Thorns, spines, wood splinters, and other vegetative materials require immediate removal because they cause intense and excessive inflammation.[20] Foreign objects that are heavily contaminated, such as fractured teeth and soil-covered objects, should be removed as soon as possible; antibiotic treatment will not take the place of foreign body removal. Glass, metal, and plastic are relatively inert, and removal can be postponed, if necessary. Glass foreign bodies in hands or feet can cause persistent pain with gripping or walking, and they can sever nerves or tendons years after the initial injury. Patients with deep, sharp foreign bodies in these locations should be referred to appropriate specialists for eventual removal.

Sometimes harmless foreign bodies are psychologically distressing to patients, particularly when they are visible under the skin surface or produce a lump. Patient concern may be a justification for elective removal.

Successful removal of foreign bodies requires adequate local or regional anesthesia and good lighting. Depending on location and depth, tourniquet control of bleeding and assistance may be needed. Depth and accessibility of the object and physician time are the limiting factors for removal of foreign bodies by the emergency physician. Foreign bodies buried deeply in adipose tissue or muscle are difficult to locate. Most foreign bodies in hands should be removed because the hand is mobile and sensitive. Deep exploration of hands by the emergency physician is not recommended because magnification and experience are needed to avoid injury to numerous closely spaced vital structures.

The emergency physician may not be able to devote more than about 15 to 30 min to the removal procedure, particularly when other seriously ill or injured patients demand attention. This amount of time is sufficient for locating most foreign bodies. The patient should be informed before the procedure that the duration of the exploration will be limited. If more time is required, the patient should be referred to a surgeon.

Methods of Localization

Accurate localization of a foreign body prior to removal is important because blind searching is time-consuming and can cause further injury. However, it is usually easier to detect the presence of a foreign body than to locate its exact position. If a foreign body is radiopaque, one can estimate its location and depth by taping radiopaque skin markers such as lead circles or paper clips on the skin at the wound entrance or directly over the object. With multiple projections, the object can be seen in relation to the markers. Hypodermic needles can be used as skin markers. Two or three needles are inserted into the skin near the object at approximately 90° to each other to provide a frame of reference around the object. Plain films taken in multiple projections allow the physician to gauge the distance of the object from the closest needle or its distance between two needles.

The limitations of this technique are that it does not provide a true three-dimensional image and that images on radiographs are distorted by divergence and parallax. Tendons and other structures may block the most accessible path to the foreign body. Alternatively, the site of injury can be rotated under fluoroscopy to visualize the object between the markers.[19] Radiation exposure should be minimized by brief, intermittent imaging and appropriate shielding. An incision is made between needles or markers, or dissection is carried along the path of the closest needle.

Specific Foreign Bodies and Removal Procedures

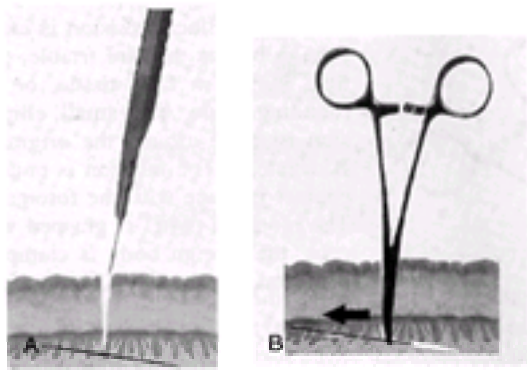
METALLIC NEEDLES   Long, thin foreign bodies such as sewing and hypodermic needles may be difficult to locate in soft tissue. Two techniques are available for removing needles that are parallel to the surface of the skin. If the needle is superficial enough to be palpable, an incision is made at one end to expose and grasp it with a hemostat. If the needle is deep, an incision is made perpendicular to the needle at its midpoint, where it can be clamped with a hemostat and pushed out of the entrance of the original wound (Fig. 42-2).


FIG. 42-2. A. (Plate 4) An incision is made perpendicular to the needle at its midpoint. **B.** The needle is grasped through the incision with a hemostat and backed out of the puncture wound.

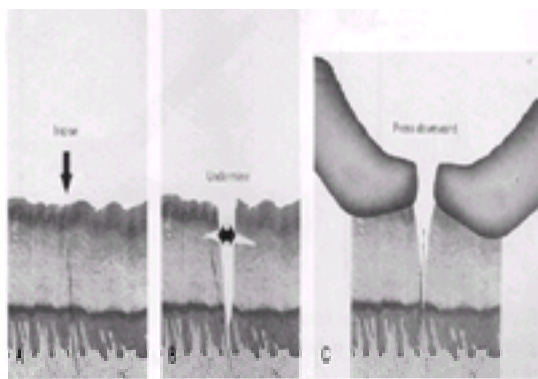
Long, thin foreign bodies that are oriented perpendicular to the skin surface can be elusive. If a needle can be reached with an alligator forceps or hemostat, it can be pulled straight out. If a needle lies beyond the reach of a hemostat, the entrance wound must be enlarged with a skin incision (Fig. 42-3). However, the incision can easily pass to the side of the object, so the skin edges should be undermined, and pressure applied on the skin edges may displace the foreign body into the center of the wound, where it can be seen and grasped. Once removed, the needle and the wound should be inspected to ensure that the object was removed in its entirety.


FIG. 42-3. A. The entrance site is enlarged with a skin incision. **B.** If the incision passes to the side of the object, the skin is undermined. **C.** (Plate 5) Pressure on the skin edges displaces the foreign body into the center of the wound.

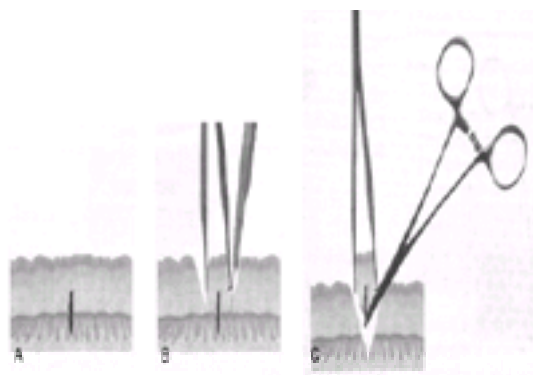
WOOD SPLINTERS AND ORGANIC SPINES   Solid foreign bodies can be pulled out of puncture wounds with forceps, but wood splinters and organic spines (e.g., cactus, sea urchin, and fish) may disintegrate with this technique. Only superficial splinters that are a few millimeters long can be grasped and removed with a fine-point splinter forceps. A splinter parallel to the skin surface should be lifted out of the wound after incising the skin along the long axis of the object (Fig. 42-4). If the splinter is lodged in the subcutaneous tissue, the entrance wound must be enlarged with a skin incision so that the foreign body can be grasped under direct visualization. Wood fragments may be impossible to locate precisely. One solution is to create an elliptical incision around the puncture wound and extract the fragment in a block of tissue (Fig. 42-5). The physician should avoid incorporating nerves, vessels, or tendons within the excised block. Either technique creates a larger wound but allows a better inspection and more thorough cleaning after removal.
FIG. 42-4. To remove a friable foreign body such as a wood splinter that is parallel to the skin surface, an incision is made along its long axis. The object can be lifted out and the entire length of the wound inspected for remnants.


FIG. 42-5. Block excision is effective for foreign bodies that are friable, difficult to find, buried in fatty tissue, or stain surrounding tissue. **A.** A small, elliptical incision is made around the original wound. **B.** (Plate 6) The incision is undercut until contact is made with the foreign body. **C.** The block of tissue is grasped with a forceps, the foreign body is clamped with a hemostat, and both are removed.

Subungual splinters must be removed because subsequent infection is almost inevitable, and the distal phalanx is at risk for osteomyelitis. If the splinter is underneath the distal end of the nail, it can be grasped by a splinter forceps or hooked by a hypodermic needle bent at its tip. More proximal splinters can be reached by anesthetizing the finger and removing a wedge of the nail overlying part of the foreign body (Fig. 42-6). If pieces of the splinter remain, the entire nail can be removed.
FIG. 42-6. Subungual foreign bodies that are beyond the reach of a splinter forceps can be exposed by excising a wedge of the overlying nail.

Numerous, tiny cactus spines in the dermis can be plucked out individually with forceps or extracted together with depilatory wax, professional-quality facial gel, rubber cement, or household glue.[20,21] Larger spines and thorns should be removed with incision or excision techniques.

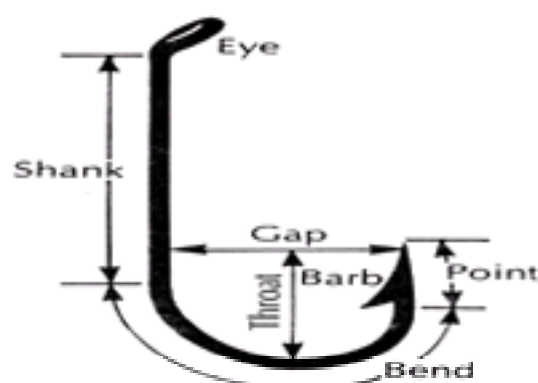
FISHHOOKS   Fishhooks have a variety of sizes and shapes based on a common pattern (Fig. 42-7). The barb, which is a projection extending backward from the point of the hook, keeps the point embedded in the fish's mouth and makes removal from skin a challenging task. Most injuries with fishhooks involve the hand, head, or face.


FIG. 42-7. Anatomy of a fishhook.

Several methods for removing fishhooks in skin have been reported. The best strategy depends primarily on the depth of the hook. If the hook has multiple barbs, precautions should be taken to avoid impaling the treating physician, bystanders, or the patient (a second time) during removal by taping or cutting off the exposed barbs. With any technique, the skin should be prepared and anesthetized at the entry site. If the hook is superficial, gentle downward pressure is placed on the shank while the hook is simply pulled in a retrograde direction along the path of entry (Fig. 42-8).
FIG. 42-8. Simple retrograde technique. While pressing the skin over the tip of the hook to disengage the barb and applying gentle downward pressure on the shank, the physician backs the hook out of the skin. If the barb catches on skin fibers, other techniques must be used.

The *string-pull method* is a variation on the retrograde technique. String is wrapped around the bend of the hook where it enters the skin. The end of the shank is depressed with one hand to disengage the barb from deeper tissue. The other hand then gives a quick pull on the string, extracting the hook (Fig. 42-9). The disadvantages of this technique are that failure can cause further pain to the patient and success can result in ripped tissue or a sharp, blood-contaminated object flying uncontrollably across the room.
FIG. 42-9. String-pull technique. String or suture material is tied to the curve of the hook. The hook is positioned as described in the simple retrograde technique, and a quick pull on the string will dislodge the hook.

The *needle-cover technique* requires physician dexterity. An 18-gauge needle is inserted into the entrance wound alongside the shank of the hook. The needle follows the bend of the hook until the lumen of the needle can be placed over the barb to sheathe it. The hook and needle are then withdrawn from the wound as a unit (Fig. 42-10).
FIG. 42-10. Needle-cover technique. The area is anesthetized, and an 18-gauge needle is inserted into the entrance wound along the hook. The lumen of the needle is placed over the barb to cover it, and both the hook and needle are backed out of the wound.

The *advance-and-cut technique* is another alternative (Fig. 42-11). The tip of the hook is advanced through the skin surface. Once exposed, the point and barb are cut with wire cutters, and the remaining part of the hook is rotated out of the original wound. If barbs along the shank are embedded beneath the dermis, the shank can be clipped near the hook's eye. The remaining part of the hook is then passed antegrade through the skin. Since the advance-and-cut method further traumatizes and contaminates tissue, it probably should be reserved for wilderness situations. However, this may be an effective method in the ED if the barb has nearly or already penetrated the surface of the skin or is embedded within a joint, cartilage, or tendon.
FIG. 42-11. Advance-and-cut technique. The area is anesthetized, and the tip of the hook is advanced through the skin surface **(A)**, the barb is cut **(B)**, and the hook is rotated back out of the original wound **(C)**.

A fifth technique requires the services of a physician but has important advantages over other methods. When the barb penetrates into the dermis, it usually cannot be backed out or pulled out of the wound. In these cases, the entrance wound should be enlarged 2 to 3 mm with a No. 11 scalpel blade. A small incision is carried along the bend of the hook to the barb until the barb is disengaged from the soft tissue. The hook can then be withdrawn easily through the larger entrance (Fig. 42-12). If necessary, the barb can be grasped with a hemostat to prevent it from snagging tissue on the way out. There are two major benefits to enlarging puncture wounds containing foreign bodies. First, the wound is more easily inspected for additional foreign bodies. In the case of fishhook impalement, the wound may be harboring the bait that was on the hook. Second, the wound tract is more easily irrigated through a larger opening. However, the physician must avoid injuring tendons, nerves, or vessels with the scalpel.

FIG. 42-12. Incision technique. The area is anesthetized, and a small incision is made along the shaft of the hook to the barb. The hook is withdrawn through the incision.

TRAUMATIC DERMAL TATTOOING   Foreign particulates may be embedded in the epidermal and dermal layers of skin by an abrasion, which permanently stains or

"tattoos" the surrounding tissue. If vigorous scrubbing does not remove the particulates, the patient can be referred to specialists for dermabrasion or block excision. The graphite from pencil lead can produce a pigmentation that will never dissolve, and graphite tattoos should be excised in cosmetic areas.

DISPOSITION

Postremoval Treatment

After removal of a foreign body, the wound should be irrigated thoroughly. A puncture wound is difficult to clean adequately because either the small wound diameter prevents the irrigation fluid from reaching the wounded tissue or the fluid enters the wound but does not completely drain. If the puncture is contaminated, the entrance wound can be enlarged to allow more effective cleaning. If foreign debris is impregnated in tissue, the contaminated area can be debrided or excised. If multiple radiopaque objects were removed, a postprocedure plain film should be obtained. The decision to close lacerations, incisions, and block excisions depends on the potential for infection; wounds where all foreign contaminants can be removed and those in locations with good blood supply can be closed primarily. Otherwise, delayed primary closure is preferred to immediate closure. Necessary tetanus immunization (TIG and/or Td) should be provided. If a foreign body is deliberately left in place, the patient should be informed. If foreign material was removed, the patient should be warned that there is always a possibility that not all pieces were found.

Delayed Removal

Many patients must be referred to surgical specialists for delayed removal of foreign bodies. It is important to inform the patient that the object is present but unlikely to cause harm before it is removed. The benefit of prophylactic antibiotics for uninfected wounds containing foreign bodies has not been studied. Antibiotics are justified for infected wounds, particularly when removal must be postponed, even though removal allows infections to clear rapidly. If a foreign body is near a joint or highly mobile region, the affected area should be splinted prior to removal to prevent further injury or migration of the object.

43 PUNCTURE WOUNDS AND BITES

Charles A. Eckerline, Jr
Jim Blake
Ronald F. Koury

PUNCTURE WOUNDS

Puncture wounds are usually accidental and usually involve the hands and soles of the feet. [1] Sharp, elongated objects that pierce the skin may penetrate into the deeper tissues, injuring underlying structures, introducing foreign bodies, and planting the inoculum for infection. Organized evaluation and management is necessary to minimize complications.

Pathophysiology

The most common sequela of puncture wounds is infection, which, depending on the location and puncturing instrument, is reported to occur from 6 to 11 percent of the time.[2,3] Infection is more common in puncture wounds than in open lacerations because of inoculation of organisms into the deep tissues, followed by skin closure. Most infections from puncture wounds are due to gram-positive organisms, with *Staphylococcus aureus* predominating, followed by other staphylococcal and streptococcal species. Many other microorganisms have also been isolated from puncture wound infections, including *Aerobacter aerogenes* and *Mycobacterium fortuitum*. Puncture wounds over joints can penetrate through the joint capsule, producing septic arthritis. Penetration to the relatively vascular cartilage, periosteum, and bone can lead to osteomyelitis. *Pseudomonas aeruginosa* is the most frequent pathogen isolated post-puncture wound osteomyelitis, particularly when foreign-body penetration occurs through the sole of an athletic shoe. [4,5] Because this organism is not detected in new shoes, it has been postulated that the foam rubber material becomes colonized in the warm, humid summer months. Post–puncture wound infections are accentuated by the presence of a foreign body, and failure of an infection to respond to antibiotics suggests the presence of a retained foreign body.

Puncture wounds that present soon after injury generally appear simple and innocuous. Appropriate history should be obtained and documented: (1) the time interval since the injury (discomfort at >6 h increases the probability of infection), (2) type and condition of the penetrating object, (3) complete or partial removal of the object, (4) residual foreign-body sensation in the wound, (5) whether footwear was worn (plantar punctures), (6) an estimation of the depth of penetration, (7) whether the injury occurred indoors or outdoors, and (8) potential contamination (rust, dirt, cloth contaminants). A retained foreign body is suggested if the patient reports either the sensation of a retained object or incomplete removal of the penetrating instrument. The incidence of post–puncture wound infection is increased if the patient has decreased resistance to infection from diabetes mellitus, peripheral vascular disease, or immunosuppression. [6] As in the case of any wound, tetanus immunization status should be determined and appropriate prophylaxis performed.

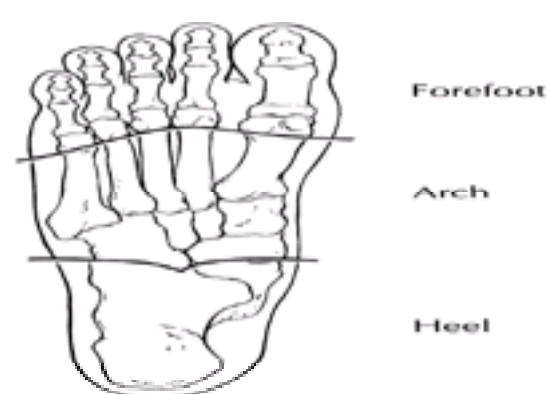
Puncture wounds associated with an increased incidence of infection are those involving (1) more than 6 h from injury to presentation, (2) larger lesions with deeper penetration, (3) obvious contamination with foreign matter and debris, (4) occurrence outdoors, (5) penetration through footwear, (6) puncture of the forefoot, and (7) patients with poor resistance to infection (Fig. 43-1).[7]


FIG. 43-1. The bony and cartilaginous structures in the forefoot region of the sole of the foot are the most prone to development of osteomyelitis after plantar puncture wounds.

Clinical Features

Physical examination of puncture wounds should evaluate and document the wounds as well as the function of underlying structures. In puncture wounds of the hand, distal function of tendons (flexor and extensor), nerves (motor and sensory), and vessels (perfusion) should be assessed. Puncture wounds should be carefully inspected for their location, the condition of the surrounding skin, and the presence of foreign matter, debris, or devitalized tissue. Wound infection is suggested by increased pain, swelling, erythema, warmth, fluctuance, decreased range of motion at joints, or drainage from a wound site.

Because puncture wounds are potentially deep and cannot be easily inspected to their depth, there remains the possibility of a foreign body. Some materials are prone to break, leaving retained fragments behind: these include wood, glass, and plastic and thin objects such as pins and needles. Probing of the wound with a sterile, thin, blunt instrument is common practice to determine the depth of the wound and the presence of foreign body. However, this practice has not been validated in prospective studies. Wound probing is usually harmless and generally useless.

Plain-film radiographs should be obtained in all infected puncture wounds and in any wound suspicious for a retained radiopaque (metal, gravel, and glass) foreign body. Radiopaque foreign bodies greater than 0.5 to 1.0 mm in size will be identifiable in 80 to 90 percent of plain films. Radiographs should be obtained with multiple views and the "soft tissue" technique to maximize detection. Most organic substances—such as wood splinters, cactus spines, thorns, and vegetable matter—have radiodensities close to that of soft tissue and cannot be identified with plain-film radiographs. Ultrasound has been successfully used to identify substances invisible on plain films, although the reported sensitivity, specificity, and accuracy varies widely in experimental studies of this modality. Computed tomography (CT) is the

method of choice for the detection of retained foreign bodies not seen with other techniques, especially wood and plastic. The ability of CT to differentiate densities permits detection of substances previously "invisible" by other imaging modalities. Magnetic resonance imaging (MRI) has excellent ability to differentiate contrast between soft tissues and may be superior to other imaging modalities in the detection of plastics. However, MRI cannot be used to image metallic objects or gravel because of the production of significant ferromagnetic artifacts. CT or MRI should be used if the penetrating object was radiolucent and there is historical or clinical evidence of a retained foreign body.

Treatment

Many aspects of the treatment of puncture wounds remain controversial.[4,8] Uncomplicated, clean punctures presenting less than 6 h after injury require only wound cleansing and tetanus prophylaxis as indicated. Soaking of the wound has no proven benefit. Low-pressure irrigation (e.g., 0.5 psi) of wounds is recommended to assist in cleansing of the wound for better visualization of the entrance site as well as removal of visible foreign matter. The injection of irrigation fluid under high (e.g., 7 psi) pressure into a closed wound tract may lead to displacement of foreign matter secondary to hydrodissection along tissue planes and disseminate bacteria deeper into the surrounding tissue.

Debridement or "coring" of the wound tract in clean wounds is sometimes recommended, but there is no evidence that this procedure reduces the risk of infection, even for plantar puncture wounds. Large objects may produce lacerations that should be anesthetized, explored, irrigated, and debrided. The expertise, time required for the procedure, and postprocedure management may dictate referral to a surgical specialist.

There is no proven benefit to routine prophylactic antimicrobial therapy in the management of clean, nonplantar puncture wounds. In fact, it has been suggested that this practice may actually contribute to the development of secondary infections with gram-negative organisms by altering the normal flora. Puncture wounds in patients with peripheral vascular disease, diabetes mellitus, and immunocompromising disorders are associated with an increased incidence of infection and *may* benefit from antibiotics.[6] Plantar puncture wounds, especially those in high-risk patients, those located in the forefoot, or those through athletic shoes should be treated with antibiotics.[9] The ability of antibiotics to reduce the incidence of wound infections is correlated with the early achievement of antimicrobial blood levels. In the past, this required parenteral (intravenous or intramuscular) administration of both a cephalosporin and an aminoglycoside in the emergency department (ED). The development of fluoroquinolones now provides the physician with a broad-spectrum antibiotic that rapidly achieves high blood levels following an oral dose.[10] Either route is acceptable in plantar puncture wounds; the choice is up to the physician's judgment. Following the initial dose in the ED, the patient should be discharged with an oral regimen. The ideal duration of treatment is not known. A dilemma is posed by plantar puncture wounds through athletic shoes, where infection with *Pseudomonas* has been reported to occur in up to 25 percent. The only oral agents consistently effective against *Pseudomonas* are the fluoroquinolones ciprofloxacin and levofloxacin, and these agents are not approved by the FDA for use in children. The alternative would be hospital admission for intravenous antibiotics. Experience with ciprofloxacin in children with cystic fibrosis indicates a low rate of complications, particularly with short courses. A tentative recommendation can be made for the prophylactic use of ciprofloxacin in children with plantar puncture wounds either in the forefoot or through athletic shoes.

Complications

Infections that develop after puncture wounds can be differentiated into (1) local cellulitis, (2) local abscess, (3) deeper spreading soft tissue infections, and (4) infections of bone or cartilage.

CELLULITIS   A localized inflammation of the dermis surrounding the puncture wound, usually without significant drainage, developing within 1 to 4 days. Distal swelling or swelling opposite the puncture site (e.g., dorsum of the foot when the puncture site is the plantar surface) is not encountered. Pain is generally noted around the puncture site, causing the patient to limit weight bearing on the affected foot.

A local abscess may develop at the puncture site, especially if a foreign body remains. Swelling, fluctuance, and local drainage may be present.

Deeper soft tissue infections also present with painful cellulitis around the puncture site that limits weight bearing on the affected foot; in addition, most patients also have pain and swelling distal to or opposite the puncture site. Serious infections may involve gram-negative and anaerobic bacteria, generating crepitus and a foul order from the site.

Cellulitis from a puncture wound can occur at any site in the foot, as contrasted with bone infections, which are limited to specific regions of the foot. Puncture wounds involving the forefoot pose the highest risk of osteomyelitis. The forefoot is a major weight-bearing region and the underlying bones, as compared with the heel and the arch, have very little overlying soft tissue. Therefore, a puncture wound is more prone to penetrate bone and cartilage in forefoot injuries, predisposing to osteomyelitis.

Patients who present with infections developing after puncture should have plain radiographs taken to detect the possibility of a radiopaque foreign body, soft tissue gas indicating a deeper infection, or the bone changes of osteomyelitis. If the wounding object was radiolucent, a CT scan may be necessary.

With simple cellulitis developing after puncture wounds in otherwise healthy patients, there is no need for routine cultures, and antimicrobial coverage should be directed at gram-positive organisms, especially *S. aureus.* Effective agents include penicillinase-resistant penicillin (e.g., dicloxacillin), first-generation cephalosporins (e.g., cephalexin, cefadroxil), or ciprofloxacin. Local abscesses are treated with incision, drainage, and careful exploration for a retained foreign body. Serious, deep soft tissue infections require surgical exploration and debridement in the operating room.

OSTEOMYELITIS   Bone and joint infections are the most disastrous sequelae of puncture wounds, often resulting in significant long-term morbidity. The overall incidence following plantar puncture wounds is about 4 percent, but this figure increases to nearly 25 percent in patients with forefoot puncture wounds through athletic shoes. Patients with post–puncture wound osteomyelitis or septic arthritis have typically received initial management of their puncture wound and tetanus immunization. Often, antimicrobial agents may have been given prophylactically or for early cellulitis, with a short period of symptomatic improvement that is typically followed by increasing pain, swelling, redness, drainage, or a combination of these. Radiographs, if taken at this time, are usually normal and a second course of antibiotics may be administered. Partial resolution or persistence of symptoms prompts patients to seek further evaluation. It is not until an average of 3 weeks after the initial injury, or even longer for diabetics, that radiographs are repeated and the diagnosis of osteomyelitis is made. Any patient who relapses or fails to improve after initial therapy for a puncture wound should be suspected of having osteomyelitis. Radiographs should be obtained and blood sent for a white blood cell (WBC) count and an erythrocyte sedimentation rate (ESR). While an elevated WBC and ESR may alert the physician to the presence of a deep infection, normal values cannot be relied upon to exclude one.[11] A bone scan will show changes consistent with osteomyelitis 48 to 72 h after the onset of symptoms. There is a poor correlation between cultures of overlying wounds and those obtained from the involved bone in osteomyelitis. For that reason, culture of wounds and drainage should not be relied upon for antibiotic selection. In general, initiation of antibiotics should wait until cultures have been obtained from the involved bone, usually in the operating room. Pending culture results, antibiotics are started that cover *Staphylococcus* and *Pseudomonas* species. An acceptable regimen would consist of parenteral nafcillin and ceftazidime. Definitive management frequently necessitates operative intervention for debridement.

The majority of those who develop local infections after puncture wounds can be managed as outpatients. These patients should be provided with instructions on rest, with avoidance of weight bearing for plantar puncture wounds, elevation, warm soaks, and information detailing events that should prompt immediate return. Close follow-up with a routine recheck within 48 h is recommended.

Needle-Stick Injuries

Needle-stick injuries are common among health care professionals. Like other puncture wounds, these injuries carry the risk of bacterial infection in addition to the risk of infection with hepatitis and human immunodeficiency virus (HIV). The risk of infection after an inadvertent needle stick from an infectious source has been estimated to be negligible for hepatitis A virus (HAV), 9 percent (range 5 to 27 percent) for hepatitis B virus (HBV), 1.8 percent (range 0 to 7 percent) for hepatitis C virus (HCV), and 0.3 percent (range 0.2 to 0.5 percent) for HIV.[12,13 and 14]

Preexposure prophylaxis is currently possible for HAV and HBV with appropriate vaccines.[12] Postexposure prophylaxis is possible for HAV with immune serum globulin (ISG), for HBV with hepatitis B immune globulin (HBIG), and for HIV with combination antiviral therapy.[12,13 and 14] There is no proven postexposure prophylaxis for HCV.[13] Many factors enter into the decision process concerning the risks and benefits of treatment: (1) location of the needle stick, (2) ability to test the source, (3) immune status of the recipient, and (4) time from injury until treatment. Recommendations in this area are complex and changing. Each hospital should have a

predesigned protocol developed by infectious disease specialists for the expeditious evaluation, testing, and possible treatment of needle-stick injuries.

High-Pressure-Injection Injuries

A high-pressure injection injury may present as a puncture wound, usually to the hand or foot. [15] High-pressure equipment is designed to force liquids such as paint, paint thinner, grease, oil, or diesel fuel through a small nozzle under high pressure—sometimes up to several thousand psi. If held against or close to the skin, the liquid stream coming out of the nozzle will be injected through the skin and deposited in the subcutaneous tissues. Pressure required to penetrate the skin is approximately 100 psi, which is easily achieved by this type of equipment. These injuries are severe owing to the intense inflammation incited by the injected liquid and the vascular compromise that develops from edema within these tight tissue compartments. The type, amount, and velocity of material injected will determine the degree of tissue inflammatory response, and this material often spreads widely along fascial planes.

Patients who present soon after injury typically have pain out of proportion to the appearance of the injection wound, and swelling is minimal. [15] Despite this innocuous appearance, potentially serious damage can develop. Neurovascular function should be carefully assessed. Pain control should be achieved with parenteral analgesics; digital blocks are contraindicated so as to avoid increases in tissue pressure with resultant further compromise in perfusion. The extremity should be elevated in order to reduce swelling. Parenteral antibiotics against the gram-positive skin flora (*Staphylococcus* and *Streptococcus*) should be administered. Radiographs should be taken because some material may be radiopaque and may demonstrate the extent of subcutaneous spread from the injection site. An appropriate hand specialist should be consulted and early surgical debridement implemented for an optimal outcome. [16]

HUMAN BITES

Human bites are most often reported on the hands and upper extremities (60 to 75 percent), head and neck (15 to 20 percent), trunk (10 to 20 percent), and lower extremities (5 percent) as the result of fighting. [17] Passionate sexual activity can lead to bites on the penis, scrotum, and vulva. Self-inflicted bites are usually on the fingers, hands, and forearms. An occlusional bite, when human teeth bite through the body part, commonly occurs at the distal portion of a digit during an altercation and may result in complete amputation. The "clenched-fist" injury (CFI) occurs on the dorsum of the metacarpophalangeal region of the fist as it strikes the mouth and teeth of another individual.[18] Human bites to the hands have serious sequelae, including infection, loss of function, and potential amputation if untreated or misdiagnosed. In the ED, patients may try to conceal or even deny the true etiology of human bite wounds. The ED physician should be suspicious, especially when confronted by any small laceration over the dorsum of the metacarpophalangeal joint, that such an injury should be considered a CFI until proven otherwise.

Pathophysiology

Human bites produce a crushing or tearing mechanism with tissue destruction and devitalization. Underlying structures, particularly in the hand, are at risk of injury; these include the tendons, vessels, nerves, deep spaces, joints, and bone. Inoculation into these wounds with the normal human aerobic and anaerobic oral flora predisposes to infection; 1 ml of human saliva can contain up to 10^8 organisms. Many infected human bite wounds are polymicrobial, with studies reporting up to 43 percent mixed gram-positive and gram-negative organisms, and 26 to 83 percent yielding both aerobic and anaerobic bacteria. [17] The most frequent aerobic organism isolated is *Streptococcus viridans*, followed by *S. epidermidis*, *Corynebacterium* sp., *S. aureus*, *Eikenella* sp., and *Haemophilus* sp. Common anaerobic isolates include *Bacteroides* sp., *Fusobacterium* sp., and anaerobic cocci (e.g., *Peptostreptococcus* sp.). *Eikenella corrodens*, a slow-growing opportunistic aerobic gram-negative bacillus, has been isolated in up to 15 percent of CFI wounds and is a common cause of osteomyelitis, septic arthritis, and abscesses in the hand. *Eikenella corrodens* is susceptible to penicillin but resistant to penicillinase-resistant penicillin, clindamycin, and metronidazole; it has variable resistance to cephalosporins.

Complications from human bites occur most frequently in hand wounds, particularly CFI. These infections include localized cellulitis, lymphangiitis, abscess formation, tenosynovitis, septic arthritis, and osteomyelitis. Human bites in locations other than the hand appear to have similar rates of infection as nonbite lacerations. It is noteworthy that human bites in children and bites in the face have low rates of infection, often less than 5 percent. Paronychia is frequent in children who suck their thumbs and may inoculate oral flora to the region of the nail bed. In addition, two viral diseases are commonly transmitted by human bites. Herpetic whitlow results from contact or bites to the finger by a person infected with herpes simplex virus. Hepatitis B virus has also been transmitted after human bites from infected individuals. The potential risk of HIV infection through human bites appears to be negligible, likely due to the low levels of HIV present in saliva.

Clinical Features

The evaluation of human bites should identify the time interval since the injury, mechanism (i.e., occlusion versus closed fist), location, estimated depth of penetration, tetanus immunization status, medications, allergies, and underlying medical conditions predisposing to poor wound healing. As mentioned, human bites in the hands have an increased predilection for infection, but clinical signs of infection may not be present even after 24 h postinjury. Documentation of the vascular, motor, and sensory examination is essential. Following appropriate anesthesia, careful wound exploration is necessary to examine underlying structures for injury and possible foreign bodies. Examination of a CFI wound must take into account the flexed position at the interphalangeal and metacarpophalangeal joints at the time of injury; the injured segment of tendon will retract proximally in the unclenched, open hand and be missed if the physician evaluates the wound only in this position. The wound must be examined with the hand taken through a full range of motion at the metacarpophalangeal joint to detect extensor tendon injury. The joint capsule should be inspected to detect potential joint-space penetration. Radiographs should be taken of human bites to the hand, particularly CFI. Radiographs may disclose radiopaque foreign bodies (e.g., fragments of teeth), fractures, and air within the joint space (indicating joint-space penetration).

Treatment

Patients presenting more than 24 h after injury may already exhibit evidence of infection, with swelling, erythema, warmth, and a purulent, often malodorous discharge. Aerobic and anaerobic cultures should be obtained from the wound prior to any irrigation or cleansing of the wound. Careful examination of the wound following irrigation and cleansing is required to inspect the tendons and joint capsules. Radiographs should be taken.

Patients who present with a fresh CFI should have careful inspection under anesthesia, as noted above, and radiographs taken. If no laceration of the extensor tendon or joint capsule is seen, the wound should be copiously irrigated; it should be left open with an appropriate dressing, the hand immobilized in a bulky dressing and elevated for 24 h, followed by reevaluation in 1 to 2 days. [18,19] If there is a laceration to either the extensor tendon or the joint capsule or radiographic findings (foreign bodies, fractures, or joint-space air), a hand specialist should be consulted; these patients usually require exploration in the operating room. [20] In general, non-CFI human bite wounds of the hand should also be left open after examination and irrigation.

Wounds in other locations—such as the face, head, and neck—can be successfully repaired with primary closure after copious irrigation and judicious limited debridement.[21,22]

Prophylactic antibiotics should be considered in all human bites of the hands and in bites to other locations in high-risk patients (asplenia, diabetes mellitus, and immune deficiency).[17,19] Antibiotics should cover the expected mouth flora. Acceptable agents include amoxicillin/clavulanate, dicloxacillin plus penicillin, a first-generation cephalosporin plus penicillin, or a fluoroquinolone. Patients allergic to penicillin can be treated with clindamycin plus trimethoprim-sulfamethoxazole. Three to 5 days of therapy is appropriate. All patients with human bite wounds should be provided with tetanus immunization according to standard guidelines.

Patients with human bite hand wounds, particularly CFI, presenting more than 24 h after injury usually have clinical evidence of infection. Mildly infected wounds, such as those showing a localized cellulitis, in otherwise healthy and reliable patients may be managed on an outpatient basis with oral antibiotics, immobilization, and close follow-up. The wound should be explored and irrigated, left open with a dressing, and immobilized in a bulky dressing. Initial antibiotics should be administered in the ED with prescriptions for an additional 7 days given to the patient on discharge. These wounds should be reexamined in 24 h.

Moderate to severe infections manifest by fever, tachycardia, spreading cellulitis, or lymphangitis or possible involvement of deep tissue require admission for parenteral antibiotic therapy. Appropriate coverage can be provided by ampicillin/sulbactam, cefoxitin, ticarcillin/clavulanate, or piperacillin/tazobactam. Penicillin-allergic patients can be treated with clindamycin plus ciprofloxacin. Additional management includes copious irrigation and drainage (usually in the operating room), bulky dressings with daily changes, elevation, and immobilization. Delayed primary closure or healing by secondary intention is the preferred approach for the closure of hand wounds.

ANIMAL BITES

It is generally recognized that estimates of the number of animal bites are inaccurate and previous figures of 1 to 2 million people bitten per year in the United States are far too low. A survey of 5238 households in 1994 produced an estimated number of almost 4.5 million for dog bites alone (18 per 1000 population), with 756,000 requiring medical attention.[23] A review of the National Hospital Ambulatory Medical Care Survey for 1992 through 1994 yielded an estimated 333,000 annual emergency department visits for dog bites alone.[24] School-age children (5 to 14 years) sustain the majority of reported animal bites. The most frequently reported sites of animal bites include the hands (48 to 59 percent), arms (16 to 26 percent), legs (15 percent), and face (8 to 30 percent). Animal bite wounds comprise punctures, lacerations, avulsions, and abrasions. Patients seek medical attention with concerns about infection, tetanus and rabies prophylaxis in addition to treatment for the wound. Wound infection is the most frequent complication; other complications seen less frequently include sepsis, septic arthritis, tenosynovitis, osteomyelitis, meningitis, and disfiguring wounds.

The risk of infection from animal bite wounds depends on several factors: (1) the type of injury (puncture, laceration, avulsion, or abrasion), (2) presence of foreign bodies, (3) anatomic location, (4) time delay to treatment, (5) wound care techniques, (6) patient's age, and (7) underlying medical conditions.[25,26] Factors that predict a probability of infection greater than 5 to 10 percent include (1) full-thickness skin puncture; (2) wounds of the hands or feet; (3) wounds requiring debridement; (4) wounds involving joints, ligaments, or tendons; (5) wounds associated with fractures; and (6) wounds in patients who are high-risk hosts. Treatment with antibiotics in such circumstances is recommended.

Animal bites should be considered tetanus-prone wounds; guidelines for tetanus immunization should be followed. The need for post-exposure rabies immunoprophylaxis must also be considered in cases of animal bite wounds. Factors to consider concern the animal type, nature of the attack, and evaluation and disposition of the animal. In general, skunks, raccoons, bats, foxes, and most carnivores should be considered as posing a high risk for rabies and postexposure immunoprophylaxis should be initiated. It is generally best to consult local public health officials for the most current recommendations.

The physician should evaluate and document the number, type, location, and depth of all bite wounds as well as the presence of any clinical evidence of infection. Lacerations and avulsions should be explored to evaluate potential involvement of any underlying structures, including vessels, nerves, tendons, soft tissue, and joint spaces. In general, fresh bite wounds do not require extension and exploration. Radiographs should be obtained if there is evidence of infection or any suspicion of foreign-body or bone involvement. Bites from animals known to have strong jaws, such as pit bulls, mastiffs, tigers, and cougars, should be assumed to produce fractures until proven otherwise by x-ray. All animal bite wounds require appropriate local wound care with copious irrigation and debridement of compromised or necrotic tissue. Primary closure following appropriate wound care has been successful in wounds to the head and neck, torso, and proximal extremities, but in general bites without cosmetic implications should be allowed to heal by secondary intention. Hand wounds are best managed open initially, followed by delayed primary wound closure in 3 to 5 days. Antibiotics should not be used as a substitute for proper local wound care.

Dog Bites

Dogs account for 80 to 90 percent of reported animal bites in the United States.[23] Boys are victims of dog bites twice as often as girls, and the dog is known to the victim in about 90 percent of cases. Dog bite injuries occur most frequently on the extremities (upper slightly more often than lower), followed by the head and neck, and least frequently on the trunk. Head and neck bites are more common in children. Infection occurs in dog bites in approximately 5 percent of cases. Factors that increase the rate of infection include (1) victim age greater than 50 years, (2) delay in seeking treatment greater than 24 h, (3) hand wounds, and (4) deep puncture wounds. Dog bites are rarely lethal, but they may produce significant damage secondary to the force delivered—approximately 150 to 450 psi.[27,28]

Infection of dog bite wounds usually results from the organisms inoculated into the depth of the wound by the animal's teeth, not from the bacterial flora normally found on the patient's skin. Infections from dog bite wounds are often polymicrobial; aerobic bacteria are present in most wounds and anaerobic bacteria are found in up to 40 percent.[25] Aerobic isolates are usually alpha-hemolytic streptococci, followed by *S. aureus*, *Pasteurella multocida*, and *S. intermedius*. Other pathogenic aerobes include b-hemolytic streptococci, g-hemolytic streptococci, *E. corrodens*, *Capnocytophaga canimorsus*, other *Pasteurella* sp., and *Haemophilus aphrophilus*. Anaerobic bacteria isolated from dog bite wounds include *Actinomyces* sp., *Bacteroides* sp., *Fusobacterium* sp., and *Peptostreptococcus* sp.

Capnocytophaga canimorsus, formerly known by the Centers for Disease Control and Prevention as "dysgonic fermenter-2" (DF-2), is a fastidious, thin, gram-negative bacillus that has been associated with severe infection in immunocompromised patients (asplenia, alcoholism, chronic lung disease, or other immunosuppression). It was first recognized as a human pathogen in 1976. Infection with this organism may produce severe sepsis with disseminated intravascular coagulation, acute renal failure, endocarditis, peripheral gangrene, and cardiopulmonary failure. Fatalities are seen in up to 25 percent of cases. Penicillin is the drug of choice when infection with this organism is suspected and should be used prophylactically in high-risk individuals. This bacterium is also usually sensitive to cephalosporins, tetracyclines, erythromycin, and clindamycin.

Lacerations of the scalp, face, and trunk from dog bites can be irrigated, debrided, and sutured in the ED with a low risk of infection.[26,30] Lacerations of the distal extremities, especially the feet and hands, should not be sutured. Lacerations of the proximal extremities—the upper arm and the thigh—can probably be closed after irrigation and exploration. Large, extensive lacerations, especially in small children, are best explored and repaired in the operating room.[27]

Discharge instructions should include information about signs and symptoms of infection and assurance of follow-up within 24 to 48 h. Bites to the hand, and wounds in high-risk individuals should receive prophylactic treatment with amoxicillin/clavulanate, clindamycin plus ciprofloxacin, or clindamycin plus trimethoprim-sulfamethoxazole for 3 to 5 days. Antibiotics should be initiated in the ED. There is no evidence that antibiotic therapy for dog bite wounds in other anatomic locations is beneficial.

Wounds obviously infected at the time of presentation need to be cultured and antibiotic therapy must be initiated. Infection developing within 24 h after injury suggests *P. multocida* and treatment with penicillin, ciprofloxacin, or trimethoprim-sulfamethoxazole is recommended. Wound infection developing beyond 24 h after the dog bite implicates *Staphylococcus* and *Streptococcus*; treatment with a penicillinase-resistant penicillin or first-generation cephalosporin is indicated. Low-risk patients with local cellulitis only and no involvement of underlying structures can be treated and observed closely as outpatients. Admission and parenteral antibiotic therapy are indicated in patients with infected wounds and evidence of lymphangitis, lymphadenitis, tenosynovitis, septic arthritis, or osteomyelitis; systemic signs such as fever; or injury to underlying structures such as tendons, joints, or bone. Aerobic and anaerobic cultures should be obtained from the deep structures, preferably during exploration in the operating room. Initial antibiotic therapy should begin with ampicillin/sulbactam or clindamycin plus ciprofloxacin. If the Gram stain shows gram-negative bacilli, a third- or fourth-generation cephalosporin or aminoglycoside should be added. When sepsis is present, broad-spectrum coverage with imipenem/cilastatin is warranted pending culture results.

Cat-Scratch Disease (CSD)

CSD most often occurs in young (80 percent less than 21 years of age) immunocompetent hosts.[31] The initial site develops a transient erythematous papule or pustule for which the patients do not often seek medical attention. They usually come after the development of persistent regional lymphadenopathy in an area of the body draining lymph from the scratch or bite, usually 7 to 12 days after the injury. Symptomatic lymphadenopathy usually resolves in 2 to 4 months. Systemic complications—with involvement of the central nervous system, eye, liver, spleen, and bone—can be seen in up to 2 percent of cases. It has been estimated that CSD affects about 22,000 individuals annually in the United States (9.3 per 100,000 population) and results in about 2000 hospitalizations. There is a male as well as a fall/winter seasonal predominance.

The precise etiologic agent has been difficult to determine. Most investigations implicate *Bartonella henselae*, a small gram-negative rod. Diagnosis is made by (1) history of cat exposure, (2) typical lymphadenopathy, (3) no other cause of lymph gland swelling, and (4) a positive serologic test for *B. henselae*. Serologic assay using the polymerase chain reaction (PCR) is the most accurate method (86 percent sensitive and 96 percent specific) and more sensitive than either the IgG indirect fluorescence assay (IgG IFA) (41 percent sensitive) or the IgM enzyme-linked immunoassay (IgM EIA) (71 to 80 percent sensitive).[32] Serologic testing can be improved by using PCR to assay pus and lymph node specimens, with sensitivities approaching 100 percent.[33]

Most patients with CSD are not seriously ill, spontaneous resolution is common, and antibiotic therapy has not been studied in large controlled clinical trials. As a result, most reviews do not recommend antibiotic therapy for uncomplicated cases. A recent controlled study of 29 patients with typical CSD found that a 5-day course of azithromycin led to more rapid resolution in lymph node volume during the first 30 days.[34] After that, there was no difference in rate or degree of resolution.

Antimicrobial susceptibility testing has shown favorable minimum inhibitory concentration (MIC) values to a number of antibiotics, but since the bacterium resides intracellularly, agents that achieve high concentrations inside human cells would probably be the most effective—rifampin, gentamicin, doxycycline, and the macrolides. Severely ill patients, those with systemic complications, and those who are immunocompromised should be treated with either rifampin or trimethoprim-sulfamethoxazole.

Cat Bites

Cat bites account for 5 to 18 percent of reported animal bites in the United States. [26] The majority of wounds are inflicted on the arm, forearm, and hand and with decreasing frequency to the head and neck, lower extremity, and trunk. Owing to the long, slender fangs of cats, most bites result in puncture wounds (57 to 86 percent); the remainder are superficial abrasions (9 to 25 percent) and lacerations (5 to 17 percent). Up to 80 percent of cat bites become infected, due to such factors as (1) older age of the patient, (2) attempting wound care at home with longer treatment delays, (3) higher percentage of puncture wounds, and (4) a higher likelihood of *P. multocida* in feline oral flora.

Pasteurella multocida is the major pathogen found in infected cat bite wounds; it is isolated in 53 to 80 percent. [25,26] These infections are characterized by a rapidly developing, intense inflammatory response, often within a few hours and rarely more than 24 h after the bite. Pain and swelling are prominent. *Pasteurella multocida* may cause serious bone and joint infections. Septic arthritis usually involves a single joint, with predilection for joints previously damaged by arthritis or prosthetic joints, and more than half the patients also have altered host defenses from glucocorticoids or alcoholism. Bacteremia may occur in serious infections with *P. multocida.*

Treatment for cat bite wounds is essentially the same as for dog bite wounds. Larger lacerations (>2 cm) can be primarily closed after cleaning without an increased risk of infection. [29] Puncture wounds and lacerations smaller than 1 to 2 cm in length cannot be adequately cleaned and should not be primarily closed. Delayed primary closure can be employed for wounds smaller than 1 to 2 cm in length located in cosmetically important areas. Prophylactic antibiotics should be administered to high-risk patients including those with punctures of the hand; immunocompromised patients; and patients with arthritis or prosthetic joints. The case can be made that all cat bites should receive prophylactic antibiotics because of the high risk of infection. Three to five days of penicillin, amoxicillin/clavulanate, cefuroxime, or doxycycline are appropriate for prophylactic treatment following cat bites. For cat bites that develop infection, evaluation and treatment is similar to dog bite infections.

Exotic Animal Bites

Extensive clinical data and treatment recommendations pertaining to bite wounds made by exotic animals and resulting infection are based on anecdotal case reports. In general, it is best to adhere to the dictum that the bacteriology of the bite wound will reflect the normal oral flora of the inflicting animal as opposed to the normal skin flora of the patient. General principles of local wound care—including irrigation and surgical debridement, wound cultures as appropriate, and tetanus and rabies prophylaxis—should be followed.

Nonhuman primate (monkey) bites are likely to be seen in animal handlers and researchers. The organisms most often encountered in the mouths of rhesus monkeys (*Macaca mulatta*) are *Neisseria* sp., a-hemolytic streptococci, and *Haemophilus parainfluenza*. Also, *E. corrodens* is a pathogen from primate bite infections. The combination of penicillin and cefoperazone has been recommended as an initial antibiotic regimen for monkey bite injuries. In addition, the potential for transmission of *Herpesvirus simiae* (B virus) must be considered, from bites, scratches, or needle sticks. The potential consequences of inoculation with B virus are grave and include local neurologic symptoms, encephalitis (91 percent), and death (68 percent). The affected area must be scrubbed with povidine-iodine for 15 min, and then copiously rinsed with water. Ocular or mucous membrane exposure requires a 15-min irrigation with saline or water. Treatment with acyclovir 800 mg PO five times a day beginning immediately after injury should be considered when a wound from a rhesus monkey is sustained. The monkey should be quarantined and carefully examined for oral mucosal lesions. Questions can be directed to the NIH B virus Research Laboratory (404-651-0808).

The large feline carnivores, such as lions and tigers, like domestic cats, also carry *Pasteurella* among their normal oral flora. Wound care should be the same as for other species, with awareness for the potential for major skeletal and internal injuries.

Alligator bites (*Alligator mississippiensis*) may be frequently encountered in the southeastern United States. Bite wounds can be polymicrobial, but the aerobic organism *Aeromonas hydrophila* has been a consistent isolate. Trimethoprim-sulfamethoxazole is considered a front-line agent for treatment, with an aminoglycoside, imipenem, meropenem, or tetracycline as an alternative. *Bacteroides* and *Clostridium* species have also been isolated from alligator bites.

Bites from the common or green iguana (*Iguana iguana*), readily available in the United States as a pet, are generally innocuous. These animals do not harbor the rabies virus. Local topical antiseptic wound care and verification of tetanus status is all that is needed for the emergency treatment of an iguana bite.

Rat bites may be complicated by leptospirosis, a zoonosis transmitted primarily through the direct or indirect exposure of mucous membranes or abraded skin to the urine of an infected animal. The domestic rat may serve as the primary reservoir of leptospirosis in urban areas. Subclinical infections are common and most clinical infections are self-limiting. Oral doxycycline for 7 days is effective when initiated within 4 days of symptom onset. Parenteral penicillin G for 7 days is indicated for the more severe icteric disease. In addition, rat-bite fever may be transmitted by several small rodents, including the rat, mouse, and gerbil. The causative organisms are *Streptobacillus moniliformis* and *Spirillum minor*. Prophylactic therapy with penicillin, amoxicillin/clavulanate, or doxycycline for 5 days is recommended.

Camels can inflict serious bites as well as other associated injuries due to their enlarged canine teeth and long necks, which allow them to reach around and bite the rider violently, lift the rider into the air, and throw him or her to the ground. The bacteriology of camel bite wounds has not been well studied; however, an anecdotal report of successful treatment with high-dose penicillin G, gentamicin, and clindamycin has been published.

44 POSTREPAIR WOUND CARE

Louis J. Kroot

Following repair in the emergency department (ED), continued care and instructions should be provided to minimize complications and optimize outcome. This chapter discusses the principles of postrepair wound care as commonly practiced in the United States. These steps may not be necessary with every patient; in fact, while many of them are based on common sense, scientific validation is lacking. [1,2]

DRESSING

The value of wound dressings has been debated for years. Studies indicate that an important component of wound repair is reepithelialization as the regenerating epithelial cells migrate across the moist exudate of a wound. [1] A moist environment is crucial for this process, and epithelial repair is significantly impaired in desiccated wounds. Wound dressings that follow this basic principle of maintaining a moist environment for the first 24 to 48 h facilitate healing.

The simplest wound dressing is a layer of petrolatum-based ointment applied directly over the sutures. This approach is most useful to treat simple, uncontaminated lacerations of the face and scalp but should not be implemented when tissue adhesives are applied. These areas have an excellent vascular supply; they heal with little risk of infection and a good cosmetic result. The addition of an antibiotic to the petrolatum-based ointment reduces the risk of infection, particularly in extremity wounds. [3] Available agents include bacitracin zinc, neomycin, and polymixin B, usually in combination. The ointment should be gently washed off and reapplied two or three times per day for the first 2 to 3 days and once a day thereafter until suture removal. [3] This approach has been criticized as being unnecessary, time-consuming, and uncomfortable. [4] Instead, the use of a topical antibiotic in a water-soluble base (such as mupirocin in polyethylene glycol) has been advocated, for abraded skin surrounding stellate lacerations. Topical antibiotic ointments, which contain povidone-iodine, should be avoided, since this antiseptic impairs wound healing. Application of ointment facilitates suture removal by preventing the exposed tails from becoming encrusted in a dried wound exudate.

Small lacerations can be dressed with self-adhesive elastic strips. These strips almost always have a nonadherent center that goes directly over the wound. Petrolatum-based antibiotic ointment can be placed either on the elastic strip or on the wound.

Most other wounds are commonly dressed; although there is little evidence that dressing reduces the risk of infection or improves ultimate cosmetic appearance. The less "scientific" but highly practical reasons for wound dressing include the following:

1. General cleanliness as the dressing absorbs exudate
2. Protection from external contamination when the patient returns home or work
3. Camouflage, so that the patient or others do not have to see the wound
4. Prevention of premature suture removal from spontaneous unraveling or the patient's curiosity
5. Prevention from excessive movement by providing a "soft" splint
6. Satisfying the patient's expectation that the repaired wound will be dressed

The basic wound dressing has four layers: (1) a nonadherent layer adjacent to the wound, (2) gauze sponges to absorb any exudate, (3) wrapping to hold the first two layers in place, and (4) tape or elastic bandage to secure the entire package (Table 44-1).

