inactivated vaccine.[14] Fomites have not been implicated in transmission. The risk of developing rabies following an animal bite or scratch by a rabid animal depends on whether a bite or scratch occurred, the number of bites, the depth of the bites, and the location of the wounds. In the absence of postexposure prophylaxis, the risk ranges from 80 to 100 percent (multiple severe bites around the face), to 15 to 40 percent (single bites), to 5 to 10 percent (superficial bites on the extremities). Contamination of open wounds with saliva carries a risk of approximately 0.1 percent.

The epidemiology of human rabies in the United States between 1946 and 1996 has been well described in a series of reports from the CDC. [15],[16],[17] and [18] In the United States, deaths in humans caused by rabies totaled 99 in the 1950s, 15 in the 1960s, 23 in the 1970s, 10 in the 1980s, and 22 from 1990 through 1996. [18] The median age of these patients was 27 (range: 4 to 82 years of age) and 20 (63 percent) were male. Cases were reported from 20 states; 7 cases (22 percent) were reported from California and 6 from Texas. Eleven patients were exposed to rabies in eight foreign countries. The onset of illness occurred in all months and with no apparent seasonal pattern.

Of the 32 patients that died of rabies between 1980 and 1996, a definite history of animal exposure was identified in only 7 (22 percent); 6 resulted from a dog bite received in a foreign country and 1 was from a bat bite received in the United States. Contact with an animal was identified in 12 persons; 8 with a bat, 2 with a dog, 1 with a cow, and 1 with a cat. For the remaining 13 patients, a potential source of animal exposure was not identified.

Current epidemiologic patterns of rabies in the United States have been summarized as follows: [18] The annual reports of rabies in wildlife far exceed those of rabies in domestic animals; rabies variants in bats are associated with a disproportionate number of infections in humans (53 percent), although bats constitute only about 10 percent of all reported rabies cases in animals annually; most other cases of human rabies diagnosed in the United States are attributable to infections acquired in areas of enzootic canine rabies in outside of the United States; most persons with a case of rabies that originated in the United States have no history of an animal bite; and rabies is diagnosed after death in more than one-third of the latter group.

Bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, rabbits, hares, and other small rodents almost never require antirabies postexposure prophylaxis. This author is at variance with Table 141-2 in that he would treat unprovoked attacks by woodchucks, beavers, and other large rodents.

TABLE 141-2   Rabies Postexposure Prophylaxis Guide[19]

PREEXPOSURE PROPHYLAXIS

Preexposure prophylaxis with rabies vaccine is highly recommended for persons whose recreational or occupational activities place them at risk for acquiring rabies (Table 141-1). Such persons include rabies research laboratory workers, rabies biologics production workers, rabies diagnostic laboratory workers, spelunkers, veterinarians and staff, animal-control and wildlife workers, travelers visiting foreign areas of enzootic rabies for more than 30 days, and veterinary students. Although the initial rabies preexposure vaccine regimen is similar, the need for booster doses, the timing of booster doses, and the need and timing of serologic tests to confirm immunity differ based on the degree of individual risk for exposure to rabies. [19] Emergency medicine health care providers should refer persons at risk for rabies who have not received preexposure prophylaxis to their local physician or health department for appropriate immunization.

TABLE 141-1   Rabies Vaccine: Criteria for Preexposure Immunizations[19]

Preexposure vaccination does not eliminate the need for additional therapy after a rabies exposure, but simplifies postexposure prophylaxis by eliminating the need for human rabies immune globulin (HRIG) and by decreasing the number of doses of vaccine required (see below).

POSTEXPOSURE PROPHYLAXIS

Postexposure prophylaxis is indicated for persons possibly exposed to a rabid animal. Administration of rabies postexposure prophylaxis is a matter of medical urgency, not a medical emergency.[14] All persons presenting with an animal bite or scratch should be evaluated for the presence of a life-threatening condition, such as arterial laceration, pneumothorax, or respiratory compromise. Appropriate emergency care for animal bites should be provided. [20] Key aspects include tetanus prophylaxis, wound cleansing, measures to prevent bacterial infection, and evaluation for rabies prophylaxis. Cleansing of the wound with a 20% solution of soap and water is an essential first step in rabies prevention. In experimental animals, simple wound-cleansing has been shown to markedly reduce the likelihood of rabies.