Petrolatum-based ointment
  Plain
  Bacitracin zinc
  Neomycin/polymyxin B/bacitracin zinc (Neosporin)
  Polymyxin B/bacitracin zinc (Polysporin)
Polyethylene glycol-based ointment
  Mupirocin (Bactroban)
Nonadherent layer
  Adaptic (Johnson & Johnson Medical)
  Epi-Lock (Lock Laboratories)
  Tegaderm (3M Health Care)
  Telfa (Kendall Healthcare Products)
  Xeroform (Kendall Healthcare Products)
Absorbent layer
  Gauze squares
  Alginate dressing
Wrapping layer
  Gauze wrap
Securing layer
  Tape
  Elastic bandages

TABLE 44-1 Wound Dressing Materials—Representative Examples

The simplest nonadherent dressing is a ribbon of petrolatum-based ointment applied to the wound with a small gauze pad over it. When wrapped with gauze and secured with tape, such a dressing will remain moist for the first 24 h. This simple approach is appropriate for clean, closed wounds with minimal exudate. Several nonadherent dressing materials have been developed for use on open, larger, and more exudative wounds and burns. These materials can be occlusive, semipermeable, or porous. While wounds treated with the newer semipermeable materials may tend to heal faster and with less pain, there is no clear benefit over the older and less expensive porous materials. The nonadherent material should be cut to extend beyond the wound area.

A layer of gauze squares is placed over the nonadherent layer to absorb any exudate. While it is possible to tape the gauze squares directly to the adjacent skin, this is uncomfortable for the patient; moreover, as the sweat loosens the tape, such a dressing usually does not last for more than a few days. In general, the first two layers are held in place by a wrap, usually of gauze. Wrapping is easy over tubular body portions (e.g., the forearm) and more difficult over irregular areas (e.g., the shoulder).

Either tape or elastic bandages secures the wrapping layer. Tape should be applied in a spiral manner to allow for edema and swelling; it should never be wrapped circumferentially around an extremity or digit. Elastic bandages must likewise be applied with allowance for expansion during the following 24 h.

DRESSING CHANGES

The general principle is that wound dressings should be changed as often as needed for removal of exudate, inspection, and general cleaning. That said, there is great variety in the need for dressing changes. A routine change in 24 h serves several purposes: removal of most of the exudate and inspection for bleeding and early signs of infection. The wound should be dressed again, often with a simpler bandage than was initially required. Thereafter, dressing changes depend on the rate of wound healing, the continued presence of exudate, and the patient's ability to keep the area clean.

PAIN CONTROL

Wounds, particularly burns and abrasions, can be painful. Patients should be instructed about the potential for pain and measures to help control it. The need for analgesics should also be considered for every wound patient. Narcotic analgesics, particularly hydrocodone and oxycodone, may be necessary. Studies have consistently found that ED patients are often untreated with analgesics for acute, painful injuries while in the ED and upon discharge. Patients who do receive appropriate analgesics upon discharge report greater satisfaction with overall care. [5] The pain from wounds decreases during the first 48 h and narcotic analgesics are not usually required beyond that time.

ANTIBIOTIC PROPHYLAXIS

As discussed in other chapters, antibiotic prophylaxis is effective when a wound has more than baseline bacterial contamination, antibiotics effective against expected pathogens are chosen, and such antibiotics are given as soon as possible to achieve antimicrobial blood levels before repair. However, as commonly practiced, antibiotic prophylaxis from the ED is suspect for the following reasons: (1) the use of antibiotics for simple, uncomplicated lacerations fails to satisfy the first requirement; (2) the use of cephalexin for cat bites fails to meet the second requirement; and (3) handing the patient a prescription on discharge fails the third. [6] Antibiotic prophylaxis should be initiated in the ED, before significant wound manipulation, and with agents that rapidly achieve antibacterial blood levels.

The following types of wounds have shown evidence to support the use of continued antibiotic prophylaxis upon discharge from the ED:

1. Intraoral lacerations: penicillin
2. Complicated human bites: amoxicillin/clavulanate or penicillin plus a first-generation cephalosporin
3. Complicated dog bites: amoxicillin/clavulanate or penicillin plus a first-generation cephalosporin
4. Cat bites: penicillin or amoxicillin/clavulanate
5. Plantar puncture wounds, particularly through athletic shoes: ciprofloxacin

Although antibiotic prophylaxis is commonly employed for patients with comorbid conditions predisposing to wound infection (diabetes, cirrhosis, advanced age, and immunosuppression), there is little supporting evidence for this practice in all circumstances except for the types of wounds described above.

ROUTINE RECHECKS

The routine recheck policy serves two purposes: (1) professional cleaning and redressing of the wound and (2) early identification of bleeding or wound infection. Routine rechecks have been criticized because: (1) most wounds are uncomplicated and do not require professional cleaning and redressing; (2) the routine recheck is usually performed at 48 h, slightly before the 3- to 5-day peak incidence for wound infection; and (3) the vast majority of wounds heal without complication and do not benefit from a recheck.

A more appropriate approach would be to implement selective rechecks on patients with complicated wounds at risk for infection. Comorbidity status and social situation may also be used to select patients for recheck. Patients may not have a clear understanding of the symptoms and signs of wound infection. Those at significant risk should be told to return on a specific day. Practically speaking, rechecks are easier when they are scheduled in the morning, when the ED is less busy and these patients can be seen expeditiously. Since the bulk of ED wound care is provided in the late afternoon and evening, having the patient return on the second and fourth day corresponds to rechecks at approximately 36 and 84 h. The first recheck would be appropriate for redressing and the second would occur when signs of wound infection usually become manifest.

CLOSURE REMOVAL

Sutures and staples are generally removed when the wound closure has become strong enough to withstand normal activity. The major exception to this principle is the face, where cosmetic outcome is important. Percutaneous sutures incite the development of small epithelial plugs at the suture puncture sites, leaving behind a "railroad track" if sutures are left in place for 7 days or more. Therefore, facial sutures are removed at 4 to 5 days, before tensile strength is adequately recovered. Such wounds may require adhesive closure strips for an additional 3 to 4 days. Sutures and staples in other areas can be removed in 7 to 14 days (Table 44-2). Sutures and staples applied over highly mobile areas, particularly the extensor surfaces of large joints, are best left in place for 3 to 4 days longer.

Face	4–5 days
Scalp	7–10 days
Trunk	10 days
Arm (surface)	10 days
Arm (joint)	10–14 days
Hand	10–14 days
Leg (surface)	10 days
Leg (joint)	10–14 days
Foot	14 days

TABLE 44-2   Timing for Removal of Cutaneous Sutures and Staples

Wounds closed with adhesive tape or tissue adhesives do not require specific removal; the tape or adhesive will slough off by itself by epithelial exfoliation. In general, such adhesives should be expected to remain on the skin for about the same time as sutures would.

WASHING AND GROOMING

Within 8 to 24 h after closure, wounds in highly vascular areas (scalp, face, and neck) can be washed without any impairment to healing or an increase in infection; shampooing of the scalp or washing of the face and neck is allowable the day after suture repair. Likewise, wounds in other areas can be washed after 12 to 24 h without increased risk of an adverse outcome. However, immersion or soaking should be avoided, as this tends to track moisture down the percutaneous sutures and macerate the wound; showering is allowable, but bathing is to be discouraged. Following cleaning, the wound should be dried with a clean towel and redressed as directed. While shaving is rarely a danger, patients may have to be told not to shave around or over a wound.

Stapled wounds can be washed and groomed in the same way as sutured wounds. However, wounds that have been closed by adhesive tape should not be moistened or washed. Wounds closed with tissue adhesive may be very gently cleaned after 24 h, but immersion should be prohibited.

DISCHARGE INSTRUCTIONS

For the majority of lacerations sutured in the ED, patients should be instructed that a small amount of bloody discharge is to be expected; enough only to form a small surface clot or to stain the dressing. More than that is unexpected, and if such is found, the patients should return for recheck. Deep, complex lacerations that require drains or remain open may bleed more, and the patient should receive appropriate instructions to this potential.

Patients should be instructed about early symptoms and signs of infection: increasing pain, redness that extends more than $\frac{1}{4}$ in. (5 mm) beyond the wound edges, red streaks that extend from the wound, purulent drainage, and fever. As noted above, many patients unfortunately do not recognize these signs of infection; in a study of 433 patients with 21 physician-diagnosed wound infections, only 11 (52 percent) were able to self-diagnose their infection. [7] Instructions must be clear, simple, and

specific.

Wounds may open spontaneously, especially during the vulnerable period: 7 to 10 days after injury. Infection, fluid, and blood collections within the wound facilitate dehiscence. Patients should be instructed to return if a wound opens, particularly if blood or pus is expressed.

Patients discharged with a planned delayed primary closure require additional instructions:

1. They will generally be given antibiotics to take after they are sent home
2. They should leave the dressing intact until they return for a recheck
3. A recheck is generally done within 4 to 5 days

In carefully selected patients, delayed primary closure is associated with a low incidence of wound infection. [8]

Patients may inquire about the long-term outcome of the wound; in such instances, the physician should respond with a candid prognosis explaining that wound outcome is primarily determined by factors beyond the physician's control, including:

1. Wounding mechanism
2. Type of wound
3. Location of wound
4. Comorbid diseases

Patients should be told that the wound's appearance will change during the healing process and that the ultimate cosmetic outcome cannot be predicted at the time of suture removal.[9,10] If necessary, wound revision should wait about 6 to 9 months from the initial injury. Some wounds on sun-exposed areas may be less pigmented than the surrounding skin and more sensitive to ultraviolet radiation. Color generally fills in over the next 12 months and sunscreens may be required for several months.

45 APPROACH TO CHEST PAIN AND POSSIBLE MYOCARDIAL ISCHEMIA

Gary B. Green
Peter M. Hill

OVERVIEW

Approximately 5 percent of all emergency department (ED) visits, or about 5 million visits a year, are for chest pain, yet accurate diagnosis remains a challenge. Owing to a complex interplay of anatomic, physiologic, and psychological factors, serious illness often mimics benign conditions. Symptoms are often intermittent, so the patient may appear well on evaluation. This chapter outlines an approach to patients presenting with chest pain and other symptoms of possible ischemia. Detailed discussion of patients with findings diagnostic of acute coronary syndromes (ACS) can be found in other chapters of this text.

Pathophysiology of Chest Pain

Afferent pain fibers are classified into two broad categories, visceral and somatic, with their stimulation resulting in distinct pain syndromes. The dermis and parietal pleura are innervated by somatic pain fibers. They enter the spinal cord at specific levels, are arranged in dermatomal patterns, and map to specific areas on the parietal cortex. Visceral pain fibers are found in internal organs such as blood vessels, the esophagus, and the visceral pleura. These fibers enter the spinal cord at multiple levels, along with somatic pain fibers, and map to areas on the parietal cortex corresponding to the cord levels shared with the somatic fibers. Therefore, pain from somatic fibers is usually easily described, precisely located, and experienced as a sharp sensation. Pain from visceral fibers is more difficult to describe and is imprecisely localized. Those experiencing visceral pain are more likely to use terms such as *discomfort, heaviness,* or *aching.* Further, patients frequently misinterpret the origin of visceral pain because it is often referred to a different area of the body corresponding to an adjacent somatic nerve. For example, diaphragmatic irritation can present as shoulder pain, and arm pain may actually represent myocardial ischemia.

Many physiologic, psychological, and cultural factors further influence how patients perceive, interpret, and communicate their symptoms. Gender, age, comorbidities, polypharmacy, drugs, and alcohol can all affect perception of pain.

Pathophysiology of Anginal Pain

For a detailed discussion of the pathophysiology of ischemia, see Chap. 47. In brief, angina pectoris can be defined as any pain syndrome that is caused by lack of oxygen supply to the heart. Anginal symptoms are typically caused by obstructive coronary artery disease or coronary spasm, or both. Atherosclerotic plaques lining the walls of coronary arteries cause luminal stenosis in patients with coronary artery disease. During periods of low myocardial oxygen demand, blood flow through the stenosed vessels may be adequate to meet demand. However, during times of increased oxygen demand, flow through the fixed lesion is limited and the region of myocardium supplied by the affected vessel may become ischemic. Cardiac myocytes respond to oxygen deprivation by switching from aerobic to anaerobic metabolism, during which sufficient ATP cannot be produced to meet the metabolic demands of the cell. The lack of ATP causes dysfunction of all intracellular ATP-dependent processes, including ion channels in the sarcoplasmic and cell membranes, causing diminished contractility and cell integrity. Chemical mediators are subsequently released, stimulating visceral afferent nerve fibers in sympathetic nerves of coronary vessels. These nerves travel through deep and superficial cardiac plexuses and the sympathetic ganglia and enter the spinal cord through the lower cervical and upper five thoracic spinal nerve roots. Because of this wide spinal cord distribution of the cardiac pain fibers, the cerebral cortex often misinterprets the location and origin of the pain, therefore confusing myocardial ischemia with pain from any of the other structures in the chest.

INITIAL APPROACH TO THE PATIENT

All chest pain patients, like trauma patients, should receive a high triage priority and be evaluated without delay. The patient care team—nurses, electrocardiography (ECG) technicians, and physicians—should be mobilized around the patient simultaneously. During this time, the patient should be placed on a cardiac monitor, have intravenous access established, oxygen administered, vital signs measured, and a 12-lead ECG obtained.

The initial moments with the patient must be considered similar to a primary survey for trauma, with the focus on identifying an immediate life threat. First, there is a rapid assessment of the patient's airway, breathing, and circulation, general appearance, and vital signs. The initial history should include only a few directed questions—e.g., as to the presence and character of any ongoing symptoms and the presence of significant underlying cardiovascular or pulmonary pathology, such as a history of pulmonary embolism, acute myocardial infarction (AMI), or coronary revascularization. A focused pulmonary and vascular exam is performed next.

If immediate life threats have not been detected or have already been addressed, a more extensive evaluation can then be performed. The secondary survey consists of a more comprehensive history and physical examination and appropriate laboratory and diagnostic testing. This evaluation should focus on those variables that will aid in establishing a tentative diagnosis.

Every patient in whom ACS is entertained, particularly those that present with CP, must have concurrent consideration of several entities that may have similar presentation. Missing any of these diagnoses carries the same order of risk of morbidity and even mortality as missed ACS. These include PE, pneumothorax, pericarditis, pneumonia, aortic dissection, perforated peptic ulcer, and under certain circumstances esophageal rupture. These represent a minimum differential diagnosis of consequence. Some authorities would add such entities as aortic stenosis (CP, syncope, DOE) and possibly acute cholecystitis and pancreatitis within the list of conditions to be simultaneously considered. It is important to emphasize that this differential must be pursued simultaneous, and the evaluation should be concerned with ruling in, or ruling out, each entity. While important history that may point to an ACS is detailed below, the history and physical exam should also include consideration of the above conditions (Table 45-1). Fortunately, the evaluation of the patient with possible ACS readily includes ancillary investigations that also appropriately consider most of the above noted entities. For example, a chest x-ray and an EKG readily consider PE, pneumothorax, pericarditis, pneumonia, dissection, and even perforated viscus. Among these, PE requires more evaluation if other evidence suggests further investigation. Cholecystitis, pancreatitis, and aortic stenosis may require additional avenues of investigation, although routine chemistries may assist in establishing or refuting the diagnosis of the first two.

Diagnosis	Presentation	Physical Exam	Ancillary Tests
Pulmonary embolism	Sudden onset, pleuritic pain, and dyspnea	Tachypnea, tachycardia, Deep vein thrombosis	ABG, CXR, V/Q scan, Angiogram
Aortic dissection	Tearing pain with radiation to back, Neurologic symptoms	New murmur, bruits, Unequal BP in upper extremities	CXR, Angiogram
Pericarditis	Positional ache, dyspnea	Rub, distended neck veins	ECG, CXR, sonogram
Pneumothorax	Pleuritic pain and dyspnea	Decreased breath sounds	CXR
ACS	Vague, pressure-like pain, Radiation to arm, neck, jaw, Associated diaphoresis, dyspnea, nausea	Diaphoresis, rales	ECG, Myocardial markers
Esophageal rupture	Constant retrosternal, epigastric pain, History of inciting event	Variable	CXR
Pneumonia	Pleuritic pain, cough, dyspnea, chills	Fever, rhonchi, Decreased breath sounds	CXR, WBC

TABLE 45-1   Life-Threatening and Serious Causes of Chest Pain and Their Clinical Characteristics

Other important diagnoses such as mitral valve prolapse (covered later in this chapter) may yet be the underlying etiology, but there is little risk of morbidity in the short term if missed during the ED evaluation. Diagnoses such as musculoskeletal chest pain, hiatal hernia, or gastritis may be a source of both concern and discomfort to the patient, but there is minimal to no consequence if such diagnoses were in fact the underlying cause but not seriously pursued in the ED.

CLINICAL FEATURES

History

Routine questions should determine the quality, location, radiation, intensity. frequency, associated symptoms, and precipitating factors of chest pain. For patients who have difficulty explaining symptoms in a narrative fashion, directed questions should be asked. Patients without previously diagnosed ischemic heart disease may have difficulty describing the quality of pain and may resort to textbook terms. Specific questioning is needed about radiation to the jaw, neck, arms, back, or epigastrium. However, lack of such specific pain location is not differentiating. Pain intensity is commonly graded on a scale of 1 to 10, with 10 representing the worst pain the patient can imagine. The frequency of pain episodes should be assessed over a continuum of the past weeks to better determine whether the condition is stable or unstable angina. Patients can be asked about episodes relative to a past holiday or event and should compare frequency to the current time frame. They should identify precipitating factors such as changes with inspiration, movement, palpation, or exertion and during sleep or at rest. The presence of associated symptoms such as diaphoresis, near syncope, nausea, or vomiting raises concern about ischemic disease. Family members, friends, or emergency medical technicians (EMTs) who may have witnessed the episode can be questioned about the patient's general appearance while in pain. If the patient is described as appearing ill, suspicion for ischemia is heightened.

The classic description of angina pectoris is that of a retrosternal left anterior chest or epigastric discomfort consisting of crushing, tightening, squeezing, or pressure. The presence of certain associated symptoms during chest pain—including dyspnea, diaphoresis, nausea, and/or vomiting—is common and indicates a twofold higher risk of ischemia. Many patients also complain of discomfort radiating from the chest to the left shoulder, arm, hand, or jaw, a finding whose presence is also associated with a significantly greater risk of ischemia. [4,5] However, atypical characteristics are the rule rather than the exception. For example, up to 22 percent of patients with AMI describe their symptoms as being sharp or stabbing in character and up to 6 percent describe a pleuritic component of their pain. [6]

Anginal pain (or other anginal symptoms) is typically described as lasting from 2 to 20 min and pain from an uncomplicated AMI lasting up to 2 h. In contrast, chest pain that is described as lasting a "split second" or only a few seconds is more likely to be due to another cause, as is constant, unremitting pain lasting 12 to 24 h or more. Anginal pain is often brought on by exertion and relieved by rest, while pain worsened by body movement or body position is suggestive (but certainly not diagnostic) of another etiology. Angina may also occur at rest and is often attributed to coronary artery spasm with or without underlying atherosclerotic lesions.

All patients should also be questioned regarding the presence of cardiac risk factors, although "risks" are valid only for predicting the presence of coronary artery disease within a given population and not in an individual patient. Major risk factors identified by the American Heart Association include age above 40, male or postmenopausal female, hypertension, cigarette smoking, hypercholesterolemia, diabetes, truncal obesity, family history, and sedentary lifestyle. Cocaine use is associated with AMI even in young people with minimal or no coronary artery disease. Chronic cocaine use has also been associated with accelerated atherosclerosis and severe coronary artery disease.

The patient's medical record should always be reviewed when analyzing chest pain. Previous ECGs should always be compared with the current tracing. Results of prior stress testing, echocardiograms, catherizations, or radionuclide scans should be reviewed, if available, and the present symptoms interpreted in light of those results. The "gold standard" for determining the presence or absence of coronary artery disease is angiography. In general, catherization reports from within the previous 2 years are considered to be generally reflective of the current extent of disease.

Ischemic Equivalents

Because of the visceral afferent innervation of the myocardium as well as the many confounding factors affecting the perception of ischemia, many patients with ACS will not experience chest discomfort. Up to one-third of AMIs may be silent, occurring without any reports of symptoms from the patient and discovered incidentally on routine ECG.[1] Many other patients present with ischemic-equivalent symptoms, which may include one or any combination of the following: dyspnea at rest or exertion; shoulder, arm, or jaw discomfort; epigastric discomfort; nausea; light-headedness; generalized weakness; acute changes in mental status; or diaphoresis. Other atypical features associated with ischemia, particularly in women, include repetitive chest pain, pain relieved by antacids, pain unrelated to exercise, pain not relieved with rest or nitroglycerin, or palpitations without chest pain. [2] Upper abdominal discomfort, despite relief with antacids, can also be a symptom of myocardial ischemia; for patients over 50 and those with known CAO, the evaluation of abdominal pain should include an ECG. Patients predisposed to sensory impairment due to diabetes, advanced age, or altered mental status are especially likely to present in atypical ways. [3]

Atypical chest pain is more common in women than in men,[2] and disorders such as vasospastic and microvascular angina and mitral valve prolapse are more common in women. In women, typical angina is strongly suggestive of cardiac ischemia, and nonischemic pain is associated with a lower though not well defined likelihood of disease.

Ischemia produces different patterns of pain in women with known coronary artery disease. Chest pain at rest but not during exercise does not decrease the likelihood of disease in women as it does in men. Women with stable angina are more likely than men to have pain during rest, sleep, or stress. Risk factors for coronary artery disease in women are listed below:[2]

Typical angina
Postmenopausal, no hormone replacement
Diabetes
Peripheral vascular disease
Hypertension
Smoking
Hyperlipidemia
Truncal obesity
Sedentary lifestyle

Palpitations are common symptoms that raise concern about myocardial ischemia. Palpitation may indicate dysrhythmia induced by ischemia, or the inducement of ischemia by a primary tachyarrhythmia. Palpitations are usually intermittent, and symptoms may have disappeared by the time ED evaluation occurs. The patient may describe palpitations in association with nonspecific chest discomfort or dyspnea, making evaluation difficult. The history should include questions about prescribed or over-the-counter medications or herbals; use of caffeine-containing beverages, symptoms of metabolic disorders such as hyperthroidism; and any prior individual or

familial heart disease. If the clinic setting suggests hypokalemia or hypomagnesemia, electrolytes can be checked.

Physical Examination

The physical examination is often normal. Abnormalities in vital signs include hyper- or hypotension, sinus tachycardia, or bradycardia. Tachycardia often results from increased sympathetic tone and decreased left ventricular stroke volume, while bradycardia is often present among patients with inferior wall ischemia.

Patients with acute ischemia have a higher incidence of abnormal heart sounds such as a diminished S $_1$, a paradoxically split S $_2$, and/or an S $_3$ or S $_4$ due to changes in ventricular function or compliance. Auscultation of the lungs may reveal the presence of ischemia-induced congestive heart failure. However, none of these findings are uniformly present, nor are they diagnostic. Chest wall tenderness reproducing the patient's pain is somewhat suggestive of a musculoskeletal etiology. However, reproducible chest wall tenderness has also been reported in up to 15 percent of patients with confirmed MI; therefore, this finding should never be used to exclude the diagnosis of myocardial ischemia.[6] Despite a lack of specific diagnostic findings, a thorough physical examination remains essential, as it may provide clues to a nonischemic origin of the patient's symptoms and is often helpful in identifying or excluding other life-threatening causes of chest pain.

Electrocardiography

The ECG may help to identify nonischemic causes of chest pain such as dysrhythmias, acute pericarditis, or pulmonary embolism.

Because of the importance of early diagnosis of MI (and hence reduced delay of thrombolytic treatment), specific recommendations have been made concerning the procurement of the initial ECG in the ED. That is, under standing orders, patients with ischemic-type pain should have a 12-lead ECG performed within 10 min of arrival in the ED and the ECG should be handed directly to the treating physician for immediate interpretation. Considering the difficulty of defining "ischemic type" pain and the frequency of atypical presentations, it would be prudent to extend this protocol to all adult patients with chest pain.

Although the ECG is a critical guide to therapy when positive, a normal or nonspecific ECG is not reassuring. Among patients presenting to the ED with AMI, only about half will present with diagnostic changes on the initial ECG. Serial ECGs, even over several hours during the patient's ED stay, will increase the sensitivity of the ECG for the detection of AMI and should therefore be encouraged.[7] The inclusion of right-sided, posterior, or 22-lead ECGs can also improve the diagnostic yield and should be considered in all patients with known or suspected ischemia of the inferior, lateral, or posterior walls or of the right ventricle.[8] The use of continuous 12-lead ST-segment monitoring in the ED may also aid in the detection of patients with transient and/or silent ischemia.

Risk stratification based on the initial ED ECG has also been suggested as a way of improving ED decision making. Although the initial ECG cannot exclude AMI, stable ED patients whose initial ECG is without ischemic changes are at low risk of subsequent life threatening complications and can usually be managed in a non-intensive-care setting.[9]

ANCILLARY TESTING

Computerized Decision Aids

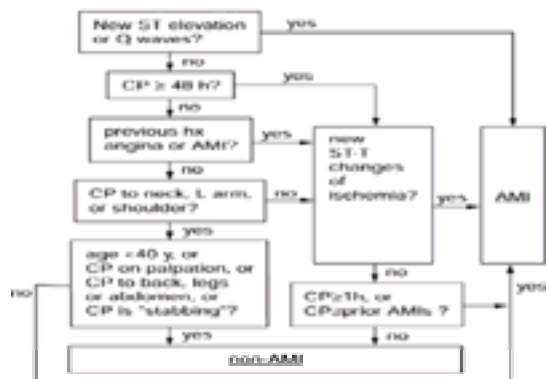
In an effort to facilitate more accurate disposition decisions and thereby reduce mounting health care costs, several investigators have developed computerized decision aids or computer-based triage protocols for ED patients with chest pain. One well-known computer-derived decision aid, developed by Goldman et al., applied recursive partitioning to clinical and ECG data to derive and prospectively validate an algorithm that could stratify ED patients into groups at variable risk of infarction (Fig. 45-1).[10] Although hypothetical testing predicted improved specificity of coronary care unit (CCU) triage decisions, a prospective study did not result in a significant decrease in the rates of CCU admission from the ED. Other methods, such as multivariate analysis and artificial neural networks, have also been used to develop predictive instruments for the detection of acute ischemic heart disease. In a large multicenter prospective trial (as yet unpublished), one of these decision aids, the time-insensitive predictive instrument (TIPI), was shown to decrease CCU admissions by 26 percent and increase ED discharges to home by 48 percent, but this approach has not yet been validated.


FIG. 45-1. Goldman algorithm. (An abridged version. Modified from Ref. 10.)

Myocardial Markers

CREATINE KINASE (CK), CK ISOENZYMES, AND ISOFORMS   CK (adenosine triphosphate creatine *N*-phosphotransferase) is an intracellular enzyme involved in the transfer of high-energy phosphate groups from ATP to creatine. Although found in small quantities in many tissues, CK is present in large concentrations in cardiac and skeletal muscle as well as brain. The enzyme is a dimer composed of two subunits, each of which may be either the M (muscle) type or the B (brain) type, thus creating three distinct dimers, or isoenzymes: CK-BB, predominantly found in brain tissue; CK-MM, the predominant isoenzyme in skeletal muscle (although CK-MB is also found there in small amounts); and CK-MB, accounting for 14 to 42 percent of the total enzyme activity present in cardiac muscle (the predominant enzyme remaining CK-MM).

The quantitative and temporal patterns of appearance and disappearance of CK and its isoenzymes in the blood occur in a reproducible manner but can vary considerably depending on the amount of CK released from cells, the amount of perfusion of damaged tissues, and the rate of clearance by the reticuloendothelial system. CK levels usually become abnormally high within 4 to 8 h after coronary artery occlusion (onset of symptoms), peak between 12 and 24 h, and return to normal between 3 and 4 days (Fig. 45-2). Reports of the sensitivity of total CK vary from 93 to 100 percent, whereas the specificity is lower, ranging from 57 to 86 percent. Owing to the presence of CK in other tissues, many conditions other than AMI may cause an elevated total CK level, thus limiting this marker's usefulness.
FIG. 45-2. Multiple marker curve.

Soon after MI, the CK-MB isoenzyme curve parallels the total CK curve, with levels detectable 4 to 8 h after onset of symptoms (Fig. 45-2). CK-MB may peak slightly earlier than total CK, and it is cleared more rapidly, usually within 48 h (versus 72 to 96 h). Using CK-MB and the ratio of MB to total CK, most studies report both sensitivity and specificity to be greater than 95 percent. Cutoff values vary between techniques, laboratories and populations, but CK-MB values in healthy controls may be up to 5 U/L and up to 5 percent of total CK. Until recently, CK-MB had been almost universally adopted as the "gold standard" for diagnosis of MI. Although specificity is generally improved over total CK, 37 conditions other than MI have been associated with elevated CK-MB levels (Table 45-2). Fortunately, most of these conditions can be easily differentiated from MI on clinical grounds. The relatively rapid return of elevated MB levels to normal is another potential disadvantage because of the possibility of missing the diagnosis in patients presenting later in the course of MI. However, this rapid clearance may be used to a different advantage because it enables the identification of infarct extension and reinfarction.

TABLE 45-2   Conditions Associated with Elevated CK-MB Levels

One major limitation of CK-MB use is that in MI, abnormal levels of the isoenzyme cannot be detected until 4 to 8 h after onset of symptoms, regardless of the assay used. This problem has been partially overcome with the development of rapid assays for CK-MB isoforms (subforms). The isoenzymes CK-MM, CK-MB, and CK-BB are dimeric molecules consisting of three different combinations of two monomers, M and B. On its release from damaged cells, the M-monomer found in tissue CK (M_t) is acted on by an enzyme present in serum, carboxypeptidase-N, which cleaves off the C-terminal lysine. This action results in its conversion into the M-monomer found in serum CK (M_s). Because lysine is a positively charged amino acid, its cleavage results in the M_s-monomer being more negatively charged than M_t. Because the rate of this conversion is limited, newly released, unmodified tissue CK-$M_t M_t$ dimers (referred to as CK-MM$_3$) undergo sequential C-terminal cleavage of its two M_t-monomers to create CK-$M_t M_s$ (CK-MM$_2$) and, subsequently, CK-$M_s M_s$ (CK-MM$_1$). Although the clinical utility of CK-MM isoform measurement is limited by its lack of specificity, the same modification also occurs to the M_t-monomer of CK-MB (CK-MB$_2$), resulting in the formation of CK-MB$_1$. By measuring MB$_2$ activity and the MB$_2$/MB$_1$ ratio, evidence of infarction can be detected before the total level of CK-MB exceeds the normal range. Using this method, one multicenter study has reported a sensitivity of 95.7 percent and specificity of 93.9 percent for AMI among 1110 patients within 1.2 h of ED presentation (6 h from symptom onset). [11]

Myoglobin is a small (17,500-Da), heme-containing protein found in striated (skeletal) and cardiac muscle cells. When disrupted, these cells rapidly release myoglobin into the serum. Myoglobin serum levels increase rapidly after significant muscle damage and return to baseline values relatively quickly in the presence of normal kidney function. This property makes myoglobin potentially valuable as a serum marker for myocardial necrosis. After MI, serum myoglobin levels begin to rise within 3 h of onset of symptoms and are abnormally elevated in 80 to 100 percent of patients after 6 to 8 h, peak from 4 to 9 h after symptom onset (Fig. 45-2), and return to baseline within 24 h. Because of this rapid rise and fall, serum myoglobin is very sensitive as a marker of MI when determined early in the course of infarction. However, a false-negative result may occur if the test is performed after myoglobin has already been cleared from the serum. Also, because the myoglobin found in myocardium is indistinguishable from that found in skeletal muscle, it is a nonspecific marker. Aside from MI, all conditions that cause significant skeletal muscle injury must be considered as possible causes of an elevated myoglobin level. Fortunately, these conditions can usually be detected clinically in patients with symptoms related to infarction.

Evaluation of the myoglobin/carbonic anhydrase III ratio can enhance the specificity of myoglobin. The enzyme carbonic anhydrase III is released from skeletal muscle in a fixed ratio with myoglobin. Combined assays can therefore help determine whether myoglobin is of skeletal or cardiac origin. When these dual assays are used, the high early sensitivity of myoglobin is maintained and specificity is improved. However, these assays are not yet commercially available and the use of dual assays for risk stratification has not yet been evaluated.

Troponin I and T

The troponin complex is the main regulatory protein of the thin filament of the myofibrils that regulate the Ca^{2+}-dependent ATP hydrolysis of actomyosin. The troponin complex consists of three subunits: an inhibitory subunit (troponin I), a tropomyosin binding subunit (troponin T), and a calcium-binding subunit (troponin C). Because each subunit has cardiac, slow-twitch, and fast-twitch skeletal isoforms, immunoassays based upon the significant heterogeneity in amino acid sequences can detect the specific isoforms. The cardiac isoform of troponin I is not found in skeletal muscle during any stage of development. As a result, elevations of cardiac troponin I do not occur in the setting of acute or chronic skeletal muscle damage in the absence of myocardial necrosis.

Following AMI, both cardiac troponin I and troponin T become elevated after approximately 6 h, peak at 12 h, and remain elevated for 7 to10 days. Both have a higher specificity for myocardial necrosis than CK-MB in selected subsets of patients, such as those presenting late in the course of MI, those with recent surgery, a cocaine habit, or skeletal muscle disease. Either troponin may be elevated in patients with renal failure. In ED patients with symptoms of possible ischemia, both troponins have been shown to have high sensitivity and specificity for AMI. Elevation of either cardiac troponin also predicts subsequent cardiovascular complications independent of CK-MB and the ECG.[12,13]

Clinical Applications of Myocardial Marker Measurements

The current literature supports the inclusion of myocardial marker measurements in protocols governing the ED evaluation of patients with chest pain for four distinct purposes (Table 45-3). First, for the ability of myocardial markers to confirm or "rule in" suspected MI within the first hours after presentation in patients with nondiagnostic ECGs. Second, for the ability of markers to identify some patients with otherwise unrecognized MI from among the many patients with atypical presentations and non-diagnostic ECGs. Third, to risk-stratify patients early in their ED course—i.e., to identify those patients at particularly high risk for subsequent adverse events. Fourth, to definitively exclude the diagnosis of AMI using an accelerated myocardial marker curve during an extended observation and monitoring period in the ED. The first three applications are discussed here, while the fourth is discussed in the following section.

TABLE 45-3   Uses of Markers of Myocardial Injury in the ED

EARLY DIAGNOSIS OF AMI   In those patients whose initial ECG is diagnostic for MI, no further testing is required and appropriate interventions can be initiated. As stated previously, approximately 50 percent of MI patients will have an initially nondiagnostic ECG. The release kinetics of currently available markers generally require 6 h or more after coronary occlusion to exclude infarction; therefore MI cannot be definitively ruled out within the first few hours of the ED visit. However, some MI patients with nondiagnostic initial ECGs will have positive marker tests upon ED arrival, and many more will develop positive tests soon after presentation. Therefore, early, rapid serial sampling of myocardial markers may identify many MI patients with nondiagnostic ECGs (rule in MI) and thus allow earlier utilization of time-dependent treatments.

Studies of single CK-MB measurement upon ED presentation have demonstrated a sensitivity for MI of less than 60 percent. However, by using serial CK-MB measurements, several authors have demonstrated sensitivities ranging from 80 to 96 percent. [14,15 and 16]

Owing to its earlier release into serum after coronary artery occlusion, the heme-containing protein myoglobin has a potential advantage over CK-MB for early diagnosis of MI. In one study, samples taken at presentation yielded a sensitivity of 62 percent for myoglobin as compared with 14 percent for CK-MB. At 3 h, the sensitivity for MI increased to 90 percent for CK-MB and to 100 percent for myoglobin. [17] A subsequent, similar study reported sensitivities at 2 h of 82.1 percent for CK-MB and 100 percent for myoglobin. [18]

IDENTIFYING "MISSED MI" PATIENTS   Single-sample myocardial marker measurements cannot be used to exclude the diagnosis of MI in the ED. However, results of several investigations suggest that the incorporation of markers into patient care algorithms for low-risk patients prior to discharge may help to identify those with unsuspected MI.

In the first such study (1987), three of 482 chest pain patients discharged from the ED were found to have had a positive CK-MB. In another investigation (1991) among 271 ED patients, 5 discharged patients and 2 admitted to unmonitored beds with noncardiac diagnoses were identified by a single positive CK-MB value and later determined to have had a clinically unsuspected MI. All 7 of these patients had nondiagnostic initial ECGs and 3 had presented with symptoms other than chest pain.[19] In a later multicenter study that prospectively assessed the effect on ED physician decision making of two CK-MB measurements drawn 3 h apart, 3 of 265 patients selected for discharge by the ED physician were identified and admitted solely on the basis of a positive CK-MB. These results suggest that ED patients to be sent home or admitted to unmonitored beds after presenting with chest pain as well as with other presentations of possible ischemia may benefit from prerelease "screening" for MI using CK-MB.[20] Although these results are promising, there is not yet sufficient data concerning either cost or clinical effectiveness of this practice to advocate it's widespread use.

EARLY RISK STRATIFICATION   As use of newer anti-ischemic therapies, such as early angiographic interventions and anti-platelet and antithrombotic drugs, become more common, the morbidity and mortality associated with ACS are likely to decline further. However, the greater risk of therapy related complications and the higher costs associated with these newer interventions necessitate a selective approach to their use. Several investigations suggest that markers of myocardial injury can successfully be used in the ED to rapidly identify those patients most likely to benefit from a more aggressive approach.

Positive CK-MB tests obtained upon presentation and 2 h later have been shown to predict up to a fivefold increased likelihood of subsequent ischemic complication, regardless of the final diagnosis. A subsequent similar study of 5120 patients from 53 EDs confirmed the prognostic significance of a positive CK-MB value, regardless of final diagnosis. Other investigations have shown that early ED testing of either troponin-T or troponin-I also yields clinically useful prognostic data and suggest that simultaneous testing of both troponin and CK-MB may identify additional high-risk patients. [12,21,22]

APPROACH TO LOW PROBABILITY OF ISCHEMIA

After initial evaluation, early data collection, and interpretation, a high potential for the presence of an ACS will be recognized in many patients. The approach to further risk stratification and treatment of these patients is detailed in Chap. 47. Many others can be classified as having a low probability of acute ischemia based on clinical information available at the time of their ED visit. However, there is currently no consensus in the literature on their optimal management or even a widely accepted definition of who belongs to this group. There is consensus on two issues: that history alone is inadequate to exclude the presence of acute ischemia and that the goal must be "zero tolerance" for missed AMI.[23] A systematic approach based on objective data is required to identify these lower-risk patients early in their course (Table 45-4) while also resulting in lower costs and, perhaps, improved outcomes (Fig. 45-3).

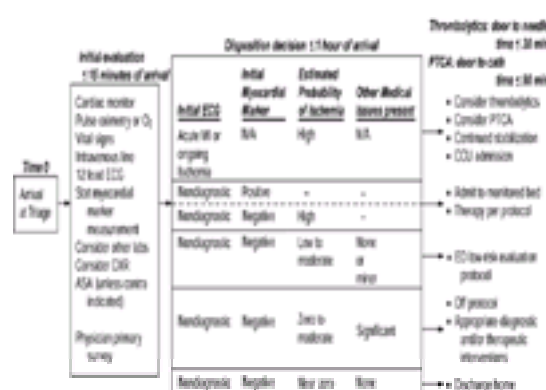
TABLE 45-4   Proposed Prognosis-Based Classification System for ED Chest Pain Patients*


FIG. 45-3. Algorithm for risk-based decision making.

Diagnostic tools now available for this group of patients include myocardial marker measurements (see above), stress testing, nuclear or ultrasound imaging, and advanced monitoring techniques. A description of the commonly used approaches for low-risk patients follows.

Characteristics of Common Diagnostic Tests Used in Emergency Cardiac Care

ECG BASED (STANDARD) EXERCISE STRESS TESTING   In the ED setting, exercise testing has been recommended for patients applied either as the final component of a chest pain observation protocol after the exclusion of AMI or, in selected low-risk patients, soon after presentation as an alternative to an extended observation period.

Many variations exist in the equipment, procedures, and interpretive algorithms used. Both treadmill and cycle ergometer devices are acceptable and commercially available. Cycle devices are smaller and less expensive, offering reduced motion artifact. However, treadmills are still more commonly used in the United States because many patients are unable to reach the desired point of maximum oxygen uptake on the cycle owing to quadriceps muscle fatigue. Other mandatory equipment includes a nearby crash cart with defibrillator and rhythm monitoring capability. Testing may be reliably performed by a trained technician or other allied health professional, although an experienced physician must be readily available. Dysrhythmia, AMI and death have been reported and can be expected to occur at rates of 4.8, 3.6 and 0.5 per 10,000 tests, respectively. [24]

Several exercise and monitoring protocols are in use, differing in duration and level of exercise reached as well as testing end points. No consensus exists on the preferred protocol, although the Bruce protocol is the most common and best studied. At the time of testing, informed consent is obtained and the procedure is explained to the patient in detail. The patient's skin is prepared for electrode placement by trimming hair, use of a defatting agent, e.g., alcohol, and abrading the superficial skin layer. After electrode placement, baseline measures of heart rate, blood pressure, and 12-lead ECG are obtained at rest in both supine and standing positions. Exercise is then initiated, with exertion increased in a step-wise fashion predetermined by protocol with the desired endpoint ideally reached within 8 to 12 min of test initiation. Throughout the test and during recovery, ECG rhythm is monitored continuously and 12 lead ECGs are recorded at least once each min. Heart rate, blood pressure, patient symptoms, and perceived exertion (via a visual analog scale) is also recorded at each workload level. Depending on the protocol followed, exercise is terminated when the subject reaches a pre-determined percentage of predicted maximum heart rate (i.e., 85 percent) or when another defined end point is reached (Table 45-5). The most commonly used definition of a positive exercise test result from an ECG standpoint is greater than or equal to 1 mm of horizontal or downsloping ST-segment depression or elevation for at least 60 to 80 ms after the end of the QRS complex.

TABLE 45-5   Indications for Terminating Exercise Testing

Exercise stress testing may be contraindicated for various reasons (Table 45-6). [25] If the patient has physical limitations preventing exercise but no other contraindications, a pharmacologic stress test using a chronotropic drug (i.e., dobutamine) may be appropriate. Exercise testing may not be safe for patients at high risk for acute ischemia or those with other uncontrolled cardiovascular or pulmonary pathology. Further, patients with an abnormal baseline ECG—such as those with left ventricular hypertrophy, bundle branch block, or digoxin effect—are less likely to benefit from standard exercise testing owing to difficulties in interpretation of exercise-induced ECG changes.

TABLE 45-6   Contraindications to Exercise Testing

The clinical utility of ED stress testing depends upon the test result's ability to modify the pretest probability of the diagnosis and to change treatment and disposition. ED stress testing is particularly difficult to quantify because test sensitivity and specificity are greatly influenced by the population being tested. As the pretest probability of significant coronary artery disease increases, the likelihood of a false-negative test also increases. Conversely, when a population with a very low pretest probability of disease is tested, the likelihood of a false-positive result increases. Therefore, based on current data, *diagnostic* stress testing is recommended for patients with a low pretest probability of coronary artery disease and is unlikely to be helpful in those at either very low risk (<5 percent) or those at moderate to high risk (>30 percent). [25,26] The pretest probability of disease can be determined semiquantitatively based on demographic, historical, and ECG data using a number of validated decision aids. ED stress testing may be of further value when applied to a broader range of patients if the goal of testing is to predict prognosis rather than diagnosis. Stress-test performance of post-AMI patients is a valid and commonly used predictor of post-event prognosis, and several recent studies suggest that ED stress testing of selected patients can reliably predict short-term prognosis.

Myocardial Imaging

Advantages of *echocardiography* include its noninvasive nature, that it does not utilize radioactive materials, and that it can be performed in the ED. Further, it is a dynamic technique, allowing time-related observations of anatomy and function at rest and/or under stress (exercise- or pharmacology-induced). Additionally, it has potential value in assessing other sources of chest pain, including aortic dissection, pericardial pathology, valvular disease, and pulmonary embolism.

The value of echocardiography in evaluating ischemic heart disease is largely based upon the experimental finding, in both animal and human studies, that acute

myocardial ischemia reliably and rapidly results in observable wall motion abnormalities. Thus, theoretically, a normal echocardiogram during chest pain should exclude the presence of ischemia. Unfortunately, this finding is limited by several factors. Since the effects of adjacent wall segments commonly lead to false-positive and false-negative interpretations of wall motion abnormalities, systolic wall thickening is used as a more specific indicator of ischemia. However, detection of wall-thickening abnormalities is highly dependent on imaging technique and interpretative skills, with up to 10 percent of tests being technically inadequate. Further, the echocardiogram cannot distinguish between myocardial ischemia and acute infaction, cannot reliably detect subendocardial ischemia, and may be falsely interpreted as positive in the presence of several conditions (conduction disturbances, volume overload, heart surgery, trauma). Finally, timing of the test relative to the onset of symptoms is critical, as transient wall motion abnormalities may resolve within minutes of an ischemic episode.

Contrast echocardiography using physiologically safe microbubbles is a newer technique that holds future promise. Studies suggest that this technique significantly improves the detection of regional wall motion abnormalities and wall thickening. In one study, 28 percent of standard stress echos performed were inconclusive due to difficulties in interpretation but were decisively normal or abnormal with the use of contrast. Further, contrast echocardiography may potentially be used to assess coronary vessel patency directly, even at the microvascular level, with sensitivity similar to or greater than that of nuclear perfusion imaging.

Myocardial perfusion imaging utilizes an intravenously injected radioactive tracer that is distributed throughout the coronary circulation. The tracer is actively transported across the sarcolemma membrane into myocardial cells. Local myocardial uptake and subsequently, myocardial imaging, is therefore dependent on both adequate regional coronary flow and myocardial cell integrity, with tracer uptake occurring in direct proportion to regional myocardial blood flow.

Thallium 201 is the oldest and most studied tracer in common use today. Thallium, a cation, behaves similarly to potassium in tissues and is rapidly redistributed after initial uptake, making it particularly well suited for the detection of stress induced ischemia. When imaging occurs within 20 min after thallium injection (immediately after exercise or pharmacologic stress testing), areas of positive uptake reflect both adequate coronary flow and viable myocardium, while areas without uptake represent either infarcted or ischemic myocardium. On repeat imaging several hours later, continued lack of perfusion ("irreversible defect") indicates an area of infarction, while areas with tracer uptake only on delayed images ("reversible defect") represent formerly ischemic myocardium. Combined with conventional ECG-based stress testing, thallium imaging offers improved sensitivity and specificity for detection of significant coronary artery disease over ECG-based testing alone. Further, thallium testing (or other perfusion imaging) is likely to be of value in patients who would not otherwise benefit from stress testing due to a confounding or potentially masking abnormal baseline ECG. There are several limitations of thallium testing. Imaging must be performed immediately after injection, making it impractical for use in patients with ongoing chest pain. Moreover, because of a long half life, the injected dose of thallium must be kept low to avoid excessive radiation exposure. This and other properties of the tracer result in a relatively poor image quality and the frequent occurrence of artifactual perfusion defects (false positives) due to overlying tissue attenuation. This is particularly common in women and obese patients. Based on these limitations and the lack of ED-based efficacy studies, a 1997 National Heart Attack Alert Program Working Group concluded that "thallium-201 does not appear to be an ideal agent for use in ED management of patients with chest pain."[27]

Owing to several technical factors, myocardial perfusion imaging using *technetium 99m* (^{99m}Tc)-labeled agents such as sestamibi offers advantages over thallium for ED use. Since the half-life of ^{99m}Tc is much shorter than that of thallium (6 versus 73 h), a larger dosage can be injected without harm to the patient. This results in the superior image quality, decreased tissue attenuation–related artifacts, and higher specificity of sestamibi imaging. Newer ^{99m}Tc agents currently under investigation are likely to further improve image quality. Additionally, in contrast to thallium, the initial distribution of ^{99m}Tc agents is stable for several hours. Therefore, accurate imaging can occur up to 3 h after injection. As with thallium, resting and stress (exercise or pharmacologic) images can be compared to yield additional data.

Low-Risk Patient Protocols

INPATIENT ADMISSION   In settings where extended observation and definitive diagnostic testing is not available in the ED, all patients whose presentation suggests any reasonable plausibility of an acute ischemic event must be admitted to an inpatient bed. Even in the presence of an ED-based cardiac evaluation protocol, inpatient admission is often prudent for patients whose presentation suggests a low probability of ischemia but who also have other acute medical, surgical, or psychiatric diseases requiring a prolonged or intensive level of attention, which cannot be optimally given in the ED. Once the need for inpatient admission has been determined, further stratification based on assessment of the patient's short-term risk of morbidity or mortality can be made based on the patient's history and physical exam, initial ECG,[9] and early myocardial marker measurement.[12,21,22] Patients with a prior history of coronary artery disease, evidence of congestive heart failure on physical exam, recurrent chest pain in the ED, or new or presumed new ischemic ECG changes are at higher short-term risk and may be more appropriately managed in an intermediate-care (step-down) unit.[6] Conversely, patients whose initial ED ECG is normal or unchanged from a previous ECG have a very low risk of adverse events and can safely be evaluated on a monitored floor or telemetry bed. Those with nonspecific changes on the initial ECG represent an intermediate risk group. A single myocardial marker measurement soon after ED presentation can also identify those patients at greater risk from among those with atypical presentations.[22]

ED OBSERVATION/MONITORING   In 1984, the Multicenter Chest Pain Study Group was formed to develop new lower-cost strategies for managing "ROMI" (rule out MI) patients. In 1991, this group published the results of a seven-center investigation of 2684 patients admitted for chest pain and reported that the diagnosis of infarction could have been safely excluded within a 12-h observation period among a subgroup identifiable at presentation as having a low probability of AMI.[28] The authors also suggest routine predischarge stress testing of these patients in order to reduce the risk of discharging patients with unstable coronary syndromes prematurely.

This approach was further refined by Gibler et al. in a study of 1010 patients admitted to an ED-based chest pain evaluation and treatment unit ("Heart ER") over 32 months. Patients with symptoms consistent but not highly suggestive of acute ischemia were observed for 9 h with continuous 12-lead ST-segment ECG monitoring and serial CK-MB testing at 0, 3, 6, and 9 h after presentation. Those who completed a negative 9-h evaluation subsequently underwent echocardiography followed by graded exercise stress testing in the ED prior to discharge. Utilizing this approach, 82.1 percent of patients were released home from the cardiac evaluation unit (CEU).[29]

The ideal length of observation (12, 9, or 8 h), the best choice and timing of myocardial marker measurements, and the value of continuous ST-segment monitoring are among the many questions that have not yet been answered definitively. Additionally, while several studies have documented cost savings associated with use of an ED-based CEU compared with traditional inpatient admission, the cost effectiveness of their widespread use is still not uniformly accepted.

Although AMI can be reliably excluded by this type of observation protocol (Fig. 45-4), normal serial ECGs and myocardial marker measurements do not preclude the presence of other ACSs (i.e., unstable angina), which may still put the patient at high risk for a subsequent adverse event. Therefore, further evaluation is usually indicated prior to discharge. The various forms of stress testing (with or without myocardial imaging) currently offer the best noninvasive method to both predict the presence of coronary artery disease as well as assess prognosis. In the Cincinnati study previously mentioned,[29] 791 patients underwent treadmill exercise stress testing after a negative observation period with no adverse events reported during testing. Among these, 9 of the patients had positive tests and 4 of these subsequently confirmed to have significant coronary artery disease not otherwise identified (positive predictive value = 44.4 percent). Of the 782 negative results, 10 were false negatives, yielding a negative predictive value of 98.7 percent. The authors concluded that although a negative observation period and stress test still does not completely rule out the possibility of coronary artery disease, they do identify a large group of patients who could be safely released from the ED with subsequent follow-up.[29] In a subsequent study, 86 percent of 502 patients who underwent a similar observation protocol and ECG stress testing were discharged after a negative evaluation, with no deaths or AMIs reported after 5 months of follow-up. In this investigation, 24 patients with subsequently confirmed ischemic heart disease were identified only through positive ED stress tests. However, the effectiveness of this technology is still not uniformly accepted. A recent consensus panel report from the National Heart Attack Alert Program cited the need for additional investigation and concluded that "ECG exercise stress testing in the ED cannot be recommended in the absence of additional data demonstrating safety and effectiveness."[26]
FIG. 45-4. Algorithm for the evaluation of low-risk patients.

IMMEDIATE SCREENING   In addition to admission or ED-based observation, immediate myocardial perfusion imaging, echocardiography, or stress testing without prior observation have been suggested as rapid, safe, and cost-effective alternatives among selected patients. However, few ED-based studies have been published concerning these approaches and many questions remain unanswered concerning their limitations and relative value.

Because of its minimal redistribution, myocardial perfusion imaging using ^{99m}Tc sestamibi (sestamibi scanning) is particularly suited for the early ED assessment of both diagnosis and prognosis among patients with *ongoing chest pain.* The agent can be injected in the ED upon presentation without interfering with other therapeutic or diagnostic interventions. Imaging can then be delayed for up to 3 h without significant degradation of the resulting image. With this technique, the image acquired will represent the state of myocardial perfusion at the time of injection, and a normal perfusion scan should therefore reliably exclude myocardial ischemia as a cause of the patient's chest pain. Indeed, multiple investigations have confirmed that an abnormal study has a high sensitivity (94 to 100 percent) for the prediction of AMI when injection occurred during active pain.

The value of resting sestamibi scanning in patients who present after the resolution of chest pain is less clear. Some investigators have reported a substantial decrease in diagnostic accuracy related to increasing delay from symptom resolution to tracer injection. However, in another study among those with greater than 30 min of chest pain within the 12 h prior to presentation, sensitivity for AMI remained 100 percent. [3c] In the largest published series to date, 100 percent sensitivity for AMI was also reported among 438 low-risk patients enrolled and scanned without regard to the presence or absence of chest pain at the time of injection. [31] In this study, among the 338 "low-risk" patients with normal perfusion scans in the ED, there were no AMIs or deaths within the 1-year follow-up period. However, seven (2.1 percent) low-risk patients with normal scans did require a coronary revascularization procedure within 1 month of their ED visit. Taken as a whole, the current literature suggests that low-risk patients with negative sestamibi scans may be safely discharged from the ED without an extended observation period. Pharmacologic or exercise stress imaging using sestamibi may subsequently be performed either after an observation period or during a follow-up visit to assess for the presence of stress-induced ischemia.

Several small studies have been published in which chest pain patients were assessed with standard *echocardiography* soon after ED presentation. Among these, the sensitivity for the detection of acute ischemia or AMI among all patients ranged from 88 to 96 percent, significantly higher than that of the 12-lead ECG. However, even among selected patients with adequate studies who are evaluated during ongoing chest pain, false-negative echocardiograms may occur in up to 8 percent of AMI patients, thus precluding the possibility of discharging a patient on the basis of a negative study. Primarily due to this limitation, the National Heart Attack Alert Program Working Group on echocardiography has concluded that this tool cannot currently be recommended for ED use. [32]

A few reports have advocated *immediate exercise testing* of low-risk chest pain patients presenting to the ED without prior observation or ruling out of AMI. One small series of 32 patients who presented with "chest pain suggestive of cardiac origin but not typical of angina," normal or nondiagnostic ECG, and less than two cardiac risk factors reported that all stress tests were negative and no adverse events occurred. Another investigation of 212 ED patients with similar inclusion criteria found that 13 percent had a positive stress test, 59 percent a negative test, and 2 percent a nondiagnostic result with no adverse events in any group. [33] The limited amount of available data concerning both clinical effectiveness and safety preclude routine application of this approach at the present time.

DIFFERENTIAL DIAGNOSIS

During the initial assessment of patients with chest pain, it is important that the diagnosis of ACS be considered in concert with other life-threatening conditions. These include aortic dissection, pulmonary embolism, pneumothorax, pericarditis, pericardial tamponade, pneumonia, and esophageal rupture (Table 45-1). Other significant causes of chest pain include mitral valve prolapse, aortic stenosis, and gastrointestinal conditions, such as perforated ulcer and cholecystitis.

Risk factors for *aortic dissection* include atherosclerosis, uncontrolled hypertension, coarctation of the aorta, bicuspid aortic valves, aortic stenosis, Marfan syndrome, Ehlers-Danlos syndrome, and pregnancy. The pain of aortic dissection—midline substernal chest pain—is classically described as tearing, ripping, or searing and radiating to the interscapular area of the back. Typically, the pain is at its worst at symptom onset and is often felt both above and below the diaphragm. Symptoms of "secondary" pathologies resulting from arterial branch occlusions—such as stroke, AMI, or limb ischemia—may overshadow the clinical presentation of the dissection and make an accurate diagnosis difficult. Aortic dissection should be considered in the patient with continuing chest pain but without ECG evidence of evolving myocardial infarction.

The most common radiographic finding is mediastinal widening (>75 percent of cases). While aortography remains the "gold standard" in evaluating aortic dissection, both transesophageal echocardiography and high-resolution contrast spiral computed tomography are less invasive techniques that are now widely accepted for this evaluation. Acute dissection is discussed in detail in Chap. 54.

Pulmonary embolism (PE) can manifest in a multitude of presentations including chest pain, syncope, shock, hypoxia, and dyspnea. The pain associated with a PE occurs when inflammation of the parietal pleura overlying the infarction causes chest pain that is generally sharp and related to respiration. Dyspnea, fever, cough, and/or hemoptysis may also be present and the chest wall may be tender to palpation. Patients with massive pulmonary emboli often present with unstable vital signs and the classic presentation of sharp, pleuritic chest pain and dyspnea associated with tachypnea, tachycardia, and hypoxemia.

Spontaneous pneumothorax may occur due to sudden changes in barometric pressure, in smokers or patients with chronic obstructive pulmonary disease, idiopathic pleural bleb disease, in AIDS patients on pentamidine, or in those with other pulmonary pathology. Patients usually complain of a sudden, sharp, lancinating, pleuritic chest pain and dyspnea. If not recognized early, the condition can progress to tension pneumothorax, which is characterized by severe dyspnea, jugular venous distention, tracheal deviation to the contralateral side, and hypotension. Auscultation of the lungs may reveal absence of breath sounds on the ipsilateral side and hyperresonance to percussion but clinical impression alone is unreliable. Diagnosis of a simple pneumothorax is made by chest x-ray.

The pain of *acute pericarditis* is typically acute, sharp, severe, and constant. It is usually described as substernal, with radiation to the back, neck, or shoulders, and is exacerbated by lying down and by inspiration. It is relieved by leaning forward. The presence of a pericardial friction rub is suggestive of the diagnosis, but absence of a rub does not exclude the diagnosis. The ECG may show diffuse ST-segment elevation and T-wave inversion. Additionally, depression of the PR segment is a highly specific ECG finding for pericarditis. The etiologies of pericarditis are many and must be pursued prior to determining a final disposition and treatment plan.

Mitral valve prolapse (MVP) is the most frequently diagnosed cardiac valvular abnormality and is more commonly diagnosed in women than in men. [34] The discomfort of mitral valve prolapse often occurs at rest, is atypical for myocardial ischemia, and can be associated with dizziness, hyperventilation, anxiety, depression, palpitations, and fatigue. The discomfort may be related to papillary muscle tension, and many patients benefit from the administration of beta-adrenergic blocking agents.[35] The more serious complications of MVP are syncope, stroke, infective endocarditis, congestive heart failure, and dysrhythmia. MVP is characterized by a midsystolic click and late systolic murmur detected on cardiac auscultation. Two-dimensional echocardiography is the diagnostic tool of choice and, together with physical exam findings, helps to stratify patients into high- and low-risk categories for developing serious complications. Patients with MVP who do not have a murmur or mitral regurgitation on Doppler have a lower rate of serious complications than those with the following abnormalities on echocardiogram: severe mitral regurgitation, left ventricular enlargement, redundant or thickened mitral valve leaflets, and left atrial enlargement. [35] Palpitations and every type of supraventricular or ventricular dysrhythmia have been associated with MVP.

Any patient who may be in the high-risk category, presenting with concerning signs and symptoms, should be considered for either inpatient evaluation or cardiology consultation and close follow-up as an outpatient.

Pneumonia can produce chest pain or discomfort that is usually sharp and pleuritic. It is usually associated with fever, cough, and hypoxia. Physical exam may reveal rales over the affected lobes, decreased breath sounds, and signs of consolidation, (i.e., bronchial breath sounds). A chest radiograph confirms the diagnosis.

Esophageal rupture (Boerhaave syndrome) is a rare but potentially life-threatening cause of chest pain. Patients classically present with a history of substernal, sharp chest pain of sudden onset that occurs immediately following an episode of forceful vomiting. The patient is usually ill-appearing, dyspneic, and diaphoretic. The

physical exam is often normal but may reveal evidence of pneumothorax or subcutaneous air. Chest radiography may be normal or may demonstrate pleural effusion (left more common than right), pneumothorax, pneumomediastinum, pneumoperitoneum and/or subcutaneous air. The diagnosis can be confirmed by a study with water-soluble contrast.

Musculoskeletal or chest wall pain syndromes are diagnoses of exclusion. These syndromes are often characterized by highly localized, sharp, pleuritic and positional chest pain. Pain that is completely reproducible by light to moderate palpation of a discrete area of the chest wall often represents pain of musculoskeletal origin, although musculoskeletal pain commonly accompanies coronary artery disease. Costochondritis is an inflamation of the costal cartilages and/or their sternal articulations and causes chest pain that is variably sharp, dull, and/or increased with respirations. Tietze syndrome is a particular cause of costochondral pain related to fusiform swelling in one or more upper costal cartilages and has a pain pattern similar to that of other costochondral syndromes. Xiphodynia is another inflammatory process that causes sharp, pleuritic chest pain reproduced by light palpation over the xiphoid process. Texidor twinge or precordial catch syndrome is described as a short, lancinating chest discomfort located near the cardiac apex associated with breathing as well as with poor posture and inactivity.

GASTROINTESTINAL DISORDERS   It is very difficult to discriminate gastrointestinal disorders from myocardial ischemia. Dyspepsia syndromes, including gastroesophageal reflux disease (GERD), often produce pain described as burning or gnawing, usually in the lower half of the chest and often accompanied by a brackish or acidic taste in the back of the mouth. The recumbent position usually exacerbates the symptoms, and although the pain is usually relieved with antacids, this therapeutic response is also common with myocardial ischemia. Esophageal spasm is often associated with reflux disease and is characterized by a sudden onset of dull, tight, or gripping substernal chest pain, frequently precipitated by the consumption of hot or cold liquids or a large food bolus and often lasting for hours. The pain also responds to sublingual nitroglycerin. Thus, nitroglycerin does not differentiate esophageal spasm from myocardial ischemia.

Peptic ulcer disease is classically characterized as postprandial, dull, boring pain located in the midepigastric region. Patients often describe being awakened from sleep by it. Duodenal ulcer pain is usually relieved after eating food, in contrast to gastric ulcer symptoms, which are often exacerbated by eating. Symptomatic relief is usually achieved by antacid medications. Acute pancreatitis and biliary tract disease present with right-upper-quadrant or epigrastric pain and tenderness but can also present with chest pain.

There are no data to support the practice of a therapeutic intervention as diagnostic challenge. The episodic nature of the pain in many of these symdromes, the very strong potential for placebo effect, and the substantial impact of "negative tests" and reassurance in alleviating anxiety and pain cannot be underestimated. There are no data to prove that chest discomfort relieved by antacids is more likely to be noncardiac in origin than pain that is not so relieved. Conversely, nitroglycerin is a smooth muscle dilator that may afford relief in cases of lower esophageal spasm or biliary colic. As a rule, diagnostic decisions should not be influenced by response to a therapeutic trial. When the history, physical examination, and diagnostic workup point to a gastrointestinal etiology of the pain, the patient may be treated with antacids and H$_2$ blockers, with follow-up referral to an internist or gastroenterologist.

46 SYNCOPE

Barbara K. Blok

Syncope is a sudden, transient loss of consciousness associated with inability to maintain postural tone. Syncope accounts for approximately 3 percent of ED visits each year. The elderly population has the highest incidence and is at increased risk for morbidity from syncopal episodes. [1] Near-syncope, a premonition of syncope without loss of consciousness, shares the same basic pathophysiologic processes as syncope.

PATHOPHYSIOLOGY

The final common pathway of syncope is a lack of vital nutrient delivery to the brainstem reticular activating system, leading to loss of consciousness and postural tone. Most commonly, an inciting event causes a drop in cardiac output, which, unless corrected rapidly, decreases oxygen and substrate delivery to the brain. Less commonly, vasospasm or other alterations in flow singularly reduce central nervous system blood flow. The reclined posture of syncope and the response of autonomic autoregulatory centers reestablish cerebral perfusion, leading to a spontaneous return of consciousness.

ETIOLOGY

The differential diagnosis of syncope is vast and includes everything from common benign disorders to life-threatening processes (Table 46-1). The most common causes of syncope are cardiac dysrhythmia and vasovagal reflex and orthostatic hypotension. [2,3]

TABLE 46-1   Etiology of Syncope

Reflex-Mediated Syncope

Under normal circumstances a physical or emotional stress leads to increased sympathetic outflow and a subsequent increase in heart rate, blood pressure, and cardiac output. In patients with reflex-mediated syncope, the stimulus produces an abnormal autonomic nervous system reflex. Most commonly, an initial increase in sympathetic outflow is inappropriately withdrawn and replaced by increased vagal tone. Hypotension with or without bradycardia follows, leading to decreased cerebral perfusion and syncope. Less commonly, the stimulus leads directly to vagal hyperactivity and symptoms. Prodromal symptoms are varied, but include blurring of vision, dizziness, pallor, nausea, and diaphoresis.

The classic example of reflex-mediated syncope is the vasovagal faint incited by a noxious stimulus (pain, fear) or a characteristic setting. Vasovagal syncope rarely occurs without warning symptoms, which may last several minutes. A clinical diagnosis of vasovagal syncope should not be made without the typical prodromal symptoms described above. The individual is usually in the vertical position at the time of the event, and attacks are aborted or resolved after assuming a reclined position, which allows an increase in central circulation and thus increases cerebral perfusion. Whereas in the past, vasovagal syncope was diagnosed by history alone, upright tilt-table testing serves as an objective measure for vasovagal syncope and has led to the diagnosis in a number of patients with previously unclear etiology. [4]

Carotid sinus hypersensitivity is another type of reflex-mediated syncope. The carotid body, located at the carotid bifurcation, is a pressure-sensitive organ. The stimulation of an abnormally sensitive carotid body by external pressure may lead to two autonomic responses. Most commonly, there is an abnormal vagal response leading to bradycardia and asystole of greater than 3 s. Less commonly, there is a vasodepressor response leading to a decrease in blood pressure of more than 50 mmHg without a significant change in heart rate. Both responses may occur simultaneously. Carotid sinus hypersensitivity is more common in men, the elderly and among those with ischemic heart disease, hypertension, and certain head and neck malignancies. Although a number of patients may have a hypersensitive carotid sinus response on testing, unless this response culminates in syncope or recurrence of prodromal symptoms and can be associated with an inciting event, such as shaving or turning of the head, it cannot be diagnosed as the cause of a syncopal event. Only 5 to 20 percent of patients with carotid sinus hypersensitivity have a true carotid sinus syndrome with spontaneous symptoms. Carotid sinus hypersensitivity should be considered in all older patients with recurrent syncope and negative cardiac evaluations.

In situational syncope, there is an abnormal or hypersensitive autonomic reflex response to a specific physical stimulus (Table 46-1). Additionally, there may be a component of raised intracranial pressure or increased intrathoracic pressure leading to decreased cerebral perfusion. The physical stimulus may be associated with another underlying disease process: esophageal stricture in swallow syncope, prostatic hypertrophy or bladder neck obstruction with micturition syncope, and constipation with defecation syncope.

Orthostatic Syncope

When a person assumes an upright posture, blood is shifted to the lower part of the body and cardiac output drops. When a drop in cardiac output or blood pressure occurs in a healthy individual, the autonomic nervous system responds with an increase in sympathetic output and a decrease in parasympathetic output. This autonomic nervous system reflex produces an increase in heart rate and peripheral vascular resistance, leading to an increase in both cardiac output and blood pressure, thereby allowing the individual to maintain an upright posture. If the autonomic response is insufficient to counter the drop in cardiac output, decreased cerebral perfusion and syncope may follow if the person remains upright. Symptom onset is usually within the first 3 min after assuming the upright posture, but may be more delayed in some patients. Symptoms are characteristic of decreased cerebral perfusion, with blurred vision, dizziness, and tunnel vision. Orthostatic

hypotension is defined as a fall in systolic blood pressure of greater than 20 mmHg upon assuming the upright posture. Caution must be taken in diagnosing a patient with orthostatic syncope based on orthostatic blood pressure measurements alone, because 5 to 55 percent of patients with other causes of syncope have orthostatic hypotension on physical examination.[5] To establish orthostasis as the cause of syncope, the patient should have recurrence of syncopal symptoms on orthostatic testing.

Serious orthostatic symptoms may be due to autonomic dysfunction, with failure of vasoconstriction during orthostatic stress. This may be a primary disease process or secondary to peripheral neuropathy, certain medications such as ganglionic blockers, spinal cord injury, and a variety of other neurologic diseases. More commonly, orthostatic symptoms are due to other conditions that lead to volume depletion, including gastrointestinal losses, bleeding, and diuresis. Medications commonly contribute to orthostatic syncope by blunting the chronotropic response of the heart to orthostatic stress or by leading to relative or absolute volume depletion. The elderly are more susceptible to orthostatic hypotension for many reasons, including use of diuretics and b-blocking agents, varying degrees of autonomic dysfunction, and other changes related to aging.

Cardiac Syncope

Cardiac syncope can be divided into two basic pathophysiologic categories: dysrhythmias and structural cardiopulmonary lesions. In both settings, the heart is unable to provide adequate cardiac output to maintain cerebral perfusion.

Although both brady- and tachydysrythmias may lead to transient cerebral hypoperfusion, there is no absolute high or low heart rate that will produce syncope. Symptoms depend on both the autonomic nervous system's ability to compensate for a decrease in cardiac output and the degree of cerebrovascular atherosclerotic disease. A variety of dysrythmias may lead to syncope (Table 46-1). A bradydysrhythmia is more likely to be an incidental finding on EKG rather than the actual cause of syncope.[6] Dysrhythmias are most likely to occur in the setting of ischemic heart disease but also may occur in other disease processes, such as in prolonged QT syndrome (torsades de pointes) and Lyme disease (heart blocks). Syncope from dysrhythmias is typically sudden, with prodromal symptoms lasting less than 3 s. Many patients report lack of any warning or premonition when questioned.

A wide variety of structural cardiopulmonary lesions may lead to an obstruction to flow and syncope. Syncope due to underlying structural cardiopulmonary disease often occurs in the setting of physical exertion but also may be seen in response to an acute vasodilation from medication or a hot environment. The resultant decrease in systemic vascular resistance is normally compensated by an increase in cardiac output to maintain arterial perfusion. In the presence of obstruction to flow, the upper limit of cardiac output is relatively fixed, limiting the compensation for decreased systemic vascular resistance and leading to a decrease in arterial perfusion and possible syncope. Aortic stenosis, a disease primarily of the elderly, is the most common structural cardiac abnormality causing syncope. In aortic stenosis there may be an additional component of abnormal reflex response, with increased ventricular pressures leading to inappropriate vasodilatation. Hypertrophic cardiomyopathy also leads to outflow obstruction and high ventricular pressures. It is characterized by asymmetric left ventricular hypertrophy and occurs most commonly in the young, although this entity is frequently present in persons over the age of 60. Pulmonary outflow obstruction may also lead to syncope. Up to 13 percent of patients diagnosed with pulmonary embolism have an initial syncopal episode that is likely secondary to the acute obstruction to flow by a large embolus.[7]

Medications

Medications frequently contribute to syncope (Table 46-2), particulary among the elderly. The most commonly implicated medications include antihypertensives and antidepressants.[8] Medications may contribute to syncope by a variety of means. Antihypertensive medications such as b blockers or calcium channel blockers commonly lead to a blunted heart rate response after an orthostatic or vasodilatory stress and may lead to bradycardia and conduction disturbances. Diuretics may produce volume depletion and subsequent orthostatic hypotension. Other medications may have proarrhythmic properties, increasing the concern for dysrhythmia as the cause of syncope. To entertain a medication as a cause of syncope, the untoward effects of the medications such as bradycardia or symptomatic orthostatic hypotension must be documented or demonstrable.

Antihypertensives
β Blockers
Cardiac glycosides
Diuretics
Antidysrhythmics
Antipsychotics
Antiparkinsonism drugs
Antidepressants
Phenothiazines
Nitrates
Alcohol
Cocaine

TABLE 46-2   Drugs Commonly Implicated in Syncope

Psychiatric Illness

Studies have reported a high incidence of syncope in patients with psychiatric illness. The most frequent psychiatric diagnoses among these patients were generalized anxiety disorder, panic disorder, and major depressive disorder.[9,10] Syncope in these patients may have a variety of causes. Hyperventilation has been used as a provocative maneuver in diagnosing panic disorders and generalized anxiety disorders and can lead to hypocarbia, cerebral vasoconstriction, and subsequent syncope.[11,12] The hyperventilation may not be obvious to the observer but has been documented by end-tidal CO_2 monitoring.[11] Additionally, patients with psychiatric disorders may not have adequate coping skills and therefore may be more likely to have a vasovagal response culminate in syncope after an acute stress. Uncommonly, syncope may be psychogenic in nature with no measurable physical basis. In general, a patient with syncope and a psychiatric disorder is likely to be young, with repeated episodes of syncope, multiple prodromal symptoms, and a universally positive review of symptoms.[9,13]

Neurologic Syncope

Cerebrovascular disorders are rarely the primary cause of syncope, but must be considered in any patient with syncope and signs or symptoms indicating central nervous system pathology.

Brain stem ischemia may cause a decrease in blood flow to the reticular activating system, leading to sudden brief episodes of loss of consciousness, called *drop attacks.* These episodes of loss of consciousness are typically associated with other signs and symptoms of posterior circulation ischemia, including diplopia, vertigo, and nausea and possibly vertebrobasilar bruits. Subclavian steal is a rare cause of brain stem ischemia. It is characterized by an abnormal narrowing of the subclavian artery proximal to the origin of the vertebral artery (more commonly on the left) such that with exercise of the ipsilateral arm, blood is shunted, or "stolen," from the vertebrobasilar system to the subclavian artery supplying the arm muscles. Because of anatomy, it is more common on the left. Physical examination may reveal decreased pulse volume and diminished blood pressure in the affected arm. Other causes of brainstem ischemia include vertebrobasilar atherosclerotic disease and basilar artery migraines.

Subarachnoid hemorrhage (SAH) is a devastating disease process that may present with syncope. Accurate data regarding frequency of syncopal presentation of SAH is not readily available, but it does not seem to be particularly common. As the intracranial pressure increases there is a decrease in cerebral perfusion pressure, which may cause syncope. The patient typically complains of sudden severe headache and may have focal neurologic findings.

Syncope in Special Populations

The majority of hospital admissions for syncope are for patients aged 55 and older. Because of both normal physiologic changes with aging and age-related disease processes, the elderly are at increased risk of syncope. They are susceptible to increased morbidity from either the trauma of a syncopal episode or from iatrogenic events during subsequent hospital admission. Additionally, syncope in the elderly is frequently recurrent.

As a person ages, the blood vessels become calcified and less compliant, leading to diminished flow rates. The left ventricle also becomes less compliant, resulting in increased diastolic filling pressures and an increased dependence on the "atrial kick." There is a general decrease in adrenergic receptor responsiveness of both the heart and the peripheral blood vessels. This decreased adrenergic responsiveness contributes to the diminished chronotropic response seen after orthostatic stresses in the elderly. The incidence of vasovagal syncope actually decreases with age, in part due to this decreased responsiveness of the autonomic nervous system. The elderly also have a less-sensitive thirst mechanism and a decreased endocrine response after volume depletion. In addition to these normal changes with aging, the elderly may have a number of pathophysiologic processes that may contribute to diminished cerebral perfusion. Cardiac disease is prevalent in the elderly population. Chronic hypertension shifts the cerebral autoregulation mechanism to higher pressures. Additionally, orthostatic hypotension and postprandial hypotension are more common among the hypertensive elderly. Atherosclerotic disease leads to ischemia and myocardial infarction and subsequent congestive heart failure and dysrhythmias. Aortic stenosis is the most common obstructive cardiac lesion in the elderly, producing a fixed cardiac output and thus a risk of syncope when increased demand for cardiac output cannot be met.[14] Diabetes is another disease process common in the elderly and may lead to autonomic dysfunction and peripheral neuropathy. Finally, medication usage is much more common in the elderly population, again increasing the risk of orthostasis and decreasing autonomic responsiveness to orthostatic stress. It is important to note that syncope in the elderly population is most often multifactorial and the etiology may, therefore, be difficult to establish, particularly in the ED.

Pregnancy is associated with numerous physiologic changes including increased heart rate, decreased peripheral resistance, and increased stroke volume. In late pregnancy, the enlarged uterus may compress the inferior vena cava, decreasing venous return. The incidence of cardiac dysrhythmias, especially premature ventricular contractions, increases during normal pregnancy in young healthy women. However, a positive correlation has not been shown between symptoms of presyncope or syncope and cardiac dysrhythmia.[15] Vasovagal syncope is the most common cause of syncope during normal pregnancy and may be the presenting cause for an ED visit.

Syncope in the pediatric population is discussed elsewhere in this text (Chap. 127).

DIFFERENTIAL DIAGNOSIS

Seizure disorders are frequently listed as a cause of syncope, and although they often cause a brief loss of consciousness, they do not share the same pathophysiologic mechanisms as syncope. Seizure is the most common event mistaken as syncope. History is very important in differentiating seizure from syncope. [16] Brief tonic movements of extremities may accompany syncope but do not represent true seizure activity. Urinary incontinence, which is often seen with seizures, may also occur with syncope. The most reliable differentiating factor is the postictal confusion period, which is commonly seen after a generalized seizure but is rarely associated with syncope. However, syncope itself may trigger a seizure, so that a seizure presentation does not exclude a syncopal origin.

EMERGENCY DEPARTMENT EVALUATION

The core components of the ED evaluation of syncope are a careful history, a thorough physical examination, and the electrocardiogram.

The history and physical examination are essential in determining a patient who is at risk of serious morbidity from subsequent syncope, and will identify the cause of syncope up to 85 percent of patients in whom a diagnosis can be established. [2] It should be obtained from the patient and any witness of the event. Emphasis should be placed on the events leading up to the loss of consciousness, the characteristics of the loss of consciousness, and symptoms occurring after regaining consciousness. The history should begin with a detailed description of the events preceding the loss of consciousness, including position, environmental stimuli, and the involvement of strenuous activity or arm exercise. All premonitory symptoms should be recorded, looking for neurologic symptoms, such as vertigo or focal weakness, and cardiac symptoms, such as palpitations. Duration of loss of consciousness and symptoms occurring after regaining consciousness should also be documented. Symptoms associated with syncope that should raise concern of an immediately life-threatening diagnosis include chest pain (acute myocardial infarction, aortic dissection, pulmonary embolism, aortic stenosis), headache (subarachnoid hemorrhage), and abdominal or back pain (leaking abdominal aortic aneurysm, ruptured ectopic pregnancy). A sudden event without warning and events associated with exertion should increase suspicion of a cardiac dysrhythmia or structural cardiopulmonary lesion. Antecedent illness or substance use should be documented. The past medical history must include details about prior cardiopulmonary events, including prior myocardial infarction, ventricular dysrhythmias, and congestive heart failure. All medications should be recorded, including over-the-counter medications such as laxatives. Patients aggressively dieting to lose weight may have electrolyte disturbances or be taking amphetamine-like medications. The family history is important in regards to history of prolonged QT syndrome, dysrhythmias, or other cardiac risks.

Particular attention should be paid to patients presenting with single-car motor vehicle crashes (especially driving off the road), particularly if the patients are elderly. Clinicians may become preoccupied by the trauma evaluation and miss the possibility of syncopal event.

Physical examination may also give important information. For example, evidence of trauma without defensive injuries to the hands or knees should raise suspicion of a sudden event without warning, such as a dysrhythmia. The physical examination should focus on both the cardiovascular and neurologic systems. Blood pressure measurements should be taken in both arms. Unequal blood pressures should increase suspicion of aortic dissection or subclavian steal. The presence of orthostatic hypotension and symptoms should be recorded. To appropriately evaluate orthostasis, the patient should be supine for a period of 5 to 10 min and then should arise to the standing position. After standing, blood pressure measurements should be taken two to three times over the next few minutes. A detailed cardiac examination may reveal the murmur of hypertrophic cardiomyopathy or aortic stenosis. The neurologic examination may uncover findings of focal neurologic disease or peripheral neuropathy. Rectal examination must be performed on all patients to evaluate for gastrointestinal bleeding.

A 12-lead ECG should be obtained, even though the electrocardiogram and rhythm strip lead to a diagnosis in only a small number of patients. [3] The ECG should be evaluated for evidence of prior cardiopulmonary disease, acute ischemia, dysrhythmia, and heart block. Patients should be monitored for abnormal cardiac activity until a cardiac origin has been reasonably excluded.

Other ED testing should be done on selected patients based on the above initial evaluation. Laboratory testing should not be performed unless the history and physical examination suggest an abnormality. For example, a patient with orthostatic symptoms and heme-positive guaiac test warrants at least a CBC. A reproductive-age female should have a urine pregnancy test. Although electrolyte abnormalities may be implicated as a cause of seizures, they are rarely the cause of syncope and therefore routine testing in the evaluation of syncope is not warranted. [3] Evidence of an irritable myocardium, profound weakness, dehydration, or diuretic use merits serum electrolyte determination.

Carotid massage is used to diagnose carotid sinus hypersensitivity. It can be done at the bedside with continuous electrocardiographic and blood pressure monitoring. Each carotid body is separately massaged for 5 to 10 s. Carotid massage should not be done if bruits are present, if there is history of recent stroke or myocardial infarction, or if there is a history of ventricular tachycardia. Only a small number of patients with carotid hypersensitivity will have the true carotid sinus syndrome.

A hyperventilation maneuver (open-mouthed, slow, deep breaths at a rate of 20 to 30 breaths per minute for 2 to 3 min) can be very useful in the young patient with undiagnosed syncope. A recurrence of prodromal symptoms or syncope significantly correlates with psychiatric (anxiety-provoking) causes of syncope. [11]

Studies fail to show any benefit of routine CT scanning, EEG, or lumbar puncture for patients who lack a history or physical examination that supports a neurologic cause of syncope.[3] An echocardiogram should be reserved for patients with a history or physical findings consistent with structural heart disease.

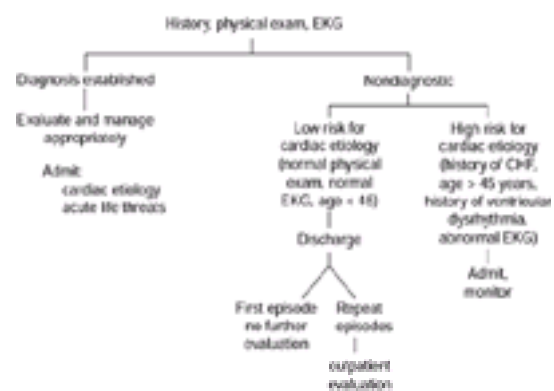
Patients with an unknown etiology of syncope after this initial evaluation need a further inpatient or outpatient medical evaluation that focuses on dysrhythmia detection and identification of vasovagal syncope or psychiatric illness (Fig. 46-1).


FIG. 46-1. Approach to the ED management of syncope.

PROGNOSIS

If a cause of syncope can be determined on ED evaluation, identification of high-risk patients is simple. Those patients with acute neurologic deficits or life-threatening disorders are at immediate risk of morbidity. Additionally, patients with cardiac causes of syncope represent a high-risk group for major morbidity or death. On evaluation in the emergency department, however, a cause of syncope is not identifiable in up to half of patients. [3] Efforts must then be focused to identify those patients at high risk for a cardiac cause of syncope. A recent prospective study focused on risk stratification based on clinical and electrocardiographic characteristics. [17] The study found four significant predictors of sudden cardiac death or significant dysrhythmia within one year of a syncopal event: abnormal electrocardiogram (anything other than nonspecific ST-T changes), age greater than 45 years, history of ventricular dysrhythmia, and history of congestive heart failure. The risk went up with increased numbers of these predictors. This supports prior studies that show that the prognosis of syncope in patients without heart disease is very good. [18,19] The young patient with syncope, a normal physical examination, and a normal electrocardiogram has a very low risk of morbidity. Additionally, patients who have recurrent syncope with more than five episodes in 1 year are more likely to have vasovagal syncope or a psychiatric diagnosis than dysrhythmia as the cause. [2]

Indications for hospital admission, therefore, include patients with acute neurologic or life-threatening disorders and patients at risk for a cardiac etiology of syncope (Fig. 46-1). Patients with more than one episode, who are discharged from the ED should be accompanied by a responsible adult and be advised not to drive, work at heights, or operate machinery until further outpatient evaluation.

47 ACUTE CORONARY SYNDROMES: UNSTABLE ANGINA, MYOCARDIAL ISCHEMIA, AND INFARCTION

Judd E. Hollander

PATHOPHYSIOLOGY

Knowledge of the anatomy of the coronary arteries is essential to understand the effects of myocardial ischemia and why some complications are more common with anterior or inferior wall myocardial infarction. (Fig. 47-1). The left coronary artery arises from the ascending aorta in the left sinus of the aortic valve. It courses through the atrioventricular sulcus on the left side and divides into the left circumflex and the left anterior descending branch. The left anterior descending branch courses down the anterior aspect of the heart around the inferior margin and anastomoses with the posterior diagonal branch of the right coronary artery. It is the main blood supply to the anterior and septal regions of the heart. The circumflex branch continues around the atrioventricular sulcus, where it anastomoses with the right coronary artery. It supplies blood to some of the anterior wall and a large portion of the lateral wall of the heart. The right coronary artery arises from the right sinus of the aortic valve and runs in the atrioventricular sulcus between the right atrium and right ventricle. It gives off a marginal branch near the lower aspect of the heart and terminates as the right posterior descending artery. The right coronary artery supplies the right side of the heart with blood and it provides some perfusion to the inferior aspect of the left ventricle through the posterior descending artery.
FIG. 47-1. Schematic diagram of the coronary arteries.

The atrioventricular (AV) conduction system receives blood supply from both the AV branch of the right coronary artery and septal perforating branch of the left anterior descending coronary artery. Similarly, both the right bundle branch and the left posterior division obtain a dual blood flow from the left anterior descending and right coronary arteries. The posteromedial papillary muscle receives blood supply from only a single coronary artery, usually the right coronary artery.

EPIDEMIOLOGY AND DEFINITIONS

Ischemic heart disease is the leading cause of death among adults in the United States. Over 6 million U.S. citizens have coronary artery disease. There are 4 to 5 million emergency department (ED) visits for acute chest pain syndromes annually. Coronary artery disease results in approximately 500,000 deaths annually in the United States. The total economic burden is over $100 billion per year.

Acute coronary syndromes (ACS) represent a spectrum of disease from chronic stable angina to acute myocardial infarction.[1] The Canadian Cardiovascular Society divides angina into four classes (Table 47-1). Class I represents those patients in whom ordinary physical activity does not cause angina and class IV is reserved for those patients who develop anginal symptoms at rest. Unstable angina has been divided into three principal presentations by the Agency for Health Care Policy and Research (AHCPR) Clinical Practice Guidelines.[1] These three presentations are rest angina, new-onset angina, and increasing angina (Table 47-2).

Class	
Class I	Angina occurs only with strenuous, rapid or prolonged exertion. Ordinary physical activity does not cause angina.
Class II	Slight limitation of ordinary activity. Angina occurs with climbing stairs rapidly, walking uphill, walking after meals, in cold, in wind, or under emotional stress.
Class III	Marked limitations of ordinary physical activity. Angina occurs on walking 1–2 blocks on level or climbing one flight of stairs at usual pace.
Class IV	Inability to carry on physical activity without discomfort; anginal symptoms may be present at rest.

Source: Braunwald et al.[1]

TABLE 47-1   Canadian Cardiovascular Society Classification of Angina

Rest angina	Angina occurring at rest and usually prolonged >20 min, occurring within a week of presentation
New onset angina	Angina of at least CCSC* III severity with onset within 2 months of presentation
Increasing angina	Previously diagnosed angina that is distinctly more frequent, longer in duration, or lower in threshold (increased by at least one CCSC class to at least CCSC III severity)

*CCSC, Canadian Cardiovascular Society Classification.
Source: Braunwald et al.[1]

TABLE 47-2 Main Presentations of Unstable Angina

The use of these classifications and definitions in the ED is problematic. When patients present with acute chest pain syndromes, it is often not clear whether the chest pain is cardiac or noncardiac in origin. The proper application of both the Canadian Cardiovascular Society Classification and the AHCPR guidelines assumes a diagnosis of ischemic chest pain. These guidelines can be difficult to incorporate into emergency practice, where the diagnosis is often uncertain. They are not as useful as other methods to assess risk of an acute cardiac event or adverse events (Table 47-3).

TABLE 47-3 Short-Term Risk of Death or Nonfatal Myocardial Infarction in Patients with Unstable Angina

Hypoxia is a reduction in oxygen supply to tissue despite adequate perfusion. Ischemia is oxygen deprivation accompanied by inadequate removal of metabolites due to reduced perfusion. Both ischemia and hypoxia must be discussed in relative terms, since conditions that result in ischemia in one patient may not result in ischemia in another. Ischemia occurs when there is an imbalance between oxygen demand and oxygen supply. Oxygen supply is influenced by the oxygen-carrying capacity of the blood and the coronary arterial blood flow. The oxygen-carrying capacity of the blood is determined by the amount of hemoglobin present. Coronary arterial blood flow is determined by diastolic relaxation of the heart and the vascular resistance. Humoral, neural, metabolic, and extravascular compressive forces and local autoregulation mechanisms determine the coronary vascular resistance.

Myocardial ischemia and its sequelae usually occur as a result of fixed atherosclerotic lesions or secondary reduction in myocardial blood flow due to coronary arterial spasm, disruption of atherosclerotic plaques, and platelet aggregation or thrombus formation. Nonatherosclerotic etiologies of acute myocardial infarction are considerably less common (Table 47-4).

TABLE 47-4 Some Nonatherosclerotic Etiologies of Acute Myocardial Ischemia

Plaque formation occurs through repetitive injury to the vessel wall. Macrophages and smooth muscle cells are the main cellular elements in plaque development, whereas lipids are the predominant in the extracellular milieu. Plaque fissuring and rupture is affected by features inherent to the plaque, such as its composition and shape, as well as local factors such as shear forces, coronary arterial tone, coronary arterial perfusion pressure, and movements of the artery in response to myocardial contractions. When plaque rupture occurs, potent thrombogenic substances are exposed to circulating platelets.

The platelet response involves adhesion, activation, and aggregation. Platelet adhesion occurs through the weak platelet interactions with subendothelial adhesion molecules such as collagen, fibronectin, and laminin and the binding of the glycoprotein 1b receptor to the subendothelial form of Von Willebrand factor. Adherent platelets are strongly thrombogenic. Subendothelial collagen is a potent inducer of platelet activation. Lipid-laden macrophages in the plaque core and adventitia of the vessel wall release tissue factor, which stimulates the conversion of prothrombin to thrombin. Thrombin, collagen, and the local shear forces are all potent platelet activators. Platelet secretion of adenosine diphosphate, thromboxane A_2, and serotonin are autostimulatory agonists of platelet activation. Activated platelet glycoprotein IIb/IIIa receptors become cross-linked by fibrinogen or Von Willebrand factor in the final common pathway of platelet aggregation.

The extent of oxygen deprivation and thus clinical presentation of acute coronary syndromes, depends upon the limitation of O_2 delivery imposed by thrombus adhering to fixed, fissured, or eroded atherosclerotic plaque. Myocardial ischemia can be manifest by chest discomfort, dyspnea, characteristic or nonspecific electrocardiographic changes, depressed myocardial function, reduced central and peripheral perfusion, or any combination. In stable angina, ischemia occurs only when activity induces O_2 demands beyond the supply restrictions imposed by a partially occluded coronary vessel. This occurs at a relatively fixed and predictable point and changes slowly over time. Atherosclerotic plaque has not ruptured and there is little if any superimposed thrombus. In unstable angina and acute myocardial infarction, atherosclerotic plaque rupture and platelet-rich thrombus develops. Coronary blood flow is reduced and myocardial ischemia occurs. The degree and duration of the oxygen supply–demand mismatch determines whether the patient develops reversible myocardial ischemia without injury (unstable angina) or myocardial ischemia with injury (myocardial infarction). More severe obstruction and prolonged obstruction is related to an increased likelihood of myocardial injury.

Acute myocardial ischemia may inhibit myocardial contractability, affecting both central and peripheral perfusion. In acute myocardial infarction, the fundamental alteration is loss of functioning myocardium. When an area of the myocardium does not receive adequate O_2, the functional deterioration is progressive through four sequentially abnormal contraction patterns. Dyssynchrony, the dissociation in time course of contraction of adjacent segments of myocardium, occurs first. Hypokinesis, the reduction in the extent of shortening with contraction, occurs next. Akinesis, the cessation of shortening with systolic contraction follows. Finally

dyskinesis, the paradoxical expansion of infarcted tissue, occurs during systole. With increasing size of the infarcted myocardium, left ventricular pump function decreases. Left ventricular end-diastolic pressure increases and left ventricular end-systolic volume increases. Cardiac output, stroke volume, and blood pressure may decrease. When left atrial and pulmonary capillary wedge pressures increase, congestive heart failure may develop. Poor perfusion to the brain and kidneys can result in altered mental status and impaired renal function, respectively.

CLINICAL FEATURES

Clinical History

The symptoms of ischemic heart disease that should be sought and characterized include chest discomfort, severity, location, radiation, duration, and quality. In addition, the presence of associated symptoms such as nausea, vomiting, diaphoresis, dyspnea, light-headedness, syncope, and palpitations may be helpful. A detailed history regarding the onset and duration of symptoms, activities that precipitate symptoms, and prior evaluations for similar symptoms should be ascertained. Cardiac risk-factor assessment should be performed.

Symptoms of chest discomfort or pain may be cardiac or noncardiac in origin. Diseases of the esophagus, lungs, stomach, mediastinum, pleura, and viscera may all simulate cardiac discomfort. In addition, many patients may have concurrent diseases.

Symptoms of acute myocardial ischemia will often be described as discomfort rather than pain. Anginal symptoms include chest pressure, heaviness, tightness, fullness, or squeezing. Less commonly but not infrequently, patients will describe their symptoms as knifelike, sharp, or stabbing. The classic location is substernal or in the left chest. Radiation to the arm, neck, or jaw may occur. Reproducible chest wall tenderness is not uncommon, since the pericardium may become inflamed and it sits beneath the chest wall. A complete discussion of the differential diagnosis of chest pain syndromes can be found in Chap. 45.

Exercise, stress, or a cold environment classically precipitates angina pectoris. Angina usually has a duration of symptoms of up to 15 to 20 min and usually improves within 2 to 5 min after rest or nitroglycerin. However, early classic descriptions of angina describe episodes as short as 2 min. On the other hand, acute myocardial infarction is usually accompanied by more prolonged and severe chest discomfort, more prominent associated symptoms (nausea, diaphoresis, shortness of breath, etc.), and little if any response to sublingual nitroglycerin. Easy fatigability may be a prominent symptom of ACS.

It is important to know the frequency of anginal episodes and any change in frequency of episodes over the past months. The patient should be questioned to determine any increase in severity or duration of symptoms or whether less effort is required to precipitate them.

Atypical presentations or silent myocardial ischemia are common. Up to 30 percent of patients with acute myocardial infarction identified in large longitudinal studies are clinically unrecognized. Some of these patients have had atypical symptoms for which they did not pursue medical advice. Others cannot recall any symptoms. The prognosis for patients who have atypical symptoms at the time of their infarction is worse than that of patients who had more typical symptoms. Women and the elderly are more likely to have atypical presentations. [2]

Cardiac risk factors are modestly predictive of coronary artery disease in asymptomatic patients. In the ED, cardiac risk factors are poor predictors of cardiac risk for myocardial infarction or other acute coronary syndromes. [1,2] Traditional cardiac risk factors—such as hypertension, diabetes mellitus, tobacco use, family history of coronary artery disease at an early age, and hypercholesterolemia—are not predictive of the cardiac risk in female ED chest pain patients. In male patients, only diabetes and family history were weakly predictive. [2] The distinction between the utility of cardiac risk factors in the asymptomatic patient and the ED chest pain patient is easy to understand. The cardiac risk factors were derived from population-based longitudinal cohort studies of asymptomatic patients. In contrast, ED chest pain patients have already been identified as being at increased risk by the very fact that they have symptoms. The mere presence of symptoms outweighs the predictive value of cardiac risk factors. A lack of cardiac risk factors does not sufficiently decrease cardiac risk in ED patients such that triage and disposition strategies should be altered. [2]

Physical Examination

The physical examination is not helpful in distinguishing patients with acute coronary syndromes from those with noncardiac chest pain syndromes unless an alternate diagnosis is clear. Patients with acute coronary syndromes may appear deceptively well without any clinical signs of distress or may be uncomfortable, pale, cyanotic, and in respiratory distress. Vital signs may reveal bradycardia, tachycardia, or irregular pulses. Bradycardic rhythms are more common with inferior wall myocardial ischemia. In the setting of an anterior wall infarction, bradycardic rhythms or heart block is an extremely poor prognostic sign. Blood pressure can be normal, elevated (due to baseline hypertension, sympathetic stimulation, and anxiety) or decreased (due to pump failure or inadequate preload). Extremes of blood pressure are associated with a worse prognosis.

The first and second heart sounds are often diminished due to poor myocardial contractility. An S_3 is present in 15 to 20 percent of patients with acute myocardial infarction. An S_4 is common in patients with long-standing hypertension or myocardial dysfunction. The presence or absence of the noted heart sounds is not usually helpful in the ED, although an S_3, if truly detected, may imply a failing myocardium. However, the presence of a new systolic murmur is an ominous sign, as it may signify papillary muscle dysfunction, a flail leaflet of the mitral valve with resultant mitral regurgitation, or a ventricular septal defect.

The presence of rales, with or without an S_3 gallop is associated with left ventricular dysfunction and left-sided congestive heart failure. Jugular venous distention, hepatojugular reflex, and peripheral edema suggest right-sided congestive heart failure. It is important to determine the patient's baseline condition from medical records or from the patient's physician to establish the presence of new findings that may help guide management.

Electrocardiography

The normal myocardium depolarizes from endocardium to epicardium and repolarizes in the opposite direction. When injured, the myocardium remains electrically more positive than the uninjured area at the end of depolarization. The relatively positive potential in this area will result in ST elevation of electrocardiogram leads over this area. Conversely, if the electrode is located over uninjured myocardium opposite the injured area, ST depression will be noted (reciprocal changes). If the injury is limited to the subendocardial area, the electrode will be separated from the injured area by the normal epicardial layer. The epicardial layer becomes more electrically negative than the injured subendocardial layer at the end of depolarization, resulting in ST-segment depressions.

Transmural myocardial ischemia also delays the repolarization process. The ischemic area is electrically more negative than the uninjured area. The T-wave recording over the ischemic area will be negative or downward. In subendocardial ischemia, the delay in repolarization does not alter the direction of the recovery period because the normal repolarization process is from the epicardium to the endocardium. T-wave inversions will not be seen. Since the electrical potential generated by the delayed repolarization in the subendocardium is not opposed, the T wave will be larger than normal (hyperacute T waves).

After acute myocardial infarction (AMI), the area of necrosis is electrically silent. The resultant forces generated from the myocardium during repolarization (the QRS complex) will be affected by this electrically silent area. Electrodes facing the infarcted area will record an abnormal negative deflection during depolarization (pathologic Q waves).

The standard 12-lead electrocardiogram (ECG), is the single best test to identify patients with acute myocardial infarction upon ED presentation. [3] National guidelines require that it be obtained and interpreted within 10 min of presentation. [4] Although it is the best immediately available test in the ED, it still has relatively low sensitivity for detection of acute myocardial infarction. The ST-segment is elevated during an AMI in approximately 50 percent, [1,3] i.e., half of the patients who present to the ED with AMI would not be detected solely on the basis of the electrocardiogram. Most patients with AMI will have some nondiagnostic abnormalities on the ECG. [3] Some 1 to 5 percent of patients with AMI have an entirely normal ECG. [3,4,5 and 6] These figures refer to myocardial infarction, not angina.

Standard diagnostic ECG criteria for AMI are shown in Table 47-5. ST-segment elevations in the distributions shown suggest acute transmural injury. ST-segment depressions in these distributions suggest subendocardial ischemia. All inferior wall acute myocardial infarctions should have a right-sided lead V$_4$ (rV$_4$) obtained because ST-segment elevation in rV$_4$ is highly suggestive of right ventricular infarction. There is no proven role for other right-sided leads.

Location	ECG Findings
Anteroseptal	QS deflections in V_1, V_2, V_3, and possibly V_4
Anterior	rS deflection in V_1 with Q waves in V_2–V_4 or Decrease in amplitude of initial R waves from V_1 through V_4
Anterolateral	Q waves in V_4 through V_6, I, and aVL
Lateral	Q waves in I and aVL
Inferior	Q waves in II, III, and aVF
Inferolateral	Q waves in II, III, aVF, V_5, and V_6
True posterior	Initial R waves in V_1 and V_2 >0.04 s and R/S ratio ≥1
Right ventricular	Q waves in II, III, and aVF and ST-segment elevation in V_{4R}

TABLE 47-5   Electrocardiographic Criteria for Acute Myocardial Infarction

Reciprocal ST-segment changes (such as ST-segment depressions in the anterior precordial leads in the setting of an inferior wall AMI) predict a larger infarct distribution, an increased severity of underlying coronary artery disease, more severe pump failure, a higher likelihood of cardiovascular complications, and increased mortality. In general, the more elevated the ST segments and the more ST segments that are elevated, the more extensive the injury.

The ECG can also be used to predict the infarct-related vessel. Inferior wall myocardial infarctions can result from occlusion of the left circumflex artery or the right coronary artery. In the setting of an inferior wall AMI, ST-segment elevation in at least one lateral lead (V_5, V_6, or aVL) with an isoelectric or elevated ST segment in lead I is strongly suggestive of a left circumflex lesion. The presence of ST-segment elevation in lead III greater than that in lead II predicts a right coronary artery occlusion. When accompanied by either ST-segment elevation in V_1 or aVR, it predicts a proximal right coronary artery lesion with accompanying right ventricular infarction. Reciprocal anterior ST-segment depressions in V_1 through V_4 are equally prevalent in both right coronary and left circumflex inferior wall AMI.

The main utility of the ECG is to detect AMI. The standard 12-lead ECG is less helpful in the detection of other acute coronary syndromes (stable angina or unstable angina). One widely used classification breaks down the ECG into six categories:

- Normal;
- nonspecific ST-segment or T-segment wave changes;
- abnormal but not diagnostic of ischemia or infarction;
- ischemia, strain, or infarction known to be old;
- ischemia, strain or infarction not known to be old;
- probable myocardial infarction.

This classification and others like it have been used to show that patients with more significant ECG abnormalities are more likely to have AMI, unstable angina, and serious cardiovascular complications. On the other hand, even the patients with normal or nonspecific ECGs have a 1 to 3 percent incidence of AMI and a 4 to 23 percent incidence of unstable angina. Patients with nondiagnostic ECGs or with ischemia that is not known to be old have a 4 to 7 percent incidence of AMI and a 21 to 48 percent incidence of unstable angina. Demonstration of new ischemia increases the risk of AMI 25 to 73 percent and the unstable angina risk to 14 to 43 percent.[3] The standard 12-lead ECG is useful for cardiovascular risk stratification of patients with acute coronary syndromes. It can be used in conjunction with clinical history and cardiac markers to determine admission location for such patients.

Novel approaches to electrocardiography have been proposed in the last decade. A continuous 12-lead ECG monitor has been developed that records a new 12-lead ECG every 20 s. When the ST-segment baseline is altered, an alarm is raised and a copy of the new ECG is automatically shared or printed. This type of technology might be useful for monitoring patients who present with non-AMI acute coronary syndromes for ECG evidence of injury.[4] Because of costs, concerns regarding labile ST-segment and T-wave changes from hyperventilation or patient movement and a lack of ED-based prospective studies, continuous-12 lead ECG monitoring has not been recommended for routine use.[4]

ECGs with 15, 18, and 22 leads have been studied.[4,7] The addition of V_{4R}, V_8, and V_9, increased the sensitivity without a loss of specificity for the detection of ST-segment elevation.[7] The addition of V_{4R} through V_{6R} and V_7 through V_9 as posterior leads led to increased sensitivity, but at the cost of decreased specificity. ECGs with 22 leads and body-surface mapping have not been sufficiently studied. The report from the National Heart Attack Alert Program recommends the use of standard ECGs with right-sided leads in the setting of inferior wall infarction. [4]

There are several clinical conditions where ECG interpretation is difficult (Table 47-6). It has been shown that in the setting of paced rhythms and left bundle branch blocks, acute myocardial ischemia can be identified. In the setting of a left bundle branch block, the presence of ST-segment elevation ³1 mm and concordant with the QRS complex or ST segment depression ³1 mm in leads V_1, V_2, or V_3 suggests acute myocardial infarction.[8] ST-segment elevation ³5 mm and discordant with the QRS complex increases the likelihood of AMI but has poor specificity.

May have ST-segment elevation in the absence of acute myocardial infarction
Early repolarization
Left ventricular hypertrophy
Pericarditis
Myocarditis
Left ventricular aneurysm
Idiopathic hypertrophic subaortic stenosis
Hyperkalemia
Paced rhythms
Left bundle branch block
May have ST-segment depression in the absence of ischemia
Hypokalemia
Digoxin effect
Cor pulmonale and right heart strain
Early repolarization
Left ventricular hypertrophy
Paced rhythms
Left bundle branch block
May have T-wave inversions in the absence of ischemia
Persistent juvenile pattern
Stokes-Adams syncope or seizures
Post-tachycardia T-wave inversion
Post-pacemaker T-wave inversion
Intracranial pathology (CNS bleeds)
Mitral valve prolapse
Pericarditis
Primary or secondary myocardial diseases
Pulmonary embolism or cor pulmonale from other causes
Spontaneous pneumothorax
Myocardial contusion
Left ventricular hypertrophy
Paced rhythms
Left bundle branch block

TABLE 47-6   Some Clinical Conditions Where the Electrocardiogram Interpretation Can Be Difficult

Right ventricular pacing causes secondary repolarization changes of opposing polarity to that of the predominant QRS complex. Most leads have predominant negative QRS complexes followed by ST-segment elevation and positive T waves. ST-segment elevation ³5 mm was most indicative of AMI in leads with predominantly negative QRS complexes. Any ST-segment elevation concordant to the QRS complex in a predominantly positive QRS complex was highly specific for AMI. The QRS complex is predominantly negative in leads V_1 to V_3. ST-segment depression in these leads had 80 percent specificity for AMI. [9]

Markers of Myocardial Injury

A detailed discussion on the physiology and value of myocardial markers can be found in Chap. 45. Only contextual material is presented here.