All persons bitten or scratched by an animal, whether domestic or wild, should be evaluated for the need to initiate rabies postexposure prophylaxis. The decision to initiate rabies postexposure prophylaxis should be based on the following: [14] geographical location of the incident; the type of animal that was involved; and how the exposure occurred (i.e., provoked or unprovoked), the vaccination status of the animal, and whether the animal can be safely captured and tested for rabies (Table 141-2; Fig. 141-1). Excellent guidelines are often available from the local health department. For the purpose of rabies postexposure prophylaxis, a bite exposure is defined as any penetration of the skin by the teeth of an animal. Bites to the face and hands carry the highest risk, but the site of the bite should not influence the decision to begin therapy.[19] Scratches, abrasions, open wounds, or mucous membranes contaminated with saliva or other potentially infectious material (such as brain tissue) from a rabid animal constitute nonbite exposures. If the material containing the virus is dry, the virus can be considered noninfectious. A fully vaccinated dog or cat is unlikely to become infected with rabies, although rare cases have been reported among animals that had received only a single dose of vaccine. No documented vaccine failures have occurred among dogs or cats that had received two vaccinations.

FIG. 141-1. Clinical guidelines for administration of rabies postexposure prophylaxis. FAT, fluorescent antibody test; HRIG, human rabies immune globulin. (Adapted from Mann JR: Rabies risk: Systemic evaluation and management of animal bites. *Compr Ther* 7:53, 1981. Used with permission.)

Other contact by itself, such as petting a rabid animal and contact with blood, urine, or feces (e.g., guano) of a rabid animal, does not constitute an exposure and is not an indication for prophylaxis.[19] Local health departments may vary in their recommendations for salivary exposure, however. Apart from corneal transplantation, bite and nonbite exposures inflicted by infected humans could theoretically transmit rabies, but no such cases have been documented. Persons with suspected rabies may be managed using "standard precautions."[21]

Bats are increasingly implicated as an important wildlife reservoir for variants of rabies virus transmitted to humans. Minor bites by bats and awakening in a room with a bat have been associated with the development of rabies. For this reason, the CDC recommends rabies postexposure prophylaxis for all persons who have sustained a bite, scratch, or mucous membrane exposure to a bat unless the bat is available for testing and is negative for evidence of rabies.[22] Postexposure prophylaxis is also appropriate, even in the absence of a demonstrable bite, scratch, or mucous membrane exposure, in situations in which there is reasonable probability that such contact occurred (e.g., a sleeping person awakens to find a bat in the room or an adult witnesses a bat in a room with a previously unattended child or a mentally disabled or intoxicated person).[22]

The CDC recommends that a healthy dog, cat, or ferret that bites a person should be confined and observed for 10 days.[23] Such animals should be evaluated by a veterinarian at the first sign of illness during confinement. Any illness in the animal should be immediately reported to the local health department. If signs suggestive of rabies develop, the animal should be euthanized, its head removed, and the head shipped under refrigeration (not frozen) for examination of the brain by a qualified laboratory designated by the local or state health department. Any stray or unwanted dog, cat, or ferret that bites a person may be euthanized immediately and the head submitted for rabies examination. Animals other than dogs, cats, or ferrets that might have exposed a person to rabies should be immediately reported to the local health department. Prior vaccination of an animal does not preclude the necessity of euthanasia and testing if the period of virus shedding is unknown for that species.

In the United States, postexposure prophylaxis consists of a regimen of 1 dose of human rabies immune globulin (HRIG) and 5 doses of rabies vaccine over a 28-day period (Table 141-3). Rabies immune globulin and the first dose of rabies vaccine should be given as soon as possible after exposure, preferably within 24 hours. Rabies vaccines available in the United States include human diploid cell vaccine (HDCV) (produced in human diploid cells; Imovax, Pasteur Merieux Connaught), rabies vaccine absorbed (RVA) (produced in fetal rhesus diploid lung cells; Rabies Vaccine Absorbed, SmithKline Beecham), and purified chick embryo cell culture vaccine (PCEC) (produced in chick embryo cells; RabAvert, Chiron).[24] All currently used vaccines are produced in cell culture and are significantly less toxic than older vaccines that were produced in neural tissue. Side effects, including mild erythema, swelling, and pain at the injection site, have been reported among 30 to 74 percent of vaccine recipients. Systemic reactions, such as headache, nausea, abdominal pain, muscle aches, and dizziness, have been reported among 5 to 40 percent of recipients. Serum-sickness-like reactions (type III hypersensitivity) have been noted among approximately 6 percent of persons receiving booster doses of HDCV, 2 to 21 days after administration of the booster dose. Such reactions have not been life threatening and have not been reported with the RVA or PCEC vaccines. Anaphylaxis and neurologic symptoms have only rarely been associated with the current rabies vaccines. Severe egg allergy is a contraindication to the use of the PCEC vaccine. Once initiated, rabies prophylaxis should not be interrupted or discontinued because of local or mild systemic adverse reactions to rabies vaccine.[19] Usually such reactions can be successfully managed with anti-inflammatory and antipyretic agents. When a person with a history of serious hypersensitivity to rabies vaccine must be revaccinated, antihistamines may be given. Epinephrine should be readily available to counteract anaphylactic reactions, and the person should be observed carefully immediately after vaccination.