The utility of cardiac markers (Table 47-7) depends upon their ability to detect and risk-stratify patients with acute coronary syndromes. Markers vary in terms of their molecular weight, cellular localization, solubility, plasma concentration, clearance, and ability to be accurately detected in serum with rapid immunochemical

techniques (see Chap. 45).

Marker	Molecular Mass (kDa)	Elevation	Peak	Duration
Myoglobin	17,800	1–4 h	6 h	24 h
Myosin light chains	25,000	6–12 h	2–4 days	6–12 days
Cardiac troponin I	23,500	3–12 h	18 h	5–10 days
Cardiac troponin T	33,000	3–12 h	12 h	5–14 days
CK-MB	86,000	3–12 h	18–24 h	2 days
MB subform	86,000	3–12 h	18 h	2 days
LDH	135,000	10 h	1–2 days	10–14 days
Glycogen phosphorylase BB	188,000	2–4 h	8 h	1–2 days
Myosin heavy chain	400,000	48 h	5–6 days	14 days

Source: Adams et al,[26] with permission.

TABLE 47-7   Characteristics of Cardiac Markers

CK-MB is the "gold standard" and most commonly used marker for the diagnosis of AMI. In the setting of AMI, CK-MB levels rise to twice normal at 6 h and peak within approximately 24 h. Serial CK-MB measurement has a sensitivity of over 90 percent 3 h after ED presentation (approximately 5 to 6 h after symptom onset); it is only 50 percent sensitive when utilized at or shortly after presentation.[10,11] and [12] Patients with skeletal muscle disease, acute muscle exertion, chronic renal failure, and cocaine use often have elevated levels of CK-MB in the absence of infarction.

CK-MB$_2$ is the subform that is released from the myocardium. Following release, it is cleaved by lysine carboxypeptidase, producing a more negatively charged molecule, CK-MB$_1$. Normally both subforms are in equilibrium. When CK-MB$_2$ is greater than 1.0 U/L or the MB$_2$:MB$_1$ ratio is >1.5, the sensitivity and specificity for the diagnosis of AMI is improved. When serial sampling every 30–60 min is used, CK-MB subforms have a sensitivity for detection of AMI of 96 percent and a specificity of 93 to 96 percent within 6 h of ED arrival. Less frequent sampling has resulted in less impressive results.[13] The value of CK-MB subforms for the risk stratification of patients with acute coronary syndromes is unknown. The main advantage of CK-MB subform analysis is that it can identify patients with AMI earlier than CK-MB.

The troponin complex is the main regulatory protein of the thin filament of the myofibrils that regulate the Ca^{2+}-dependent ATP hydrolysis of actomyosin. The troponin complex consists of three subunits: an inhibitory subunit (troponin I), a tropomyosin binding subunit (troponin T), and a calcium-binding subunit (troponin C). Because each subunit has cardiac, slow-twitch, and fast-twitch skeletal isoforms, immunoassays based upon the significant heterogeneity in amino acid sequences can detect the specific isoforms. The cardiac isoform of troponin I is not found in skeletal muscle during any stage of development. As a result, elevations of cardiac troponin I do not occur in the setting of acute or chronic skeletal muscle damage unless concurrent myocardial necrosis is present.

Following AMI, cardiac troponin I becomes elevated after approximately 6 h, peaks at 12 h, and remains elevated for 7 to 10 days. Troponin I has a higher specificity for myocardial necrosis than CK-MB in selected subsets of patients with acute coronary syndromes such as those with recent surgery, cocaine use, chronic renal failure, and skeletal muscle disease.[14] In ED patients with symptoms of acute coronary syndromes, cardiac troponin I has been shown to have similar sensitivity and specificity for detection of acute myocardial infarction as CK-MB.[15,16 and 17] In patients with acute coronary syndromes, elevations in cardiac troponin I values predict cardiovascular complications independent of CK-MB and the ECG.[16,17] The cardiac specificity of troponin I is clearly an advantage, especially when CK-MB elevations are suspected to be false.

The cytosolic component of cardiac troponin T is released from the cell within 2 to 6 h following symptom onset. Its diagnostic sensitivity for AMI approaches 100 percent 10 h after symptom onset and it remains elevated for 7 to 10 days after injury. This extended period of elevation results from disintegration of the contractile apparatus and the continued release of cardiac troponin T. It is not as specific for myocardial injury as cardiac troponin I. It may be elevated in patients with renal disease who do not have acute coronary syndromes. Cardiac troponin T is an independent marker of cardiovascular risk in patients with acute coronary syndromes.[16,18] Risk can be further stratified when cardiac troponin T is combined with the ECG and CK-MB. However, the lower specificity of troponin T compared with cardiac troponin I is a disadvantage.

Myoglobin has a lower molecular weight and is released more rapidly than CK-MB during AMI. As a result, serum myoglobin levels rise faster than CK-MB, reaching twice normal values within 2 h and peaking within 4 h of AMI symptom onset. The sensitivity of older assays was poor. The newer monoclonal immunoassay techniques demonstrate higher sensitivity and specificity of myoglobin for AMI than older assays in patients presenting within 3 h of symptom onset. Serial quantitative testing with an immunochemical assay for myoglobin has 91 percent sensitivity and up to a 99 percent negative predictive value for AMI within 1 h of ED presentation (approximately 3 to 4 h after symptom onset).[19] The advantage of myoglobin is early detection of patients with acute myocardial infarction. The disadvantage is that it has poor specificity for AMI in patients with concurrent trauma renal failure, rhabdomyolysis, and various hemolytic syndromes.

Evaluation of the myoglobin/carbonic anhydrase III ratio can enhance the specificity of myoglobin.[20] Carbonic anhydrase III is released from skeletal muscle in a fixed ratio with myoglobin. Combined assays can therefore help determine whether myoglobin is of skeletal or cardiac origin. With use of these dual assays, the high early sensitivity of myoglobin is maintained and specificity is improved. These assays are not yet commercially available. The use of dual assays for risk stratification has not yet been evaluated.

Other cardiac markers, such as glycogen phosphorylase BB and myosin light chains, are currently being evaluated. In addition, markers of platelet activation such as P-selectin and other integrins are theoretically attractive as indicators of acute coronary syndrome. They might detect platelet activation prior to myocardial injury. Their role in the diagnosis and triage of patients with acute coronary syndromes remains to be determined.

Cardiac Imaging

The use of echocardiography and nuclear imaging for risk stratification of chest pain patients was discussed in Chap. 45. Echocardiography can identify myocardial wall motion abnormalities. It has sensitivity for detection of AMI of approximately 93 percent but a specificity of only 53 to 57 percent.[4] Despite the high sensitivity, it cannot distinguish old from new infarcts. As a result, it is more useful in patients without prior coronary artery disease. Larger areas of infarction and more depressed left ventricular function predict a higher likelihood of cardiovascular complications and increased mortality.[21] Early echocardiography can be used for risk stratification and should be considered to help determine the need for transfer from smaller community to larger tertiary-care hospitals.

Sestamibi imaging may be useful for ED risk stratification of patients experiencing chest pain at the time of study. Technetium sestamibi is a radioisotope that is taken up by the myocardium in proportion to myocardial blood flow. It has prolonged retention in the myocardium and redistributes minimally after injection. This allows injection during symptomatic episodes but enables imaging after patient stabilization. This imaging modality is highly sensitive and specific for coronary artery disease. Sestamibi has higher independent predictive value in detecting acute coronary syndromes than the clinical history or ECG.[22] In one study, an abnormal sestamibi scan in the ED during pain predicted a 50-fold relative risk of AMI, 15-fold risk of revascularization, and 30-fold increased risk of death at 1 year. Disadvantages of sestamibi scanning include the need for 24 h availability of nuclear radiology technicians and time needed to prepare the isotope.

Exercise stress testing has become commonplace in EDs with chest pain observation units. Exercise treadmill testing with or without nuclear imaging, as well as stress echocardiography, can assist in cardiovascular risk stratification in the ED. Current studies demonstrate that patients with an uneventful observation period, negative cardiac markers, and a normal stress test can be safely discharged with a referral for follow-up in 24–48 hours. Stress testing is usually used on patients at very low risk for acute coronary syndromes or patients who have been "ruled out" for AMI. It is not routinely used for patients with acute coronary syndromes while in the ED. Further details on various forms of stress testing can be found in Chap. 45.

COMPLICATIONS OF MYOCARDIAL INFARCTION AND ISCHEMIA

Myocardial perfusion and cardiac function affect blood flow to the entire body. As a result, any end organ can be damaged when cardiac pump function is decreased. In this section, discussion of the complications of acute coronary syndromes is limited to the direct effects on the heart. The systemic effects of cardiac function are discussed in organ-appropriate chapters of this book. The treatment of these complications is discussed in the following chapter.

Dysrhythmias

The genesis, diagnosis, and treatment of dysrhythmias are presented in Chap. 24. The effect dysrhythmias have in complicating the course of patients with acute coronary syndromes is the subject of this section.

Dysrhythmias occur in 72 to 100 percent of AMI patients treated in the coronary care unit. Table 47-8 shows the approximate frequency of the various dysrhythmias observed in patients with AMI. Many of these dysrhythmias occur in the prehospital and ED setting. The main consequence of these dysrhythmias is that they may impair hemodynamic performance, compromise myocardial viability by increasing myocardial oxygen requirements, and predispose to even more serious rhythm disturbances by diminishing the ventricular fibrillation threshold.

Dysrhythmia	Frequency of Occurrence
Bradydysrhythmias	
Sinus bradycardia	13–40%
First-degree AV block	4–14%
Second-degree AV block—type I	4–10%
Second-degree AV block—type II	<1%
Third-degree AV block	5–8%
Asystole	1–14%
Tachydysrhythmias	
Sinus tachycardia	33%
Atrial premature contractions	50%
Supraventricular tachycardia	2–11%
Atrial fibrillation	10–15%
Atrial flutter	1–5%
Ventricular premature beats	>90%
Accelerated idioventricular rhythm	8–20%
Ventricular tachycardia	10–40%
Ventricular fibrillation	4–18%

Source: Pasternak et al,[8] with permission.

TABLE 47-8 Frequency of Occurrence of Arrhythmias during Acute Myocardial Infarction

Early in the course of AMI, patients frequently exhibit evidence of increased autonomic nervous system activity. Sinus bradycardia, atrioventricular block, and hypotension may occur from increased vagal tone. Activation of atrial and ventricular receptors in the myocardium may result in enhanced efferent sympathetic activity, increased circulating catecholamines, and increased local catecholamine release. These increased catecholamines in the setting of a sensitive myocardium form the substrate for the generation of tachyarrhythmias. Electrical instability during acute myocardial infarction results in ventricular premature beats, ventricular tachycardia, ventricular fibrillation, accelerated idioventricular rhythms, and some AV junctional tachycardias.

The hemodynamic consequences of dysrhythmias are dependent on ventricular function. Patients with left ventricular dysfunction have a relatively fixed stroke volume. They depend upon changes in heart rate to alter cardiac output. The range of heart rate that is optimal becomes narrowed with increasing dysfunction. Slower or faster heart rates may further depress cardiac output.

Additionally, maintenance of the atrial kick is important for patients with AMI. Patients with normal hearts have a loss of 15 to 20 percent of left ventricular output when the atrial kick is eliminated. Patients with reduced left ventricular compliance, as occurs from AMI, have a 35 percent reduction in stroke volume when the atrial systole is eliminated.

"Pump" failure with resultant increased sympathetic stimulation results in sinus tachycardia, atrial fibrillation/flutter, and supraventricular tachycardias. Conduction disturbances result in bradydysrhythmias such as sinus bradycardia, junctional escape rhythms, and atrioventricular and idioventricular blocks.

The significance of cardiac dysrhythmias during acute myocardial infarction is the subject of some debate. Sinus bradycardia during the early phases of AMI may predispose to hypotension and repetitive ventricular dysrhythmias. On the other hand, it appears to be protective because it reduces the myocardial oxygen requirement. The net effect is that the presence of sinus bradycardia does not appear to increase mortality during AMI.

Almost all patients with first-degree AV block have infranodal disturbances above the His bundle and will not progress to higher degrees of AV block. Mobitz I (Wenckebach) accounts for 90 percent of second-degree AV block. It generally occurs within the AV node, is associated with narrow QRS complexes, and results from ischemic injury. It is more common with inferior than anterior AMI, is intermittent usually during the first 72 h after infarction, and rarely progresses to complete heart block or other pathologic rhythm. Conversely, Mobitz 2 second-degree heart block originates from conduction lesions below the His bundle, is associated with a wide QRS complex, is usually associated with anterior AMI, and does progress to complete heart block.

Complete heart block can occur in patients with both anterior and inferior AMI. This is because the atrioventricular conduction system receives blood supply from both the AV branch of the right coronary artery and the septal perforating branch of the left anterior descending coronary artery. Complete heart block occurs in the setting of inferior myocardial infarction; it usually progresses from lesser forms of AV block. This form of third degree block is usually stable and should resolve. In the absence of right ventricular involvement, the mortality is approximately 15 percent. It rises to greater than 30 percent when right ventricular involvement is present. In contrast, complete heart block in the setting of an anterior MI is seldom benign and portends a grave prognosis. Junctional rhythms are usually transient and occur within 48 h of infarction. Whether they affect long-term prognosis is not clear.

Sinus tachycardia is quite prominent in patients with anterior wall AMI. Because of increased myocardial oxygen utilization, persistent sinus tachycardia is associated with a poor prognosis. The etiology of the sinus tachycardia should be determined. It may include anxiety, pain, left ventricular failure, fever, pericarditis, hypovolemia, atrial infarction, pulmonary emboli, or use of medications that accelerate heart rate. Similarly, paroxysmal supraventricular tachycardia, atrial fibrillation, and atrial flutter are associated with an increased mortality. Atrial premature contractions are common. They occur in up to 50 percent of AMI patients, and are not associated with an increased mortality related to the acute event.

Ventricular premature contractions are common in patients with AMI. They do not appear to have much prognostic ability. Accelerated idioventricular rhythms in patients with AMI have not been shown to have an effect on prognosis. Ventricular tachycardia shortly after AMI is often transient and does not portend a poor prognosis. When ventricular tachycardia occurs late in the course of AMI, it is usually associated with transmural Q-wave infarction and left ventricular dysfunction, induces hemodynamic deterioration, and is associated with a mortality rate approaching 50 percent. Primary ventricular fibrillation, occurring shortly after symptom onset does not appear to have a large effect on mortality and prognosis. Delayed or secondary ventricular fibrillation during hospitalization is associated with severe ventricular dysfunction and a 75 percent in-hospital mortality.

Intraventricular conduction disturbances occur in 10 to 20 percent of patients with AMI. Approximately half of these disturbances are already present at the time of ED presentation and may not represent a new finding. Blood supply to the left anterior division comes from septal perforators of the left anterior descending coronary artery. Both the right bundle branch and the left posterior division obtain a dual blood flow from both the left anterior descending and right coronary arteries. For this reason, left anterior hemiblock is more common.

New right bundle branch block occur in approximately 2 percent of AMI patients, most commonly anteroseptal AMI, and is associated with an increased mortality because it often leads to complete AV block. New left bundle branch block occurs in 5 percent of patients with AMI and is associated with a high mortality. The left posterior fascicle is larger than the left anterior fascicle. Thus, left posterior hemiblock is associated with a higher mortality than isolated left anterior hemiblock because it represents a larger area of infarction. Bifascicular block (right bundle branch block and a left hemiblock) is associated with an increased likelihood of progression to complete heart block; it represents a large infarction and is associated with an increased likelihood of pump failure and mortality. Other combinations of heart block and their treatment are discussed in Chap. 48.

Cardiac Failure

Some 15 to 20 percent of patients with AMI present in some degree of congestive heart failure. One-third of these patients have circulatory shock. In the setting of AMI, congestive heart failure can occur through either diastolic dysfunction alone or a combination of systolic and diastolic dysfunction. Left ventricular diastolic dysfunction leads to pulmonary congestion. Systolic dysfunction is responsible for decreased forward flow, reduced cardiac output, and reduced ejection fraction. In general, the more severe the degree of left ventricular dysfunction, the higher the mortality. The degree of left ventricular dysfunction in any single patient is dependent upon the net effect of prior myocardial dysfunction (prior AMI), baseline myocardial hypertrophy, acute myocardial necrosis, and acute reversible myocardial dysfunction ("stunned myocardium").

Patients with AMI can be classified into four subsets based upon hemodynamic status (Forrester-Diamond classification) and clinical status (Killip classification), shown in Table 47-9 and Table 47-10. These classifications are useful to guide therapy and predict response to treatment. Patients with decreasing cardiac outputs or increasing pulmonary congestion have an increasingly higher mortality in the setting of AMI. Class I patients have a mortality of 2 to 5 percent. Class IV patients, (i.e., those with cardiogenic shock), are at very high risk of mortality (50 to 80 percent).

Class	Cardiac Index, L/min per m²	Pulmonary Artery Wedge Pressure, mmHg	Approximate Mortality
I. No pulmonary congestion or hypoperfusion	>2	<18	2–3%
II. Isolated pulmonary congestion	>2	>18	10%
III. Isolated peripheral hypoperfusion	<2	<18	20–25%
IV. Both pulmonary congestion and peripheral hypoperfusion	<2	>18	50–55%

TABLE 47-9 Forrester-Diamond-Swan Hemodynamic Classification

Class	Approximate Mortality
I. No congestive heart failure	5%
II. Mild congestive heart failure (bibasilar rales and an S₃)	15–20%
III. Frank pulmonary edema	40%
IV. Cardiogenic shock	80%

TABLE 47-10 Killip Clinical Classification

The presence of shock in AMI results in a complex spiral relationship. Coronary obstruction leads to myocardial ischemia, which, in turn, impairs myocardial contractility and ventricular outflow. The resulting reduction in arterial blood pressure leads to further decreases in coronary arterial perfusion, resulting in worsening myocardial ischemia and more severe myocardial necrosis. Interruption of this downward spiral requires careful attention to fluid management, preload, afterload, and the Frank-Starling relationships. Resolution of ischemia and preventing or minimizing the area of stunned myocardum that progresses to infarction is imperative.

Mechanical Complications of AMI

Sudden decompensation of previously stable patients should always raise concern of the "mechanical" complications of AMI. As a group, these complications usually involve the tearing or rupture of infarcted tissue. Therefore, they are unlikely to occur in patients with non-AMI acute coronary syndromes. The clinical presentation of these entities depends upon the site of rupture (papillary muscles, interventricular septum, or ventricular free wall).

Free wall rupture occurs in 10 percent of AMI fatalities, usually 1 to 5 days after infarction. Rupture of the left ventricular free wall usually leads to pericardial tamponade and death (in more than 90 percent). Patients may complain of tearing pain or sudden onset of severe pain. They will be hypotensive and tachycardic and may have onset of confusion and agitation. Increased neck veins, decreased heart sounds, and pulsus paradoxus may be present. Echocardiography is the diagnostic test of choice, although near equalization of right atrial, right ventricular middiastolic, and right ventricular systolic pressures on pulmonary artery catheterization may also be useful. Treatment is surgical.

Rupture has been attributed to intense necrosis at the distal end of blood supply along with poor collateral blood flow and a thin apical left ventricular wall in conjunction with the shearing effects of muscle contraction. Anti-inflammatory medications, steroids, and late administration of thrombolytic agents have all been linked to an increased likelihood of cardiac rupture. However, studies remain contradictory. The elderly appear to be more prone to cardiac rupture. Left ventricular hypertrophy appears to be protective.

Rupture of the interventricular septum is more often detected clinically than rupture of the ventricular free wall, despite the fact that rupture of the ventricular free wall is more commonly detected in autopsy studies. The size of the defect determines the degree of left-to-right shunt and the ultimate prognosis. Clinically, interventricular septal rupture presents with chest pain, dyspnea, and sudden appearance of a new holosystolic murmur. The murmur is usually accompanied by a palpable thrill and is heard best at the lower left sternal border. Doppler echocardiography is the diagnostic procedure of choice. Demonstration of left-to-right shunt by pulmonary catheter blood sampling may be useful. An oxygen step up of more than 10 percent from right atrial to right ventricular samples is diagnostic. Rupture of the interventricular septum is more common in patients with anterior wall myocardial infarction and patients with extensive (three vessel) coronary artery disease.

Papillary muscle rupture occurs in approximately 1 percent of patients with AMI, is more common with inferior myocardial infarction, and usually occurs 3 to 5 days after AMI. In contrast to rupture of the interventricular septum, papillary muscle rupture often occurs with a small to modest-sized AMI. Patients may have relatively limited coronary artery disease. Patients present with acute onset of dyspnea, increasing degree of congestive heart failure, and a new holosystolic murmur consistent with mitral regurgitation. The posteromedial papillary muscle is most commonly ruptured because it receives blood supply from only a single coronary artery, usually the right coronary artery. Echocardiography can often distinguish rupture of a portion of the papillary muscle from other etiologies of mitral regurgitation. Treatment is surgical.

Pericarditis

Post-AMI pericarditis occurs in 10 to 20 percent of patients. It is more common in patients with transmural AMI. It results from inflammation adjacent to the pericardium on the epicardial surface of a transmural infarction. It generally occurs 2 to 4 days after AMI. Pericardial friction rubs are more often detected with inferior wall and right ventricular infarction because the right ventricle lies immediately beneath the chest wall. The pain of pericarditis can be confused with that of infarct extension or post-AMI angina. Classically the discomfort of pericarditis becomes worse with a deep inspiration and may be somewhat relieved by sitting forward. Echocardiography may demonstrate a pericardial effusion, but pericardial effusions are much more common than pericarditis and are often present in the absence of pericarditis.

Similarly, pericarditis can be present in the absence of a pericardial effusion. The resorption rate of post-AMI pericardial effusions are slow, often taking several months. Dressler syndrome (post-AMI syndrome) occurs 2 to 10 weeks after AMI and presents as chest pain, fever, and pleuropericarditis.

Right Ventricular Infarction

Isolated right ventricular infarction is extremely rare and it is usually seen as a complication or other infarction. The right ventricle most commonly receives its blood supply from the right coronary artery. In patients with left dominant systems, the blood supply may come from the left circumflex. The anterior portion of the right ventricle is supplied by branches of the left anterior diagonal artery. Approximately 30 percent of inferior wall myocardial infarctions involve the right ventricle. The presence of right ventricular infarction is associated with a significant increase in mortality and cardiovascular complications. Right ventricular infarction can be diagnosed by the presence of ST-segment elevation in the right precordial lead V_4 (rV_4), in the setting of an inferior wall myocardial infarction. The presence of elevated neck veins or hypotension in response to nitroglycerin is also suggestive. Echocardiography or nuclear imaging can be diagnostic, but they are less readily available in the ED.

The most serious complication of right ventricular infarction is shock.[24] The severity of the hemodynamic derangement in the setting of right ventricular infarction is related to the extent of right ventricular dysfunction, the interaction between the ventricles (the right and left ventricle share the interventricular septum), and the interaction between the pericardium and the right ventricle. Right ventricular infarction results in a reduction in right ventricular end-systolic pressure, left ventricular end-diastolic size, cardiac output, and aortic pressure as the right ventricle becomes more of a passive conduit to blood flow. Left ventricular contraction causes bulging of the interventricular septum into the right ventricle, with resultant ejection of blood into the pulmonary circulation. As a result, right ventricular infarction with concurrent left ventricular infarction has a particularly devastating effect on hemodynamic function. Fluid balance and maintenance of adequate preload is critical in the treatment of right ventricular infarction. Treatment of right ventricular infarction is discussed in Chap. 48.

Other Complications

Other complications of AMI that occur but are not usually seen in the ED include left ventricular thombus formation, arterial embolization, venous thrombosis, pulmonary embolism, postinfarction angina, and infarct extension. With the more rapid discharge of uncomplicated AMI patients, the emergency physician should keep these possibilities in mind for patients who return to the ED shortly after hospital discharge.

SPECIFIC ISSUES

Age and Gender

Age and gender play a role in the presentation of patients with acute coronary syndromes. Both increased age and female gender are associated with more atypical presentations. There is no evidence that AMI patients should be evaluated differently in the ED as a result of age or gender.

Postprocedure Chest Pain

Patients who present with symptoms of an acute coronary syndrome shortly after percutaneous coronary interventions such as angioplasty or stent placement should be assumed to have had abrupt vessel closure until proven otherwise. Subacute thrombotic occlusion following stent placement occurs in approximately 4 percent of patients 2 to 14 days postprocedure. Although less common than closure following percutaneous transluminal coronary angioplasty (PTCA), it is associated with a high likelihood of major ischemic complications. Patients should be treated aggressively for an acute coronary syndrome, and cardiology or interventional cardiology consultation should be obtained. Patients with chest pain syndromes following coronary artery bypass grafting may also have abrupt vessel closure; however, symptoms of recurrent ischemia must be distinguished from post-AMI pericarditis or Dressler syndrome, as discussed above.

Cocaine Use

Myocardial ischemia and infarction can occur secondary to cocaine insufflation, smoking, intravenous use, and possibly withdrawal. Serum levels or route of administration does not play a role in the likelihood of developing ischemia.

Patients with cocaine-associated acute coronary syndromes frequently have atypical chest pain or chest pain delayed for hours to days after their most recent use of cocaine. AMI can occur after use of only small amounts of cocaine. Approximately 6 percent of patients with cocaine associated chest pain syndromes sustain AMI.[25] An additional 20 to 60 percent suffer from transient myocardial ischemia. Most infarctions occur within 24 h of cocaine use; however, reports of cocaine use leading to AMI several weeks after last use exist.

Cocaine causes myocardial ischemia through a complex pathophysiology resulting from its acute and chronic effects.[24] Acutely, cocaine results in coronary artery vasoconstriction, tachycardia, systemic arterial hypertension, increased myocardial oxygen demand, platelet aggregation, and in situ thrombus formation. Chronic cocaine users develop accelerated atherosclerosis and left ventricular hypertrophy, which can further exacerbate the O_2 supply–demand mismatch. Myocardial ischemia and infarction have occurred in patients without any underlying atherosclerotic disease or other evidence of preexisting heart disease. Q-wave and non-Q-wave infarctions occurred with equal frequency. Although cocaine can cause myocardial ischemia in patients without coronary artery disease, the majority of patients with cocaine-associated AMI have atherosclerotic coronary artery disease. Patients with cocaine-associated myocardial infarction should receive an evaluation for underlying coronary artery disease.

Risk stratification of patients with cocaine-associated acute coronary syndromes has been difficult. Clinical criteria have not been useful. ECGs reveal abnormalities consisting of ST-segment elevation and T-wave inversions that often persist during hospitalization; however, the ECG is less sensitive and less specific for myocardial infarction in patients who have recently used cocaine. CK-MB assays have diminished specificity for AMI in cocaine users. Cardiac troponin I appears to be more useful. On the other hand, risk stratification of patients with cocaine-associated acute coronary syndromes may be less important, since even patients with cocaine-associated myocardial infarction have a favorable short-term prognosis. The 1-year mortality in patients with cocaine-associated acute coronary syndromes is largely related to comorbid conditions and continued cocaine use.

DISPOSITION

All patients with acute chest pain syndromes need to be evaluated for the possibility of acute coronary syndromes. Based upon the initial history, physical examination, and ECG, patients can be subdivided into those with and without known coronary artery disease. Patients with known coronary artery disease should be further subdivided into those who meet criteria for AMI (and may or may not meet criteria for reperfusion therapy), those with a stable anginal pattern that do not require acute intervention, and those with unstable angina. Patients with unstable angina should be treated according to their risk for acute myocardial infarction and death (Table 47-1).

Patients without known coronary artery disease who do not have an obvious myocardial infarction should be evaluated for their likelihood of coronary artery disease (Table 47-11) and the possibility of an alternative diagnosis (not ischemic heart disease). Those with a clear alternative diagnosis should be treated accordingly.

TABLE 47-11   Likelihood of Significant Coronary Artery Disease in Patients with Symptoms Suggesting Unstable Angina

Patients at high risk of coronary artery disease, AMI, or death should be admitted to an intensive care unit (ICU). Moderate risk patients should be admitted to a non-ICU monitored setting. Patients at low risk can be treated in a non-ICU monitored setting or can be observed in an ED observation unit. Both ED observation units and non-ICU monitored settings are safe and cost-effective for patients with normal ECGs and other low-risk clinical features. Prior invasive and noninvasive assessments of cardiac function should be taken into account in making disposition decisions. Patients known to have severe coronary artery disease or depressed left ventricular function might be triaged to a more intensive setting than patients with a similar presentation without such dysfunction.

Results of prior cardiac catheterization are very useful for risk stratification. Patients who have previously been documented to have minimal (less than 25 percent) stenosis or normal coronary arteriograms have an excellent long-term prognosis. More than 98 percent of patients with this profile are free from myocardial infarction 10 years later.[26] Repeat cardiac catheterizations an average of 9 years later found that approximately 90 percent of patients did not develop even single-vessel coronary artery disease. Thus, a recent (in the past 2 years) cardiac catheterization with normal or minimally diseased vessels almost eliminates the possibility of an acute coronary syndrome, due to atherosclerosis. It would not eliminate the possibility of vasospasm. Without other complicating circumstances, even observation protocols are unnecessary.

Stress tests are less useful because the precise results of such tests may not be available. When patients complete all stages of the emergency protocol, have no ECG changes, and have normal imaging studies, exercise testing can rule out acute ischemic syndromes with sensitivities in the range of 80 to 90 percent. When patients do not meet their target heart rates, exercise testing has poor sensitivity (less than 80 percent) leading to false-negative results. Unless the patient reached the maximal heart rate (220 beats per minute minus the patient's age), had no ECG changes, and had normal imaging (when done), one cannot rely heavily on the results of prior exercise testing in making disposition decisions. However, a negative maximal exercise stress predicts a favorable 1-year survival free of cardiac events.

48 INTERVENTION STRATEGIES FOR ACUTE CORONARY SYNDROMES

Judd E. Hollander

Acute coronary care syndromes (ACS) can be inhibited or reversed with a wide variety of interventions. In this chapter, major therapeutic treatment trials are summarized. Where available, evidence-based consensus panel treatment recommendations are provided. Some dosage recommendations are intentionally not provided because ongoing clinical trials are likely to result in changed dosing strategies.

Treatment of ACS is individualized based on duration and persistence of symptoms, cardiac history, and findings on physical examination and initial electrocardiogram. Generally speaking, patients with persistent symptoms and ST-segment elevation should receive therapy or mechanical reperfusion (angioplasty). Treatment with heparin, b antagonists, nitrates, and angiotensin-converting enzyme inhibitors should be considered, based on symptoms, vital signs, and the presence or absence of heart failure. Patients with unstable angina or non-Q-wave infarctions without ST-segment elevation should be treated with aspirin and heparin, and possibly b antagonists and nitrates. Patients refractory to these therapies or patients scheduled to undergo percutaneous interventional procedures also benefit from the use of glycoprotein IIb/IIIa antagonists.

GENERAL MEASURES

Intravenous access and continued electrocardiographic monitoring should be established in all patients with ACS. Supplemental oxygen may reduce ST-segment elevation in patients with acute myocardial infarction. It is therefore reasonable to provide 2 to 4 L of oxygen routinely by nasal cannula, but higher doses can lead to arterial vasoconstriction and increased afterload. Treatment strategies are those that achieve immediate reperfusion and those that limit infarct size (Table 48-1).

TABLE 48-1   Recommended Doses of Drugs Used in the Treatment of Coronary Care Syndromes

REPERFUSION

Reperfusion therapies can be mechanical or pharmacologic. Angioplasty, coronary stent placement, and atherectomy are the major methods of mechanical reperfusion. Pharmacologic interventions include fibrinolytic and antiplatelet therapy.

Fibrinolytics

Fibrinolytic agents act on the acute coronary thrombosis directly or indirectly as plasminogen activators. Plasminogen, an inactive proteolytic enzyme, binds directly to fibrin during thrombus formation, forming a plasminogen-fibrin complex. This plasminogen-fibrin complex is more susceptible to activation than plasma plasminogen, and this promotes fibrin proteolysis.

Randomized controlled clinical trials comparing streptokinase to placebo for treatment of acute myocardial infarction demonstrated that fibrinolytic therapy improved left ventricular function and short-term and long-term mortality rate. [1,2 and 3] A meta-analysis of all nine clinical trials that randomized more than 1000 patients to fibrinolytic therapy or control treatments found that the net benefit of treatment in the first 3 h was more than 30 lives saved per thousand patients. The loss of benefit per hour delay in thrombolytic administration was 1.6 lives per 1000 patients per hour.

Fibrinolytic therapy is indicated for patients with symptoms compatible with acute myocardial infarction, a time to treatment of less than 6 to 12 h, and an electrocardiogram that has at least 1-mm ST-segment elevation in two or more contiguous leads. [4] Therapy is most beneficial if given early and is more beneficial for larger infarctions and anterior infarctions than it is for smaller or inferior wall infarctions.

In the elderly, the overall risk of mortality from acute myocardial infarction (AMI) is high with and without therapy. The proportionate reduction in mortality rate appears to be less in patients older than age 75, but the absolute number of patients who may be saved is still large.

Contraindications to thrombolytic therapy are those that increase the risk of hemorrhage (Table 48-2). The most catastrophic complication is intracranial bleeding. Clinical variables that can be assessed in the emergency department and predict an increased risk of intracranial hemorrhage are age (older than 65 years, odds ratio of 2.2), low body weight (less than 70 kg, odds ratio 2.1), and hypertension on presentation (odds ratio, 2.0). [4] Intracranial hemorrhage is also more common with tissue plasminogen activator (tPA) than with streptokinase (odds ratio, 1.6). Patients with relative contraindications may still receive fibrinolytic therapy when the benefits of therapy outweigh the risks of the complications, but institutions with direct percutaneous intervention availability might consider direct angioplasty over fibrinolytic therapy in the presence of relative contraindications. Reperfusion therapy with fibrinolysis is the standard of care for patients with ST-segment elevation AMI. However, this treatment has limitations. First, even the most potent fibrinolytic agents do not achieve early and complete restoration of coronary blood flow in 40

to 50 percent of patients. Fibrinolytics are plasminogen activators. When fibrin is lysed, thrombin is exposed. The exposed thrombin is one of the most potent biologic platelet activators known. As a result, the more fibrin that is lysed, the more thrombin is exposed and more prothrombotic substrate is engendered. The second limitation of fibrinolytic therapy is that approximately 1 percent of patients have intracranial hemorrhage, which usually results in death or disabling stroke.

Absolute contraindications
Previous hemorrhagic stroke at any time
Bland strokes or cerebrovascular accident in past year
Known intracranial neoplasm
Active internal bleeding (excluding menses)
Suspected aortic dissection
Diabetic retinopathy

Relative contraindications
Severe uncontrolled blood pressure (>180/100 mmHg)
History of prior cerebrovascular accident or known intracranial pathology not covered in contraindications
Current use of anticoagulants with international normalized ratio >2 to 3
Known bleeding diathesis
Recent trauma (past 2 weeks)
Prolonged cardiopulmonary resuscitation > 10 min
Major surgery < 3 weeks
Noncompressible vascular puncture
Recent internal bleeding (2-4 weeks)
Prior allergic reaction to streptokinase (should not receive streptokinase)
Pregnancy
Active peptic ulcer disease
History of chronic severe hypertension

TABLE 48-2   Contraindications to Fibrinolytic Therapy in Acute Myocardial Infarction

Controversy continues to surround the choice of fibrinolytic agent. There have been three large trials comparing streptokinase to tPA and one large trial comparing reteplase to alteplase.

STREPTOKINASE   Streptokinase is a polypeptide derived from b-hemolytic *Streptococcus* cultures. It binds 1:1 to plasminogen, causing a conformational change that activates the plasminogen-streptokinase complex. This complex cleaves peptide bonds on other plasminogen molecules to activate them. This activated complex does not have fibrin specificity.

Initial trials demonstrated a reduction in mortality rate and improvement in left ventricular function with streptokinase relative to placebo. [1,2 and 3] Other fibrinolytic agents have not been evaluated in large randomized placebo-controlled clinical trials.

Antibodies may develop after treatment, so retreatment should be avoided. Streptokinase allergy can be seen in approximately 5 percent of patients treated for the first time, especially those with a recent *Streptococcus* infection. Self-limited allergic reactions usually respond to antihistamines. Fewer than 0.2 percent of patients experience a serious anaphylactic reaction. During intravenous administration, approximately 15 percent of patients will experience hypotension, which usually responds to decreasing the rate of infusion and volume expansion. The 1998 recommended dose of streptokinase is 1.5 million units over 60 min, which produces a fibrinolytic state for up to 24 h. Streptokinase is less costly than other fibrinolytic agents.

TISSUE PLASMINOGEN ACTIVATOR   tPA is a naturally occurring enzyme produced by the vascular endothelium and other tissues. It has a binding site for fibrin that allows it to attach to a formed thrombus and trigger fibrinolysis (fibrin specificity). Small trials (28 to 144 patients) compared infarct-related patency rates of tPA to placebo and found that tPA achieved higher patency rates than was seen with placebo or in trials of streptokinase. Three large randomized controlled clinical trials have compared streptokinase to tPA. Using the composite end point of stroke or death at 30 to 35 days, GISSI-2 (more than 20,000 patients) found that tPA resulted in an increased rate of stroke/death of 5 per 1000 patients relative to streptokinase. [5] ISIS-3 (27,000 patients) found a 1 per 1000 patient benefit in favor of tPA. [6] GUSTO-1 found a 5.4 per 1000 patient benefit in favor of tPA, which increased to 9 patients per 1000 when the accelerated tPA regimen was given. [7] As a result, most cardiologists recommend the use of the accelerated tPA regimen.

When these trials are taken together, these three megatrials found no statistical difference between streptokinase and tPA with respect to the composite end point of stroke and death. A meta-analysis of the data from these three trials found that tPA offered a nonstatistical benefit of 1.6 ± 1.9 per 1000 patients (p = 0.4). Using only death as the end point, tPA rather than streptokinase use results in a nonstatistical difference of 2.0 ± 1.9 lives saved per thousand patients ($p > 0.1$). Based on this analysis, the choice of which thrombolytic agent to use is probably less relevant than the speed of thrombolytic administration (which results in saving an additional 1.6 per 1000 lives per hour earlier that treatment is provided). In addition, it is probably better to choose streptokinase over tPA when the risk for intracranial hemorrhage is highest (elderly, etc.) since tPA has an increased likelihood of resulting in hemorrhagic stroke. [4]

The mechanism of improved benefit of tPA in the GUSTO angiographic substudy is early patency of the infarct-related vessel. [8] For tPA, streptokinase-subcutaneous heparin, streptokinase-intravenous heparin, and streptokinase-tPA, the patency rates at 90 min were 81, 56, 61, and 73 percent, respectively. [8] These patency rates were predictive of survival outcomes.

The accelerated regimen of tPA, as used in the GUSTO trial, is an initial bolus of 15 mg, followed by 0.75 mg/kg (up to 50 mg) in the first 30 min and 0.5 mg/kg (up to 35 mg) in the next hour. [7]

RETEPLASE   rPA is a genetically engineered modification of tPA with a prolonged half-life (18 min vs 3 min) and reduced fibrin binding. GUSTO-3 compared rPA to tPA in 15,000 patients and found similar mortality and stroke rates between the two agents. [9] Smaller studies suggest that reteplase has a faster time to reperfusion. Reteplase can be given as a double bolus, 10 mg each, 30 min apart.

Other genetically engineered molecules are currently in the developmental stages, and results of clinical trials are not yet available. TNK-tPA is another tPA mutant with prolonged half-life, that is resistant to endogenous plasminogen activator inhibitor-1 (PIA-1) inactivation, and has high fibrin specificity and binding. In animal models, it produces more active and complete fibrinolysis with less risk of intracranial bleeding. Results of clinical trials are pending. n-PA is a deletion and point mutant of tPA that has a more extended half-life (30 to 45 min) with improved lytic activity in animal models and reduced fibrin affinity.

Mechanical Reperfusion

Coronary angioplasty is the most common percutaneous intervention. Alternatives include coronary stent placement, atherectomy, and laser angioplasty. Balloon angioplasty increases the size of the arterial lumen through endothelial denudation; cracking, splitting, and disruption of atherosclerotic plaque; dehiscence of intima and plaque from underlying media; and stretching or tearing of underlying media and adventitia. [10] With successful dilation, small amounts of arterial wall dissection and aneurysmal expansion may be seen. The greater the increase in luminal size, the lower is the risk of restenosis. On the other hand, more aggressive balloon inflation can be associated with excessive dissection, platelet deposition, thrombus formation, and plaque hemorrhage. [10]

Alternative percutaneous interventional procedures have been developed in an attempt to limit complications. Directional and rotational coronary atherectomy extract atherosclerotic tissue from the coronary artery. Excimer laser atherectomy vaporizes atheromatous tissue. Their use results in larger luminal diameters but has not reduced rates of restenosis or other complications associated with percutaneous angioplasty procedures.

Coronary stents are fenestrated stainless-steel tubes that are expanded by a balloon to provide scaffolding within the coronary arteries. The addition of antiplatelet therapies (in particular, glycoprotein IIb/IIIa inhibitors) has been associated with reduced rates of abrupt vessel closure and improved outcomes up to 3 years following the procedure.

Direct coronary angioplasty has compared favorably with fibrinolytic therapy for the treatment of patients with AMI. In centers with significant expertise in direct angioplasty, primary angioplasty reduces the cardiovascular complication rate in patients with AMI relative to fibrinolytic therapy. The PAMI trial compared the efficacy of intravenous tPA with immediate percutaneous coronary angioplasty (PTCA) in 395 patients with AMI. The in-hospital mortality rate in the tPA group was 6.5 percent and in the PTCA group was 2.6 percent. In-hospital reinfarction rates, 6-month rates of reinfarction or death, and rates of intracranial hemorrhage were all lower in the PTCA group. [11] In GUSTO IIb, 1138 patients who presented within 12 h of AMI were randomized to accelerated tPA or to primary angioplasty. The incidence of death, nonfatal reinfarction, and nonfatal disabling stroke was 33 percent lower in patients who received primary angioplasty. [12] A large study of patients presenting to

community hospitals did not show a benefit of direct angioplasty over fibrinolysis. [13]

Primary angioplasty may offer benefits in highly specialized centers with ready availability of cardiac catheterization and skilled operators that are not apparent with longer delays or less skilled operators. The decision to use primary interventional procedures rather than fibrinolysis should be individualized based on the institutional expertise and availability and risk of complications from fibrinolysis.

Antiplatelet Agents

Platelets are at the core of coronary artery thrombosis. [14] Platelet activation and adhesion to subendothelial matrix elements occur as a result of plaque rupture. Platelet aggregation may be initiated by shearing forces, fibrinolytics, thrombin, thromboxane A_2, ADP, epinephrine, serotonin, or plasmin. These trigger the arachidonic acid pathway, the protein kinase C pathway, or other pathways that result in platelet aggregation. The final common pathway of platelet activation is exposure of glycoprotein IIb/IIIa receptors on the surface of the platelet. Bivalent fibrinogen molecules cross-link activated platelets together by using these receptors. The glycoprotein IIb/IIIa antagonists are considerably stronger antiplatelet agents than aspirin, because they interrupt platelet activation regardless of agonist. In contrast, aspirin only inhibits platelet aggregation stimulated through thromboxane A_2 and mediated through the arachidonic acid pathway.

GLYCOPROTEIN IIb/IIIa INHIBITORS Several different forms of glycoprotein IIb/IIIa antagonists are available. Abciximab (ReoPro) is a chimeric antibody that binds irreversibly to the glycoprotein IIb/IIIa antagonists. The duration of action is longer than that of the smaller peptide molecules. As a result, benefits may be realized with a shorter duration of infusion. Eptifibatide (Integrelin) is a synthetic heptapeptide that binds reversibly to the glycoprotein IIb/IIIa receptor. Lamifiban and tirofiban (Aggrastat) are synthetic small molecules with reversible binding to the glycoprotein IIb/IIIa receptor. All require a 48- to 72-h infusion to demonstrate sustained benefits. Reversal of platelet inhibition following cessation of infusion is more rapid with the polypeptide or small molecules, offering an advantage when bleeding complications occur.

The glycoprotein IIb/IIIa inhibitors have been evaluated for use in three clinical areas: percutaneous interventional procedures (PCI), in combination with low-dose fibrinolysis, and for medical stabilization of patients with ACS. In EPIC, 2099 high-risk patients receiving PTCA or atherectomy were randomized to abciximab bolus alone, abciximab bolus plus 12-h infusion, or placebo, in conjunction with aspirin and heparin. [15] Patients who received abciximab bolus plus infusion had a 35 percent reduction in the composite end point of death, AMI, or urgent reintervention. Some of this benefit was sustained for up to 3 years (13 percent reduction). Of note, the rate of bleeding was increased twofold in the patients treated with abciximab. The EPILOG trial randomized 2792 patients undergoing PCI to abciximab plus low-dose weight-adjusted heparin, abciximab plus standard-dose heparin, or placebo plus standard-dose heparin. This trial, using lower doses of heparin, retained the reduction in the risk of death, AMI, or urgent revascularization (56 percent at 30 days and 43 percent at 6 months), without an increased risk of bleeding complications. [16] As a result of these trials, glycoprotein IIb/IIIa inhibitors are often used in high-risk patients undergoing percutaneous interventions in the cardiac catheterization laboratory.

A variety of glycoprotein IIb/IIIa antagonists have been shown to be efficacious for patients with ACS. In the CAPTURE trial, [17] 1265 patients who had failed medical stabilization with heparin and nitroglycerin were randomized to abciximab or placebo bolus and infusion in addition to aspirin, standard-dose heparin, and intravenous nitroglycerin while waiting 24 h for percutaneous intervention. Medical therapy with abciximab resulted in a 71 percent decrease in AMI and 29 percent decrease in composite end point of death, AMI, or urgent reintervention. This reduction in adverse cardiovascular events occurred prior to the percutaneous intervention, suggesting a role for glycoprotein IIb/IIIa antagonists in medical stabilization of refractory unstable angina patients.

Four large trials (PURSUIT, PRISM, PRISM-PLUS, and PARAGON) evaluated glycoprotein IIb/IIIa antagonists for the medical stabilization of patients with unstable angina or non-Q-wave AMI. [18,19,20 and 21] In the PRISM study, [18] 3232 patients who were already receiving aspirin were randomized to additional treatment with intravenous tirofiban or heparin for 48 h. The composite end point (death, AMI, or refractory ischemia at 48 h) was 32 percent lower in the glycoprotein IIb/IIIa antagonist group. The reduction in mortality rate persisted to 30 days. In PRISM-PLUS, [19] 1915 patients were randomized to tirofiban, heparin, or both for 3 days. Patients treated with tirofiban and heparin had a reduction in the composite end point of death, AMI, or refractory ischemia at 7 days. Reduction in rates of death and AMI persisted for up to 6 months. Notably, in contrast to the PRISM results, patients who received tirofiban alone had an increased rate of adverse cardiovascular events. PURSUIT randomized 10,948 patients to bolus and infusion treatment with eptifibatide or placebo for up to 72 h. [20] The glycoprotein IIb/IIIa antagonist resulted in 1.5 percent absolute reduction (10 percent relative reduction) in death and nonfatal AMI that was evident by 96 h and persisted to 30 days. The PARAGON trial randomized patients to various doses of lamifiban with or without heparin and did not find that lamifiban reduced clinical events at 30 days; however, there was a 40 percent reduction in death and AMI at 6-month follow-up. [21]

Taken together, these trials strongly suggest a role for the glycoprotein IIb/IIIa antagonists in the treatment of patients with refractory unstable angina. The various glycoprotein IIb/IIIa antagonists have not been compared with one another in any trial. Long-term benefits have been documented with abciximab and tirofiban. Abciximab differs from the other glycoprotein IIb/IIIa antagonist in terms of duration of infusion (12 h vs 48 to 72 h) and duration of sustained benefit (up to 3 years in the EPIC study). In contrast, the intracranial hemorrhage rate of the glycoprotein IIb/IIIa antagonists is considerably lower (0.1 percent) than with fibrinolysis, although severe catheter site bleeding and transfusion needs are approximately 6 percent.

COMBINATION FIBRINOLYTIC AND GLYCOPROTEIN IIb/IIIa INHIBITORS Although most of the coronary thrombosis is red clot (fibrin and erythrocytes), the central platelet thrombus (white clot) is fully resistant to fibrinolytic therapy. These platelets secrete PAI-1, which is a potent inhibitor of fibrinolysis. In theory, combination therapy with antiplatelet agents and fibrinolytics will attack both components of coronary thrombosis. This is one explanation why even a weak antiplatelet agent reduces mortality rate as much as treatment with streptokinase alone. [3]

Preclinical studies of low-dose fibrinolytic therapy with glycoprotein IIb/IIIa antagonists that have utilized a reduction in the standard fibrinolytic dose to 50 percent of the standard dose have found that fibrinolysis occurs more rapidly and is more stable. TIMI-14 evaluated abciximab plus either tPA or streptokinase in patients who also received aspirin and low-dose heparin. [22] Abciximab was able to increase the rate of TIMI grade 3 flow by 20 to 25 percent (a 10 percent absolute improvement). The SPEED trial is a dose finding trial to determine the optimal doses of abciximab and reteplase to be used together. GUSTO-IV will compare low dose fibrinolysis in combination with abciximab versus standard dose fibrinolysis alone to determine if the theoretical benefits of low dose fibrinolytics in conjunction with glycoprotein IIb/IIIa antagonists can be realized.

ASPIRIN Aspirin should be given as soon as possible to all patients with ACS. In platelets, aspirin prevents formation of thromboxane A_2, an agonist of platelet aggregation. This inhibition persists for the 9 to 10 life of the platelet, since platelets are unable to generate new cyclooxygenase. [23] Aspirin alone has been shown to be efficacious as streptokinase alone. [3] Aspirin alone reduces mortality rate by 23 percent. In conjunction with streptokinase, mortality rate is reduced 43 percent. Aspirin used in conjunction with fibrinolytic therapy further reduces ischemic events and coronary artery reocclusion. Doses greater than 160 mg cause immediate near complete inhibition of thromboxane A_2. Lower doses may be effective for long-term prophylaxis but may not be effective for acute use. Aspirin reduces vascular events in patients with AMI and patients with unstable angina. [4,24] In patients with prior myocardial infarction or stroke, it reduces vascular events by up to 40 events per 1000 patients. [23]

The side effects of aspirin are mainly gastrointestinal and dose related. They can be reduced by using diluted or buffered aspirin solutions, lowest possible doses, or concurrent antacid or H_2 antagonist administration. In the setting of acute ischemia, the delay in absorption of enteric-coated aspirin may be best avoided. Due to the substantial benefits of aspirin therapy during AMI, it should not be withheld from patients with minor contraindications (vague allergy, history of remote peptic ulcer, or gastrointestinal bleeding). [4] Other antiplatelet agents, such as ticlopidine, can be substituted if true aspirin allergy or active peptic ulcer disease exists. [4] The aspirin dose should be at least 160 mg.

TICLOPIDINE This is an antiplatelet agent that inhibits platelet aggregation induced by a wide range of agonists. The inhibitory effect of ticlopidine is delayed 24 to 48 h after its administration. [4] It is effective in reducing 6-month vascular death and AMI rate in patients with unstable angina. [25] Side effects include neutropenia, which is more common in patients treated for more than 2 weeks. The dose is 250 mg twice per day.

Antithrombins

HEPARIN Heparin is a specific antithrombin agent. [23] As already discussed, thrombin generation plays an intricate role in the pathogenesis of coronary artery thrombosis. Thrombin converts soluble fibrinogen to insoluble fibrin; activates coagulation factors V and VIII, which exert positive feedback on coagulation through the

prothrombinase complex; and activates factor XIII, which stabilizes thrombus formation by promoting fibrin cross-linking. In addition, thrombin serves as a platelet agonist.

Unfractionated heparin consists of a mixture of molecules with molecular weights varying between 2000 and 20,000. The different-sized molecules have different effects on the coagulation system. Heparin complexes with antithrombin III, and this complex inactivates both thrombin and activated factor X. The heparin-antithrombin III complex is not effective against clot-bound thrombin. Heparin reduces the risk of AMI and death during the acute phase of unstable angina. [26] The combination therapy of aspirin and heparin reduces the short-term risk of death or myocardial infarction by 56 percent, compared with aspirin alone. [26] When heparin is used in combination with aspirin, reactivation of ischemia is prevented after cessation of the heparin infusion. [27] Thus, combination therapy with aspirin and heparin is indicated for patients with ACS not treated with fibrinolytic agents.

For patients who have been treated with aspirin and fibrinolytic therapy, the incremental value of the addition of heparin is small. The 35-day mortality rate is not improved, and the rate of major or severe bleeding is slightly increased.

Unfractionated heparin has some limitations. It has an unpredictable anticoagulant response because the bioavailability of heparin is variable. It requires careful laboratory monitoring and dose adjustment.

LOW-MOLECULAR-WEIGHT HEPARINS The low-molecular-weight heparins (LMWHs) have greater bioavailability, lower protein binding, a longer half-life, and achieve a more reliable anticoagulant effect. As a result, they can be administered in a fixed dose subcutaneously once or twice a day and achieve a stable therapeutic response without the need for monitoring anticoagulation.

Several clinical trials have compared LMWH to standard heparin regimens for treatment of ACS. The ESSENCE trial randomized 3171 patients with unstable angina and non-Q-wave myocardial infarction to treatment with aspirin and either subcutaneous enoxaparin (LMWH) or intravenous unfractionated heparin. [28] At 14 and 30 days, the risk of death, AMI, or recurrent angina was more than 15 percent lower in patients who received LMWH, without an increase in major bleeding complications.[28] The dose of enoxaparin for treatment of ACS is 1 mg/kg body weight. The dose may change depending upon results of ongoing trials.

Direct Thrombin Inhibitors

These bind to the catalytic site of thrombin, bind to thrombin in clot, and are resistant to agents that degrade heparin. Hirudin, a 65-amino-acid peptide, is derived from the medicinal leech and is one of the most potent naturally occurring anticoagulants. A recent large clinical trial was terminated because hirudin resulted in an increased incidence of intracranial bleeding relative to heparin (1.3 vs 0.7 percent). [29] Bivalirudin (Hirulog) reduced the short-term risk of postischemic complications relative to high-dose unfractionated heparin in patients who underwent percutaneous interventions for unstable or postinfarction angina, but benefits did not persist long term.[30] Also, a low-molecular-weight thrombin inhibitor, inogatran, does not appear to offer benefits over unfractionated heparin for the treatment of patients with ACS.[31] Thus, at this time, there is no clearly defined role for direct thrombin inhibitors in the treatment of ACS.

LIMITING INFARCT SIZE

Nitrates

Nitrates relax vascular smooth muscle in arteries, arterioles, and veins through the metabolic conversion of organic nitrates to nitric oxide. The pulmonary capillary wedge pressure, systemic arterial pressure, and left ventricular end-systolic and end-diastolic volumes all decrease. Reduction in right and left ventricular filling pressures that result from peripheral dilatation combined with afterload reduction that results from arterial dilatation decrease cardiac work and myocardial oxygen requirements. Nitroglycerin has direct vasodilator effects on the coronary vascular bed, increasing global and regional myocardial blood flow. When obstructing atherosclerotic lesions contain intact vascular smooth muscle, nitrates may dilate these vessels, improving blood flow. Platelet aggregation is also inhibited by nitroglycerin.

When nitroglycerin is used in AMI patients who are not treated with thrombolytics, several clinical trials have demonstrated a reduction in infarct size, improved regional function, and decreased rate of cardiovascular complications. [32,33 and 34] The mortality rate appears to be reduced by 35 percent with the use of nitrates. [34] It is important to note that, in most studies, intravenous nitroglycerin was titrated to 10 percent reduction in mean arterial pressure for normotensive patients and 30 percent reduction in mean arterial pressure for hypertensive patients. It was not titrated to symptom resolution. Thus, when intravenous nitroglycerin is used for patients with AMI, the dose should be titrated to blood pressure reduction rather than to symptom (chest pain) resolution.

Studies in patients who have received fibrinolytic agents have not found a benefit to the use of nitroglycerin. Unfortunately, large numbers of the control (non-nitroglycerin) patients were prescribed nitroglycerin by their physician, precluding optimal data interpretation.

The American College of Cardiology/American Heart Association (ACC/AHA) guidelines recommend the use of intravenous nitroglycerin for the first 24 to 48 h for patients with AMI and recurrent ischemia, congestive heart failure, or hypertension. [4] Benefits are likely to be greatest in the patients not receiving concurrent fibrinolytic therapy. The Agency for Health Care Policy and Research (AHCPR) unstable angina guidelines recommend that intravenous nitroglycerin be used in patients with unstable angina who are not responsive to an initial three sublingual nitroglycerin tablets and initiation of b-antagonist therapy. [24]

The most serious side effect of nitroglycerin is hypotension, which may result in reflex tachycardia and worsening ischemia. Nitrates should not be used for patients with right ventricular infarction. [35] Nitroglycerin should be used very cautiously for patients with inferior wall ischemia, because one-third of such patients might have right ventricular involvement. Patients with right ventricular infarction are volume dependent. Administration of nitrates reduces preload and commonly results in hypotension in these patients. The development of hypotension is associated with an increased infarct size.

When nitroglycerin results in hypotension and bradycardia, the drug should be discontinued, legs elevated, and fluid administered. Atropine may be necessary in some cases.[4]

b Blockers

b-Adrenergic antagonists have antiarrhythmic, anti-ischemic, and antihypertensive properties. During AMI, they diminish myocardial oxygen demand by decreasing heart rate, systemic arterial pressure, and myocardial contractility. Prolongation of diastole may augment perfusion to ischemic myocardium. [32]

Immediate b-antagonist administration in AMI reduces chest pain, wall stress, infarct size, incidence of cardiovascular complications, and mortality rate for patients not treated with fibrinolytics. The International Collaborative Study Group randomized 144 patients with AMI to treatment with timolol or placebo. [36] The timolol group had a reduction in pain, analgesic use, and infarct size. The Metoprolol in Acute Myocardial Infarction (MIAMI) trial randomized 5778 patients to metoprolol or placebo. Metoprolol reduced mortality rate in high-risk patients, and infarct size was reduced in patients treated within 7 h of symptom onset. [37] ISIS-1 randomized 16,027 patients to atenolol or placebo and found a 14 percent sustained reduction in mortality rate equating to 6 lives saved per 1000 patients. [38]

For patients treated with fibrinolytics, the TIMI-II trial showed that b antagonists decrease the risk of nonfatal reinfarction and recurrent ischemia if given within 2 h after symptom onset. Mortality rate and ventricular function were not affected. [39]

The ACC/AHA guidelines recommend that all patients with Q-wave AMI who do not have a contraindication to b antagonists be treated with these agents within 12 h of onset of infarction, regardless of whether they have received fibrinolytic therapy. [4] Patients with recurrent ischemia and tachyarrhythmias should receive b-antagonist therapy. The role of b antagonists in non-Q-wave infarctions is less clear. The AHCPR guidelines do recommend that patients with unstable angina receive treatment with b antagonists, when possible. [24]

Relative contraindications to b-adrenergic antagonists are heart rate less than 60 beats per minute, systolic blood pressure less than 100 mmHg, moderate to severe left ventricular failure, signs of peripheral hypoperfusion, PR interval more than 0.24 s, second-degree or third-degree atrioventricular block, severe chronic obstructive pulmonary disease, history of asthma, severe peripheral vascular disease, and insulin-dependent diabetes mellitus. [4] Use of b antagonists should be

individualized for patients with these conditions.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors reduce left ventricular dysfunction and left ventricular dilatation and slow the development of congestive heart failure during AMI. Studies have consistently shown a reduction in mortality rate for patients treated with oral ACE inhibitors during and soon after AMI. [32] A meta-analysis of 15 trials including over 100,000 patients supports a 6.5 percent reduction in short-term mortality rate, with an absolute benefit of 4.6 fewer deaths per 1000 patients treated with early ACE inhibitor therapy. [40] Intravenous enalaprilat was associated with increased hypotension and is not recommended for use during AMI.

The ACC/AHA guidelines recommend that patients with AMI and ST-segment elevation in two or more anterior precordial leads or with clinical heart failure in the absence of contraindications receive treatment with ACE inhibitors. [4] Contraindications to ACE inhibitors include hypotension, bilateral renal artery stenosis, renal failure, or history of cough or angioedema due to prior ACE inhibitor use. The efficacy of ACE inhibitors in unstable angina has not been well evaluated.

Magnesium

Magnesium produces systemic and coronary vasodilatation, possesses antiplatelet activity, suppresses automaticity, and protects myocytes from calcium influx during reperfusion. One meta-analysis of seven randomized trials found a significant mortality-rate benefit in patients with AMI. [41] In the 2316 patients in the Leicester Intravenous Magnesium Intervention Trial (LIMIT-2), magnesium-treated patients had a 21 to 25 percent reduction in short-term mortality rate and the incidence of congestive heart failure and 4-year cardiovascular mortality rate was also reduced. [42] Studies, however, are conflicting: some have found mortality rate reduced by about 75 percent, whereas others have showed no benefit at all. The disparity in findings may be related to the interval between symptom onset and magnesium administration, and various concurrent therapies (including fibrinolysis). In light of these conflicting data, the ACC/AHA guidelines support correction of documented hypomagnesemia during AMI and treatment of torsades-type ventricular tachycardia with a prolonged QT interval. [4] Magnesium bolus and infusion in high-risk patients, such as the elderly and those in whom reperfusion therapy is not suitable, is considered possibly beneficial. [4]

Calcium-Channel Antagonists

Calcium-channel blockers have antianginal, vasodilatory, and antihypertensive properties. [32] Calcium antagonists have not been shown to reduce mortality rate after AMI. In fact, they may be harmful to some patients with cardiovascular disease. [4] Nifedipine is the most studied of the calcium-channel blockers for the treatment of AMI. This short-acting dihydropyridine has been associated with a nonsignificant increase in mortality rate when given during or shortly after AMI in several clinical trials. [43] Immediate-release nifedipine may be harmful as a result of a coronary "steal" syndrome in which coronary perfusion pressure is reduced through disproportionate dilatation of the coronary arteries adjacent to the ischemic zone and/or reflex activation of the sympathetic nervous system with a resultant increase in myocardial oxygen demand.

Diltiazem has also been found to be associated with increased mortality rate, particularly for patients with congestive heart failure. [44] Similarly, studies evaluating verapamil have not found mortality-rate benefits. [32] Verapamil is detrimental for patients with congestive heart failure or bradydysrhythmias. There are no data supporting the use of second-generation dihydropyridines (amlodipine and felodipine) for treatment of AMI.

The ACC/AHA guidelines state that "these agents are still used too frequently in patients with acute MI and that beta-adrenoreceptor blocking agents are a more appropriate choice."[4] Verapamil and diltiazem are considered potentially beneficial for use in patients with ongoing ischemia or atrial fibrillation with rapid ventricular response who do not have congestive heart failure, left ventricular dysfunction, or atrioventricular block, and b-adrenergic antagonists are contraindicated. [4,24]

SPECIAL ISSUES IN TREATMENT OF AMI COMPLICATIONS

Recurrent or Refractory Ischemia

Patients unresponsive to medical management with continued ischemia should be treated on an individual basis. Depending on the infarct distribution and coronary anatomy, decisions could be made regarding continued medical management, rescue angioplasty, or coronary artery bypass grafting. Emergency cardiology referral should be considered. Refractory ischemia is often investigated with coronary catheterization.

Intraaortic balloon counterpulsation delivers phased pulsations synchronized to the electrocardiograph so that balloon inflation will occur at the time of aortic valve closure and deflation occurs just prior to onset of systole. The augmented coronary perfusion pressure during diastole enhances coronary blood flow. Balloon deflation during systole allows the left ventricle to eject blood against a lower resistance. The net effect of intra-aortic balloon counterpulsation is an increase in cardiac output, reduction in systolic arterial pressure, increase in diastolic arterial pressure, little change in mean arterial pressure, and reduction in heart rate. The reduction in left ventricular afterload leads to reduced myocardial oxygen consumption, decreasing the amount of myocardial ischemia. Intraaortic balloon counterpulsation is recommended for patients with ACS who are refractory to aggressive medical management or are hemodynamically unstable, as a means to bridge a patient's stability en route to the cardiac catheterization laboratory or the operating room. [24]

Cardiogenic Shock

This is discussed in [Chap. 29](#).

Right Ventricular Infarction

One-third of patients with inferior wall myocardial infarction have right ventricular involvement. The most serious complication of right ventricular infarction is shock. Right ventricular infarction results in a reduction in right ventricular end-systolic pressure, left ventricular end-diastolic size, cardiac output, and aortic pressure as the right ventricle becomes more of a passive conduit to blood flow. Left ventricular contraction causes bulging of the interventricular septum into the right ventricle, with resultant ejection of blood into the pulmonary circulation. As a result, right ventricular infarction in the setting of a large left ventricular infarction has a particularly devastating effect on hemodynamic function. Factors that reduce preload (volume depletion, diuretics, and nitrates) or decrease right atrial contraction (atrial infarction and loss of atrioventricular synchrony) and factors that increase right ventricular afterload (left ventricular failure) can lead to significant hemodynamic derangements.

Treatment of right ventricular infarction includes maintenance of preload, reduction of right ventricular afterload, and inotropic support of an ischemic right ventricle, in addition to early reperfusion. [45] Patients with right ventricular infarction should not be treated with drugs, such as nitrates, that reduce preload. In the setting of right ventricular infarction, nitrates will often reduce cardiac output and produce hypotension. Instead, patients with marginal preload or hypotension should be treated with volume loading (normal saline). The increased preload will improve right ventricular cardiac output. If cardiac output is not improved after 1 to 2 L of normal saline, inotropic support with dobutamine should be initiated.

High-degree heart block is very common in patients with right ventricular infarction. The loss of right atrial kick can greatly compromise right ventricular cardiac output. Restitution of atrioventricular synchrony is important. For patients who require pacing in the setting of right ventricular infarction, it may be necessary to establish atrioventricular sequential pacing leads. Patients who do not attain hemodynamic improvement after placement of a ventricular pacer may still improve with atrioventricular sequential pacing reestablishing a right atrial kick.

When right ventricular infarction is accompanied by left ventricular dysfunction, the use of nitroprusside to reduce afterload, or intra-aortic balloon counterpulsation, may be of benefit. Reduction in left ventricular afterload may help passive movement of blood through the right ventricle.

Selected Dysrhythmias in AMI

ATRIAL FIBRILLATION   Atrial fibrillation associated with AMI most typically occurs in the first 24 hours and is usually transient. It more often occurs in patients with excess catecholamine release, hypokalemia, hypomagnesemia, hypoxia, chronic lung disease, and sinus node or left circumflex ischemia. Patients with

supraventricular tachycardia, atrial fibrillation, and atrial flutter who have hemodynamic compromise should receive cardioversion with 100 J, then 200 to 300 J, then 360 J if lower energies fail. Patients without hemodynamic compromise, clinical left ventricular dysfunction, reactive airway disease, or heart block can be treated with beta-adrenergic antagonists, such as atenolol (2.5–5 mg over 2 min to a total of 10 mg) or metopropol (2.5–5 mg every 2–5 min to a total of 15 mg). Patients with contraindications to beta-adrenergic antagonists can be treated with digitalis (0.3 mg–0.5 mg initial bolus with a repeat in 4 h) or a calcium antagonist such as verapamil or dilitiazem. Digitalis will take longer to work but is still preferred by the ACC/AHA guidelines because of the potential negative inotropic effects of calcium antagonists, their lack of efficacy in reducing mortality during AMI, and potentially harmful effects in some subsets of AMI patients. [2] The etiology of the tachydysrhythmia should also be addressed. Heparin should be given since atrial fibrillation during AMI is associated with a 3-fold risk in systemic embolization.

BRADYDYSRHYTHMIAS   The increased mortality in patients with heart block during AMI is related to more extensive myocardial damage and not the heart block itself. As a result, pacing has not been shown to reduce mortality in patients with AV block or intraventricular conduction delay. Nonetheless, pacing is still recommended to protect against sudden hypotension, acute ischemia, and precipitation of ventricular dysrhythmias in certain patients.

The risk of developing third degree heart block during AMI is increased in the setting of first degree AV block, both types of second degree AV block (more likely with Mobitz II), left anterior hemiblock, left posterior hemiblock, right bundle branch block, and left bundle branch block. The prognosis is related to the site of infarction, site of the block (intranodal vs. infranodal), the type of escape rhythm, and the hemodynamic response to the rhythm.

Atropine is recommended for sinus bradycardia when it results in hypotension, ischemia, or ventricular escape rhythms and for treatment of symptomatic AV block occurring at the AV nodal level (second degree type 1 or third degree AV block). Atropine will reverse decreases in heart rate, systemic vascular resistance, and blood pressure that are mediated by parasympathetic activity. It should be used cautiously in the setting of AMI because the parasympathetic tone is protective against infarct extension and ventricular fibrillation.

Temporary *transcutaneous* pacers are recommended for patients at moderate to high risk of progression to AV block, e.g: unresponsive symptomatic bradycardia, Mobitz-II, or higher AV blocks, new LBBB and bifascicular blocks, RBBB, or LBBB with 1 degree block. It can also be considered for some cases with stable bradycardia and new or indeterminate age RBBB. *Transvenous* pacing should be considered in patients who require permanent pacing and in patients with a very high likelihood (>30%) of requiring permanent pacing, e.g. asystole, unresponsive symptomatic bradycardia, Mobitz-II, 3 degree block, alternating BBB, or RBBB or LBBB with 1 degree block. It can also be considered in some cases of RBBB with left anterior or posterior hemiblocks, new or indeterminate age LBBB, for atrial or ventricular overdrive pacing in unresponsive V_T, and unresponsive recurrent sinus pauses (>3 s). Patients with right ventricular infarction who are very dependent on atrial systole may require atrioventricular sequential pacing to maintain cardiac output.

Cocaine Associated Myocardial Ischemia

Management of patients with cocaine associated myocardial ischemia focuses on reversal of coronary vasoconstriction, hypertension, tachycardia, and predisposition to thrombus formation.[31] Central nervous system protection and decreased sympathetic outflow should be accomplished with the administration of benzodiazepines. Multiple animal experiments and widespread anecdotal experience in humans support the use of diazepam as the initial agent for the management of cocaine intoxicated patients. Diazepam alone will often calm the agitated patient and return abnormal vital signs to the normal range. Reduction in hypertension and/or tachycardia will decrease the myocardial oxygen demand.

Aspirin and/or heparin should be used as they would be in patients with myocardial ischemia unrelated to cocaine, despite the lack of any clinical or experimental data. The success with platelet inhibitors and anticoagulants in traditional myocardial infarction patients and the propensity of cocaine to induce platelet aggregation supports their use.

Specific anti-ischemic therapy begins with nitroglycerin. Nitroglycerin reverses cocaine induced coronary artery vasoconstriction and relieves cocaine associated chest pain. Although infarct size reduction or mortality benefits have not been assessed, based on direct vasodilatory effects of nitroglycerin, experimental reversal of coronary vasoconstriction, and clinical relief of chest pain, it should be used. [31]

Patients with continued myocardial ischemia, after the use of nitroglycerin should be treated with either phentolamine, calcium channel blockers, or thrombolytic agents depending on the clinical circumstances. [31] Phentolamine blocks the alpha adrenergic effects of cocaine and reverses the coronary vasoconstrictive effects of cocaine. Phentolamine should be used with caution, as it is generally considered contraindicated after benzodiazepine use, and may result in marked hypotension. Low doses (1 mg every 2.5 min) have been used multiple times without any adverse consequences.

Verapamil, a calcium channel antagonist, reverses cocaine induced coronary artery vasoconstriction. Unfortunately, animal studies demonstrate enhanced central nervous system toxicity from concurrent administration of cocaine and any one of several calcium antagonists (verapamil, diltiazem, and nifedipine). The potentiation of cocaine associated central nervous system toxicity, combined with the limited success of calcium antagonists in traditional myocardial infarction patients makes them less attractive for use in patients with cocaine associated myocardial infarction. [31]

Thrombolytic therapy has become the standard of care for patients with myocardial infarction unrelated to cocaine, however, the use of these agents in cocaine associated myocardial ischemia must proceed with great caution. Although initial concerns regarding safety have been tempered, there has been no demonstrated efficacy in this patient population. Up to 43% of patients with cocaine associated chest pain without myocardial infarction meet TIMI criteria for the administration of thrombolytic agents despite the fact they did not infarct. The potential administration to patients who are not infarcting coupled with a very low mortality from cocaine associated myocardial infarction limits the utility of thrombolytic agents. Patients who have new ST segment elevations (based on comparison with prior electrocardiograms), or echocardiographic wall motion abnormalities may be suitable candidates since "false positive" ST elevations should be less of a concern.

Beta adrenergic antagonists should be avoided in patients who have recently used cocaine. [31] They have been shown to increase central nervous system toxicity and exacerbate coronary artery vasospasm in several animal models of cocaine toxicity. Clinical series have demonstrated that they fail to reverse the hpertensive and tachycardic effects of cocaine. The alpha-adrenergic agonist effects of cocaine on the coronary vasculature are enhanced by beta adrenergic antagonists which worsen the severity of cocaine induced coronary vasoconstriction. Thus, despite the overwhelming success of beta adrenergic antagonists in patients with myocardial infarction unrelated to cocaine, they are to be avoided in patients who have recently used cocaine. Labetalol does not appear to offer any advantage over the use of pure beta adrenergic antagonists.

The treatment of post infarction dysrhythmias secondary to cocaine has not been well studied. The local anesthetic and sodium channel blocking effects of cocaine were hypothesized to be worsened by concomitant lidocaine administration, however, several animal models have yielded conflicting results. One clinical series, in which patients received lidocaine more than 4 hours after cocaine use, did not find serious dysrhythmias or central nervous system toxicity after lidocaine administration. Sodium bicarbonate narrows the QRS complex in cocaine induced dysrhythmias through its effects of the sodium channels. Sodium bicarbonate is recommended for the early treatment of cocaine induced dysrhythmias.[31] Lidocaine can also be used for treatment of patients with later development dysrhymias. [31]

49 HEART FAILURE AND PULMONARY EDEMA

Charles B. Cairns

HEART FAILURE

The principal functions of the heart are to receive blood from the veins, send it to the lungs for oxygenation, and pump the oxygenated blood to the body. *Heart failure* occurs when there is a substantial disruption of these functions secondary to a loss of normal contractile ability.[1] Heart failure that results in abnormal fluid retention is commonly referred to as *congestive heart failure* (CHF). The major clinical manifestation of heart failure is shortness of breath, especially with exercise. The heart may fail when it performs excessive work for a prolonged period, such as in patients with hypertension and valvular heart disease. Heart failure is also seen in a variety of infectious, inflammatory, and infiltrative conditions that affect heart muscle. In the acute setting, heart failure is commonly due to a loss of heart muscle via infarction or to a loss of nourishment via ischemia.[1,2] The common causes of heart failure are summarized in Table 49-1.[1,2,3,4,5,6,7,8 and 9]

TABLE 49-1   Common Causes of Heart Failure and Pulmonary Edema

Over 2 million people in the United States have heart failure.[3] The incidence of heart failure appears to be increasing, and over 500,000 new cases are detected each year.[4] In addition, the mortality rate from heart failure is also increasing,[5] and one-half of patients with severe heart failure (left ventricular ejection fraction less than 35 percent) die within 1 year of diagnosis.[6]

Pathophysiology of Heart Failure

The three factors of contractility, preload, and afterload determine ventricular stroke volume.[1] Coupled with heart rate, stroke volume determines cardiac output. Cardiac *contractility* is related to the amount of myocardial stretch, known as *preload*. Clinical measurements of cardiac stretch include the ventricular end-diastolic pressure and volume. *Afterload* is defined as the ventricular wall tension that develops during systole and reflects the resistance to outward blood flow. It is clinically estimated by the systolic arterial pressure. Many sorts of heart failure are associated with decreased contractility. The Frank-Starling relationships between stroke volume, preload, and contractility in both normal hearts and failing hearts are illustrated in Fig. 49-1.[1]

FIG. 49-1. Left ventricular (LV) performance (Frank-Starling) curves relate preload, measured as LV end-diastolic volume (EDV) or pressure (EDP), to cardiac performance, measured as ventricular stroke volume or cardiac output. On the curve of normal individuals (*middle line*), cardiac performance continuously increases as a function of the preload. States of increased contractility (e.g., dobutamine infusion) are characterized by an augmented stroke volume at any level of preload (*top line*). Conversely, decreased LV contractility (commonly associated with heart failure) is characterized by a curve that is shifted downward (*bottom line*). Point *a* is an example of a normal individual at rest. Point *b* represents the same individual after developing systolic dysfunction and heart failure (e.g., after a large myocardial infarction): stroke volume has fallen, and the decreased LV emptying results in elevation of the EDV. Because point *b* is on the ascending portion of the curve, the increased EDV serves a compensatory role because it results in an increase in subsequent stroke volume, albeit much less so than if operating on the normal curve. Further augmentation of LV filling (e.g., increased circulating volume) in the heart failure patient is represented by point *c*, which resides on the relatively flat part of the curve: stroke volume is only slightly augmented, but the markedly increased EDP results in pulmonary congestion.

Heart failure can be further classified into three categories related to physiology and functional anatomy: high versus low cardiac output, right versus left heart failure, and systolic versus diastolic dysfunction.[1,2,7,8,9,10,11 and 12]

Heart failure can produce either low or high cardiac output states.[1] Whereas *low-output failure* is due to an inherent problem in myocardial contraction, *high-output failure* is due to an inability of functionally intact myocardium to keep up with excess functional demands. The causes of high-output failure are relatively few and include anemia, thyrotoxicosis, large arteriovenous shunts, beriberi, and Paget disease of the bone.

In congestive heart failure, excess fluid accumulates behind the affected chamber of the heart. In patients with left ventricular dysfunction due to either mechanical overload or infarction, excess fluid develops in the lungs. This resulting *pulmonary edema,* or congestion, is the cardinal manifestation of *left-sided heart failure.* In patients where the right ventricle is compromised (pulmonary embolus, right ventricular infarction), jugular venous distention and other signs of *right-sided heart failure*

occur. Long-standing heart failure, however, usually results in compromise of both ventricles. [11]

Systolic heart failure is characterized by an impairment of myocardial contraction, and diastolic failure by an impairment in myocardial relaxation. *Systolic failure* can occur from excessive afterload (systemic hypertension) or from damaged myocytes (infarction).[11] *Diastolic failure* can be seen in both acute and chronic heart failure. Inhibited early diastolic relaxation as seen in myocardial ischemia is due to altered energy availability. [10] Chronic processes such as hypertrophic cardiomyopathy increase ventricular stiffness and inhibit relaxation. Many etiologies, such as transient myocardial ischemia, can result in either systolic or diastolic failure.

Once heart failure has developed, several neurohormonal compensatory mechanisms occur. [12] Alterations in adrenergic tone redistribute blood flow to the brain and myocardium, reducing blood flow to the skin, kidneys, gastrointestinal tract, and skeletal muscle. The reduction in blood flow to the kidneys results in increased stimulation of the renin-angiotensin-aldosterone axis and secretion of antidiuretic hormone. The end result of these processes is enhanced sodium and water retention by the kidneys, which leads to fluid overload and the clinical manifestations of CHF. Additionally, the increased adrenergic tone leads to arteriolar vasoconstriction, a significant raise in afterload, and finally, to increased cardiac work.

Clinical Features of Heart Failure

The clinical features of heart failure may be due to impaired perfusion or elevated venous pressures and relate to which ventricle is primarily affected (Table 49-2). Patients may present with either the chronic progressive symptoms of heart failure or with acute pulmonary edema due to sudden left-sided decompensation. [1,2,7,8]

Symptoms	Physical Findings
Left sided	
Fatigue	Tachycardia, tachypnea
Dyspnea	S_3 gallop
Paroxysmal nocturnal dyspnea	Diaphoresis
Orthopnea	Pulmonary rales, wheezes
Right sided	
Dependent edema	Jugular venous distention
Right upper quadrant pain	Peripheral edema
	Hepatomegaly
	Hepatojugular reflux

Source: Adapted from Coday et al,[1] with permission.

TABLE 49-2   Common Symptoms and Physical Findings in Heart Failure

The manifestations of heart failure depend on which ventricle is primarily affected (Table 49-2). Left ventricular failure can result from either diastolic or systolic dysfunction and can lead to increased pulmonary venous pressures, interstitial lung fluid, and pulmonary edema. Right ventricular failure leads to jugular venous distention, peripheral edema, hepatic congestion, and ascites.

The most common symptom of left-sided heart failure is breathlessness, or *dyspnea,* particularly with exertion.[1,7] When pulmonary venous pressure reaches a critical level (20 mmHg), there is movement of fluid into the pulmonary interstitium, compressing airways and alveoli. [1] The increased resistance to airflow intensifies the work of breathing. In addition, stimulation of the juxtacapillary receptors (J receptors) causes rapid shallow breathing. Other manifestations of pulmonary congestion include orthopnea and paroxysmal nocturnal dyspnea (PND). [1,8,9,10 and 11] Orthopnea is the sensation of breathlessness while lying flat and is relieved by sitting upright. Orthopnea results from the redistribution of intravascular blood from the gravity-dependent portions of the body to the lungs. The degree of orthopnea is usually assessed by the number of pillows a patient uses at night to avoid breathlessness. PND is severe breathlessness that awakens a patient from sleep 2 to 3 h after lying down. PND is due to the gradual reabsorption of interstitial lower extremity edema after lying down, with subsequent greater venous return to the heart and lungs.[1]

Clinical manifestations of left-sided heart failure due to alterations in blood flow include fatigue, altered mental status, and reduced urine output (especially during the day). At night, urine output may increase due to increases in venous return. The increased urinary frequency at night is termed nocturia. [1]

Right-sided heart failure causes increased systemic venous pressures and peripheral edema. [1,8] Additional edema of the gastrointestinal tract causes anorexia and nausea, and right upper quadrant abdominal pain occurs as the liver becomes engorged.

Physical findings of left-sided heart failure include dusky or pale skin, diaphoresis, and cool extremities due to poor perfusion and peripheral arterial vasoconstriction.[1,8] Pulmonary congestion commonly results in tachypnea and bilateral inspiratory crackles on auscultation. Additional auscultatory findings include rhonchi and wheezing ("cardiac asthma") due to airway edema. Pleural effusions may develop, detected by dullness to percussion at the lung bases. In advanced heart failure, Cheyne-Stokes respiration can occur and is a respiratory pattern characterized by periods of hyperventilation separated by periods of apnea. [1]

Frequently, sinus tachycardia secondary to sympathetic nervous system activity is present in heart failure patients. [1,8] Cardiac auscultation may reveal a third heart sound (S_3), an early diastolic sound resulting from abnormal filling into the dilated ventricle. Also present may be a fourth heart sound (S $_4$), which results from forceful atrial contraction into a stiffened ventricle. Finally, *pulsus alternans* (alternating strong and weak contractions detected in the peripheral pulse) may occur in advanced heart failure.[1]

Right-sided heart failure may result in additional physical findings due to elevated systemic venous pressures. Jugular venous distention (JVD) is common. [1,8] Engorgement of the liver results in hepatomegaly, right upper quadrant tenderness, and the presence of the hepatojugular reflux (JVD with liver palpation). Peripheral edema accumulates in the dependent areas of the body, including the ankles and legs of ambulatory patients and the presacral region of bedridden patients. [1,8]

Radiographic manifestations of left-sided CHF generally relate to the increases in pulmonary venous pressures. [1] When the pulmonary pressures exceed 15 mmHg, hydrostatic pressure increases in the gravity-dependent edematous lower zones of the lung. Because of the higher resistance to flow in the lower regions, blood flow is selectively shunted to the upper regions, and the chest radiograph shows upper-zone vascular redistribution. As pulmonary pressures exceed 20 mmHg, interstitial edema occurs with loss of distinct vascular margins on chest x-ray. Interlobular edema results in Kerley B lines, which are short linear markings at the periphery of the lower lung fields on the chest x-ray.[1] When pulmonary pressures reach 25 mmHg, alveolar pulmonary edema develops with opacification of the airspaces on x-ray. However, in patients with long-standing CHF, enhanced lymphatic drainage may minimize these radiographic findings. [1]

Depending on the cause of the CHF, additional radiographic findings include cardiomegaly and pleural effusions. [1] Cardiomegaly is defined as a cardiothoracic ratio greater than 0.5 on a posteroanterior film.[1] Pleural effusions may occur in either left-sided or right-sided failure but are usually the result of bilateral heart failure. High right atrial pressure may cause azygos vein enlargement on chest x-ray.

The electrocardiogram (ECG) may reveal evidence of acute myocardial infarction or ischemia as a cause of acute decompensation of CHF. In chronic CHF, the ECG usually reveals evidence of ventricular hypertrophy, atrial enlargement, or conduction abnormalities. [1]

In patients with dyspnea or evidence of pulmonary edema, arterial blood gases will help define the acid-base status and are necessary to quantitate the level of respiratory effort. Hypoxia is a frequent finding with pulmonary edema and, when associated with hypercarbia and acidosis, can portend impending respiratory failure.[1,8]

Treatment of Chronic Congestive Heart Failure

The treatment of heart failure involves either correction of the underlying cause of the heart failure or elimination of the symptoms. [1,7] Treatment of the underlying condition may be curative in patients with readily correctable conditions such as valvular disorders, acute infections, or dysrhythmias. For the remaining patients with CHF, treatment is geared toward reduction of cardiac work, control of fluid retention, and enhancement of myocardial contractility.

The reduction of cardiac work is accomplished by restriction of both physical and emotional activity coupled with pharmacologic afterload reduction. Vasodilators help to reduce the increase in afterload that occurs with the neurohormonal compensatory response to CHF. Even a modest reduction in afterload may elevate the stroke volume of the heart and reduce ventricular end-diastolic pressures.

Vasodilators can be classified by their effects—primarily on the venous bed, arterial bed, or both beds—or by their route of administration. [4,7,13,14] Venodilators tend to shunt blood away from the chest to the peripheral circulation, reducing preload. Venodilators include nitroglycerin and isosorbide dinitrate. Arteriolar dilators reduce afterload and enhance stroke volume. Arteriolar dilators include hydralazine, minoxidil, and calcium-channel blockers. Agents with mixed venous and arterial effects include prazosin and the angiotensin-converting enzyme (ACE) inhibitors. Intravenous agents with mixed venous and arterial dilatory effects include sodium nitroprusside and phentolamine.

The control of excess fluid retention in patients with CHF is accomplished mainly by dietary restriction of sodium intake and the use of diuretics. Diuretics reduce intravascular volume and preload by promoting the elimination of sodium and water via the kidney. However, overly vigorous reduction of preload with diuresis can result in a marked reduction of cardiac contractility. [4] Therefore, the use of diuretics in CHF is usually restricted to those patients with evidence of pulmonary or peripheral edema.[4]

Diuretics acting on the loop of Henle are the most potent and include furosemide, bumetanide, and ethacrynic acid. [7] Thiazide diuretics are useful in mild CHF when renal perfusion is preserved.[8] The most important adverse effects of these drugs are overdiuresis, with impairment of cardiac output, and electrolyte abnormalities, including hypokalemia and hypomagnesemia. Potassium-sparing diuretics, such as spironolactone and triamterene, can potentiate the action of thiazides and loop diuretics. Such combinations are useful in severe CHF, although they should not be used in patients with impaired renal fucntion or hyperkalemia. [4,8]

Enhancement of myocardial contraction with inotropic agents can be useful in patients with systolic dysfunction. [1,4,7,8,10] Inotropic drugs increase cardiac output by shifting the Frank-Starling curve upward. Thus, for any given preload, stroke volume and contraction are augmented. The inotropic therapy of chronic CHF is mainly through the use of digitalis glycosides. In addition to enhancing contractility, digitalis reduces afterload by blunting the cardiac sympathetic response. Digitalis prolongs the refractory period of the atrioventricular node and is effective in controlling the ventricular response to atrial fibrillation. Digitalis intoxication, however, can be a life-threatening disorder characterized by atrial and ventricular dysrhythmias and hyperkalemia, as well as central nervous system and gastrointestinal complaints.[1,8]

The long-term use of other inotropic agents, such as sympathomimetic amines, is limited by a lack of oral forms and the development of drug tolerance.

In patients with diastolic dysfunction, the use of inotropic drugs is contraindicated. [4,7] Diuretics may reduce pulmonary congestion and peripheral edema, and calcium-channel blockers may be useful in cases of hypertension and hypertrophic cardiomyopathy.

While the use of b-adrenergic blockers is usually contraindicated in patients with significant systolic dysfunction, b blockade may be useful in counteracting the effects of excessive sympathetic stimulation. Recent studies have demonstrated a functional benefit with the use of b-adrenergic blockers, although a benefit in survival has not yet been found.[7]

Prognosis

The prognosis of patients with heart failure secondary to acute myocardial infarction has been related to their hemodynamic status. The Killip-Scheidt classification [15] is based on the physical examination findings: class I (no evidence of pulmonary edema or shock), class II (rales in less than one-half of lung fields), class III (rales in greater than one-half of lung fields; and class IV (cardiogenic shock with arterial systolic pressure greater than 90 mmHg). These hemodynamic classifications were modified by Forrester and colleagues [16] to include pulmonary capillary wedge pressure (PCWP) measurements: class I, no pulmonary edema (normal vital signs; PCWP, <18 mmHg), class II, isolated pulmonary edema (normal vital signs; PCWP, >18 mmHg), class III, isolated cardiogenic shock (hypotension; PCWP, <18 mmHg), and class IV, both pulmonary edema and cardiogenic shock (hypotension; PCWP, >18 mmHg).

Unfortunately, heart failure is a progressive, fatal condition. In the absence of a correctable underlying cause, the prognosis of patients with CHF is poor, with a 5-year mortality rate of 50 percent.[1,4,5,11] Most of these deaths are due to development of refractory failure, although a large number of patients die suddenly, presumably of ventricular dysrhythmias. There is no evidence, however, that these fatal dysrhythmias can be prevented by the use of antiarrhythmic medications.

Recent studies have found that ACE inhibitors prolong survival in patients with heart failure and delay the onset of death in patients with impaired heart function. [1,8] Combined with b-adrenergic receptor blockers, these drugs may be helpful in prolonging the life of patients with heart disease at risk for developing heart failure.

PULMONARY EDEMA

Cardiogenic pulmonary edema is an acute, life-threatening form of left-sided heart failure. [1,4,7,8] Severe hypoxia can result in this condition due to the shunting of pulmonary blood flow to hypoventilated alveoli.

Treatment of Acute Pulmonary Edema

While attention must be given to potential precipitating causes, acute pulmonary edema is a life-threatening emergency that requires immediate improvement of systemic oxygenation. (See Table 49-3.)

- Oxygen
- Nitroglycerin, 0.4–0.6 mg sublingually q 5–10 min up to 4 times or 0.3–0.5 µg/kg/min IV infusion
- Furosemide 20–80 mg IV
- Morphine sulfate 1–5 mg IV, with caution in pulmonary insufficiency
- Cardiovascular supportive drugs: nitroprusside, dobutamine, dopamine
- Thrombolytic therapy or urgent revascularization if due to acute myocardial infarction
- CPAP, BiPAP, or intubation and mechanical ventilation if refractory
- Definitive repair of underlying anatomic cause if indicated and feasible

---

TABLE 49-3   Treatment of Cardiogenic Pulmonary Edema[7]

OXYGENATION AND VENTILATION   Oxygen (100%) should be given by mask and arterial blood gases obtained. The patient should be seated upright to pool systemic blood and reduce venous return. If hypoxia persists with supplemental oxygen, then positive pressure ventilation is required. Positive end-expiratory pressure (PEEP) applied via face mask as continuous positive airway pressure (CPAP) or bilevel continuous positive airway pressure (BiPAP) or via endotracheal tube can be used to prevent alveolar collapse. [8] Although impedance of venous return with PEEP via the endotracheal tube can be beneficial in reducing preload, care

must be taken in using the lowest possible pressure in order to avoid compromising cardiac output. Noninvasive pressure support decreases the work of breathing, enhances oxygen and carbon dioxide exchange, and increases cardiac output. If hypercarbia and acidosis are also present, then endotracheal tube ventilation is warranted.[4,7]

VASODILATORS   Nitrates are effective preload reducers. Nitroglycerin can be given by the sublingual, oral, topical, or intravenous routes. [4,7] For acute pulmonary edema, higher doses of sublingual nitroglycerin than those used in angina may be required (0.4 to 0.8 mg sublingually, 5 to 10 min × 4). [4] Intravenous administration of either nitroglycerin or sodium nitroprusside can rapidly reduce preload and afterload. Because nitroprusside has the potential to induce ischemia, intravenous nitroglycerin is preferred in the treatment of pulmonary edema in patients with coronary artery disease. [4] Infusion of nitroglycerin is safer with close hemodynamic monitoring. Dosing should begin at 0.3 to 0.5 (μg/kg)/min and titrated to relief of symptoms or until mean blood pressure falls 30 percent or systolic blood pressure below 90 mmHg.[1]

DIURETICS   Intravenous furosemide (20 to 80 mg IV) can rapidly induce a potent diuresis. [7] These doses may be repeated in 10 to 15 min, and higher doses may be required in patients with renal failure. [8] Although furosemide can have a venodilatory effect, use of intravenous furosemide alone may not significantly lower preload until 30 min after administration. [17] In contrast, the combination of intravenous furosemide and nitrates can rapidly reduce preload. [13,17] In a recent randomized trial, the combination of intravenous high-dose isosorbide dinitrate with low-dose furosemide was more efficacious in the treatment of pulmonary edema than was low-dose isosorbide dinitrate with high-dose furosemide. [13]

The effects of furosemide may be augmented by pretreatment with metolazone (2.5 to 5 mg PO) or chlorothiazide (250 to 500 mg PO). [8] An alternative diuretic for patients with acute pulmonary edema is bumetanide (0.5 to 1.0 mg IV initially; double the dosage every 2 h to a total daily dose of 10 mg). [8]

INOTROPIC AGENTS   In patients refractory to oxygen, nitrates, and diuretics, intravenously administered b-adrenergic agonists can be used to augment myocardial contractility.[4,7] *Dopamine* is particularly useful in the setting of pulmonary edema and hypotension. [4,7] At low doses (1 to 2 μg/kg/min), dopamine increases renal and mesenteric blood flow by stimulation of dopaminergic receptors. At moderate doses (2 to 10 μg/kg/min), dopamine increases myocardial contractility via b $_1$-adrenergic stimulation, and at high doses (more than 20 μg/kg/min), arterial pressure is elevated due to a-adrenergic stimulation. [4] *Dobutamine* at a dose of 2 to 20 μg/kg/min may produce a more favorable balance between myocardial oxygen supply and demand and is the choice for treatment of pulmonary edema in normotensive patients. [4] The administration of these drugs should be accompanied by close ECG and arterial pressure monitoring and may be optimized with pulmonary artery pressure recording. There is a minimal role for digitalis in the management of acute congestive heart failure. [4]

MORPHINE   Morphine in doses of 1 to 5 mg IV decreases afterload and produces a sedative effect, thereby reducing cardiac work. [4,7] It should be given with caution to those with respiratory insufficiency and sustained respiratory acidosis. [4,18] The use of nitrates has supplanted the use of morphine in many instances. [19] Morphine's vasodilatory effects are in part due to histamine release, and it can cause potenthypotension.

PHLEBOTOMY   Phlebotomy is a rapid, effective method of reducing circulating volume and may be particularly useful in the renal failure patient with acute pulmonary edema.[1] The practice of rotating tourniquets has not been found to be clinically beneficial. [20]

50 VALVULAR EMERGENCIES AND ENDOCARDITIS

David M. Cline

Ninety percent of valvular disease is chronic, with decades between the onset of the structural abnormality and symptoms. The emergency physician most commonly encounters patients with valvular disease after the diagnosis has been made but is occasionally the first to suspect valvular dysfunction based on the patient's symptoms and examination. Through chronic adaptation by dilation and hypertrophy, cardiac function can be preserved for years, which may delay the diagnosis for one to two decades until a murmur is detected on auscultation. In contrast to the more common chronic presentations, acute rupture of a cardiac valve presents with dramatic symptoms.

The four heart valves prevent retrograde flow of blood during the cardiac cycle, allowing efficient ejection of blood with each contraction of the ventricles. The mitral valve has two cusps, while the other three heart valves normally have three cusps. The right and left papillary muscles promote effective closure of the tricuspid and mitral valves, respectively. The papillary muscles are attached to the cusps of the atrioventricular valves by tendinous cords, the chordae tendineae. Abnormalities of the valvular cusps, the papillary muscles, the chordae tendineae, or the cardiac chambers themselves can cause valvular dysfunction.

The pathophysiology of and clinical findings for each of the classic valvular disorders are presented below. Following these descriptions, the treatment of the disorders is presented collectively. When important differences occur in the indicated management, these recommendations are contrasted and explained.

MITRAL STENOSIS

Pathophysiology

Despite its declining frequency, rheumatic heart disease is still the most common cause of mitral valve stenosis. Scarring from rheumatic endocarditis causes fusion of the commissures and matting of the chordae tendineae, which interfere with valve closure. Calcification over time makes the valve less mobile. Progressive stenosis may lead to pulmonary hypertension, which may signal the need for surgery. The majority of patients eventually develop atrial fibrillation because of progressive dilation of the atria. Pulmonary hypertension may lead to pulmonary and tricuspid valve incompetence.

Clinical Features

Even though mitral stenosis is a chronic condition, increased demands on cardiac output may precipitate acute symptoms. Conditions that prompt symptoms in mitral stenosis include exertion, tachycardia, anemia, pregnancy, infection, emotional upset, and atrial fibrillation. As with all valvular diseases, exertional dyspnea is the most common presenting symptom (80 percent of patients with mitral stenosis). Paroxysmal nocturnal dyspnea may occur with more severe disease. Hemoptysis is the second most common presenting symptom and may be massive if a bronchial vein ruptures. Other common symptoms and signs include orthopnea, premature atrial contractions, and atrial fibrillation, which is almost inevitable with the passage of time. Systemic emboli may occur and result in myocardial, kidney, central nervous system, or peripheral infarction. Embolic stroke is more frequent in the presence of atrial fibrillation. As the disease progresses, symptoms of right heart failure may develop.

Signs of mitral stenosis include middiastolic rumbling murmur, with crescendo toward the S_2. With the onset of atrial fibrillation the presystolic accentuation of the murmur disappears. Typically the S_1 is loud and is followed by a loud opening "snap" that is high-pitched and heard best at the right of the apex. A prominent *a* wave in the neck may be seen, as may an early systolic parasternal lift, which is due to right heart pressure overload. The apical impulse is small and tapping, representing an underfilled left ventricle. Systemic blood pressure is typically normal or low. Rales may be heard at the lung bases as the disease progresses. If pulmonary hypertension is present, signs may include a thin body habitus, peripheral cyanosis, and cool extremities because of low cardiac output. With pulmonary hypertension the auscultatory findings are less evident.

The electrocardiogram (ECG) may demonstrate notched or diphasic P waves and right axis deviation. On the chest radiograph, straightening of the left heart border, indicating left atrial enlargement, is a typical early radiographic finding. Eventually, findings of pulmonary congestion are noted: redistribution of flow to the upper lung

fields, Kerley B lines, and an increase in vascular markings. The chest radiograph is useful in assessing the degree of pulmonary congestion.

MITRAL INCOMPETENCE

Pathophysiology

Infective endocarditis or myocardial infarction can cause acute rupture of the chordae tendineae or papillary muscles or cause perforation of the valve leaflets. Inferior myocardial infarction due to right coronary occlusion is the most common cause of ischemic mitral valve incompetence. Rarely, trauma may cause acute mitral incompetence. Patients with acute mitral valve rupture deteriorate rapidly. Intermittent mitral incompetence can be due to ischemia, which causes papillary muscle dysfunction. Rheumatic heart disease is the most common cause of chronic mitral incompetence. Recently, an association has been found between the use of appetite suppressant drugs (fenfluramine and phentermine, or dexfenfluramine) and cardiac valve incompetence, [1] although this has been questioned. [2]

Acute regurgitation into a noncompliant left atrium quickly elevates pressures and causes pulmonary edema. In contrast, in the chronic state the left atrium dilates so that left atrial pressure rises little, even with a large regurgitant flow. As an adaptation, the total stroke volume of the left ventricle increases so that effective forward flow into the aorta is maintained despite the large regurgitant volume across the mitral valve.

Clinical Features

Acute mitral incompetence presents with dyspnea, tachycardia, and pulmonary edema. Usually an S_3 and S_4 will be heard. Acutely, the harsh apical systolic murmur starts with S_1 and may end before S_2. Patients may quickly deteriorate to cardiogenic shock or cardiac arrest. Intermittent mitral incompetence usually presents with acute episodes of respiratory distress due to pulmonary edema and can be asymptomatic between attacks. The pronounced dyspnea may mask angina that accompanies the ischemia. Patients may have an active apical impulse, systolic thrust, and thrill at the apex. Jugular venous distention may be seen, with a prominent *a* wave and a left parasternal lift. The ECG may show evidence of acute inferior wall infarction (more common than anterior wall infarction in this setting). On the chest radiograph, acute mitral incompetence from papillary muscle rupture may result in a minimally enlarged left atrium and pulmonary edema, with less cardiac enlargement than expected.

Chronic mitral incompetence may be tolerated for years or even decades. The first symptom is usually exertional dyspnea, sometimes prompted by atrial fibrillation. If patients are not anticoagulated, systemic emboli occur in 20 percent and are often asymptomatic. Endocarditis is still a feared complication. Signs of chronic mitral incompetence include a late systolic left parasternal lift. There is a high-pitched holosystolic murmur that is best heard in the fifth intercostal space, mid left thorax, which radiates to the axilla. The first heart sound is soft and often obscured by the murmur. An S_3 is usually heard and is followed by a short diastolic rumble, indicating increased flow into the left ventricle. The ECG may demonstrate findings of left atrial and left ventricular hypertrophy (LVH). On the chest radiograph, chronic mitral incompetence produces left ventricular and atrial enlargement that is proportional to the severity of the regurgitant volume.

MITRAL VALVE PROLAPSE

Pathophysiology

The etiology of mitral valve prolapse (MVP), or the click-murmur syndrome, is not known but may be congenital. MVP is the most common valvular heart disease in industrialized countries, affecting about 3 percent of the population. [3] One or both of the mitral valve leaflets prolapse into the atrium during systole, and this may or may not be accompanied by regurgitant flow. Male sex, age over 45, and the presence of regurgitation, recognized clinically by a short diastolic murmur, places the patient in a higher risk group for complications. [4] Click-murmur syndrome has unique symptoms that differentiate it from other forms of mitral regurgitation.

Clinical Features

Most patients are asymptomatic. Symptoms include atypical chest pain, palpitations, fatigue, and dyspnea unrelated to exertion. Symptoms are more common in those who know they have the syndrome. However, there is an increased incidence of sudden death and dysrhythmias in patients with MVP. There is also an increased incidence of transient ischemic attacks under the age of 45. In patients with MVP without mitral regurgitation at rest, exercise provokes mitral regurgitation in 32 percent of patients and predicts a higher risk for morbid events. [5] The classic cardiac finding is a midsystolic click. The second heart sound may be diminished by the late systolic murmur, with crescendos into S_2 (not present in all patients). Some patients may have pectus excavatum, a straight thoracic spine, or scoliosis. The ECG is usually normal, as is the chest radiograph unless the thoracic cage abnormalities described above are seen.

AORTIC STENOSIS

Pathophysiology

Congenital heart disease is the most common cause of aortic stenosis, with the presence of a bicuspid valve accounting for 50 percent of cases. Rheumatic heart disease is the second most common cause, followed by degenerative heart disease or calcific aortic stenosis, which is the most common cause in patients over age 70. Blood flow into the aorta is obstructed, producing progressive LVH and low cardiac output. This produces a marked reduction in coronary blood flow.

Clinical Features

The classic triad is dyspnea, chest pain, and syncope. Exercise may induce acute symptoms. Symptoms appear late in the course of the disease. In active persons, the symptoms appear more rapidly. Dyspnea is usually the first symptom, followed by paroxysmal nocturnal dyspnea, syncope on exertion, angina, and myocardial infarction. Atrial fibrillation is less common than in mitral disease, but 10 percent of patients have atrial fibrillation at time of surgery. With isolated aortic stenosis, endocarditis occurs in only 2 percent of patients.

The most common signs include a pulse of small amplitude. The carotid pulse can be most accurately assessed and is found to have a slow rate of increase. Blood pressure is normal or low, with a narrow pulse pressure. LVH is common. There is paradoxic splitting of S_2, and S_3 and S_4 are commonly present. Classically, there is a harsh systolic ejection murmur that is best heard in the second right intercostal space and that radiates to the right carotid artery. Brachioradial delay is an important finding in aortic stenosis. The examiner palpates simultaneously the right brochial artery of the patient with the thumb and the right radial artery of the patient with the middle or index finger. Any palpable delay between the brachial artery and radial artery is considered abnormal. [6] Sudden death, usually from an dysrhythmia, occurs in 25 percent of patients. The ECG usually demonstrates criteria for LVH and, in 10 percent of patients, left or right bundle branch block. The chest radiograph is normal early, but eventually LVH and findings of congestive heart failure are evident if the patient does not have valve replacement.

AORTIC INCOMPETENCE

Pathophysiology

In 20 percent of patients, the cause of aortic incompetence is acute in nature. Infective endocarditis accounts for the majority of acute cases; aortic dissection at the aortic root causes the remainder. In acute cases, a sudden increase in backflow of blood into the ventricle raises left ventricular end-diastolic pressure, which may cause acute heart failure. Increased ventricular pressure elevates pressure in the left atrium, and pulmonary congestion results. Rheumatic heart disease and congenital disease cause the majority of chronic cases. Syphilis, ankylosing spondylitis, and Reiter syndrome are less frequent causes. An association between the appetite-suppressant drugs (fenfluramine and phentermine or dexfenfluramine) has also been found for aortic incompetence. [2] Chronic disease is more common in males than in females, with a ratio of 3:2. In chronic disease, the ventricle progressively dilates to accommodate the regurgitant blood volume. Wide pulse pressures result from the fall in diastolic pressure, and marked peripheral vasodilation is seen. During exercise and tachycardia, the diastolic filling period shortens, thus decreasing the number of times per minute that regurgitation can occur. Cardiac function is therefore close to normal with exercise early in the course of the disease. In contrast, isometric exercise or stress may precipitate symptoms.

Clinical Features

In acute disease, dyspnea is the most common presenting symptom, seen in 50 percent of patients. Many patients have acute pulmonary edema with pink frothy sputum. Patients may complain of fever and chills if endocarditis is the cause. Patients may present with systemic emboli or a persistent sinus tachycardia. Dissection of the ascending aorta typically produces a "tearing" chest pain that may radiate between the shoulder blades. Sudden death is common in patients with both acute and chronic aortic incompetence.