TABLE 141-3   Type of Treatment and Regimen for Rabies Postexposure Prophylaxis by Vaccination Status[19]

HRIG is administered only once (i.e., at the beginning of antirabies prophylaxis) to provide immediate antibodies until the patient responds to rabies vaccine by producing antibodies. Failure to use HRIG has led to rabies, despite appropriate postexposure prophylaxis with human diploid cell vaccine. If HRIG was not given when vaccination was begun, it can be given through the seventh day after administration of the vaccine.[19] Beyond the seventh day, HRIG is not indicated because an antibody response is presumed to have occurred. The CDC recommends that as much as possible of the full dose be infiltrated around the wound.[22] HRIG should never be administered in the same syringe or into the same anatomic site as the vaccine. Even if the wound has to be sutured, it should be infiltrated locally with HRIG. This practice is safe and does not create an additional risk of infection.[25] However, caution is needed when injecting into a tissue compartment, such as the finger pulp, because excessive HRIG can increase compartment pressure and lead to necrosis.[26]

The CDC recommendations for postexposure prophylaxis should be followed EXACTLY. Although no postexposure prophylaxis vaccine failures have been reported in the United States since HDCV's licensing in 1980, 13 persons outside the United States have contracted rabies after postexposure prophylaxis with tissue culture-derived vaccine.[5] Each of these cases involved deviation from the recommended protocol; wounds not cleansed, passive immunization with HRIG not provided, or rabies vaccine injected into the gluteal rather than the deltoid area.

POSTEXPOSURE PROPHYLAXIS IN SPECIAL CIRCUMSTANCES

Prior Rabies Immunization

If exposed to rabies, persons previously vaccinated should receive two intramuscular doses (1 mL each) of vaccine, one immediately and one three days later.[19] Previously vaccinated refers to persons who have received one of the recommended preexposure or postexposure prophylaxis regimens of HDCV, RVA, or PCEC, or those who have received another vaccine and had a documented rabies antibody titer. HRIG is unnecessary and should not be given in these cases because an

anamnestic antibody response will follow the administration of a booster regardless of the prebooster antibody titer. [27]

Immunocompromised Persons

Immunization of immunocompromised persons presents special challenges. First, vaccines may represent a danger to the immunocompromised person. Second, the immune response of immunocompromised persons to vaccination may not be as good as that of immunocompetent persons; higher doses or additional immunizations may be required, although even with these modifications, the immune response may be suboptimal. The Advisory Committee on Immunization Practices (ACIP) considers these persons severely immunocompromised: congenital immunodeficiency; human immunodeficiency virus (HIV) infection; leukemia lymphoma; aplastic anemia; generalized malignancy; or therapy with alkylating agents, antimetabolites, radiation, or large amounts of corticosteroids. [28]

Because rabies vaccine is formulated with inactivated virus, it does not represent a danger to immunocompromised persons and may be administered to such persons using the standard recommended doses and schedule (Table 141-3).[28] Further, the recommendations for the use of HRIG are the same in immunocompromised and immunocompetent persons.[28] However, corticosteroids, other immunosuppressive agents, and immunosuppressive illnesses can interfere with the development of active immunity and predispose the patient to developing rabies if exposed. Immunosuppressive agents should not be administered during postexposure prophylaxis, unless essential for the treatment of other conditions. When rabies postexposure prophylaxis is administered to persons receiving steroids or other immunosuppressive therapy, it is especially important that serum be tested for rabies antibody to ensure that an adequate response has developed. [28] To test the adequacy of the immune response, serum collected 2 to 4 weeks after the postexposure prophylaxis should completely neutralize challenge virus at a 1:25 serum dilution by rapid fluorescent focus inhibition test (RFFIT). [19]

Travelers

Preexposure prophylaxis is recommended for international travelers based upon the local incidence of rabies in the countries to be visited, the availability of appropriate antirabies biologics, and the intended activity. [29] Such persons include veterinarians, animal handlers, field biologists, spelunkers, and certain laboratory workers. Chloroquine phosphate (and possibly other structurally related antimalarials such as mefloquine, which is administered for malaria chemoprophylaxis) may interfere with the antibody response to rabies vaccine. Always immunize persons receiving antimalarial chemoprophylaxis by the intramuscular route.

Between 1980 and 1996, six persons died in the United States from rabies after having been bitten by a dog while visiting a foreign country. In that same period, three U.S. citizens died in foreign countries from exposure that occurred in the foreign country. For this reason, all persons who have returned from abroad should be questioned regarding whether they received an animal bite or scratch in an area with endemic rabies. Persons bitten or scratched by an animal in an area with endemic rabies should receive appropriate postexposure prophylaxis if the injury has occurred within the known incubation period (which may extend up to five years).