The two major causes of acute aortic incompetence present with different signs. Elevated temperature is common with acute endocarditis. ECG changes may be seen with aortic dissection, including ischemia or findings of acute inferior myocardial infarction, suggesting involvement of the right coronary artery. Patients commonly have signs of peripheral circulatory collapse, such as sweating, marked tachycardia, tachypnea, and rales. Classically there is a high-pitched blowing diastolic murmur heard immediately after S_2, best heard in the right second or third intercostal parasternal area. There may be an S_3 with long diastolic murmurs, and there may be a systolic flow murmur. In the acute state, the chest radiograph demonstrates acute pulmonary edema with less cardiac enlargement than expected.

In the chronic state, about one-third of patients have palpitations associated with a large stroke volume and/or premature ventricular contractions. Frequently these sensations are noticed in bed. Patients may complain of stabbing chest pain, fatigue, or dyspnea. Two-thirds of patients have no symptoms for up to 20 years despite a hemodynamically significant lesion, defined as a diastolic blood pressure under 70 mmHg. Symptoms of left ventricular failure may occur late in the course of the disease and include dyspnea, pulmonary edema, ischemic chest pain, and sweating.

In the chronic state, signs include a wide pulse pressure with a prominent ventricular impulse, which may be manifested as head bobbing. "Water hammer pulse" may be noted; this is a peripheral pulse that has a quick rise in upstroke followed by a peripheral collapse. Other classic findings may include accentuated precordial apical thrust, pulsus biferiens, Duroziez sign (a to-and-fro femoral murmur), and Quincke pulse (capillary pulsations visible at the proximal nailbed, while pressure is applied at the tip). In chronic aortic incompetence, the ECG demonstrates LVH, and the chest radiograph shows LVH, aortic dilation, and possibly evidence of congestive heart failure.

HYPERTROPHIC CARDIOMYOPATHY (IDIOPATHIC HYPERTROPHIC SUBAORTIC STENOSIS)

Hypertrophic cardiomyopathy (HCM) is known by other terms, including idiopathic hypertrophic subaortic stenosis and asymmetrical septal hypertrophy. This disorder is best described as *hypertrophic cardiomyopathy* and is defined by a hypertrophied, nondilated left ventricle. In 95 percent of cases, the septum is asymmetrically enlarged, but the free wall of the ventricle is also hypertrophied. The atrium is typically enlarged, and the mitral valve is thickened. Only one-fourth of patients with this disorder have a ventricular outflow obstruction sufficient to cause symptoms; therefore, *idiopathic hypertrophic subaortic stenosis* incompletely describes this disorder. This disease is discussed in Chapter 51, "Cardiomyopathies, Myocarditis, and Pericardial Disease," and is mentioned here only to aid in its differentiation from valvular aortic stenosis.

Clinical Features

Patients with HCM may become symptomatic at any age, but most present between age 30 and 40 years, approximately 10 years earlier than the average of onset of symptomatic valvular aortic stenosis. Symptoms are similar to those of aortic stenosis, except that the patient with HCM may report that symptoms are relieved with squatting.

Signs may be absent in this disease. The classic auscultatory finding is a crescendo-decrescendo harsh systolic murmur heard best at the fifth left intercostal space, mid left thorax, which radiates to the lower left sternal border. The Valsalva maneuver intensifies the murmur by decreasing venous return, which contracts the left ventricle and increases the obstruction. Squatting and passive leg elevation diminish the murmur. Listening at the apex, one can hear an increased murmur as the patient goes from a squatting to a standing postion, due to decreased venous return from pooling. There is no opening snap, as is commonly heard in valvular aortic stenosis. The apical impulse may be double secondary to an abrupt interruption of early systolic ejection by the asymmetrical septum, which blocks outflow, as the ventricle contracts. The pulse has a brisk rise and a double peak, unlike valvular aortic stenosis, in which the pulse has a slow rise and a sustained single peak.

HCM is one cause of sudden death among athletes, and all patients are at significant risk. The mechanism of sudden death is not well understood and is probably due to several mechanisms, including dysrhythmias and massive myocardial infarction. Patients with HCM are at risk for endocarditis, usually involving the thickened mitral valve. Antibiotic prophylaxis is recommended for certain procedures performed in the emergency department (Table 50-1).

TABLE 50-1   Prophylaxis for Infective Endocarditis

RIGHT-SIDED VALVULAR HEART DISEASE

Pathophysiology

Right-sided valvular heart disease is much less common than left-sided valvular disease. Drug users with endocarditis due to aggressive organisms, such as *Staphylococcus aureus,* are the largest group of patients with isolated tricuspid disease. Right ventricular failure with dilation may lead to tricuspid incompetence. Rheumatic heart disease may affect more than one valve, and tricuspid disease is frequently seen in conjunction with left-sided valvular disease. Rarely, blunt trauma can lead to tricuspid incompetence.

Pulmonary incompetence is most commonly due to pulmonary hypertension, and symptoms of pulmonary hypertension dominate the clinical picture. The most common cause of pulmonary stenosis is congenital tetralogy of Fallot, which is usually corrected surgically in infancy.

Clinical Features

The most common presenting symptoms of right-sided valvular disease are dyspnea and orthopnea. Because of the organisms involved, patients presenting with tricuspid incompetence in association with endocarditis are acutely ill with sepsis. As the disease progresses, signs of right-sided heart failure are evident: jugular venous distention with a prominent *a* wave, peripheral edema, hepatomegaly, splenomegaly, and ascites.

In tricuspid incompetence, the murmur is soft blowing, holosystolic, and best heard along the lower left sternal border. In tricuspid stenosis, the rumbling crescendo-decrescendo diastolic murmur occurs just prior to S_1. This murmur is best heard along the lower left sternal border.

MULTIVALVULAR DISEASE

Multivalvular disease is common, but the presence of more than one abnormal valve makes the diagnosis of others more difficult. In addition, there may be coexisting stenosis and incompetence of diseased valves. Multivalvular and combined stenotic-incompetent valvular disease present with slightly different symptoms from the classic symptoms of single-valve disease.

Pathophysiology

Rheumatic heart disease remains an important cause of combined aortic and mitral disease. Between 32 and 50 percent of patients with cardiac manifestations of rheumatic fever have both aortic and mitral disease. In aged patients, calcification can lead to both aortic stenosis and mitral incompetence. Infective endocarditis can extend from either the mitral or aortic valve to the adjacent valve though the inflammatory process. Intravenous drug users may have multivalvular disease. Tricuspid regurgitation often occurs with right ventricular dilation secondary to pulmonary hypertension that may be due to mitral disease or combined aortic and mitral disease.

Clinical Features

Patients with combined valvular disease generally present at a younger age than those with a single chronic lesion. The most common symptom of combined valvular disease is dyspnea. Symptoms of multivalvular disease may resemble those of single-valve disease when advanced disease of one valve dominates the clinical picture. Although both syncope and angina pectoris are infrequent in patients with mitral regurgitation alone, chest pain and syncope are more common with incompetence of both the aortic and mitral valves. The presence of a chronic lesion of one valve exaggerates the effects of an acute lesion of another valve.

Physical signs are more difficult to interpret in mixed lesions. With combined aortic and mitral stenosis, the aortic systolic murmur is reduced. The mitral opening snap is infrequently audible in this setting. In regurgitant lesions of both aortic and mitral valves, the usual fall in diastolic blood pressure commonly seen with aortic incompetence may be absent. As many as 40 percent of patients with this combined valvular disease have diastolic blood pressures above 70 mmHg.

DIAGNOSIS OF VALVULAR HEART DISEASE

The loud background noise in the emergency department makes the accurate auscultation of subtle murmurs difficult. Despite this, the emergency physician may suspect undiagnosed valvular dysfunction on incidental cardiac auscultation. The ECG and chest radiograph may be of help, but neither is confirmatory. The suspected diagnosis should be confirmed by echocardiography and/or consultation with a cardiologist. Transesophageal echocardiography yields a more complete analysis of valvular dysfunction, especially for the mitral valve. However, transthoracic echocardiography is generally performed first. [7] The urgency for an accurate diagnosis and appropriate referral depends on the severity of symptoms and the suspected diagnosis. For example, a patient presenting with syncope and auscultatory findings of aortic stenosis should be admitted to the hospital for observation and further evaluation.

DIAGNOSING A NEWLY DISCOVERED MURMUR   The first step in diagnosing a newly discovered murmur is to consider it in the context of the patient's medical condition. Patients with normal cardiac anatomy may have murmurs associated with anemia, thyrotoxicosis, sepsis, fever, renal failure with volume overload, pregnancy, and other clinical conditions. A diastolic murmur or a new murmur associated with symptoms at rest should always be considered abnormal and warrants referral for a workup and possible echocardiographic study and admission. Figure 50-1 presents an algorithm for the clinical assessment of a newly discovered systolic murmur. The algorithm, based on the work of Etchells and colleagues, [8] presents a step-by-step method of assessment to uncover an abnormal murmur. Each murmur category lists characteristics or maneuvers that have been shown to predict the presence of the named abnormal murmurs. The studies referred to by Etchells and colleagues have used cardiologists as examiners, and these issues have not been tested in the emergency department setting. However, the algorithm can be expected to prompt the clinician to perform the appropriate examinations and maneuvers to help uncover an abnormal murmur. Whenever the clinician is uncertain of the diagnosis of a newly discovered murmur, referral should be made to a cardiologist or back to the primary care physician for an appropriate workup.

FIG. 50-1. Algorithm for workup of newly discovered systolic murmur.

A truly innocent (physiologic) murmur is associated with no abnormal symptoms or signs. The soft systolic ejection murmur begins after S_1 and ends before S_2, and the heart sounds are completely normal. The review of systems should elicit no symptoms compatible with cardiovascular disease, and findings upon complete physical examination are normal with the exception of the flow murmur.

Acute mitral and aortic incompetence are important and urgent diagnoses. Due to the severity of symptoms, it is unlikely that such a patient would go unnoticed in the emergency department, but the patient may be admitted with the murmur unrecognized. Acute mitral or aortic incompetence should always be suspected in patients with acute pulmonary edema, especially when the heart is smaller than expected on the chest radiograph or when the patient does not respond to conventional therapy. When aortic dissection is suspected as the cause of acute aortic incompetence and the patient is sufficiently stable, transesophageal echocardiography or computed tomographic (CT) scanning of the chest is useful. Angiography may still be required after CT scanning.

In infants, a newly diagnosed murmur demands the consideration of congenital heart disease, such as ventricular septal defect, atrial septal defect, and pulmonic stenosis in association with tetralogy of Fallot. See Chapter 115, "Heart Disease," for a more detailed discussion of congenital heart disease in children.

EMERGENCY DEPARTMENT CARE OF SYMPTOMATIC VALVULAR HEART DISEASE

There is little that the emergency physician can do to change the structural abnormality of the diseased cardiac valve. The exception to this rule is acute mitral incompetence due to myocardial infarction. The infusion of thrombolytic therapy may reestablish blood flow to the papillary muscle, with restoration of function. [9] The alternative to thrombolytic therapy is coronary angioplasty. [10] The majority of treatments are directed toward symptomatic relief of the manifestations of valvular disease. However, there are certain medical treatments that can reduce the consequences of the mechanical defect. The regurgitation of aortic and mitral valves may be lessened by reducing afterload. When the cause of mitral incompetence is myocardial ischemia, regurgitation can be lessened by treatment with nitrates.

Pulmonary edema should be treated with oxygen, intubation for failing respiratory effort, diuretics, and nitrates if tolerated. Patients with aortic stenosis usually have normal-to-low blood pressure and do not tolerate afterload reducers. In contrast, patients with mitral incompetence or aortic incompetence can benefit from intravenous nitroprusside or nitroglycerin even with normal blood pressures. [11] Reducing afterload helps to reduce regurgitation and relieve pulmonary edema. Tachycardia reduces the regurgitant volume by reducing the time during the cardiac cycle during which backflow may occur. Therefore, artificially lowering the pulse with a b-blocking agent may worsen symptoms.

The hypertension associated with aortic dissection should be controlled with intravenous nitroprusside and b blockade. Labetalol has been used with success in this

setting. Patients with valvular heart disease and acute pulmonary edema should be considered for Swan-Ganz catheter insertion. The presence of valvular disease, especially stenosis, may complicate the procedure of catheter insertion. In patients who do not respond to medical management, intraaortic balloon counterpulsation should be considered. However, this is contraindicated in wide-open aortic regurgitation.

Rapid atrial fibrillation, which may precipitate symptoms in patients with silent valvular disease, should be rate-controlled with intravenous diltiazem or digoxin. Intravenous propranolol or verapamil may be considered, but their negative inotropic action may cause more problems. Emergency cardioversion may be needed in severely compromised patients, but dysrhythmia recurrence is common. The most common cause of the dysrhythmia in valvular heart disease, a dilated atrium, remains unchanged by cardioversion. The danger of embolization is greater in patients with atrial fibrillation.

Hemoptysis associated with valvular heart disease most frequently accompanies pulmonary edema and is frothy pink. This form of hemoptysis does not in and of itself require treatment. However, if pulmonary hypertension is present, gross hemoptysis may occur from the rupture of distended bronchial veins. Mitral stenosis is the most frequent valvular heart disease associated with hemoptysis, which can be severe enough to require blood transfusion and emergency surgery.

In the event of embolization, anticoagulation should be undertaken with intravenous heparin as long as there is no evidence of central nervous system bleeding. Anticoagulation is especially needed in the setting of atrial fibrillation.

Emergency surgery should be considered in all cases of acute symptomatic valvular disease. [12] Because stenotic lesions are slowly progressive, emergency surgery is rarely needed for stenotic defects. However, a patient with new onset of syncope in association with aortic stenosis should be considered for urgent repair. The need for emergency surgery most commonly accompanies acute regurgitant lesions of the mitral or aortic valves. Patients are acutely ill and present considerable surgical risks. The urgency of these two acute regurgitant lesions leaves little time for intubation, intravenous afterload reducers, echocardiography, and assembling the surgical team for emergency valve replacement.

Patients with acute fevers should be suspected of having infective endocarditis. The evaluation and management of endocarditis are discussed below, under "Infective Endocarditis." Antibiotic prophylaxis for infective endocarditis is recommended during procedures that may produce bacteremia in patients at risk for developing endocarditis, and the American Heart Association guidelines, which were revised in 1997, should be followed. [13] Patients considered at risk include those with a prosthetic heart valve, a history of endocarditis, rheumatic heart disease, acquired and congenital valvular disease, idiopathic hypertrophic subaortic stenosis, mitral valve prolapse with a murmur, or surgically constructed pulmonary shunts or conduits. The common procedures performed by emergency physicians that require prophylaxis are listed in Table 50-1. Endotracheal intubation does not require antibiotic prophylaxis. When a febrile patient is being evaluated for urinary tract infection, emergency physicians should consider the need for prophylaxis before using a catheter to obtain a urine specimen. However, recent data from an epidemiologic study suggest that medical and dental procedures cause only 5 percent of endocarditis cases and prophylaxis does not prevent all cases. [13]

Admission Considerations

The presence of persistent symptoms in patients with valvular heart disease determines the indications for admission to the hospital. Patients with acute onset of valvular incompetence are acutely ill and require admission. This should be clinically obvious. Patients with aortic stenosis presenting with syncope on exertion should be considered for admission because of the critical limitation of blood flow that syncope usually heralds. Patients with valvular heart disease and a new symptomatic dysrhythmia should also be considered for admission. Considerations for admission of patients with suspected infective endocarditis are discussed later in this chapter. Patients with intermittent symptoms from valvular heart disease can be management dilemmas. Consultation with a cardiologist may be required to determine the need for hospital admission.

Discharge Instructions

Stable patients suspected of having valvular heart disease not previously diagnosed should be referred to a cardiologist or back to their private physician for an evaluation and possible echocardiographic study. Patients should be instructed to avoid strenuous exercise and work, and psychologically stress-provoking activity until they have been cleared for such activity by the referral physician.

PROSTHETIC VALVE DISEASE

Prosthetic valves are implanted in 40,000 patients per year in the United States. There are approximately 80 types of artificial valves, each with advantages and disadvantages. Patients who receive prosthetic valves are instructed to carry a descriptive card in their wallet. The prosthetic valves can be divided into two basic groups: mechanical, nontissue models and bioprostheses using porcine, bovine, or human valves. Complications of prosthetic valves are more common in patients who have advanced heart disease, including cardiac dilation, LVH congestive heart failure, or dysrhythmias, at the time of their original operation.

Pathophysiology

Prosthetic valves tend to be slightly stenotic, and a very small amount of regurgitation is common because of incomplete closure. Patients with mechanical valves require continuous anticoagulation. Some bioprostheses do not require anticoagulation. Several complications can lead to dysfunction of artificial valves. Thrombi can form on a prosthetic valve and become large enough to obstruct flow or prevent closure. The dysfunction due to thrombi can be acute or slowly progressive. Bioprostheses may gradually degenerate, undergoing gradual thinning, stiffening, and possibly tearing, which result in valvular incompetence. The sutures that secure the prosthetic valve may become disrupted, leading to paravalvular regurgitation as a fistula forms at the periphery of the valve. Mechanical models may suddenly fracture or fail. These failures usually bring sudden symptoms and often are fatal before corrective surgery can be accomplished.

Bleeding and systemic embolism originating from a thrombus on the prosthetic valve are the most important complications of mechanical heart valves, occurring at a rate of 1.4 percent and 1 percent per year, respectively, for patients on warfarin. Life-long anticoagulation is required to reduce the risk of thromboembolism and valve thrombosis. The optimal anticoagulation regimen is controversial, with disagreement concerning the intensity of warfarin therapy as well as the need for an antiplatelet agent. Embolism is more common after mitral valve replacement. Embolism occurs less frequently with bioprostheses, and bleeding complications depend on the therapy given.

Patients with artificial valves develop endocarditis at a rate of 0.5 percent per year. Infections occur more frequently during the first 2 months after operation. The most common organisms during this period are *Staphylococcus epidermidis* and *S. aureus.* Gram-negative organisms and fungi are also frequent causes of endocarditis during this early period. Late cases of endocarditis are similar to those affecting native valves. The most frequent organism is *Streptococcus viridans,* but *Serratia* and *Pseudomonas* also occur. Patients with prosthetic valves and endocarditis may develop a ring abscess around the valve, which requires valve replacement. Patients with mechanical prostheses have an increased rate of intravascular destruction of red blood cells. Usually the red blood cell loss is easily corrected by the bone marrow, but hemolytic anemia may be severe and indicate a paravalvular leak. Finally, patients with prosthetic valves may be particularly susceptible to hemodynamic compromise from a new dysrhythmia, such as atrial fibrillation.

Clinical Features

Many patients have persistent dyspnea and reduced effort tolerance after successful valve replacement. This is more common in the presence of preexisting heart dysfunction or atrial fibrillation. Many symptoms of valvular dysfunction described in the preceding sections on specific valvular disease may occur in the setting of prosthetic valves. However, in addition to those symptoms, patients with prosthetic valves experience symptoms specific to the presence of the artificial valve.

Large paravalvular leaks usually present with congestive heart failure or hemolytic anemia. Patients with new neurologic symptoms may have thromboembolism associated with the valve thrombi or endocarditis. Minor embolic episodes, such as transient neurologic symptoms, amaurosis fugax, or self-limited ischemic episodes in the extremities or organs in the absence of endocarditis, are common. Patients may present with major embolic events, including stroke, mesenteric infarction, or sudden death. Major bleeding due to anticoagulant therapy can also occur, with hemorrhagic stroke the most common lethal bleeding complication.

Patients with prosthetic valves usually have abnormal cardiac sounds. Mechanical valves have loud, metallic closing sounds. Systolic murmurs are commonly present with mechanical models. Loud diastolic murmurs are generally not present with mechanical valves. Patients with bioprostheses usually have normal S_1 and S_2, with no abnormal opening sounds. The aortic bioprostheses is usually associated with a short midsystolic murmur. Only the mitral bioprostheses is normally associated with a

diastolic rumble.

Diagnosis of Prosthetic Valve Dysfunction

New or progressive symptoms referable to the heart suggest a prosthetic valve disorder. Therefore, new or progressive dyspnea of any form, new onset or worsening of congestive heart failure, decreased exercise tolerance, or a change in chest pain compatible with ischemia all suggest valvular dysfunction. [14] Severe hemolytic anemia may indicate a paravalvular leak. Persistent fever in patients with prosthetic valves should be evaluated for possible endocarditis. Changes in valve position may be noted on chest radiographs if comparison views are available. Blood studies that may be helpful include a blood count with red blood cell indices and coagulation studies if the patient is on warfarin. Emergency echocardiographic studies should be requested if there is any question about valve dysfunction. Ultimately, echocardiography and/or cardiac catheterization may be required for diagnosis.

Emergency Department Management and Admission Indications

The medical management of patients with valvular dysfunction is the same as that described under "Emergency Department Care of Symptomatic Valvular Heart Disease," above. The evaluation and management of endocarditis is described in the following section. Acute prosthetic valvular dysfunction due to thrombotic obstruction has been successfully treated with thrombolytic therapy, but the diagnosis requires angiography and therefore is not be done by an emergency physician without consultation with a cardiologist.

Patients suspected of having acute prosthetic valvular dysfunction or endocarditis require admission to the hospital and evaluation for possible valve replacement. Disposition of patients with worsening of symptoms can be problematic, and consultation with the patient's regular physician is needed.

INFECTIVE ENDOCARDITIS

The preferred term, *infective endocarditis*, encompasses all types of endocarditis caused by infectious organisms and represents an infection of the endocardium occurring on the valve leaflets, the walls of the heart cavities, or the tissue surrounding prosthetic heart valves. The infection may be subacute or acute, depending on the virulence of the organism, the susceptibility of the host, and the presence of intravenous drug use. Because of the declining frequency of rheumatic heart disease, the increasing number of cardiac surgical procedures, and the increasing numbers of intravenous drug users, the nature of this disease has changed dramatically in the last 20 years.[15]

Pathophysiology

The cardiac valve leaflets are the portion of the heart most susceptible to infection because of their limited blood supply. Endocarditis can occur with normal valves but is more common with congenital and acquired valve disease and prosthetic valves. Bacteria and fungi gain entry to the circulation through various routes and settle on valvular tissue. A platelet-fibrin matrix forms, and further growth of the organisms forms a vegetation on the valve that makes the organisms inaccessible to normal cellular host defenses. Risk factors for infective endocarditis include congenital or acquired valvular heart disease, intravenous drug abuse, prosthetic valves, hemodialysis or peritoneal dialysis, indwelling venous catheters, postcardiac surgery, and calcific valve degeneration that occurs with increasing age. Rheumatic heart disease, although still important, is declining in frequency.

Infective endocarditis can be divided into acute and subacute forms, depending on the virulence of the infecting organism. Subacute disease more commonly infects abnormal valves, while acute disease more commonly infects previously normal valves. In the acute form, devastating complications are more common, including rapid disruption of the valve, leading to incompetence and heart failure. Embolism of the vegetations is responsible for many of the clinical features of the disease in both forms. Younger patients are more likely to have acute endocarditis, while older individuals are more likely to have subacute disease. In the subacute form, anemia is common and is probably a reflection of the chronicity of the disease. Antibodies form in reaction to foreign antigen, and immune-complex injury to basement membranes of the kidney may result in glomerulonephritis, which can occur in both acute and subacute disease.

Endocarditis can be further divided into left and right heart disease. Left-sided disease (aortic and mitral involvement) is the most common, except in injecting drug users. The most common organisms include *S. viridans* (declining in frequency), *S. aureus* (increasing in frequency), *Enterococcus,* and fungal organisms. *Pseudomonas* and *Serratia* are important etiologic agents in intravenous drug users in certain areas of the United States, especially Detroit and San Francisco, respectively. Cardiac failure is the most common cause of death in left-sided disease, but deaths due to neurologic complications are increasing. Patients with aortic involvement are more prone to ring abscess and atrioventricular block. Vegetations may embolize from the left heart, causing neurologic complications, systemic infarction, or metastatic infection.

Right-sided disease is usually seen in intravenous drug abusers (60 percent) and is caused by *S. aureus* (75 percent) and *Streptococcus pneumonia* (20 percent), gram-negative organisms (4 percent), and fungal organisms. [16] Vegetations may embolize from the right heart, causing pulmonary infection or infarction. The fatality rate for right-sided endocarditis is lower than that for left-sided disease because the incidence of cardiac failure is less than that for left-sided disease.

Children with endocarditis most commonly have complex congenital heart disease (35 percent) or unrepaired ventricular septal defect (14 percent). [17] Echocardiography may fail to uncover vegetations despite the presence of acute infection. *Staphylococcus aureus* is the most common organism isolated.

Clinical Features

Acute left-sided disease presents with a picture of sepsis with or without cardiac failure. Typically, patients appear ill with fever, chills, and tachycardia and may have significant congestive heart failure symptoms, such as dyspnea, frothy sputum, and chest pain. Patients may quickly deteriorate, with acute rupture of mitral or aortic valves. Murmurs are typically the sounds of aortic or mitral regurgitation; however, the murmur is often absent or unable to be heard over lung sounds in acute cases. Neurologic symptoms secondary to aseptic meningoencephalitis and embolization of vegetations account for about one-third of emergency department presentations. These complications most commonly are mental status changes, hemiplegia, aphasia, ataxia, or severe headache. Monocular blindness may also occur.

Patients with subacute left-sided disease present with recurrent intermittent fever and constitutional symptoms such as malaise, anorexia, or weight loss. The diagnosis is frequently missed. Patients may give a history of recurrent "flu" or report several courses of antibiotics for presumed bacterial infections, such as bronchitis. The majority of patients with left-sided subacute disease have a murmur of aortic or mitral regurgitation or a change in their previous murmur at the time of their admission to the hospital. However, many admitted patients have been examined previously by a physician who did not detect the murmur. Patients may have Roth spots, which are retinal hemorrhages with central clearing. Peripheral evidence of endocarditis includes Osler nodes, tender nodules on the tips of the toes and fingers, and Janeway lesions, nontender plaques on the soles of the feet and palms of the hands, and clubbing. Petechiae may be seen on the conjunctiva, hard palate, neck, and upper trunk. Splinter hemorrhages may be seen in the nails of the fingers or toes. Splenomegaly is noted in 25 percent of patients. Patients may present with back pain as their only complaint. New criteria for diagnosis that include echocardiographic findings have been suggested. [18,19]

Right-sided disease is usually acute and presents with fever and respiratory symptoms: cough, chest pain, hemoptysis, and dyspnea. Subacute presentations are unusual with right-sided disease. Murmurs are detectable in fewer than 50 percent of patients with right-sided disease. The chest radiograph may reveal pulmonary effusions and multiple pulmonary infiltrates of variable size and shape. Although meningitis coexists in only 5 percent of patients with left-sided disease, bacterial meningitis is seen in up to 30 percent of patients with right-sided disease.

Diagnosis

The diagnosis of endocarditis is based on positive blood culture results and echocardiographic evidence of valvular injury or vegetations. Three separate cultures from different veins should be obtained. Aerobic, anaerobic, and fungal cultures should be obtained before antibiotics are started. Echocardiography is helpful but should not delay appropriate stabilizing treatments. Transesophageal echocardiography is preferred, but in experienced centers transthoracic echocardiography may suffice. Evidence of vasculitis or embolic events contributes to the clinical diagnosis. Nonspecific laboratory findings that support the diagnosis of endocarditis include leukocytosis, elevated C-reactive proteins, positive rheumatoid factor, normocytic anemia, hematuria (25 to 50 percent), and pyuria.

Emergency Department Care

The first priority in the care of patients with acute infective endocarditis is stabilization of respiratory and cardiac symptoms. For patients with mental status changes and hypoxia or a compromised airway, intubation may be required. Cardiac decompensation is usually due to left-sided valvular incompetence and/or rupture. Acute rupture of the mitral or aortic valve should be stabilized with afterload reducers such as sodium nitroprusside, with insertion of a Swan-Ganz catheter for monitoring therapy as soon as possible. Preparation for emergency surgery should be made for patients suspected of acute valvular rupture. [20] Aortic balloon counterpulsation may be helpful for mitral valve rupture but is contraindicated for wide-open aortic valve rupture.

The second priority is drawing three blood cultures from different sites and then starting empiric antibiotic therapy. [21] For acute infective endocarditis, a penicillinase-resistant penicillin, such as oxicillin 2 g q4h, should be given with an aminoglycoside, such as gentamicin 1 mg/kg up to 80 mg q8h, chosen on the basis of local patterns of susceptibility. In areas where there is a high incidence of methicillin-resistant *Staphylococcus* or in the case of a patient taking oral antibiotics already, vancomycin 1 g intravenously should be used in addition to an aminoglycoside. Patients with prosthetic valve endocarditis should be treated with antibiotics that cover *S. epidermidis,* usually vancomycin, 1 g intravenously, in addition to an aminoglycoside and rifampin. Although subacute cases are frequently caused by *S. viridans* and this bacteria is covered by penicillin G, patients with subacute presentations that require admission should be started on a newer cephalosporin, such as ceftriaxone, 1 g intravenously, in addition to an aminoglycoside until cultures and sensitivities are known. For patients with subacute disease who were taking oral antibiotics for another presumed infection, consideration should be given to collecting at least seven cultures or waiting until culture results turn positive before giving intravenous antibiotics.

Admission Indications

In general, patients with suspected endocarditis should be admitted to the hospital. Currently, injecting drug users who present to the emergency department with fever are admitted routinely at many centers regardless of whether there are other findings or potential explanations for the fever. Since only 10 percent prove to have evidence of endocarditis, studies are currently under way to determine whether emergency department "rules" can be developed for risk categorization.

Ambulatory Treatment

The ambulatory treatment of culture-proven *S. viridans* endocarditis has been advocated.[22] Patients treated with intramuscular injections of ceftriaxone, 2 g daily for 4 weeks, did well. This finding should not affect emergency medicine practice, however, since cultures are not usually available until some time after admission to the hospital. For patients for whom blood cultures are drawn and who are then sent home, a referral should be made to a cardiologist for evaluation and follow-up.

NONVALVULAR INFECTIONS OF THE HEART

Nonvalvular infections of the heart involve the endocardium, the myocardium, and the pericardium. [23] In addition, pacemakers; automatic, implantable cardioverter-defibrillators; and other cardiac devices may become infected in the subcutaneous device pocket or along the vascular tracks leading to and including the heart. Most commonly these devices become infected at the device pocket, where they are more readily diagnosed because of tenderness and erythema easily noted on physical examination. Myocardial abscesses and mural endocarditis are discussed here because of their similarities to valvular endocarditis. These two conditions are difficult to diagnose because their signs and symptoms are subtle.

Pathophysiology

Risk factors for the development of myocardial abscesses or mural endocarditis include chronic debilitating illness, immunosuppression, indwelling catheters, prolonged antibiotic therapy, and valvular endocarditis. The source of infection may be from hematogenous seeding or contiguous extension from valvular endocarditis. These two infections may coexist, or one may lead to the development of the other. In the case of mural endocarditis, bacteria may seed damaged endocardium or aneurysms in the ventricular wall. In the case of myocardial abscesses, multiple areas of the myocardium may be involved, but when valvular endocarditis is the source of bacterial seeding, the paravalvular areas are usually involved. The most common organisms in these nonvalvular infections of the heart are *S. aureus, S. viridans,* and other organisms associated with valvular endocarditis.

Clinical Features

The symptoms and signs may be completely nonspecific, especially with myocardial abscesses. Patients usually experience vague fevers and chills but may present with more obvious sepsis. Frequently patients are given antibiotics on an outpatient basis for some presumed bacterial infection, such as bronchitis. Patients may be suspected of having valvular endocarditis and may be admitted to the hospital for intravenous antibiotics, and yet the correct diagnosis is not made and symptoms recur after discharge. Many symptoms, including positive blood culture results, peripheral embolization, and splenomegaly, are found in both valvular and nonvalvular infections of the heart. Frequently patients have sudden fatal complications, such as myocardial rupture, tamponade, or severe peripheral embolization, diagnoses made only at autopsy.

Diagnosis

The diagnosis of myocardial abscess and mural endocarditis is difficult. Blood culture results are positive in 75 percent of patients with myocardial abscess, but this finding is nonspecific. In cases of mural endocarditis, patients frequently have peripheral embolization and splenomegaly, but these findings do not distinguish mural from valvular endocarditis. When these conditions are found at autopsy in a previously undiagnosed patient, endocarditis is frequently the misdiagnosis. Whenever patients present with findings compatible with endocarditis and yet both physical examination and echocardiographic study fail to demonstrate valvular lesions, myocardial abscess and mural endocarditis should be considered. Unfortunately, diagnosis with echocardiography or even cardiac angiography is difficult. Transesophageal echocardiography may offer the best results.

Emergency Department Management

When nonvalvular infections of the heart are suspected by the emergency physician, the patient should be admitted to the hospital. Accurate structural and microbiologic diagnosis is essential to proper management, which may include surgical drainage and repair. Therefore, antibiotics should be withheld until the plan for diagnostic evaluation can be initiated.

51 THE CARDIOMYOPATHIES, MYOCARDITIS, AND PERICARDIAL DISEASE

James T. Niemann

THE CARDIOMYOPATHIES

The term *cardiomyopathy* is used to describe a group of diseases that directly alter cardiac structure and impair myocardial function. Four types of cardiomyopathy are currently recognized: (1) dilated cardiomyopathy (DCM), (2) hypertrophic cardiomyopathy (HCM), (3) restrictive cardiomyopathy, and (4) arrhythmogenic right ventricular cardiomyopathy.[1] It is acknowledged that there are some primary heart muscle disorders that do not fit readily into one of these four groups, and these conditions have been termed unclassified cardiomyopathies. Finally, the term *specific cardiomyopathies* is now used to describe heart muscle diseases that are associated with specific cardiac or systemic disorders. They often present with hemodynamic findings similar to those of the idiopathic dilated or restrictive form of cardiomyopathy. Some specific cardiomyopathies are listed in Table 51-1. The cardiomyopathies, as a group, are the third most common form of cardiac disease encountered in the United States, following coronary (ischemic) heart disease and hypertensive heart disease. HCM is the second most common cause of sudden cardiac death in the adolescent population and the leading cause of sudden death in competitive athletes.[2]

Toxins
  Ethanol
  Chemotherapeutic agents (doxorubicin)
  Antiretroviral drugs (zidovudine, didanosine)
  Phenothiazines
  Cocaine
Infections
  Viruses (coxsackievirus, echovirus, cytomegalovirus, HIV)
  Rickettsia
  Bacteria (diphtheria, rheumatic fever)
  Mycobacteria
  Fungal
  Parasitic (toxoplasmosis, Chagas disease)
Collagen vascular disorders
  Scleroderma
  Systemic lupus erythematosus
  Dermatomyositis
Hypersensitivity myocarditis
Peripartum cardiomyopathy
Metabolic
  Nutritional deficiency (thiamine)
  Endocrine (hypothyroidism, Cushing disease, hyperthyroidism)
  Electrolyte disturbances (hypophosphatemia, hypocalcemia)
Neuromuscular disorders (muscular dystrophy, Friedreich ataxia)
Familial cardiomyopathy

TABLE 51-1   Common Causes of Specific Cardiomyopathies

Dilated Cardiomyopathy

Hemodynamically, DCM is characterized by depressed myocardial systolic function and systolic pump failure. Left ventricular (LV), and often right ventricular (RV), contractile force is diminished, resulting in a low cardiac output and increased end-systolic and end-diastolic ventricular volumes and intracavitary pressures. LV, and often RV, dilatation accompanied by compensatory hypertrophy are the hallmarks of DCM. Histologic findings are nonspecific.

Approximately 80 percent of cases of DCM are of unknown etiology; that is, they are not associated with specific cardiac or systemic disorders (Table 51-1) and are considered idiopathic.[3] The idiopathic form of DCM is the cause in approximately 25 percent of all cases of congestive heart failure (CHF) and the primary indication for cardiac transplantation in the United States. The prevalence of idiopathic DCM is estimated to be approximately 36 cases per 100,000 population. Blacks and males have a 2.5-fold increase in risk compared to whites and females. Most patients are diagnosed between the ages of 20 and 50 years, and the majority have advanced symptoms of CHF at the time of initial presentation.[3]

CLINICAL FEATURES AND DIAGNOSIS   As a result of systolic pump failure, the patient presents with signs and symptoms of CHF: dyspnea on exertion, orthopnea, and paroxysmal nocturnal dyspnea. Depressed ventricular contractile function and dilatation may result in the formation of mural thrombi, and the patient may present with manifestations of peripheral embolization (e.g., an acute neurologic deficit, flank pain, and hematuria or a pulseless, cyanotic extremity). Chest pain with features of typical angina pectoris occurs in approximately one-third of patients. Chest pain in these patients is felt to be due to limited coronary vascular reserve rather than atherosclerotic coronary artery disease.

Murmurs are frequently heard during cardiac auscultation and are not necessarily indicative of primary valvular disease. Ventricular dilatation and the resultant annular dilatation and displacement of the papillary muscles of the atrioventricular valves inhibit leaflet coaptation and complete valve closure. Holosystolic regurgitant murmurs of mitral and tricuspid valve origin are frequently heard at the apex or lower left sternal border in the patient with biventricular failure. On occasion an apical diastolic rumble may be heard and is due either to accentuated, early-diastolic atrial-to-ventricular flow (the result of mitral regurgitation and left atrial overload) or to a loud summation gallop. An enlarged, pulsatile liver may be found if tricuspid insufficiency is significant. Bibasilar rales and dependent edema are common additional findings.

The chest x-ray invariably shows an enlarged cardiac silhouette and increased cardiothoracic ratio; biventricular enlargement is common. Evidence of pulmonary venous hypertension ("cephalization" of flow and enlarged hila) is also frequent and may serve to differentiate cardiac enlargement due to myocardial failure from that due to a large pericardial effusion.

The electrocardiogram (ECG) is almost always abnormal. Left ventricular hypertrophy and left atrial enlargement are the most common findings. Q or QS waves and poor R-wave progression across the anterior precordium may produce a pseudoinfarction pattern. Atrial fibrillation and ventricular ectopy are frequently encountered rhythm disturbances.

Echocardiographic studies in a symptomatic patient demonstrate a decreased ejection fraction, increased systolic and diastolic volumes, and ventricular and atrial enlargement.

TREATMENT AND DISPOSITION   A timely workup is indicated in patients who present with newly diagnosed symptomatic CHF, and evaluation typically requires hospitalization. Echocardiography is indicated to exclude known causes of heart failure that may be correctable (e.g., precordial effusion or valvular disease), to estimate ejection fraction, and to rule out other potential complications (e.g., mural thrombi) that may be amenable to therapy. Symptom-directed therapy is best initiated in the in-patient setting in order to minimize adverse drug effects. Almost all patients will benefit symptomatically from digitalis glycoside therapy and diuretics, but these drugs have not been shown to improve survival rates. The use of angiotensin-converting enzyme inhibitors and b blockers, specifically carvedilol, have been

shown to improve survival rates in patients with DCM and CHF. [4,5] Patients with complex ventricular ectopy may benefit from amiodarone therapy. [6]

Patients with a known DCM and chronic CHF may present to the emergency department with a mild-to-moderate worsening of symptoms. In most instances, the cause is noncompliance with medical therapy or dietary indiscretion. Such patients can often be managed in the emergency department with intravenous diuretics, reinstitution of prescribed medications, counseling of the patient, and timely referral to the primary care physician. [7] However, other causes of an acute exacerbation of symptoms in a disease characterized by a slow and progressive history must be considered (Table 51-2) and, if present or suspected, require hospitalization for definitive management.

Anemia

Infection

Noncompliance (diet, medications)

Paroxysmal atrial fibrillation

Bradyarrhythmias or heart block

Acute valvular insufficiency

Renal dysfunction (overdiuresis, angiotensin-converting enzyme inhibitor in-
    duced)

Myocardial ischemia or infarction

Pulmonary thromboembolism

Thyroid dysfunction

TABLE 51-2   Cause of Acute Exacerbation of Chronic Congestive Heart Failure

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is characterized by LV and/or RV hypertrophy that is usually asymmetrical and involves primarily the interventricular septum. The diagnostic hallmarks of the disease are echocardiographic asymmetical septal hypertrophy and histologic hypertrophy associated with myocardial fiber disarray surrounding areas of increased loose connective tissue. [8] In approximately 50 percent of cases, it is a familial disease with autosomal dominant inheritance. In the rest, it is sporadic. There is no apparent sex or ethnic predilection. Molecular genetics has demonstrated that HCM is a heterogeneous disease of the sarcomere with many mutations. The most common mutation involves the b-myosin heavy chain. There is evidence that particular genotypes have more rapidly progressive courses. The prevalence in the general population is approximately 1 in 500. The annual mortality rate the unselected population is about 1 percent per annum but 4 to 6 percent in childhood and adolescence.

Hemodynamically, HCM is characterized by abnormal LV diastolic function due to reduced compliance of the hypertrophied left ventricle. This decreased compliance is reflected by an increase in LV filling pressure. Cardiac output, ejection fraction, and end-systolic and end-diastolic volumes are usually normal. During cardiac catheterization and hemodynamic monitoring, a systolic pressure gradient between the body of the left ventricle and the subvalvular outflow tract can be recorded in some patients at rest or after provocation (e.g., exercise or isoproterenol infusion). The majority of clinical symptoms in this heart muscle disease are the result of impaired diastolic relaxation and restricted LV filling.

CLINICAL FEATURES AND DIAGNOSIS   Severity of symptoms in most instances is related to the patient's age; the older the patient, the more severe the symptoms. Dyspnea on exertion is the most frequent initial complaint and is due to exercised-induced sinus tachycardia, which results in an abrupt elevated LV diastolic pressure and pulmonary venous hypertension. Additional symptoms include chest pain, palpitations, and syncope. A family history of death due to cardiac disease, frequently described as "massive heart attack" or "heart failure," is not uncommon. Complaints of paroxysmal nocturnal dyspnea and pedal edema are infrequent.

Chest pain in HCM patients is due to an imbalance between the oxygen demand of the hypertrophied left ventricle and the available myocardial blood flow. In older patients, associated atherosclerotic coronary artery disease may further limit myocardial perfusion. Precordial or retrosternal chest discomfort in HCM may mimic angina pectoris or may be "atypical." Response to nitroglycerin administration is poor and highly variable.

The HCM patient may be aware of forceful ventricular contraction and complain of an abnormal heartbeat or "palpitations." Atrial and ventricular dysrhythmias are not uncommon in these patients; rapid atrial dysrhythmias, especially atrial fibrillation, and particularly poorly tolerated because of the increased importance of the atrial contribution to LV filling in the poorly compliant heart and require aggressive management in hemodynamically unstable patients.

Jugular venous pressure is usually not elevated; however, a prominent a wave may be noted on close inspection of the neck veins. The upstroke of the carotid arterial pulse is rapid and frequently biphasic or bifid (pulsus bisferiens). The apical impulse is sustained and hyperdynamic, and a presystolic lift is common.

The first and second heart sounds are usually normal, and a fourth sound (S_4) will be heard in most patients. The characteristic systolic ejection-type murmur of HCM is heard best at the lower left sternal border or at the apex and rarely radiates to the carotid arteries. Easily performed bedside maneuvers can be used to increase the intensity and duration of the murmur (Table 51-3). Interventions that decrease LV filling and the distending pressure in the LV outflow tract or that increase the force of myocardial contraction accentuate the murmur of HCM. Such interventions include standing and the Valsalva maneuver. The murmur is also louder with the first sinus beat following a premature ventricular contraction. Maneuvers that increase LV filling (squatting, passive leg elevation, and hand grip) have an opposite effect on murmur characteristics. The murmurs of HCM and mitral valve prolapse are similar and are compared in Table 51-3.

	Hypertrophic Cardiomyopathy	Mitral Valve Prolapse
Valsalva maneuver	Murmur increased	Click closer to S_1, murmur increased
Standing after squatting	Murmur increased	Click closer to S_1, murmur increased
Passive leg elevation by supine patient	Murmur decreased	Click closer to S_2, murmur decreased
Hand grip	Murmur decreased	Click closer to S_1, murmur increased
Squatting	Murmur decreased	Click closer to S_2, murmur decreased

TABLE 51-3   Effect of Bedside Interventions on the Murmur of Hypertrophic Cardiomyopathy Compared to Mitral Valve Prolapse

ECG findings of LV hypertrophy and left atrial enlargement are found in 30 percent and 25 to 50 percent, respectively, of HCM patients. Evidence of chamber enlargement is most common in patients with large gradients across the LV outflow tract. Q waves of considerable amplitude (more than 0.3 mV), termed septal Q waves, are seen in about 25 percent of patients and may be encountered in the anterior, lateral, or inferior leads. These Q waves may mimic those seen following myocardial infarction (pseudoinfarction pattern). The polarity of the T wave may serve as a diagnostic clue in the separation of HCM septal Q waves from Q waves due to myocardial infarction. Upright T waves in those leads with QS or QR complexes are usually found in HCM; T-wave inversion in such leads is highly suggestive of ischemic heart disease.

The chest x-ray is frequently normal, and identifiable abnormalities are largely nonspecific. Many patients do not show radiographic evidence of LV or left atrial

enlargement. Evidence of pulmonary venous congestion is unusual but has been reported.

Echocardiography has played a substantial role in the diagnosis of HCM, in the correlation of the auscultatory and hemodynamic events with LV anatomic changes, and in defining inheritance patterns. The characteristic echocardiographic finding is disproportionate septal hypertrophy. Additional described echocardiographic abnormalities include normal or reduced LV end-diastolic dimensions, systolic anterior motion of the mitral valve, and midsystolic closure of the aortic valve.

TREATMENT AND DISPOSITION   The majority of patients with HCM who seek medical care typically do so because of declining exercise tolerance, chest pain, or syncope.[9] Symptoms may mimic those of ischemic heart disease, or in the young patient, symptoms may be ascribed to a noncardiac cause. The patient who presents complaining of exercise intolerance or chest pain in whom the typical murmur of HCM is heard should be referred for echocardiographic evaluation. Syncope in patients with HCM typically occurs during or immediately after exercise. If HCM is suspected in a patient with syncope, hospitalization is indicated. The workup in such cases is extensive and includes echocardiographic studies as well as extended ambulatory (Holter) monitoring, exercise stress testing to assess blood pressure response, and tilt testing. Syncope in patients with HCM may be due to one or more factors and may presage sudden cardiac death. [9] Vigorous exercise is discouraged for such patients, and preparticipation screening guidelines have been developed for competitive athletes to minimize the risk of sudden death due to HCM.[10] b blockers are the mainstay of therapy for patients with chest pain.

Restrictive Cardiomyopathy

The restrictive forms are among the least common of the described cardiomyopathies. *Restrictive cardiomyopathy* is defined as heart muscle disease that results in "restricted" ventricular filling, with normal or decreased diastolic volume of either or both ventricles. Systolic function is usually normal, and ventricular wall thickness may be normal or increased, depending on the underlying cause. The hemodynamic hallmarks include (1) elevated LV and RV end-diastolic pressure, (2) normal LV systolic function (ejection fraction greater than 50 percent), and (3) an abrupt and rapid rise in early-diastolic ventricular pressure following a marked decline at the onset of diastole. The rapid rise and abrupt plateau in the early-diastolic ventricular pressure trace produce a characteristic "square-root sign" or "dip-and-plateau" filling pattern due to increased myocardial stiffness. This pattern is not diagnostic, however, and may be seen in constrictive pericarditis, with which restrictive cardiomyopathy is commonly confused. Differentiation between the two is critical because constrictive pericarditis can be cured surgically. The diagnosis of restrictive cardiomyopathy should be considered in a patient presenting with CHF but no evidence of cardiomegaly or systolic dysfunction. [11]

Restrictive cardiomyopathy may result from systemic disorders (Table 51-4), but most cases are idiopathic. The idiopathic form is sometimes familial, with autosomal dominant transmission. There has been no clearly demonstrated predilection for gender or ethnicity.

Idiopathic
Amyloidosis
Sarcoidosis
Hemochromatosis
Progressive systemic sclerosis (scleroderma)
Carcinoid heart disease
Endomyocardial fibrosis
Hypereosinophilic syndrome

TABLE 51-4   Common Causes of Restrictive Cardiomyopathy

CLINICAL FEATURES AND DIAGNOSIS   Symptoms are typical of CHF and include dyspnea, orthopnea, and pedal edema. Right-sided manifestations may predominate and result in hepatomegaly, right upper quadrant pain, and ascites. Chest pain is uncommon, except in amyloidosis.

Findings on physical examination depend on the stage or severity of myocardial involvement. An S_3 is almost always present, and an S_4 is often heard if the patient is in sinus rhythm. Pulmonary rales, jugular venous distention, Kussmaul sign (jugular venous pulse rises during inspiration rather than falling), hepatomegaly, pedal edema, and ascites are also typical findings.

The chest x-ray may reveal signs of CHF in the absence of cardiomegaly. Chamber enlargement due to wall thickening, but not dilatation, and nonspecific ST-T-wave changes are usually noted on the ECG. Cardiac conduction disturbances are common in amyloidosis and sarcoidosis. Atrial fibrillation may occur in the setting of atrial enlargement. Low-voltage QRS complexes (QRS amplitude less than 0.7 mV) have been frequently described in patients with restrictive cardiomyopathy secondary to amyloidosis and hemochromatosis.[12]

TREATMENT AND DISPOSITION   Symptoms and signs of CHF, particularly right-sided failure, with a normal-size cardiac silhouette on chest x-ray should prompt a suspicion of underlying restrictive cardiomyopathy, constrictive pericarditis, or diastolic LV dysfunction (most commonly due to ischemic heart disease, hypertension, or age-related changes in ventricular diastolic compliance). Doppler echocardiographic studies and cardiac catheterization with hemodynamic assessment are often required to differentiate between the above-mentioned entities. Computed tomography and magnetic resonance imaging of the heart have also been shown to be of value in differentiating constrictive pericarditis and restrictive cardiomyopathy. [11] Timely diagnosis is important because constrictive pericarditis can be surgically corrected and diastolic LV dysfunction not due to restrictive cardiomyopathy usually responds well to drug therapy (b blockers or calcium-channel blockers). The medical management of restrictive cardiomyopathy is less effective and symptom directed (diuretics and angiotensin-converting enzyme inhibitors) unless due to sarcoidosis (corticosteroid therapy) or hemachromatosis (chelation therapy). The need for admission is usually determined by the severity of symptoms and the availability of a timely and usually invasive workup.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic cardiomyopathy, or dysplasia, is the rarest of the cardiomyopathies. Familial disease is common in an autosomal dominant inheritance pattern with incomplete penetrance. This cardiomyopathy is characterized by progressive replacement of the RV myocardium with fibrofatty tissue in an eventual global distribution. The left ventricle and septum are usually spared. [13]

CLINICAL FEATURES AND DIAGNOSIS   The typical presentation is that of sudden death or ventricular dysrhythmia in a young or middle-aged patient. The findings upon physical examination are normal. The chest x-ray shows no specific findings, and the heart size is not enlarged. The ECG may show a right bundle branch pattern and precordial T-wave inversion. Echocardiographic studies, radionuclide angiography, and cardiac catheterization are routinely required to confirm the diagnosis. The echocardiogram has the highest sensitivity and positive predictive value for the diagnosis of RV abnormalities and typically shows RV contraction abnormalities and RV enlargement.[13] Magnetic resonance imaging has been shown to detect fatty infiltration of the myocardium and may become the preferred diagnostic test.

TREATMENT AND DISPOSITION   The majority of patients present after aborted sudden cardiac death, with syncope, or with complex ventricular ectopy. Due to the nature of these complaints, hospitalization is indicated. Ventricular tachycardia can be suppressed with antiarrhythmic drugs, but ablative procedures or implantation of an antiarrhythmic device may be necessary.

MYOCARDITIS

Definition

Myocarditis is broadly but nonspecifically defined as inflammation of the heart muscle and is most frequently characterized pathologically by focal infiltration of the

myocardium by lymphocytes, plasma cells, and histiocytes. Varying amounts of myocytolysis and destruction of the interstitial reticulin network are also seen. [14] The pathologic changes have been ascribed to a number of infectious agents (Table 51-5), some of which involve the myocardium secondarily as part of a systemic disease process. Myocarditis is frequently accompanied by pericarditis.

Viral Agents	Bacteria
Coxsackie B virus	*Corynebacterium diphtheriae*
Echovirus	*Neisseria meningitides*
Influenzavirus	*Mycoplasma pneumoniae*
Parainfluenzavirus	β-Hemolytic streptococci (rheumatic fever)
Epstein-Barr virus	Lyme disease
Hepatitis B virus	
HIV	

TABLE 51-5   Common Infectious Causes of Myocarditis

Clinical Features and Diagnosis

Fever is common, as is sinus tachycardia, which is usually "out of proportion" with respect to the extent of temperature elevation. Signs and symptoms depend on the extent of myocardial involvement and resultant depression of myocardial systolic function. In severe cases, progressive heart failure, with its associated symptoms, may be seen. With less extensive myocardial involvement, pericarditis and the clinical manifestations of systemic illness (fever, myalgias, headache, and rigors) may overshadow clinical signs of myocardial dysfunction, and myocarditis may not be suspected. Retrosternal or precordial chest pain is a frequent presenting complaint and is most commonly secondary to associated pericardial inflammation (myopericarditis). This chest pain may mimic angina in its character. A pericardial friction rub is commonly heard in patients with myopericarditis.[15]

The chest roentgenogram is usually normal, and reported abnormalities (cardiomegaly and pulmonary venous hypertension and/or pulmonary edema) vary with disease severity and are nondiagnostic. Reported ECG changes include nonspecific ST-T-wave changes, ST-segment elevation (due to associated pericarditis), atrioventricular block, and prolonged QRS duration. Levels of cardiac enzymes (creatine kinase and CK-MB) and troponin may be elevated. [16] Echocardiographic studies may reveal depressed systolic function in severe cases.

Treatment and Disposition

Current therapy in cases of idiopathic or viral myocarditis is largely supportive and symptom directed. Myocarditis in rheumatic fever and complicating diphtheria or meningococcemia necessitates directed antibiotic therapy. Immunosuppressive therapy is of unproven value. Because most patients present with rapidly progressive CHF, admission is usually indicated.[17]

UNEXPLAINED HEART FAILURE AND CARDIOMEGALY: DIFFERENTIAL DIAGNOSIS AND EVALUATION

Symptoms of CHF and associated cardiomegaly or evidence of cardiomegaly in an asymptomatic patient necessitates a directed evaluation. In the vast majority of instances, one of the following five disease entities will eventually be diagnosed. Where appropriate, recognized diagnostic clues are noted.

1. *Hypertensive heart disease.* Systemic arterial hypertension affects 10 to 20 percent of the adult population. This is a disease with a high prevalence that may be diagnosed at a number of stages. Patients with a dilated cardiomyopathy and untreated cardiac failure frequently present with an elevated blood pressure due to autonomically mediated compensatory reflexes. Isolated involvement of the myocardium as the major manifestation of systemic arterial hypertension is rare. A careful search for evidence of other end-organ damage due to arterial hypertension should be undertaken (examination of fundi, assessment of renal function, evaluation for focal neurologic changes, or history of such entities).
2. *Ischemic heart disease (ischemic cardiomyopathy).* Most patients with clinical signs of biventricular heart failure and cardiomegaly due to obstructive coronary arterial disease relate a history of typical anginal pain or documented myocardial infarction. A few do not, and clinical presentation and physical findings in these cases mimics those of an idiopathic dilated cardiomyopathy.
3. *Valvular heart disease.* Although the incidence of rheumatic heart disease in the United States is low, it remains prevalent in underdeveloped countries and is frequently first diagnosed in recent immigrants. The growing geriatric population is prone to calcific aortic stenosis and mitral annular calcification. In addition, bicuspid or unicuspid aortic valve abnormalities remain the most common congenital heart disease. All valvular diseases may present with CHF or incidental cardiac enlargement, and systolic and diastolic murmurs may be noted. Echocardiographic studies are the diagnostic tests of choice in patients with suspected valvular heart disease. Hemodynamic and angiographic studies may be confirmatory.
4. *Myocarditis.* Patients with severe myocarditis may present with signs and symptoms of cardiac insufficiency. Such patients are usually young, have no significant past cardiac history, have few risk factors for atherosclerotic coronary arterial disease, and present with a recent, abrupt onset of symptoms during or immediately following a systemic or viral illness.
5. *Idiopathic cardiomyopathy.* This diagnosis should be considered only if the first four entities have been excluded. A careful search for potential causes should then be undertaken.

PERICARDIAL DISEASE

The pericardium consists of a serous or loose fibrous membrane (visceral pericardium) overlying the epicardium and a dense collagenous sac (parietal pericardium) surrounding the heart. The space between the visceral and parietal pericardium may contain up to 50 mL of fluid under normal conditions, and intrapericardial pressure is normally subatmospheric. Because its layers are serosal surfaces and because of its proximity and attachments to other structures, the pericardium may be involved in a number of systemic or localized disease processes (Table 51-6). The clinical presentation of pericardial heart disease is variable and dependent on the pericardium's response to injury and how this response affects cardiac function. In this section the clinical manifestations and evaluation of acute and constrictive pericarditis and nontraumatic cardiac tamponade are discussed.[18]

Idiopathic

Infectious
   Viral (coxsackievirus, echovirus, HIV)
   Bacterial [especially Staphylococcus, *Streptococcus pneumoniae*; β-hemolytic streptococci (acute rheumatic fever), *Mycobacterium tuberculosis*]
   Fungal (especially *Histoplasma capsulatum*)

Malignancy (leukemia, lymphoma, metastatic breast and lung carcinoma, melanoma)

Drug-induced (procainamide, hydralazine)

Connective tissue disease

Radiation-induced

Postmyocardial infarction (Dressler syndrome)

Uremia

Myxedema

TABLE 51-6   Common Causes of Acute Pericarditis

Acute Pericarditis

CLINICAL FEATURES   The most common symptom is precordial or retrosternal chest pain, which is most frequently described as sharp or stabbing. It may be of sudden or gradual onset and radiate to the back, neck, left shoulder, or arm; referral to the left trapezial ridge (due to inflammation of the joining diaphragmatic pleura) is a particular distinguishing feature. Chest pain due to acute pericarditis may be aggravated by inspiration or movement. It may be most severe when the patient is supine and is often relieved when the patient sits up and leans forward. In most instances, these characteristics allow the pain of acute pericarditis to be distinguished from the ischemic pain of angina or acute myocardial infarction.

Associated symptoms include (1) low-grade, intermittent fever, particularly if pericarditis is infectious in origin or of the idiopathic type; (2) dyspnea, due to accentuated pain with inspiration; and (3) dysphagia, ascribed to irritation of the esophagus by the posterior pericardium.

A pericardial friction rub is the most common and important physical finding in pericarditis. A pericardial rub most closely resembles a superficial grating or scratching sound. It is best heard with the diaphragm of the stethoscope at the lower left sternal border or apex when the patient is sitting and leaning forward or in the hands-and-knees position. It may be audible only during a certain phase of respiration and characteristically is transient (e.g., heard one hour and not the next). No inference as to the amount of pericardial fluid should be drawn from the presence or absence of a pericardial friction rub.

A pericardial rub is most often triphasic in character, consisting of a systolic component, an early diastolic component occurring during the early phase of ventricular filling, and a presystolic component synchronous with atrial systole. It is less commonly biphasic, with a systolic component with either an early diastolic or presystolic component. A monophasic rub is unusual (18 percent of cases) but is most often systolic.

DIAGNOSIS   **Electrocardiogram**   Serial ECGs recorded over a number of days may be diagnostic in acute pericarditis. The evolutionary ECG changes during acute pericarditis and convalescence have been divided into four stages. During stage 1, or the acute phase, ST-segment elevation (reflecting associated subepicardial inflammation and/or injury) is prominent in the precordial leads, especially V_5 and V_6, and in standard lead I. PR-segment depression may be noted in leads II, aV_f, and V_4 to V_6 (Fig. 51-1). In stage 2, the ST segment begins returning to the isoelectric line, and T-wave amplitude decreases. T-wave inversion is rarely seen until stage 3. Stage 3 is characterized by an isoelectric ST segment and T-wave inversion in those leads previously showing ST-segment elevation. Resolution of repolarization abnormalities is the hallmark of stage 4.

FIG. 51-1. This series of ECGs was recorded in a 28-year-old male who presented complaining of pleuritic retrosternal pain, cough, and fever. The initial ECG (dated 10-20) demonstrates diffuse ST-segment elevation (stage I). The ST-segment to T-wave amplitude ratio measured in V_6 is 5 mm/10 mm, or 0.50, thus meeting criteria for pericarditis rather than early repolarization (see the text). The ECG dated 10-29 demonstrates a return of the ST segment to the isoelectric point in most leads in which they had been elevated (stage II). The third tracing (dated 11-3) demonstrates resolution of ST changes and the appearance of T-wave inversion in the anterior precordial leads (stage III). These evolutionary changes are typical of and diagnostic for pericarditis and usually occur over several weeks.

If a large pericardial effusion develops during the course of acute pericarditis, additional ECG abnormalities may be noted, including low-voltage QRS complexes and electrical alternans. These phenomena are due to the "insulating" effect of pericardial fluid, which attenuates electrical signals of myocardial origin, and the pendular motion of the heart within the fluid-filled pericardial space.

Although serial ECG tracings are of diagnostic value in acute pericarditis, sequential ECG assessment is not a diagnostic luxury afforded the emergency physician. Differentiating pericarditis from the normal variant with "early repolarization" is a common problem and can be difficult when only a single 12-lead ECG is available. Acute pericarditis is a common cause of chest pain and abnormal ECGs in young adults. The ST-T-wave changes present in the early repolarization or normal variant ECG mimic those of pericarditis and have been reported in 2 percent of healthy young adults. Investigations attempting to distinguish these two conditions have yielded conflicting results. However, a simple criterion offers considerable diagnostic utility, namely, the ST-segment/T-wave amplitude ratio in leads V_5, V_6, or I.[19] Using the end of the PR segment as baseline, or 0 mV, the amplitude or height of the ST segment at its onset is measured in one of the aforementioned leads and recorded in millivolts. The height of the T wave in the same lead is measured from the baseline to the T-wave peak. If the ratio of ST amplitude (in millivolts) to T-wave amplitude (in millivolts) is below 0.25, a normal variant or early repolarization is most probable. If the ratio is above 0.25, acute pericarditis is likely. This criterion may allow differentiation of acute pericarditis (stage 1) from early repolarization during emergency department evaluation (Fig. 51-1). Pericarditis alone does not cause significant cardiac rhythm disturbances.

Radiographic Assessment   Conventional posteroanterior and lateral chest x-rays are of limited value. The cardiac silhouette may be of normal size and contour in acute pericarditis and, in some instances, the setting of cardiac tamponade. If previous chest x-rays are available for comparison, a recent increase in the size of the cardiac silhouette or an increase in the cardiothoracic ratio without radiographic evidence of pulmonary venous hypertension aids in distinguishing an expanding pericardial effusion from left heart failure. The epicardial "fat-pad sign" is rarely seen on the lateral chest x-ray and has been reported in only 15 percent of cases of acute pericarditis during fluoroscopy with image intensification. If acute pericarditis is suspected on the basis of history, physical examination, or ECG, posteroanterior and lateral chest x-rays, which may demonstrate a pleuropulmonary or mediastinal abnormality, may assist in establishing a cause (e.g., neoplastic or infectious).

Echocardiographic Studies   Echocardiography has become the procedure of choice for the detection, confirmation, and serial follow-up of patients with acute pericarditis and a pericardial effusion.[18]

Normally, the pericardial sac is only a "potential" space, and the myocardium is echocardiographically in direct contact with surrounding thoracic structures. The anterior RV wall is in contact with the chest wall, and the posterior LV wall is in contact with the posterior pericardium and adjacent pleura. When a pericardial effusion is present, the pericardial space fills with echo-free fluid. Echocardiographically, a separation is seen between the right ventricle and the chest wall and between the left ventricle and the posterior pericardium. Quantitation of the size of the effusion is arbitrary and is determined by where the echo-free space is seen (anterior or posterior) and when in the cardiac cycle it occurs. For example, when an echo-free space is seen only posteriorly and only during systole, a small effusion is said to present.

Ancillary Laboratory Evaluation   The laboratory studies listed in Table 51-7 may be of value in establishing an etiologic diagnosis. Creatine kinase and CK-MB may be elevated in acute pericarditis due to associated myocarditis.

TABLE 51-7   Ancillary Diagnostic Studies in Acute Pericarditis

TREATMENT AND DISPOSITION   Most patients with idiopathic or presumed viral pericarditis will respond to nonsteroidal anti-inflammatory agents administered for 7 days to 3 weeks. If a specific cause is identified, therapy should be directed toward the underlying disease. [20] Patients with an enlarged cardiac silhouette on chest x-ray should be admitted for early Doppler echocardiography to assess the extent of the effusion and degree of hemodynamic compromise.

Nontraumatic Cardiac Tamponade

PATHOPHYSIOLOGY   An increase in the amount of fluid within the pericardial sac results in an increase in intrapericardial pressure. The normal fibrocollagenous parietal pericardium has elastic properties and stretches to accommodate increases in intrapericardial fluid. The initial portion of the pericardial volume-pressure curve is flat: relatively large increases in volume result in comparatively small changes in intrapericardial pressure. The curve becomes steeper as the parietal pericardium reaches the limits of its distensibility. If fluid continues to accumulate, intrapericardial pressure rises to a level greater than that of the normal filling pressures of the right heart chambers. When this occurs, ventricular filling is restricted and results in cardiac tamponade. The point at which this occurs is determined by the slope of the pericardial volume-pressure curve, which is dependent on the rate of fluid accumulation, pericardial compliance (a thickened parietal pericardium is less distensible), and intravascular volume (hypovolemia lowers ventricular filling pressure). [18] Common causes of cardiac tamponade in nontrauma patients are listed in Table 51-8. [21,22 and 23]

Cause	Approximate Frequency, %
Metastatic malignancy	40
Acute idiopathic pericarditis	15
Uremia	10
Bacterial or tubercular pericarditis	10
Chronic idiopathic pericarditis	10
Hemorrhage (anticoagulant)	5
Other (systemic lupus erythematosus, postradiation, myxedema, etc.)	10

TABLE 51-8   Cardiac Tamponade in Medical (Nontrauma) Patients

CLINICAL FEATURES AND DIAGNOSIS   Symptoms are nonspecific, and patients most commonly complain of dyspnea and profound exertional intolerance. Additional complaints may be present due to the underlying disease (e.g., uremia) or if the pericardial effusion has developed gradually (e.g., tuberculous pericarditis). Such symptoms may include weight loss, pedal edema, ascites, and so on.

Physical examination most commonly reveals tachycardia and low systolic arterial blood pressure with a narrow pulse pressure. Pulsus paradoxus may also be present. A paradoxical arterial pulse is said to be present when the cardiac rhythm is regular and there are apparent dropped beats in peripheral pulse during inspiration. There is usually a greater than 10-mmHg decrease in systolic blood pressure during inspiration in the supine position. A value greater than 25 mmHg usually separates true tamponade from lesser degrees of restricted cardiac filling. [24] Pulsus paradoxus occurs because there is an inspiratory decrease in LV filling secondary to the dominance of inspiratory right heart filling within the confined intrapericardial space. Pulsus paradoxus is not diagnostic of cardiac tamponade and may be noted in other cardiopulmonary processes, as listed in Table 51-6. The neck veins are usually distended with an absent *y* descent. The apical impulse is indistinct or tapping in quality. Cardiac auscultation may reveal "distant" or soft heart sounds. Pulmonary rales are usually absent, and there may be right upper quadrant tenderness due to hepatic venous congestion.

The chest x-ray may or may not reveal an enlarged cardiac silhouette, and this finding is dependent on the amount of intrapericardial fluid accumulation. The pulmonary vasculature typically appears normal. An epicardial fat-pad line, or sign, may occasionally be seen within the cardiac silhouette.

The ECG usually shows low-voltage QRS complexes (less than 0.7 mV) and ST-segment elevation (due to the inflammation of the epicardium) with PR-segment depression, as in pericarditis. Electrical alternans (beat-to-beat variation in the amplitude of the P and R waves unrelated to the respiratory cycles) is a classic but uncommon finding (about 20 percent of cases). Electrical alternans is demonstrated in Fig. 51-2.

FIG. 51-2. This rhythm strip *(lead II, top tracing)* and plethysmograph *(bottom tracing)* were recorded in a patient who presented with dyspnea, hypotension, and clinical and echocardiographic evidence of cardiac tamponade. A paradoxical pulse was noted on palpation of the radial artery. The amplitude of the R waves varies from beat to beat (electrical alternans). Similar changes are seen in P-wave amplitude. These ECG changes are not related to the respiratory cycle.

The diagnosis should be suspected based on the clinical examination and chest x-ray findings. Echocardiographic assessment is the diagnostic test of choice. In addition to a large pericardial fluid volume, typical echocardiographic findings described in cardiac tamponade are listed in Table 51-9. [25]

Right atrial compression

Right ventricular diastolic collapse

Abnormal respiratory variation in tricuspid and mitral flow velocities
 (Doppler)

Dilated inferior vena cava with lack of inspiratory collapse

TABLE 51-9 Echocardiographic Findings in Cardiac Tamponade

TREATMENT AND DISPOSITION   Volume expansion with a bolus of normal saline solution (500 to 1000 mL) will increase intravascular volume, facilitate right heart filling, and increase cardiac output and arterial pressure. However, it is a temporary measure, and patients will require pericardiocentesis as initial definitive therapy and for diagnostic evaluation.

Pericardiocentesis should be performed under optimal circumstances, usually within the cardiac catheterization laboratory using echocardiographic guidance. The major potential complications, namely, cardiac perforation and coronary artery laceration, can be minimized. In addition, a pigtail catheter can be inserted to allow continuous fluid drainage and prevention of fluid accumulation.

Pericardiocentesis must be performed within the emergency department if dictated by hemodynamic instability. The subxiphoid approach with the patient sitting at a 45° angle is the preferred technique. A 16- to 18-gauge spinal needle is inserted between the xiphoid process and the left costal margin at a 30 to 40° angle to the skin. The needle is directed toward the right shoulder and continuous negative pressure applied to the syringe until fluid is withdrawn. Due to the shape of the pericardial volume-pressure curve, removal of only a small volume of fluid (e.g., 50 mL) can result in dramatic hemodynamic improvement. If time permits and the equipment is available, the V lead of an ECG monitor electrode can be attached to the needle using an alligator clip or Harrison adapter to detect epicardial contact (ST-segment elevation) as the needle is advanced beneath the skin.

If the equipment is available, echocardiographically guided emergency pericardiocentesis can be performed in the emergency department. Definitive management (insertion of an intrapericardial pigtail catheter through a pericardial window) is best undertaken following admission. After pericardiocentesis, patients require admission in a monitored setting.

Constrictive Pericarditis

PATHOPHYSIOLOGY   Constrictive pericarditis is pathologically distinct from acute pericarditis.[18] Following pericardial injury and the resultant inflammatory and reparative process, fibrous thickening of the layers of the pericardium may occur. This fibrous reparative process is most commonly encountered after cardiac trauma with intrapericardial hemorrhage, after pericardiotomy (open-heart surgery, including coronary revascularization), in fungal or tuberculous pericarditis, and in chronic renal failure (uremic pericarditis). When the fibrous and/or collagenous response prevents passive diastolic filling of the normally distensible cardiac chambers, constriction is said to be present. Intrapericardial fluid is not required to produce such a hemodynamic effect. By its nature, constrictive pericarditis is most commonly a clinically chronic process. However, clinical manifestations may occur early if fluid also accumulates within the thickened, noncompliant pericardial sac (so-called effusive constrictive pericarditis). In the vast majority of cases of constrictive pericarditis, proved by hemodynamic assessment (see below), a specific cause is never determined.

CLINICAL FEATURES   The symptoms of constrictive pericarditis usually develop gradually and may mimic those of CHF and restrictive cardiomyopathy.[11] If symptoms develop within months of a pericardial injury, a combination of pericardial effusion and constriction should be suspected. Exertional dyspnea and decreased exercise tolerance are common complaints; however, orthopnea, paroxysmal nocturnal dyspnea, and chest pain are unusual. Lower-extremity swelling (pedal edema) and increasing abdominal girth (ascites) are also common complaints and are the result of decreased RV diastolic compliance and the resultant increase in systemic venous pressure.

In most instances, physical findings and their correct interpretation will lead the clinician to suspect constrictive pericarditis.[18] Examination of the neck veins with the torso of the patient at a 45° angle from horizontal will reveal jugular venous distention and a rapid y descent of the cervical venous pulse. Elevated venous pressure is also seen in CHF, but a rapid y descent is infrequently encountered. The Kussmaul sign (inspiratory neck vein distention) is frequently but not invariably noted in constrictive pericarditis but rarely noted in uncompensated CHF. A paradoxical pulse is found in a minority of patients, and thus its absence does not exclude a diagnosis of constrictive pericarditis. On cardiac auscultation, an early diastolic sound, a pericardial "knock," may be heard at the apex 60 to 120 ms after the second heart sound. The pericardial knock sounds like a ventricular gallop but occurs earlier than the S $_3$ of CHF, which it may mimic. The knock is due to accelerated RV inflow in early diastole and early myocardial distention, followed by an abrupt slowing of further ventricular expansion. There is usually no pericardial friction rub. Hepatomegaly, ascites, and dependent edema of varying severities are usually found.

DIAGNOSIS **Electrocardiogram**   Diagnostic ECG changes have not been described in constrictive pericarditis. However, low-voltage QRS complexes and inverted T waves are common.

Radiographic Assessment   Conventional posteroanterior and lateral chest x-rays most commonly demonstrate a normal or slightly enlarged cardiac silhouette, clear lung fields, and little or no evidence of pulmonary venous congestion. Pericardial calcification, which may be evident in up to 50 percent of patients with constrictive pericarditis, is seen best on the lateral chest x-ray but is not diagnostic of constrictive pericarditis.

Echocardiographic Studies   On occasion, two-dimensional echocardiography may demonstrate pericardial thickening and abnormal ventricular septal motion in a patient with suspected constrictive pericarditis. However, its diagnostic utility is much less than in a patient with acute pericarditis. Doppler echocardiography is preferred, and cardiac computed tomography and magnetic resonance imaging may also be useful.

TREATMENT AND DISPOSITION   In cases of significant constriction and impaired ventricular filling, pericardiectomy is the treatment of choice.

52 Pulmonary Embolism

Charles N. Schoenfeld

Pulmonary embolism (PE) is difficult to diagnose. It has a significant mortality, especially if not recognized in a timely fashion, but lacks a typical presentation. Only with a high index of suspicion and knowledge of predisposing risk factors, coupled with an understanding of the limitations of the diagnostic tests used, can the clinician reliably confirm or exclude the disease and initiate timely and appropriate therapy.

EPIDEMIOLOGY

The incidence of PE in the United States is estimated to be 650,000 cases per year; with over 200,000 patients dying each year, PE is the third leading cause of death. Approximately one-third of these deaths occur within the first hour and over 16,000 patients die despite treatment. Overall mortality ranges from 2 to 10 percent in patients treated for PE and from 20 to 30 percent in those with unrecognized PE. More than 50 percent of fatal PE is diagnosed at autopsy. [1] PE is more common in males than females before the age of 50; this gender difference disappears in older age groups. PE is the most common cause of nonsurgical maternal death in the peripartum period. Pregnant women over the age of 40 and those of African-American descent are at highest risk. [2]

The overwhelming majority of PEs are caused by thromboemboli. In situ pulmonary artery thrombosis is rare. When sought, deep venous thrombosis (DVT) of the lower extremities proves to be the source of 80 to 90 percent of cases.[3] DVT of the upper extremity has been reported to cause 10 to 15 percent of PE, especially if associated with indwelling central venous catheters. [4] Other sources of PE include pelvic vein thrombosis, right heart thrombosis, and amniotic or fat emboli. Septic emboli—associated with valvular vegetations in right-sided endocarditis, infected central venous catheters, and septic thrombphlebitis from intravenous drug use (IDU)—present unique diagnostic and therapeutic challenges.

PATHOPHYSIOLOGY

In the presence of predisposing factors (Table 52-1), clot forms in the deep venous system. Thrombosis usually begins at venous valve sinuses and propagates proximally over minutes to hours. Lysis of the clot generally occurs over 1 to 2 weeks. The risk of embolization is highest in the first week of thrombus formation.

Immobilization	Burns
Hospitalization/bed rest	History of DVT or PE
Stroke/spinal cord injury	Hypercoagulable states
Prolonged travel	Pregnancy
Recent surgery	Protein C deficiency
Trauma (especially lower extremity, pelvis)	Protein S deficiency
	Antithrombin III deficiency
Obesity	Malignancy
Cardiac disease	Estrogen therapy

TABLE 52-1   Predisposing Factors for Thromboembolic Disease

The pathophysiologic effects of PE are caused both by mechanical obstruction of the pulmonary arterial system and by the release of vaso- and bronchoactive mediators. Mechanical obstruction produces the clinical picture of acute cor pulmonale. The trigger for the release of chemical mediators is platelet degranulation in the lung. These mediators—prostaglandins, catecholamines, serotonin, and histamine—cause bronchoconstriction as well as pulmonary artery vasoconstriction. This results in an overall reduction in lung compliance. Vasoconstriction is the predominant effect, leading to a ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch. Vasoconstriction may be severe enough to cause pulmonary hemorrhage or infarct, producing an infiltrate on the chest radiograph. The infiltrate of pulmonary hemorrhage usually resolves in 1 to 2 weeks, while that of infarct may take months to disappear. [5]

PE tend to be multiple and bilateral, with the right lower lobe of the lung being the most commonly involved lung segment. Angiographic evidence of PE generally resolves in 1 to 4 weeks and pulmonary artery (PA) pressure usually normalizes within a month. If the PE fails to resolve, chronic cor pulmonale may occur.

CLINICAL FEATURES

Predisposing Factors

PE usually results from DVT, and DVT occurs because of predisposing risk. Thus, patients at risk for DVT are at risk for PE. Venous stasis, hypercoagulability, and endothelial damage—Virchow's triad—are well-recognized factors favoring the development of DVT. Table 52-1 lists the commonly recognized risk factors for DVT and PE. The majority of patients with PE will have at least one risk factor, with immobilization being the most prevalent. [6] While a minority of patients may not have clinically evident risk factors at presentation, they will generally be found to have abnormalities of coagulation or occult cancer on further evaluation. IDU may cause septic or aseptic thrombophlebitis by extension from superficial phlebitis, external compression by and septic extension from a perivascular abscess, or direct injection into the deep venous system. In addition, agents contaminating illicit drugs, such as talc and bacteria, have direct thrombogenic properties.

Clinical Presentation

There is no typical presentation of PE. The classic triad of dyspnea, hemoptysis, and pleuritic chest pain occurs in less than 20 percent of patients. Table 52-2 lists the frequency of symptoms and signs found in patients with angiographically proven PE. [5] Chest pain (usually pleuritic) and dyspnea were the only symptoms and tachypnea (respirations >16/min) was the only sign occurring with sufficient frequency to be clinically useful. The absence of any of these three findings is strong though inconclusive clinical evidence in excluding the diagnosis of PE. The presence of any of these, especially in association with predisposing risks for DVT, must

raise the index of suspicion for PE if no other cause is found.

TABLE 52-2   Symptoms and Signs of 327 Patients With Angiographically Proven PE

PE may present as syncope or near-syncope in 10 to 15 percent of cases and should be considered in the differential diagnosis of this presenting complaint. [5,7] Altered mental status, especially in the elderly, may be the presenting complaint, as may be generalized seizures. Anxiety, a diagnosis of exclusion in all emergency department (ED) patients, occurs in more than 50 percent of patients with PE.[5]

Physical Examination

The physical findings in patients with PE are as varied and nonspecific as the clinical presentations. Vital signs reveal tachypnea (RR > 16/min) in over 90 percent of cases, while tachycardia (PR > 100/min) and fever (>37.8°C) occur in less than 50 percent. [5] Blood pressure may be elevated, normal, or low.

Depending on the extent of the PE and preexisting cardiopulmonary disease, the patient may appear to be in no apparent distress or be found to be anxious, diaphoretic, or dyspneic. Cyanosis is uncommon, generally signifying massive PE or underlying cardiopulmonary disease.

Findings of acute right heart dysfunction—neck vein distention, accentuation of the pulmonic heart sound, and right parasternal heave—may occur in massive and submassive PE. Chest exam reveals a pleural friction rub in less than 20 percent of cases. Rales are a more common but less specific finding. Localized wheezes are suggestive of PE but uncommon. Clinical evidence of DVT occurs in less than 50 percent of patients. However, up to 80 percent of patients with PE have positive venography.[3]

CLASSIFICATION OF PE

Patients with PE are characterized as having massive or submassive PE. Massive PE presents in dramatic form, including hypotension and hypoxemia, which may be refractory to therapy. In general, 40 to 50 percent of the pulmonary arterial circuit must be occluded to produce these effects. Patients with preexisting cardiac or pulmonary disease may show the signs of massive PE with lesser degrees of occlusion. Massive PE accounts for approximately 5 percent of all PE but has a mortality of about 40 percent.

Submassive PE presents with normal systemic hemodynamics and hypoxemia, which is correctable with supplemental oxygen. Mortality is low (about 2 percent) if the diagnosis is made and therapy initiated. Failure to make the diagnosis and treat accordingly increases the mortality 10-fold.

A subset of patients with submassive PE warrants special mention. These patients, while having normal systemic pressures on presentation, have evidence of moderate to severe right ventricular dysfunction by physical exam or echocardiography. If not treated, this dysfunction may progress to right ventricular infarction, leading to hypotension and death. Lungs scans reveal perfusion defects of more than 30 percent of the pulmonary circuit. More aggressive therapy than simple anticoagulation may be warranted in this set of patients. [8,9]

DIAGNOSIS

Establishing or excluding the diagnosis of PE is a challenge requiring the synthesis of clinical suspicion, awareness of predisposing risk factors, and the interpretation of diagnostic studies utilizing pretest probability of PE. While only a negative pulmonary angiogram excludes the diagnosis of PE, [10] this test is required only when sufficient doubt about the diagnosis or contraindications to empiric therapy exist. [11]

Unexplained chest pain, dyspnea, or tachypnea should always raise the question of PE as the cause. If these findings occur in a patient at risk for thromboembolic disease the diagnosis of PE must be strongly considered. All patients with chest pain, dyspnea, or tachypnea not explained by the history or physical exam should undergo screening tests, including an electrocardiogram (ECG), chest x-ray (CXR), and arterial blood gas (ABG) analysis.

Electrocardiography

The most common ECG abnormality in PE is nonspecific ST-T wave changes, seen in more than 40 percent of patients. T-wave inversions in the precordial leads mimicking subendocardial infarction may be seen in massive PE. Other ECG changes include new right bundle branch block, p-pulmonale, S1Q3T3 pattern, and clockwise axis rotation.

Sinus tachycardia is the most common rhythm disturbance, although atrial fibrillation or flutter may occur. [7] There is no diagnostic pattern of PE on the ECG. The greatest utility of the ECG is to exclude disorders such as pericarditis or myocardial infarction.

Chest X-ray

The initial CXR is normal in nearly one-third of patients with PE. [7] A normal CXR in the setting of dyspnea and hypoxemia without evidence of reactive airway disease is strongly suggestive of PE.[12] The overwhelming majority of patients will develop some CXR abnormality during the course of their disease. [13] Infiltrate or atelectasis will appear in nearly 50 percent, while an elevated hemi-diaphragm occurs in about 40 percent, often in association with a pleural effusion. [7]

The classically described Hampton hump, a pleural-based wedge-shaped infiltrate, is uncommon. The Westermark sign, relative oligemia distal to engorged pulmonary arteries, may be seen in patients with massive PE (Fig. 52-1). The CXR is of greatest utility in ruling in other causes of the patient's complaints, such as pneumothorax or pneumonia. It is essential for the subsequent interpretation of lung scans and pulmonary arteriograms.

FIG. 52-1. Westermark sign: AP CXR demonstrating relative oligemia in right upper lobe and dilated proximal pulmonary artery.

Arterial Blood Gas

Hypoxemia occurs in about 90 percent of patients with PE, but the Pa_{O_2} may be normal. While a Pa_{O_2} of 80 to 90 mmHg is 90 to 95 percent sensitive in identifying patients with PE, it is less than 50 percent specific. [5] Further, the degree of hypoxemia fails to accurately predict the size of the PE. [5] However, a Pa_{O_2} of less than 70 mmHg not explained by findings on the CXR strongly suggests PE. The calculation of the alveolar-arterial (A-a) oxygen gradient may be useful in reducing the suspicion of PE if it and the Pa_{CO_2} are both normal.[14]

$$\text{A-a gradient } 5 \; [(F_iO_2) \times (\text{barometric pressure} - 47)]$$
$$- \; [(1.2) \times (Pa_{CO_2})] - (Pa_{O_2})$$

However, the A-a gradient has been shown to be normal in nearly 25 percent of patients with PE [15] and should never be used alone to exclude the diagnosis. The A-a gradient has been shown to be even less useful in the elderly. [16] These screening tests (ECG, CXR, and ABG) are most useful in defining the patient's complaints to be caused by diseases other than PE. A normal ECG, presenting CXR, Pa_{O_2}, Pa_{CO_2}, and A-a gradient cannot be used to exclude the diagnosis of PE in patients at risk for thromboembolic events. In this subset of patients, a number of additional tests are used to increase or decrease the clinical suspicion of PE.

Biochemical Tests

A variety of biochemical tests have been studied as aids in the confirmation or exclusion of the diagnosis of PE. The combination of elevated lactate dehydrogenase (LDH) and bilirubin in association with a normal serum glutamic oxaloacetic transaminase has long been recognized as insufficiently sensitive or specific. The absence of fibrinopeptide A in the urine combined with a low-probability lung scan may be useful in excluding PE but needs further study. [17] Plasma DNA measurements have received variable acceptance in the diagnosis of PE.

Measurement of serum levels of dimerized plasmin fragment D (D-dimer) is considered by many to have utility in excluding the diagnosis of PE. D-dimer is a sensitive but nonspecific indicator of thromboembolic disorders, and a level less than 500 U/mL is strong evidence against thrombosis (negative predictive value of about 90 percent). Recent reviews question the utility of this test in excluding PE, since results are highly dependent on the assay used and have a high incidence of false positives. At the present time there is no biochemical test, alone or in combination, that possesses sufficient sensitivity and specificity to allow the confirmation or exclusion of the diagnosis of PE.

Imaging Studies

Echocardiography, either transthoracic or transesophageal, may demonstrate right atrial, right ventricular, or proximal pulmonary arterial emboli. If right ventricular dysfunction is present in combination with normal systemic hemodynamics the need for careful monitoring and consideration of more aggressive therapy is suggested.[18] Transesophageal echocardiography is also useful in excluding thoracic aortic dissection as well as detecting massive PE in transit in hemodynamically unstable patients.[18,19] The ability to perform these tests at the bedside is especially useful in critically ill patients.

Other studies are used to detect DVT in the lower extremities, since the treatment of DVT and hemodynamically stable PE is the same. Noninvasive studies such as duplex ultrasonography (DUS) and impedance plethysmography (IPG) have largely replaced invasive contrast venography, although this last test remains the "gold standard." Using the criteria of vein compressibility, DUS is 95 to100 percent sensitive and more than 95 percent specific in diagnosing proximal DVT. Both IPG and DUS are insensitive in detecting DVT below the knee, but PE from this site is rare without proximal propagation. If DVT is strongly suspected and DUS or IPG are negative, serial exams are needed to detect extension of thrombus into the ileofemoral system.

$\dot{V}/\dot{Q}$ scans of the lung often raise more questions than they answer. Although they are commonly used to diagnose or exclude PE, they have been shown to be reliable only at the extremes of interpretation—normal or high probability. All other results require further investigations to confirm or exclude PE, depending on the à priori probability.

One of the difficulties in interpreting $\dot{V}/\dot{Q}$ scans is that they are reported as "probabilities" rather than normal or abnormal. This probability must then be judged based on the clinical suspicion for PE. Table 52-3 shows an interpretation of $\dot{V}/\dot{Q}$ probabilities based on PIOPED data.[20] This demonstrates that a high-probability scan (Fig. 52-2*A* and Fig. 52-2*B*) is only 80 percent accurate in diagnosing PE, while a low-probability result is only 20 percent accurate in excluding the diagnosis. Overall, $\dot{V}/\dot{Q}$ scans are 98 percent sensitive but only 10 percent specific in the diagnosis of PE. [10] Infiltrate on CXR, preexisting cardiopulmonary disease, and previous PE all increase the rate of false-positive results.

A. Ventilation - Equilibrium phase   B. Perfusion - Anterior View   C. Perfusion - RAO view

FIG. 52-2. High-probability $\dot{V}/\dot{Q}$ scan of patient whose CXR is shown in Fig. 52-1. **A.** Ventilation, equilibrium phase, demonstrates no ventilation defect. Washout phase demonstrated no air trapping. **B.** Perfusion, anterior. **C.** Right anterior oblique projections show multiple segmental defects. Note absence of flow to right upper lobe.

TABLE 52-3   Definition of $\dot{V}/\dot{Q}$ Scan Probabilities

Combining $\dot{V}/\dot{Q}$ results with the degree of clinical suspicion for PE has been shown to increase the accuracy of the test. [10] The combination of a low-probability scan with a low clinical suspicion has a 96 percent predictive value for the exclusion of PE, while a high-probability scan in the setting of high clinical suspicion has a 96 percent positive predictive value. The presence or absence of PE in this study was confirmed by pulmonary arteriography. Unfortunately, only a minority of patients (174 out of 887) in the PIOPED study were found to have the diagnosis of PE confirmed or excluded by the combination of pretest probability and $\dot{V}/\dot{Q}$ results. [10]

Further difficulty arises in defining "clinical suspicion." While most authors use the terms *high, moderate,* or *low* suspicion and some studies even assign a percent probability, no universally accepted diagnostic algorithm is available. The presence or absence of risk factors predisposing to the development of DVT is of prime importance, although unrecognized risk factors (e.g., occult cancer, deficiency of protein C or S) may exist in a given patient. The existence of unexplained symptoms of chest pain and dyspnea or signs such as tachypnea should raise the index of suspicion for PE. Findings of DVT, an elevated A-a gradient unexplained by exam or CXR, and the presence of a Westermark sign are all strong predictors of PE.

Spiral computed tomography (CT) compared favorably to pulmonary arteriography in one study, with an overall sensitivity of 82 to 90 percent and specificity of 93 to 96 percent. Accuracy was lowest in the setting of subsegmental PE. [21] Magnetic resonance imaging (MRI) angiography has reported sensitivity of 75 to 100 percent and specificity of 95 to 100 percent in PE proven by pulmonary arteriography. [22] It is of limited utility in unstable patients, however.

Pulmonary arteriography remains the standard by which all other studies are judged. A negative study reliably excludes the diagnosis of PE. [7,10] It should be obtained when clinical suspicion for PE is high and other studies ($\dot{V}/\dot{Q}$ scans, tests for leg DVT) are inconclusive or likely to produce false-positive results. It is often used prior to the initiation of thrombolytic therapy but is not necessary. Indeed, it increases the risk of bleeding complications in these patients. [18] Pulmonary arteriography has a mortality rate up to 0.5 percent and morbidity of 4 percent. These complications may be reduced by the use of selective angiography.

Diagnostic Approach

Suspect PE in a patient presenting with unexplained chest pain, dyspnea, tachypnea, syncope, or shock. Figure 52-3 is an algorithm for the approach to patients with suspected PE.

**FIG. 52-3. A.** Evaluation of stable patients with suspected PE.
*Refer to text and Chap. 55.
†Refer to text.
B. Further evaluation of patients with suspected PE whose earlier tests have been negative.
*Perform these studies only if not previously obtained.
†The clinician may proceed directly to pulmonary arteriography depending on local availability and practice.

Historical evidence of risk for DVT, physical findings suggestive of DVT or PE and findings from ECG, CXR, and ABG are used to determine a pretest probability of PE.

Patients whose signs and symptoms remain unexplained should undergo further diagnostic evaluation, taking into account their clinical stability (Fig. 52-3). Stable patients should be studied for leg DVT (DUS, IPG, or venography) or PE ($\dot{V}/\dot{Q}$ scan). If DVT is confirmed, the patient should be admitted for anticoagulation therapy.

If a $\dot{V}/\dot{Q}$ scan is of high probability and clinical suspicion for PE is high, admission for anticoagulation is warranted. If the $\dot{V}/\dot{Q}$ scan is of low probability and the pretest suspicion also low, another diagnosis should be sought. A normal $\dot{V}/\dot{Q}$ scan reliably excludes PE regardless of clinical suspicion. All other combinations of $\dot{V}/\dot{Q}$ probabilities and clinical suspicion require further evaluation, whether pulmonary angiography, spiral CT, or MRI angiography.

For unstable patients suspected of having PE, transthoracic or transesophageal echocardiography is especially useful. Evidence of proximal pulmonary artery emboli or right ventricular embolus in transit is sufficient evidence to justify thrombolytic therapy without pulmonary angiography. [18] Echocardiography has the additional benefit of identifying patients with acute right ventricular dysfunction and normal systemic hemodynamics—a group at risk for catastrophic clinical deterioration. Sending an unstable patient to the nuclear medicine or angiography suite is potentially hazardous, requires intensive nursing and physician support, and should be done only as a last resort.

TREATMENT

All patients with significant chest pain, dyspnea, or tachypnea should receive cardiac monitoring, intravenous access, and supplemental oxygen while their evaluation proceeds. Failure to correct hypoxemia with supplemental oxygen may necessitate endotracheal intubation in order to provide a higher F_IO_2 directly. Shock in the absence of pulmonary edema should be treated with aggressive intravenous administration of crystalloid. If vasopressors are required, dopamine is considered the drug of choice in PE.

Stable patients with PE are treated with anticoagulant (AC) therapy. After obtaining baseline coagulation studies, intravenous heparin is administered first as a bolus

(either 5000 U or 80 U/kg) and then as a constant infusion (1280 U/h or 18 U/kg per hour). Dosing of heparin based on the patient's weight is preferred, as it is less likely to produce subtherapeutic levels. The activated partial thromboplastin time (aPTT) is measured every 6 h, altering the heparin infusion, until a stable aPTT of 50 to 90 s is achieved; it is then checked daily. After 24 h of heparin, oral warfarin is begun at 5 to 10 mg/day and the prothrombin time (PT) is checked daily. Warfarin administration is best delayed owing to an initial hypercoagulability effect of reducing protein before reduced prothrombin levels are achieved. The dose is adjusted until PT measurements show a stable International Normalized Ratio (INR) of between 2 and 3 (or PT of 1.5 to 2.5 times control). Heparin and warfarin therapy should overlap for at least 4 days. Patients should continue warfarin therapy for at least 3 months, with monitoring of the PT. Low-molecular-weight heparin (LMWH) has been shown to be as safe and effective as unfractionated heparin,[23] allows for twice daily subcutaneous administration, and precludes the need for aPTT measurements. For these reasons many consider LMWH preferable in the treatment of DVT and PE. Chapter 216 discusses the major complication of AC therapy and their treatment.

Thrombolytic therapy is used in patients with massive PE associated with refractory hypoxemia or circulatory collapse. It should also be considered for patients with moderate to severe right ventricular dysfunction, since they may progress to circulatory collapse. Urokinase (4400 U/kg load followed by 4400 U/kg per hour by infusion for 12 to 24 h), streptokinase (250,000 U load followed by 100,000 U/h infusion for 24 h) and recombinant tissue plasminogen activator (r-tPA) at 100 mg over 2 h have all been shown to be effective in normalizing pulmonary artery pressures, improving right ventricular function, correcting hypoxemia, and improving systemic hemodynamics. However, r-tPA has been shown to be fastest in improving these parameters. Beneficial effects may be seen with thrombolytic therapy up to 2 weeks after the PE is activated, although the effects are greatest early in the course of the disease.[24] Therapy with heparin and warfarin is begun after the thrombolytic infusion is completed. Intrapulmonary artery infusion is no more effective than peripheral intravenous administration, and the risk of bleeding at the site of pulmonary artery catheter placement is high. The use of thrombolytics has largely replaced embolectomy in unstable patients.

Septic emboli, whether from indwelling central venous catheters or associated with IDU, represent a diagnostic and therapeutic challenge. Septic DVT requires not only appropriate AC therapy but also antibacterial or antifungal treatment. Removal or drainage of septic foci, whether due to an intravenous catheter or an abscess cavity, must be accomplished. In some circumstances surgical removal of an infected vein segment is required. AC therapy of septic PE from right-sided endocarditis is controversial, since heparin administration in endocarditis is associated with a higher incidence of intracranial hemorrhage.

Patients with recurrent PE despite adequate AC therapy or those with contraindications to AC therapy may require interruption of the inferior vena cava. Transvenous placement of a Greenfield (umbrella) filter is most commonly used for this.

DISPOSITION

All patients with known PE should be admitted for close monitoring and AC or thrombolytic therapy. Patients strongly suspected of having PE should be admitted if the diagnosis cannot be rapidly confirmed. Generally, the patient should be admitted to the service of an internist, pulmonologist, or cardiologist. A radiologist must be consulted to arrange and interpret invasive and noninvasive leg studies for DVT, $\dot{V}/\dot{Q}$ scans, spiral CT, MRI, and pulmonary arteriograms. Consultation with a thoracic surgeon is necessary if pulmonary embolectomy is contemplated.

The decision to initiate AC therapy prior to establishing the diagnosis of PE should be made in consultation with the admitting physician. The clinical situation and degree of suspicion for PE dictate this decision. AC therapy should be continued for at least 3 months in patients with first-time PE. Recurrent PE may dictate the need for chronic AC therapy.

53 HYPERTENSION

Melissa M. Wu
Arjun Chanmugam

Hypertension is considered one of the most important modifiable risk factors for cardiovascular disease and is the fourth most prevalent chronic medical condition in the United States.[1,2] Up to 24 percent of the United States general adult population and 32 percent of African Americans may be affected by hypertension.[3]

Overall morbidity and mortality rates, and, in particular, the risk of developing serious cardiovascular, renal, or cerebrovascular disease increase with poorly controlled blood pressure. Although the public has become more knowledgeable, only two-thirds of Americans with high blood pressure are aware of their diagnosis. Of greater concern is that nearly 75 percent of adult Americans with hypertension are not controlling their blood pressure to below 140/90 mmHg, and only half are taking their prescription medications as directed.[1,3] Accordingly, elevated blood pressure is frequently encountered in many emergency department (ED) patients.

The primary responsibilities of emergency physicians in the approach to hypertensive patients are to recognize and treat true emergencies, to manage the complications of chronic disease, and to arrange the most appropriate follow-up for nonemergent cases. To fulfill these responsibilities, emergency physicians need to have an understanding of the definitions, pathophysiology, and pharmacotherapy of hypertension.

CLASSIFICATION

Among individuals, a wide variation in blood pressures occurs along a continuum from normotensive to hypertensive. In an effort to standardize terminology, the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure developed a consensus regarding the definition of hypertension, which includes a graded classification dependent on risk factors and clinical condition (Table 53-1).[1] In general, either a systolic blood pressure (SBP) greater than 140 mmHg or a diastolic blood pressure (DBP) greater than 90 mmHg constitutes hypertension. However, management of hypertension depends more on the individual's clinical condition rather than the absolute systolic or diastolic values. In the ED, it is helpful to consider four general categories for the management of high blood pressure.

Category	Systolic Blood Pressure (mmHg)	Diastolic Blood Pressure (mmHg)
Optimal	< 120	<80
Normal	<130	<85
High-normal	130–139	85–89
Hypertension		
Stage 1	140–159	90–99
Stage 2	160–179	100–109
Stage 3	≥180	≥110

Note: When systolic and diastolic pressures fall into different categories, the higher category should be used to classify the individual's blood pressure status.

TABLE 53-1   Classification of Blood Pressure for Adults Aged 18 Years and Older

Hypertensive emergencies are those situations that require immediate blood pressure reduction to prevent or limit damage to target organs (i.e., brain, eyes, heart, or kidneys). The terms *malignant hypertension* or *hypertensive crisis* may also be used to refer to this category. Target-organ damage occurs in syndromes such as hypertensive encephalopathy, intracranial hemorrhage, acute left ventricular failure with pulmonary edema, unstable angina pectoris, acute myocardial infarction, dissecting aortic aneurysm, and eclampsia.[1] A hypertensive emergency is not defined by any absolute pressure measurements but, instead, is contingent on the presence of relative blood pressure increases combined with injury to any of the so-called target organs. In fact, a patient with a low baseline pressure can present with "normal" or mildly elevated pressure and be considered to have a true hypertensive emergency, if there is evidence of concurrent related central nervous system (CNS), cardiovascular, or renal dysfunction.

The treatment goal in hypertensive emergency is the immediate reduction of mean arterial pressure (MAP = [1/3(SBP-DBP) + DBP]) in a controlled, graded manner, using improvement in the patient's condition as a guide. Blood pressures should not exceed a 20 to 25 percent reduction within the first 30 to 60 min. Although hypertensive emergencies are the most serious complications of hypertension, they occur in only 1 percent of all hypertensive patients.

Hypertensive urgency is less clearly defined in the literature. Most sources concur that hypertensive urgency occurs when the blood pressure elevation presents a risk for imminent target-organ damage. Although acute organ injury has not yet occurred in hypertensive urgency, the risk of injury is high if the elevated blood pressure is allowed to persist. In many cases of hypertensive urgency, elevated blood pressure in the presence of preexisting conditions (e.g., renal insufficiency, congestive heart failure, coronary artery disease, or CNS disorders) increases the likelihood of target-organ damage. As with hypertensive emergencies, in hypertensive urgencies, relative increases in blood pressure are more important than absolute values. The main challenge for the clinician is determining whether the asymptomatic hypertensive patient is experiencing a hypertensive urgency. The first priority in recognizing this condition is to determine whether target-organ dysfunction exists. If dysfunction does not exist, the clinician must determine whether damage to the CNS, cardiovascular, or renal system is impending, given the elevated blood pressure and relevant past medical history. If target-organ dysfunction exists, the emergency physician must identify whether the end-organ dysfunction is chronic and at risk of acute further impairment, or whether the dysfunction is acute and related to the hypertension (i.e., then to be considered an emergency rather than an urgency). This may be difficult without knowledge of the patient's past medical history, including prior laboratory values and clinical findings. In many cases, the clinician may be obligated to initiate antihypertensive treatment without being certain of the diagnostic classification.

The treatment goal in hypertensive urgencies is the gradual reduction of blood pressure within 24 h by using oral antihypertensive agents, although the recommended duration to reduce the blood pressure varies in the literature from a few hours to 48 h. Because a common cause of hypertensive urgency is noncompliance with medications, restarting a patient on a previously established regime is an acceptable strategy. Any patient with a diagnosis of hypertensive urgency should be started on an antihypertensive medication with follow-up in 24 h. Admission decisions depend on the patient's comorbid conditions, and the clinician's impression of the patient's anticipated response to therapy.

Acute hypertensive (nonemergency/nonurgency) episode occurs when a patient is found to have stage 3 hypertension (Table 53-1; systolic pressure of 180 mmHg or more, and diastolic pressure of 110 mmHg or more) with no signs or symptoms of evolving or impending target-organ damage.[4] Although many of these patients receive treatment in an effort to prevent target-organ damage, there is some controversy regarding the need for immediate treatment. There is evidence to show that in some cases acute interventions may actually be harmful.[4] In chronically hypertensive individuals, complications of acute blood pressure reduction can include altered sensorium, seizures, transient ischemic attacks, and amaurosis and other visual changes. In addition, there is no evidence of a beneficial effect of acute blood pressure reduction on long-term control or on the chronic effects of hypertension. In general, these patients require no acute intervention but should be referred to a primary care physician for follow-up and initiation of therapy. If these patients have previously been diagnosed as hypertensive but have been noncompliant with medications, a reasonable strategy would be to restart the patients on their previous treatment regimen and then refer for appropriate follow-up care within 24 to 48 h.

Transient hypertension occurs in association with other conditions such as anxiety, alcohol-withdrawal syndromes, and some toxicologic substances. One specific type of transient hypertension is *white-coat hypertension*,[5] a phenomenon that occurs when a patient has an elevated blood pressure in a clinical setting but has a normal pressure at other times. White-coat hypertensive patients have elevated pressures only in a medical setting but are normotensive when followed over a 24-hour period with ambulatory blood pressure monitoring. A number of studies have shown that at least 20 percent of newly diagnosed hypertensive individuals are actually normotensive in their normal environment.[5] The cardiovascular morbidity and mortality rates of individuals with white-coat hypertension correlate with their ambulatory blood pressure as opposed to their pressure measurements in the medical setting. Therefore, a single encounter in the ED setting should not be the basis for diagnosis of new-onset hypertension, nor does it constitute an indication to initiate antihypertensive therapy. However, patients do require prompt and close follow-up care for repeat blood pressure testing.

PATHOPHYSIOLOGY

Systemic blood pressure is related to vascular smooth muscle tone. At the cellular level, postsynaptic a_1 and a_2 receptors are stimulated by norepinephrine released from the presynaptic sympathetic nerve ending, ultimately leading to the release of intracellular calcium stores. Calcium release results in smooth muscle contraction via activation of actin and myosin. The increase in smooth muscle tone results in increased peripheral vascular resistance thereby causing increased blood pressure. The presynaptic a_2 receptors, when stimulated by norepinephrine, help to limit this response by preventing further release of norepinephrine through a negative-feedback loop.

There are two major theories to explain how hypertension develops: (1) as a result of alterations in the contractile properties of smooth muscle in arterial walls, or (2) as a response to failure of normal autoregulatory mechanisms. Most individuals with hypertension have elevated peripheral vascular resistance with normal cardiac output. However, some patients may also have elevated cardiac output as a result of increased a-adrenergic and b-adrenergic tone.

The concept of autoregulation is important in the vascular beds of the vital organs, including the heart, kidneys, and brain, but has been most extensively studied in the latter.[6] In the brain, as blood pressure falls, cerebral vasodilation occurs. When blood pressure rises, the autoregulatory response is vasoconstriction, ensuring a stable cerebral blood flow rate among a range of blood pressures. However, autoregulation is effective only within a specific range of blood pressures. Most authorities specify a range of 50 to 150 mmHg for MAP, within which there is effective autoregulation in an uninjured brain. At pressures beyond this narrow range, the limits of autoregulation are breached, and hypoperfusion or hyperperfusion results. In patients with chronically elevated blood pressure, the narrow range at which autoregulation functions is shifted higher. Thus, chronically hypertensive patients can develop symptoms of brain hypoperfusion if their blood pressure is lowered to "normal" levels, because normal levels may be below the limits of the individual's adjusted autoregulation. The lower limit of cerebral autoregulation is based on a patient's baseline MAP and is generally about 25 percent below this baseline.[6]

When poorly controlled blood pressure is allowed to persist long enough, it can cause damage to specific organs and vascular beds. The pathologic change responsible for target-organ damage is fibrinoid necrosis of small arterioles. At a microscopic level, this process begins when vessels in capillary beds dilate in response to an elevated blood pressure that overwhelms the autoregulatory mechanism. The persistently elevated pressures cause injury to the endothelium, leading to increased vascular permeability and vascular wall injury. Eventually, endothelial damage leads to deposition of fibrin within the vessel walls and causes activation of mediators of coagulation and cell proliferation.[7] A recurrent cycle of vascular reactivity develops, with an increased release of vasoconstrictors, endothelial damage, platelet aggregation, myointimal proliferation, and progressive narrowing of arterioles.

Hypertensive retinopathy is traditionally graded into four categories. In grade I, there is minimal diffuse or focal narrowing of arterioles. In grade II, "copper" and "silver" wiring (increased light reflex) is evidence of long-standing uncontrolled hypertension. These are considered relatively mild target-organ effects. In grade III and IV retinopathy, cotton-wool spots (focal ischemia), hard exudates and hemorrhages (vessel leakage), and extensive microvascular changes are seen. Grade IV retinopathy is distinguished by disk edema and defines malignant hypertension or hypertensive crisis. (The term *papilledema* is frequently used, but the disk edema is due to infarction and hypoxia of the optic disk. Thus, the term papilledema is best reserved for disk edema associated with elevated cerebrospinal fluid pressure.) Grade I and grade II retinopathy are evidence of chronic hypertension. Grades III and IV are evidence of accelerated retinopathy particularly in the young. Also grade III and IV changes might not be seen in the elderly. The mechanism of underlying pathology—arteriolar spasm—ultimately leads to degeneration of the muscle of the blood vessel, with subsequent degeneration of the endothelial cells of the vessel lumen. The elderly, who are likely to have arteriosclerotic vessels, are paradoxically protected by the presence of this other pathology.

In the brain, an abrupt, sustained rise in blood pressure exceeding the limits of cerebral autoregulation may be associated with stroke, intracerebral hemorrhage, or hypertensive encephalopathy.[6] Vascular injury caused by an abrupt or persistent elevation in blood pressure may result in ischemia or infarction in vulnerable regions of the brain. Intracerebral bleeding from dilated vessels may result in cerebral or subarachnoid hemorrhage. Hypertensive encephalopathy is characterized by marked vasospasm with ischemia, punctate hemorrhages, and increased vascular permeability all leading to cerebral edema (a mechanism similar to retinopathy). This mechanism is different from localized cerebral edema in the area of ischemic stroke caused by emboli or thrombi. An increase in blood pressure may be a physiologic response to maintain adequate cerebral perfusion to areas distal to the occlusion and may not justify classification as a hypertensive emergency.

In the heart, increased afterload occurring after an acute rise in blood pressure results in increased left ventricular wall tension that, in turn, increases myocardial oxygen demand. Angina or myocardial infarction occurs when hypertension causes a decrease in coronary blood flow relative to an increased demand. Pulmonary edema occurs when the sudden increase in MAP results in elevated end-diastolic pressure and decreased end-diastolic filling volume precipitating acute left ventricular failure.

In the kidneys, impaired autoregulation due to elevated blood pressure results in decreased renal perfusion. Decreased renal perfusion stimulates the renin-angiotensin (I and II) cascade, leading to increased vasoconstriction. If this cycle continues, arteriolar necrosis occurs, ultimately leading to renal impairment. Angiotensin II can exacerbate hypertension not only by causing vasoconstriction but also by stimulating aldosterone secretion to promote sodium retention. Sodium retention induces hypertension in susceptible individuals by a variety of mechanisms, including (1) increased sympathetic nervous system activity; (2) decreased

response to dopamine; (3) change in calcium and potassium metabolism; (4) resistance to insulin; and (5) inappropriate response of renal vasculature and adrenals to angiotensin II.[8]

Hypertension is associated with major cardiovascular risk factors such as smoking, hyperlipidemia, diabetes mellitus, age older than 60 years, gender (men and postmenopausal women), obesity, and a family history of cardiovascular disease.[1] In addition, dietary sodium excess in salt-sensitive individuals (50 percent of hypertensive patients) can induce hypertension. Although no single cause of hypertension has been identified, a combination of factors such as these are believed to contribute to elevated blood pressure.

Although most cases of hypertension are considered to be essential with no known cause, several specific causes do exist. Of the known causes, renal disease is the most prevalent and includes renal arteriostenosis, fibromuscular disease of the renal arteries, chronic pyelonephritis, and nonspecific glomerulonephritis. Coarctation of the aorta, although uncommon, is also an important cause of secondary hypertension and should be suspected in any patient with the triad of upper extremity hypertension, a systolic murmur best heard over the back, and delayed femoral pulses. Another cause of hypertension is excessive glucocorticoids, seen in Cushing syndrome, but usually due to exogenous steroid therapy. Endogenous overproduction is less common but results from excessive adrenocorticotropic hormone (ACTH) production by a pituitary tumor, ectopic ACTH production by a nonpituitary tumor, or glucocorticoid production by tumors of the adrenal cortex. Pheochromocytomas are tumors that produce catecholamines arising from cells of the sympathetic nervous system (most commonly from the adrenal medulla) and account for fewer than 1 percent of cases of hypertension. The characteristic feature of pheochromocytomas is paroxysms of hypertension associated with palpitations, tachycardia, malaise, apprehension, and sweating.[9] Finally, ingestion of foods containing large amounts of tyramine can raise blood pressure by causing release of norepinephrine stored in nerve endings. This normally transient response may become prolonged in patients taking monoamine oxidase (MAO) inhibitors, since these agents block the enzyme that destroys tyramine.

CLINICAL EVALUATION AND MANAGEMENT

Overview

The clinical evaluation of hypertensive patients is aimed at determining the underlying reason for the hypertensive episode and ascertaining the effects on end organs. Management is determined by this assessment. Although patients with hypertension present to the ED relatively frequently, the number of individuals who actually require emergent intervention is small.[10] ED management should begin with an accurate blood pressure measurement, confirmed by repeat assessment in both arms if the initial value is elevated. The challenge is to determine whether the presenting blood pressure reading is only a transient circumstantial elevation or is representative of the patient's baseline. The approach to hypertensive patients in the ED is summarized in the flow diagram in Fig. 53-1.

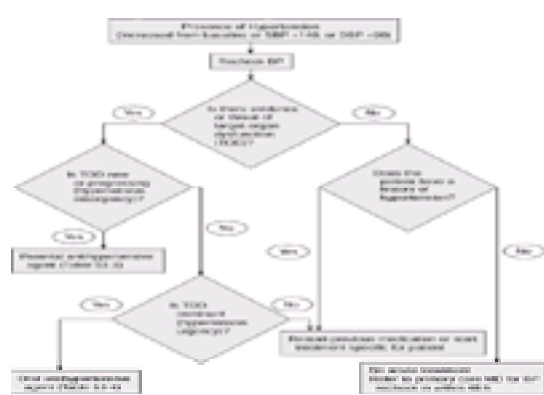

FIG. 53-1. Algorithm for approach to hypertensive patients.

Medical History

Any prior diagnosis of hypertension, including treatment regimens, compliance patterns, and baseline recordings of past blood pressures, are important to determine. Elevated blood pressure in the context of several months of noncompliance with antihypertensive medications likely represents a patient's baseline, whereas hypertension after several days of noncompliance could be a more serious abrupt cessation syndrome. A history of all medication use, including over-the-counter and illicit drugs, should be obtained, since many commonly used agents—including cocaine, amphetamines, decongestants, stimulants, oral contraceptives, and nonsteroidal anti-inflammatory drugs (NSAIDs)—may elevate blood pressure. MAO inhibitors in combination with tyramine-containing foods (e.g., beer and aged cheese) or certain drugs (e.g., amphetamines and tricyclic antidepressants) can also precipitate acute blood pressure elevation. Any past medical history of cardiovascular, cerebrovascular, or renal disease; diabetes; hyperlipidemia; chronic obstructive pulmonary disease (COPD); asthma; or gout; or a family history of hypertension or premature heart disease should also be elicited.[1] Patients with elevated pressures should be asked specifically about CNS symptoms (e.g., headache, diplopia, blurred vision, confusion, hemiparesis, and seizures), cardiac symptoms (e.g., chest pain, dyspnea, tachycardia, and palpitations), and renal symptoms (e.g., hematuria and anuria) that may be indicative of progressive end-organ damage.[1]

Physical Examination

The blood pressure should be measured with a cuff of the appropriate size for the patient. The width of the inflatable portion of the cuff should be about 40 percent of the circumference of the limb and the length of the inflatable portion should equal 80 percent of the limb's circumference. Using a cuff that is too short or narrow or too loose may cause falsely high readings. The blood pressure should be measured at least twice if the first value is elevated (SBP of more than 140 mmHg or DBP of more than 90 mmHg). For severe elevation, measure pressure in both arms and legs, and palpate pulses in all extremities. In adults, a differential in brachial systolic pressures of more than 20 mmHg may indicate the presence of aortic coarctation, aneurysm, or dissection.

Focus the physical examination on the detection of target-organ damage and determine the acuity. Neurologic examinations that reveal focal findings or mental status changes may indicate hypertensive encephalopathy, subarachnoid hemorrhage, or stroke. A careful funduscopic examination may reveal acute changes such as hemorrhages, cotton-wool exudates, or disk or retinal edema (grade III or IV retinopathy). Alternatively, grade II retinopathy suggests chronic uncontrolled hypertension. Hyperreflexia with peripheral edema in a pregnant woman is suggestive of preeclampsia. This physical finding may also be found in elderly patients with multiple small ischemic strokes (lacunes).

On cardiovascular examination, auscultate for carotid bruits, murmurs, third and fourth heart sounds (S_3 and S_4), and a pericardial rub. An S_3 occurs in association with ventricular failure (either right or left), whereas an S_4 occurs when there is left ventricular hypertrophy and a noncompliant left ventricle. A right-sided S_4 may be heard with coexisting pulmonary hypertension. Left-sided congestive heart failure is associated with unexplained tachycardia as an early finding and pulmonary rales as a late finding. Diminished extremity pulses may be found in patients with coarctation of the aorta or aortic dissection. The abdomen should be examined for a bruit and a palpable pulsatile mass that may indicate the presence of an abdominal aortic aneurysm.[1]

Diagnostic Studies

Blood urea nitrogen (BUN), creatinine, electrolyte, and glucose levels should be determined, and complete blood count (CBC), electrocardiography (ECG), urinalysis, and chest x-ray should be obtained in cases of suspected hypertensive emergencies to look for evidence of target-organ damage.[1] Renal impairment may present as hematuria, proteinuria, or elevations in BUN, creatinine, and potassium levels. Red cell casts suggest glomerulonephritis. The blood glucose level is important because hypoglycemia can elevate blood pressure and also simulate hypertensive encephalopathy or stroke. The CBC may reveal microangiopathic hemolytic anemia that may occur as a result of vascular damage after an acute, severe rise in blood pressure. The ECG should be compared with previous tracings. ST-T wave changes may be evidence of ischemia, electrolyte abnormalities, or left ventricular hypertrophy. The chest x-ray may be helpful in showing evidence of left-sided congestive heart failure or aortic dissection. In patients with neurologic symptoms, computed tomography (CT) of the head should be performed to look for evidence of

stroke or hemorrhage.

TYPES OF HYPERTENSIVE EMERGENCIES

Hypertensive Encephalopathy

Although no specific blood pressure is pathognomic, the elevated pressure must exceed the limits of cerebral autoregulation of the small-resistance arteries, resulting in cerebral hyperperfusion with loss of integrity of the blood-brain barrier. In most cases, autoregulation usually cannot accommodate a constant cerebral blood flow above a MAP of 150 to 200 mmHg. Immediate reduction of blood pressure by 20 to 25 percent will help reverse the vasospasm that occurs at these pressures; however, excessive reduction in blood pressure must be avoided in order to prevent hypoperfusion and further cerebral ischemia. [11,12]

Hypertensive encephalopathy is usually acute in onset and reversible. It is characterized by severe headaches, nausea, and vomiting, and may also include altered mental status. Neurologic symptoms can range from confusion and drowsiness to seizures, decreased visual acuity, focal deficits, or even coma. Since the pathologic mechanisms are the same, accelerated hypertensive retinopathy is often seen. The differential diagnosis is wide and includes intracranial hemorrhage, stroke, meningoencephalitis, brain tumors, toxidromes, and metabolic coma. If hypertensive encephalopathy is suspected, antihypertensive therapy should be initiated while awaiting the results of certain key studies such as chemistry tests and CT scan.

Hypertensive encephalopathy is a true medical emergency and, if left untreated, can progress over hours and lead to coma and death. The treatment of choice is sodium nitroprusside infused at an initial dose of 0.5 (μg/kg)/min and titrated up to a maximum of 10 (μg/kg)/min. Intravenous nitroglycerin and labetalol have been successfully used, but they have not replaced nitroprusside as first-line therapy for hypertensive encephalopathy.

Stroke Syndromes (see Chap. 220)

Elevated blood pressure is commonly associated with stroke syndromes and is often the result of a physiologic response to the stroke itself (to maintain adequate cerebral perfusion to the viable but edematous tissue surrounding the ischemic area) and not its immediate cause. In the area of the stroke, cerebral autoregulation is lost, causing tissue blood flow to become directly pressure dependent. Most patients suffering from embolic or thrombotic strokes without associated hemorrhage do not have substantial elevations in blood pressure and do not need aggressive antihypertensive treatment. Furthermore, if the patient has a long-standing history of hypertension, any rapid reduction in blood pressure may further reduce cerebral blood flow to watershed areas and cause increased ischemia. [11,12] In the rare case of a stroke patient with extreme blood pressure elevation or sustained diastolic pressure greater than 140 mmHg, the blood pressure may be reduced in a controlled manner by no more than 20 percent with intravenous labetalol in small doses beginning with 5-mg increments.

In contrast to the relatively minor blood pressure elevations with most strokes, intracranial hemorrhage commonly results in profound reactive rise in blood pressure. Causes of intracranial hemorrhage include hypertensive vascular disease, arteriovenous anomalies, arterial aneurysms, bleeding associated with tumors, and trauma. Hypertension associated with hemorrhagic stroke is usually transitory and the result of increased intracranial pressure and irritation of the autonomic nervous system. The acute management of blood pressure associated with intracranial hemorrhage is controversial. In the case of subarachnoid hemorrhage, oral nimodipine (60 mg every 4 h) has been used to reverse the vasospasm associated with subarachnoid blood. Intravenous nicardipine (2-mg boluses followed by a 4- to 15-mg/h infusion) is also beginning to have a role in the management of hypertension during this type of hemorrhage.

Acute Pulmonary Edema

The hypertension associated with acute pulmonary edema is usually a result of increased peripheral vascular resistance caused by elevated catecholamines. In some cases, pulmonary edema occurs because an abrupt rise in blood pressure precipitates acute left ventricular failure. The blood pressure must be lowered to reverse this process, and nitroprusside and intravenous nitroglycerin are the agents of choice, although the latter does not reduce blood pressure as much as nitroprusside. Additional standard therapy for pulmonary edema includes nitrates (to reduce preload and afterload), oxygen, diuretics, and morphine sulfate.

Acute Coronary Syndromes

Increased left ventricular end-diastolic pressure increases the workload of the heart. Wall tension is one of the greatest determinants of myocardial oxygen needs. Increases in oxygen demand secondary to hypertension may result in angina. Myocardial infarction may also develop particularly among those with fixed lesions in coronary arteries, preventing appropriate delivery of required oxygen. Acute left ventricular failure with pulmonary edema may also develop. Treatment of left-sided heart failure should include agents that decrease both preload and afterload. Other agents that have been used as adjuvant therapy include oxygen, morphine sulfate, and diuretics. The use of agents that increase myocardial oxygen demand, such as diazoxide, hydralazine, and minoxidil, should be avoided.

In cases of hypertension and angina, immediate blood pressure reduction is indicated to prevent myocardial damage, and therapy should be initiated with nitroglycerin, either sublingually or parenterally. For a greater degree of pressure reduction, sodium nitroprusside may be started.

Aortic Dissection (see Chap. 54)

Because aortic dissection is associated with hypertension in about 90 percent of cases, medical therapy aimed at reducing blood pressure can limit the extent of the dissection. The process begins as a tear in the aortic intima, allowing blood to dissect into the media and then to reenter the lumen of the aorta via a second intimal tear, resulting in a double-barreled aorta. Approximately half of all nontraumatic dissections begin in the ascending aorta, a third in the arch, and the rest in the descending aorta. The dissection may extend proximally to involve the carotid arteries, coronary arteries, or pericardium, or it may extend distally to include the spinal artery or renal arteries.

The classic description is the abrupt onset of severe, tearing chest pain, radiating to the back or the abdomen. The location of the pain, the signs and symptoms, and the findings on physical examination vary with the site of the dissection and the direction in which it extends. The blood pressure is generally elevated but may be normal or even low. There may be differences in the pulses and blood pressure in different extremities. Because of the variety of presentations, the diagnosis of aortic dissection is often a difficult one and may require the aid of imaging studies. In 80 to 90 percent of cases, the chest x-ray may show a widening of the cardiac silhouette or, less often, a widened superior mediastinum may be evident. The chest x-ray may also show a separation of calcified intima from the aortic wall, but other more definitive studies, including transesophageal ultrasound, CT, magnetic resonance imaging, and aortography, may be needed to confirm the diagnosis and identify the level of dissection (see Chap. 54 for details).

The initial medical therapy for a suspected dissection is the use of an antihypertensive agent to lower the blood pressure and reduce the ventricular ejection force (rate of change in pressure with time, dp/dt) of the heart. Treatment of choice includes either a combination of a b-adrenergic antagonist (such as esmolol) and sodium nitroprusside, or labetalol alone. Emergency surgical consultation should be obtained for all suspected aortic dissections, although dissections involving the descending aorta are often medically managed. Surgical intervention is indicated in dissections involving the ascending aorta or aortic arch and in cases in which pain and blood pressure cannot be adequately controlled.

Renal Failure

Blood pressure and renal function are intrinsically related. Hypertension may cause acute renal failure or exacerbate chronic renal failure, whereas renal disease may result in hypertension. In patients with renal disease, the control of hypertension can delay the progression of further injury. Worsening renal function in the setting of elevated pressure, with elevation of BUN and creatinine levels, proteinuria, or the presence of red cells and red cell casts in the urine, is considered a hypertensive emergency that requires immediate reduction of blood pressure. Nitroprusside is the preferred agent in these cases. Patients who have known renal failure and are dialysis dependent and have volume overload may require emergent dialysis if they present with uncontrolled hypertension with other evidence of end-organ dysfunction.

Preeclampsia and Eclampsia

These are discussed in Chapter 101.

Childhood Hypertensive Emergencies

Hypertension is an uncommon problem in children, occurring in less than 5 percent, [13] and is defined as SBP or DBP equal to or greater than the 95th percentile for age and sex. Blood pressure should be measured with a cuff of the appropriate size as noted earlier. In the majority of confirmed cases of hypertension, renal/renovascular disease and pheochromocytoma are the most common etiologies.

Children often will have nonspecific complaints such as throbbing frontal headache or blurred vision. Physical findings associated with hypertension are similar to those found in adults.

The decision to treat is based on the combination of blood pressure and symptoms, but a guideline for urgent treatment is blood pressure that exceeds previous measurements by 30 percent. The goal of treatment, as in adults, is to reduce pressure within 1 h by 25 percent. Nitroprusside [0.5 to 8 (μg/kg)/min] and labetalol [1 to 3 (mg/kg)/h] are the agents of choice to treat hypertensive emergencies of childhood. Pediatric hypertension that may require intervention in the ED probably mandates consultation and likely admission.

SELECTION OF AN ANTIHYPERTENSIVE AGENT

The following section outlines therapies for hypertensive emergency and urgency. For those patients in an ambulatory setting, Table 53-2 summarizes guidelines for the selection of an antihypertensive agent for patients with various coexisting conditions. [14] Diuretics should be one of the agents of first choice in patients with renal disease and congestive heart failure who are judged to be volume overloaded. Because of their greater prevalence of stage 3 hypertension (systolic pressure of 180 mmHg or more, and diastolic pressure of 110 mmHg or more), African American patients may require multidrug therapy. For treatment of patients with angina pectoris or postmyocardial infarction, b blockers are indicated. They are also indicated for those patients with a history of migraines, atrial fibrillation with rapid ventricular response, paroxysmal supraventricular tachycardia, and senile tremor. The use of b blockers is safe in the latter part of pregnancy, but their use should be avoided in early pregnancy because of an association with fetal growth retardation. Angiotensin-converting enzyme (ACE) inhibitors should be used in patients with congestive heart failure and can also be used in patients with a history of diabetes mellitus, especially those with diabetic nephropathy. The use of ACE inhibitors should be avoided in pregnant women. In the elderly, diuretics are the first choice for antihypertensive therapy because the pathophysiology of their hypertension is usually related to total peripheral resistance rather than cardiac output. b blockers are also recommended as alternative therapy. Use of agents that cause significant orthostatic changes (e.g., calcium-channel blockers, peripheral adrenergic blockers, and a blockers), as well as drugs that cause cognitive dysfunction (e.g., central a_2 agonist), should be avoided in the elderly.

TABLE 53-2   Antihypertensive Treatment Regimens for Specific Populations

AGENTS FOR TREATMENT OF HYPERTENSIVE EMERGENCIES

Agents used in hypertensive emergencies are shown in Table 53-3.

TABLE 53-3   Parenteral Agents for Hypertensive Emergencies

Sodium Nitroprusside (Nipride)

ACTIONS AND PHARMACOLOGY   This rapidly acting arteriolar dilator and venodilator is the drug of choice for hypertensive emergencies and is the standard against which all other agents are compared. It acts by reacting with cysteine to form nitrosocysteine, a potent activator of guanylate cyclase, which in turn stimulates the formation of cyclic GMP to relax smooth muscle in both arteries and veins. This decreases preload and afterload, resulting in decreased myocardial oxygen demand. The heart rate may increase slightly secondary to a baroreceptor-mediated reflex, but there is no change in cardiac output or myocardial blood flow unless there is preexisting coronary artery disease which can result in a significant reduction in regional blood flow ("coronary steal") (see below). Cerebral blood flow may be affected, decreasing in a dose-dependent manner. Renal blood flow remains unchanged, but plasma renin activity is increased. Pulmonary shunting may occur with nitroprusside use.

The rate of onset is extremely rapid, with a duration of action of 1 to 2 min and a plasma half-life of 3 to 4 min. Nitroprusside is metabolized to thiocyanate in the liver and is excreted slowly by the kidneys. Cyanide is an intermediate metabolite, but cyanide toxicity is rare. [15]

INDICATIONS   Sodium nitroprusside is an excellent agent for all hypertensive emergencies except eclampsia prior to delivery (because it crosses the placenta). It is only indicated for postpartum eclampsia or in eclampsia resistant to other interventions.

USE   The MAP should not be reduced by more than 20 to 25 percent within 30 to 60 min. [15] The solution is made by mixing 50 mg of sodium nitroprusside in 500 mL of 5% dextrose in water (D_5W) (10 mg/mL). The infusion is usually started at 0.5 (μg/kg)/min, titrating up to a maximum of 10 (μg/kg)/min until the desired blood pressure has been achieved. The blood pressure needs to be closely monitored; therefore, an arterial line should be placed once the infusion is initiated. Because of rapid degradation and sensitivity to light, sodium nitroprusside solution should be used within 24 h of mixing and be protected from the light by wrapping the solution

and tubing in aluminum foil.

SIDE EFFECTS AND CONTRAINDICATIONS   The most common complication is hypotension. Prolonged infusions may lead to the rare complications of cyanide toxicity, which may occur in patients with hepatic dysfunction, and thiocyanate toxicity, which is associated with renal failure. [15] This rarely occurs in the ED. Because nitroprusside inhibits hypoxia-induced vasoconstriction in the pulmonary vasculature, there may be increased perfusion to nonventilated areas of the lung. Myocardial ischemia may be worsened by a coronary steal syndrome because of dilation of coronary arteries or by the combination of nitroprusside and clonidine. Another consequence of the vasodilatory effect of nitroprusside is increased intracranial pressure.

Labetalol

ACTIONS AND PHARMACOLOGY   This antihypertensive agent is a competitive, selective a_1 blocker and a competitive, nonselective b blocker, with the b-blocking action being 4 to 8 times the a-blocking action. It can be given either orally or intravenously. It lowers blood pressure by blocking a_1 adrenoreceptors in vascular smooth muscle but, because of the simultaneous b blockade, causes no reflex tachycardia.

When given intravenously, the distribution to peripheral tissues is rapid, with a large volume of distribution (15.7 L/kg). Onset of action is 5 to 10 min, and the duration of action is 8 h. The elimination half-life is 5.5 h. When taken orally, it is rapidly absorbed, with an absorption half-life of about 12 min and peak plasma concentrations at about 50 min. Labetalol is safe for use in patients with renal insufficiency, because it is predominantly (95 percent) hepatically metabolized; however, oral dosing may need to be reduced in patients with hepatic disease, because of significant first-pass hepatic metabolism. Oral bioavailability is only 25 percent but increases in the elderly or when taken with food or cimetidine. The elimination half-life after an oral dose is 8 h.

Labetalol reduces systolic arterial pressure and total peripheral vascular resistance. Cardiac output may be slightly decreased or unchanged, pulmonary artery and wedge pressures decrease, and angiotensin II activity decreases, while cerebral blood flow, renal blood flow, and glomerular filtration rates are unchanged. With prolonged use, fluid retention may occur. Labetalol should be used with caution in patients with asthma and COPD, because of its nonselective b-blocking activity, which decreases the forced expiratory volume in 1 s (FEV_1) by causing bronchospasm. The use of labetalol should also be avoided in patients with bradycardia and second- or third-degree heart block.

INDICATIONS   Labetalol can be used intravenously for hypertensive emergencies and be easily converted to the oral formulation as the first-line agent for hypertensive urgencies. It offers the advantages of providing a steady, consistent drop in blood pressure without decreasing cerebral blood flow or producing reflex tachycardia. It can be safely used in patients with cerebral vascular disease and coronary artery disease. Labetalol is ideal for use in syndromes associated with excessive catecholamine stimulation, such as from pheochromocytoma, MAO inhibitor-induced emergencies, and abrupt clonidine withdrawal. It has also been used in pregnancy-induced hypertension. It is a class C drug in pregnancy.

USE   Labetalol can be given for hypertensive emergencies with repeated, incremental boluses starting with 20 to 40 mg IV, until the target blood pressure is achieved or a total dose of 300 mg is reached. After an intravenous bolus, the blood pressure falls in 5 min, with a maximum response in 10 min, and antihypertensive effect lasting for up to 6 h. After a 20-mg loading dose, labetalol may also be given as a continuous infusion by mixing 200 mg in 200 mL of D_5W and running this at 2 mg/min (2 mL/min). The infusion should be stopped when the target pressure has been achieved.

The initial oral dose in hypertensive urgencies is 200 mg. Patients can experience the onset of effects within 1 to 3 h. [16]

SIDE EFFECTS AND CONTRAINDICATIONS   Labetalol has a prolonged action because of its large volume of distribution and long elimination half-life. In 5 percent of patients, orthostatic hypotension is a complication of therapy. The nonselective b-blocking action can exacerbate heart failure and induce bronchospasm. A paradoxical hypertensive effect may occur when the drug is used in low doses in catecholamine-induced crisis, because of the predominant b blockade, leaving relatively unblocked a receptors for the circulating catecholamines. [17] In addition, patients with ischemic heart disease may experience exacerbation of angina and, in some cases, myocardial infarction after abrupt discontinuation of oral therapy.

Esmolol

ACTIONS AND PHARMACOLOGY   This is an ultra-short-acting b_1-selective adrenergic blocker, which has rapid distribution and elimination half-lives of 2 and 9 min, respectively. When given as an intravenous bolus, followed by an infusion, 90 percent of b blockade is achieved within 5 min; however, when given as an infusion without a bolus, steady-state blood levels are reached within 30 min. Within 2 min of discontinuing an infusion, there is a significant decrease in the b-antagonist activity, and, generally, all blockade will resolve within 30 min. Because of its rapid onset of action, short duration of action, and easy reversibility—properties not found in other b blockers—esmolol is very useful in acute settings. [18] When compared with sodium nitroprusside, esmolol provides similar rapid control of hypertension without producing the excessive reduction in DBP and reflex tachycardia that are seen with sodium nitroprusside.

INDICATIONS   Esmolol has been used in the treatment of supraventricular tachycardias; to lower pulse and blood pressure in perioperative patients and in patients with myocardial infarction, unstable angina, and thyrotoxicosis; and to blunt rises in blood pressure associated with intubation. It has also been used for severe hypertension but is not particularly efficacious as monotherapy.

USE   A loading dose of 0.5 (mg/kg)/min may be given over 1 min prior to the initiation of an infusion of 0.05 to 0.3 (mg/kg)/min. Esmolol may also be given without a loading dose but then takes longer to reach a steady state. It is usually used in combination with other agents such as nitroprusside or phentolamine for hypertensive emergencies.

SIDE EFFECTS AND CONTRAINDICATIONS   Because of its b-antagonist activity, the use of esmolol should be avoided in patients with asthma or COPD. It also should not be used to treat patients with cocaine-induced cardiovascular complications, because of the predominant b blockade, leaving relatively unblocked a receptors.

Intravenous Nitroglycerin

ACTIONS AND PHARMACOLOGY   This agent acts by causing both arteriolar dilation and venodilation, with a greater effect on the venous system than on the arterial vasculature. Onset of action is almost immediate when nitroglycerin is given intravenously, and the half-life is 4 min. The mechanism of action is thought to involve the reduction of sulfhydryl groups at a smooth muscle nitrate receptor, resulting in an increase in cyclic GMP. Nitroglycerin is hepatically metabolized. Cardiac output usually remains unchanged but may decrease slightly.

INDICATIONS   The main indication for nitroglycerin is in the setting of myocardial ischemia, because it is a better vasodilator of the coronary vessels than is nitroprusside; therefore, it is the agent of choice for moderate hypertension complicating unstable angina, myocardial infarction, or pulmonary edema. It also has a less harmful effect on pulmonary gas exchange than does nitroprusside.

USE   The initial infusion rate should be 5 to 20 μg/min, with 5-μg/min incremental increases every 5 min until symptoms are improved or adverse effects necessitate stopping the infusion.

SIDE EFFECTS AND CONTRAINDICATIONS   The most common side effects include headache, tachycardia, nausea, vomiting, hypoxia, and hypotension.

Hydralazine

ACTIONS AND PHARMACOLOGY   This agent acts as a direct arteriolar dilator, with onset of action within 10 min when given intravenously and a duration of action of 4 to 6 h. The onset of action increases to 20 min when hydralazine is given intramuscularly and to 30 min after an oral dose. The plasma half-life is 2 to 4 h, but the antihypertensive affect may outlast this time interval. Its mechanisms of action are not well understood, but it is known to directly relax vascular smooth muscle, resulting in vasodilation. Hydralazine is metabolized by acetylation in the liver and gut walls by ring hydroxylation and conjugation. In patients who are "slow acetylators" (50 percent of the US population), there is a higher incidence of hypotension and toxic complications. Within 24 h, 80 percent of hydralazine and its

metabolites are excreted in the urine. Doses need to be decreased in patients with renal insufficiency.

INDICATIONS   The main indication for use of intravenous hydralazine is pregnancy-induced hypertension. [19] The drug can be used orally and in combination with other drugs.

USE   In cases of eclampsia, hydralazine can be given as either a 10- to 20-mg intravenous dose or a 10- to 50-mg intramuscular dose. This dose can be repeated in 30 min.

SIDE EFFECTS AND CONTRAINDICATIONS   Hydralazine should not be used in patients with aortic dissection or a history of coronary artery disease, because it causes reflex tachycardia and increases plasma renin and catecholamines. It also causes sodium and water retention and can cause headaches, nausea, tachycardia, lethargy, and postural hypotension. A lupuslike syndrome can result from chronic oral use.

Trimethaphan

ACTIONS AND PHARMACOLOGY   This is a ganglionic blocking agent that inhibits both sympathetic and parasympathetic discharge by occupying receptor sites, thus stabilizing postsynaptic membranes from the effects of acetylcholine. This blockade results in vasodilation, improved blood flow to some vascular beds, and a decrease in blood pressure. The heart rate may rise in response to the decrease in peripheral vascular resistance. Cardiac output, stroke volume, and left ventricular work decrease. It has a rapid onset of action, and its effects are of short duration.

INDICATIONS   Historically, trimethaphan had been the drug of choice for acute aortic dissection, especially of the descending type. However, because it causes a number of serious side effects, it has been replaced by the combination of nitroprusside and b blockade as the therapy of choice. It continues as a second-line agent in this setting.

USE   Trimethaphan is given by intravenous infusion at a rate of 0.3 to 3.0 mg/min. It is sometimes used in combination with propranolol (1 to 3 mg IV or 10 to 40 mg orally qid) to reduce the velocity and force of left ventricular ejection.

SIDE EFFECTS AND CONTRAINDICATIONS   A number of serious side effects can occur including bladder atony with urinary retention, ileus, gastric atony, cycloplegia, severe postural hypotension from blockade of circulatory reflex pathways, and even respiratory arrest. Tolerance develops with continued use; therefore, it is mainly useful for short-term administration such as in patients awaiting surgery or in inoperable patients until oral therapy with another agent can be started.

AGENTS FOR TREATMENT OF HYPERTENSIVE URGENCIES

See Table 53-4.

TABLE 53-4   Oral Agents for Hypertensive Urgencies

Sublingual Nitroglycerin

INDICATIONS   It is the agent of choice for unstable angina, for immediate treatment of pain in acute myocardial infarction, and for the treatment of left ventricular insufficiency and pulmonary edema.[20]

USE   Nitroglycerin is absorbed very quickly through the oral mucosa. It is given as a 0.3- to 0.6-mg tablet or spray under the tongue. The onset of hypotensive effect is in 5 min and can last several hours.

SIDE EFFECTS AND CONTRAINDICATIONS   The most common side effects include headache, tachycardia, nausea, vomiting, hypoxia, and hypotension. It should be used with caution in patients with aortic stenosis.

Clonidine

ACTIONS AND PHARMACOLOGY   This agent is a centrally acting, a$_2$-adrenergic agonist that decreases central sympathetic activity, lowering plasma catecholamine levels. Clonidine causes little postural hypotension, because vasomotor reflexes are unchanged. It also does not increase heart rate or cardiac output and does not change renal blood flow or glomerular filtration rates. Overall, the effect of clonidine is to lower blood pressure, slow the heart rate, and cause sedation.

The onset of action is 30 to 60 min after an oral dose, with peak effect in 2 to 4 h. The duration of action is 6 to 8 h. Clonidine crosses the blood-brain barrier. Because approximately 50 percent is excreted unchanged in the urine in the first 24 h, it can accumulate in patients with renal insufficiency and is not dialyzable; however, in cases of renal failure, it is excreted in the feces.

INDICATIONS   This is considered to be a second-line agent for the treatment of hypertensive urgencies. It can be used safely in the elderly and in renal failure. However, because it sometimes requires up to 6 h for an adequate response, it is not ideal for ED use.

USE   The initial dose is 0.1 mg, with additional doses of 0.1 mg every hour until the diastolic pressure is below 115 mmHg or a maximum dose of 0.7 mg has been given. A patient who is given clonidine in the ED setting does not need to be discharged on this specific agent long term.

SIDE EFFECTS AND CONTRAINDICATIONS   The most common side effects include dry mouth, drowsiness, and constipation. Rarely, bradycardia can occur in patients with sick sinus syndrome. Clonidine may interact with other drugs, causing adverse effects such as orthostatic hypotension in patients taking diuretics, decreased antihypertensive effects with cyclic antidepressants, increased sedation with alcohol, and bradyarrhythmias or other dysrhythmias with negative inotropic agents. When high doses of clonidine are abruptly stopped, the well-documented phenomenon of clonidine withdrawal with severe rebound hypertension, tachycardia, flushing, and abdominal symptoms may be seen. If this syndrome occurs, the patient should be given clonidine therapy promptly. The use of b blockers should be avoided because they may worsen the withdrawal symptoms.

Captopril

ACTIONS AND PHARMACOLOGY   This is an angiotensin-I-converting enzyme inhibitor that is rapidly absorbed orally, with an onset of action within 15 to 30 min, peak effects of blood pressure reduction between 50 and 90 min, and duration of antihypertensive effect of 4 to 6 h. It causes no change in cardiac output, heart rate,

or cerebral blood flow. Since captopril is renally metabolized, its dosing must be decreased in patients with renal insufficiency. Postural hypotension is a rare problem, because it has no effect on baroreceptor reflexes.

INDICATIONS   Captopril is effective in cases of refractory acute congestive heart failure and is also useful in treating hypertensive urgencies with known renovascular hypertension.

USE   The usual oral dose is 25 mg. The dose-response curve for captopril is flat; therefore, increasing doses generally do not cause greater reductions in blood pressure.

SIDE EFFECTS AND CONTRAINDICATIONS   Several common side effects include skin rash, cough, and loss of taste. Laboratory abnormalities that can occur include leukopenia, proteinuria, and hyperkalemia. Captopril should not be used in combination with potassium-sparing diuretics. It also should not be given to patients with bilateral renal artery stenosis or unilateral stenosis with one kidney, because of the risk of acute renal failure. In patients with chronic renal failure or collagen-vascular disease, there is an increased risk of side effects. A potentially life-threatening complication of this therapeutic agent is angioneurotic edema, which can result in airway compromise.[18] This condition presents as a pale and sometimes severe swelling of the face and upper airway, and should be treated with epinephrine, antihistamines, and glucocorticoids.

Nifedipine

ACTIONS AND PHARMACOLOGY   This dihydropyridine calcium-channel antagonist has been one of the most extensively studied agents for rapid control of blood pressure. Until the last few years when awareness of serious side effects became more widespread, it had been the most frequently used agent for acute blood pressure lowering in hospitalized patients. It is a coronary and peripheral arterial dilator, which causes a slight increase in heart rate but rarely causes postural hypotension. It can be given orally, sublingually, or rectally and has been shown to lower blood pressure quickly and in a rapid dose-dependent manner. After sublingual administration, the onset of action is 1 to 5 min, with a maximal effect at 20 to 60 min. The duration of action is 3 to 5 h. The clearance half-life is 2 to 4 h and the time to peak level remains constant with all doses. It undergoes extensive hepatic metabolism.

With an oral dose, peripheral vascular resistance falls, cardiac output increases, and pulmonary capillary wedge pressures decrease. There is a slight increase or no change in the glomerular filtration rate and renal blood flow. Nifedipine may improve cardiac performance in patients with impaired ventricular function but, because of its negative inotropic effect, should be used with caution in patients with severe congestive heart failure.

INDICATIONS   The US Food and Drug Administration (FDA) has never specifically approved the use of short-acting nifedipine for the treatment of hypertension of any kind. Because of the risks of serious adverse reactions, such as acute coronary events or an ischemic stroke, the US National Heart, Lung, and Blood Institute issued a warning in 1995 stating that this agent should not be used in the treatment of hypertension, angina, and myocardial infarction.[21] The extended-release form of nifedipine appears to have less adverse effects than the short-acting formulations.

SIDE EFFECTS AND CONTRAINDICATIONS   The common side effects of flushing, headache, pedal and periorbital edema formation, and palpitations are relatively well tolerated. The less common, but more serious, complications that have occurred include cerebral ischemia, syncope, complete heart block, symptomatic hypotension, sinus arrest, retinal ischemia, congestive heart failure, and myocardial ischemia/infarction. Rebound hypertension can also occur when nifedipine therapy is stopped abruptly.

Although nifedipine has been used widely for hypertensive urgencies, some patients are predisposed to unfavorable outcomes with the use of this drug. Five effects have been identified that can cause complications when nifedipine is used to treat acute hypertension in some vulnerable patient populations.[22] These are (1) proischemic effects—the potential to worsen ischemia unpredictably, especially in areas of the myocardium with good collaterals, (2) prohemorrhagic effects—antiplatelet activity combined with vasodilation, (3) negative inotropy—especially in patients with a history of congestive heart failure, (4) hypotension—with resultant hypoperfusion of the subendocardium, and (5) arrhythmogenic effects—predisposition to ventricular tachyarrhythmias in some populations.

PROMISING NEW ANTIHYPERTENSIVE AGENTS

Enalaprilat

ACTIONS AND PHARMACOLOGY   This agent, which is the first intravenous ACE inhibitor approved for clinical use, is the biologically active form of the oral ACE inhibitor enalapril that occurs after deesterification in the liver. It is effective in patients with chronic heart failure with left ventricular ejection fractions of 20 to 44 percent, because it causes coronary vasodilation and significant reduction in mean arterial blood pressure and pulmonary capillary wedge pressure. It also improves cardiac index and stroke volume without affecting the heart rate or stroke work index.[18]

The onset of antihypertensive effect is within minutes of an intravenous bolus injection, with the maximal decrease in DBP in 30 min and duration of action up to 6 h. The degree of blood pressure reduction seems to be associated with the degree of pretreatment plasma renin activity, thus suggesting that the mechanism of antihypertensive effect may be renin-angiotensin inhibition.[18] Enalaprilat is excreted primarily by the kidney; therefore, its dosage should be decreased in patients with severe renal insufficiency.

INDICATIONS   Enalaprilat is an effective intravenous antihypertensive agent in hypertensive emergencies that can be easily replaced by oral enalapril for long-term maintenance therapy.

USE   An initial dose of 0.625 to 1.25 mg by intravenous bolus has been found to be effective in reducing blood pressure and heart rate. Doses of 2.5, 5, and 10 mg, up to a maximum of 40 mg, have been tried in different studies but have not been found to show appreciable difference in the magnitude of blood pressure reduction with increasing dose.[23] A bolus can be given every 6 h. The onset of hypotensive effects is variable.

SIDE EFFECTS AND CONTRAINDICATIONS   This agent produces complications and effects that are similar to those of other ACE inhibitors, most notably angioneurotic edema and deterioration of renal function.

Fenoldopam

ACTIONS AND PHARMACOLOGY   This antihypertensive agent is a selective postsynaptic dopaminergic receptor (DA_1) agonist that has potent vasodilative and natriuretic properties.[18] Recent clinical trials have shown this intravenous agent to be effective in the treatment of severe hypertension without causing a change in heart rate. The onset of action is 4 min, with duration of antihypertensive effect of 8 to 10 min.

INDICATIONS   Fenoldopam shows promise for use in treating hypertensive emergencies but is not yet FDA approved for this purpose.

USE   The initial dose is 0.05 to 0.1 (mg/kg)/min and can be increased at increments of 0.1 (mg/kg)/min to a maximum infusion rate of 1.6 (mg/kg)/min or to a diastolic pressure of less than 110 mmHg.

SIDE EFFECTS AND CONTRAINDICATIONS   Mild side effects of headache and flushing occur in about 25 percent of patients.

Nicardipine

ACTIONS AND PHARMACOLOGY   This is a dihydropyridine calcium-channel blocker that decreases afterload by reducing total peripheral resistance without reducing cardiac output and without apparent negative inotropic effect on the heart. It improves left ventricular pumping activity in patients with mild to moderate heart failure.[18] Nicardipine also displays a greater vasodilator effect on coronary than on systemic vessels and produces a clinically significant decrease in cerebral vasospasm after subarachnoid hemorrhage.[24] The onset of action is 15 to 30 min, with a duration of action of 40 min.

INDICATIONS It has been used for the treatment of postoperative hypertension, stable angina, and congestive heart failure, and shows promise for use in patients with subarachnoid hemorrhage.

USE Nicardipine can be given initially as a 2-mg intravenous bolus, followed by a 4- to 15-mg/h infusion.

SIDE EFFECTS AND CONTRAINDICATIONS Nicardipine does not produce the negative inotropic effects seen with other calcium-channel blockers such as nifedipine. Headache occurs as a side effect in 20 to 50 percent of patients. Other less common effects include hypotension, tachycardia, nausea, and vomiting. The use of nicardipine is contraindicated in patients with severe aortic stenosis.

Losartan

ACTIONS AND PHARMACOLOGY This is a highly selective angiotensin II receptor antagonist that blocks the vasoconstrictor and aldosterone-secreting effects of angiotensin II. It selectively blocks the binding of angiotensin II to specific receptors found in vascular smooth muscle and the adrenal gland. [16] It undergoes substantial first-pass metabolism by cytochrome P-450 enzymes and is converted to an active metabolite. The half-life of losartan is about 2 h and of the metabolite is about 6 to 9 h. Peak concentrations of losartan and its active metabolite are reached in 1 h and in 3 to 4 h, respectively.

INDICATIONS Losartan has been used in clinical trials in the treatment of hypertensive urgency.

USE It is available as 10-, 25-, or 50-mg tablets. The 50-mg dose has been found in studies to produce better results than the lower doses, but higher doses do not produce a more significant blood pressure reduction.

SIDE EFFECTS AND CONTRAINDICATIONS Because of potential fetal injury, the use of losartan should be avoided in the second and third trimesters of pregnancy. Dosing should be decreased in patients with hepatic insufficiency.

54 AORTIC DISSECTION AND ANEURYSMS

Gary A. Johnson

Thoracic and abdominal aneurysmal disease comprises a significant subset of emergencies. A ruptured aneurysm or dissecting aneurysm is a prominent cause of sudden death as well as severe abdominal, chest, or back pain. These diseases disproportionately affect the elderly. As our patient population becomes older, the incidence of presentations for aneurysms will continue to increase. [1,2 and 3]

Abdominal aortic aneurysms (AAA) have a clear familial trend. Eighteen percent of patients with AAA have a family history of aneurysm (a first-degree relative) compared with less than 3 percent of controls. Patients with Marfan syndrome have been found to have mutations in the FBN1 gene on chromosome 15. [2] Other genetic abnormalities have been investigated as well. [2,3]

The incidence of AAA increases with age and rarely presents before age 50. Most patients are older than 60 and males have an increased risk of disease. Patients with other aneurysms and peripheral arterial disease are at an increased risk as well.

PATHOGENESIS

Risk factors for aneurysms include connective tissue disorders, familial history of aneurysm, and atherosclerotic risk factors (age, smoking, hypertension, hyperlipidemia, and diabetes). These risk factors combine to increase the expansile force on the aortic wall or to impair the patient's ability to withstand these forces. The Laplace law [wall tension = (pressure × radius)/tensile force] dictates that as the aorta dilates, the force on the aortic wall increases, therefore causing further aortic dilation.

The destruction of the media of the aorta is a prominent feature in aneurysm pathogenesis. Elastin and collagen are markedly reduced in the aneurysmal aorta and fibrolamellar units are dramatically decreased. In addition, the normal abdominal aorta has a decreasing number of elastic lamellae as the aorta becomes more distal. This may help account for the prominent infrarenal location of aneurysm in many patients.

Histologic examination of an aneurysmal wall will show an intima that is infiltrated by atherosclerosis and a thinned media. There may be intraluminal thrombus, and the adventitia has often been infiltrated by inflammatory cells. Patients with saccular outpouchings (blisters) may have an increased risk of rupture. Such blisters have been shown to increase the incidence of rupture of small (less than 5-cm) aneurysms. [4]

Rate of aneurysmal dilation is variable. As a consequence of the LaPlace law, larger aneurysms will expand more quickly than smaller ones. An average rate may be 0.25 to 0.5 cm per year.[4] Patients with known aneurysms must be followed closely for unpredictably fast expansion.

Dissecting Aneurysms

Aortic dissections occur from a violation of the intima, which allows blood to enter the media and dissect between the intimal and the adventitial layers. Common sites for tear include the ascending aorta and the region of the ligamentum arteriosum. The dissecting column of blood ruptures the intima and thus maintains a true and false lumen. The dissection may extend proximally, distally, or both. The patient's symptoms may cease abruptly when the dissection extends back through the intima; this may suggest a spontaneous cure. Alternatively blood may dissect through the adventitia and will nearly always be fatal.

Aortic dissection presents in a bimodal fashion. One group consists of younger patients with specific predisposing conditions. The predominant group is patients above age 50 with hypertension. Atherosclerosis is only a minor contributor to the pathogenesis of dissection.

Predisposing conditions for dissection include multiple forms of congenital heart disease, connective tissue disease, and pregnancy. Approximately 25 to 30% of patients with Marfan syndrome develop a dissection. Dissection may also be iatrogenically induced from aortic catherization or cardiac surgery.

Aortic dissections have been classified by two separate systems. The Stanford classification considers any involvement of the ascending aorta a type A dissection and dissections restricted to the descending aorta type B. DeBakey classified type I dissections as those that involve the ascending aorta, the arch, and the descending aorta. Type II involves only the ascending aorta and type III only the descending aorta.

Pseudoaneurysms

Pseudoaneurysms (or "false aneurysms") may occur when there is a violation of the intima, which creates an ulcer into the aortic media. This type of lesion may slowly dilate or cause a deepening of the ulcer and form a pseudoaneurysm; it occurs most commonly in the descending thoracic aorta. Pseudoaneurysms do not commonly evolve into dissections and rarely rupture. [5]

Other Aneurysms

Patients may have aneurysms at anastomoses from prior vascular reconstruction. The aneurysm occurs at the site where the graft is sewn to the artery. Anastomotic aneurysms may occur in the aortic, ileac, or femoral arteries. These aneurysms commonly rupture and cause catastrophic bleeding; however, they may also present with smaller sentinel hemorrhages. Anastomotic aneurysms may erode into the adjacent intestine and form an aortoenteric fistula.

CLINICAL FEATURES

Abdominal Aortic Aneurysms

Symptomatic abdominal aortic aneurysms may present as syncope, back or belly pain, shock, or sudden death. Sudden death most commonly occurs from intraperitoneal rupture of the aneurysm. These ruptures lead to massive, rapid blood loss and it will not be possible to resuscitate the patient. History that is often cited as classic for acute rupture of the abdominal aneurysm is syncope with no warning symptoms followed by severe abdominal or back pain. Syncope is caused by rapid blood loss and a lack of cerebral perfusion. Patients often regain consciousness after their own compensatory mechanisms have been invoked, but they will

most often slip again into shock without prompt medical intervention.

Patients will most often present with variations on the classic history.[2] Pain may occur before syncope, and the pain may not be severe in some cases. The pain also may be unilateral and may be located in a flank, costovertebral angle of the groin, or in a single quadrant of the abdomen. Hip pain, tenesmus, and urinary bladder symptoms have been described. Constitutional symptoms such as nausea and vomiting are commonly present.

Physical examination of a patient with acute rupture of an aortic aneurysm may detect the aneurysm. Tenderness to palpation of an aneurysm is commonly interpreted as a sign of rupture. However, a lack of tenderness cannot imply an intact aorta. Patients with an obese abdomen are difficult to exam for the presence of an aortic aneurysm. Very thin patients may have an aorta that is easily palpable, and the diameter of the aorta should be measurable.

Evidence of retroperitoneal hematoma may be seen as periumbilical ecchymosis (Cullen's sign) or flank ecchymosis (Grey-Turner's sign). Retroperitoneal blood may also dissect into the perineum or groin. Scrotal hematomas or inguinal masses may be seen on exam. Retroperitoneal blood may also irritate the psoas muscle and produce an iliopsoas sign. Blood may compress the femoral nerve and present as a neuropathy. The presence or rupture of an AAA does not typically alter femoral arterial pulsations.[6]

Aortoenteric fistulas must be considered in all patients with unexplained gastrointestinal bleeding. A history of aortic graft placement should increase the clinical suspicion of fistula.[7] The duodenum is most frequently involved; and therefore bleeding may manifest as hematemesis, melenemesis, melena, or (if there is rapid transport) hematochezia. These fistulas commonly present as massive, life-threatening bleeding. However, mild "sentinel" bleeding may precede a full-blown rupture. Aortic aneurysms may also erode into the venous vasculature and form aortovenous fistulas, which may present as high-output cardiac failure, decreased arterial blood flow distal to the fistula, and increased central venous volume.

Abdominal aortic aneurysms may uncommonly present as chronic contained ruptures.[8] A retroperitoneal rupture may cause enough fibrosis to limit blood loss. The inflammatory response commonly causes pain, which may continue for a significant length of time. Despite the seriousness of this pathology, the patient may appear remarkably well.

An asymptomatic aneurysm may be found on physical examination or radiologic evaluation. Any aneurysm that is found should be referred for follow-up. Aneurysms greater than 5 cm in diameter are at an increased risk of rupture. Aneurysms of less than 5 cm are unlikely to rupture, however, patients with such asymptomatic aneurysms must be closely followed by their primary care physicians or surgeons. The management of patients with small, asymptomatic aneurysms (including the timing of surgery) is a controversial topic.[2,9] Symptomatic aneurysms of any size should be considered emergent.

Thoracic Aortic Aneurysm

Thoracic aortic aneurysms may become symptomatic by compressing or eroding into adjacent structures. Presenting symptoms can include esophageal, tracheal, bronchial, or even neurologic disorders. A thoracic aneurysm that erodes to an adjacent structure is generally immediately fatal. Rare patients may survive with the assistance of hemodynamic resuscitation.

Dissecting Aortic Aneurysms

Aortic dissections will commonly present (>90 percent) with an abrupt and severe pain in the chest or between the scapulae. Patients often describe the pain as tearing or ripping. Pain in anterior chest is often associated with involvement of the ascending aorta. Back pain may indicate involvement of the descending aorta. Dissection often presents with dynamic pathology; therefore, pain patterns often change as the anatomic injury migrates.[10]

The aortic dissection will cause a spectrum of symptoms based on the anatomic course of the lesion. Dissection into a carotid artery may lead to a classic stroke presentation. Some 40 percent of patients with dissection will have neurologic sequelae. Paraplegia may occur if the arterial blood supply to the spinal cord is interrupted. Abdominal or flank pain may be caused by dissection into the abdominal aorta, renal arteries, or ileac arteries. Dissection may lead to pericardial effusion and tamponade.

Systemic constitutional symptoms may occur with the dissection. Nausea, vomiting, and diaphoresis are common. Patients are frequently apprehensive and express their feelings of impending doom.

Physical examination may help to eliminate some differential diagnoses but will most likely reveal a normal heart and lung. The diastolic murmur of aortic insufficiency may be heard. Decreased pulsation in the radial, femoral, or carotid arteries should significantly raise the suspicion of an aortic lesion and is present in 50 percent of patients.[10] Specific threshold values of blood pressure changes between extremities have not been defined. Hypertension and tachycardia are commonly present, but the dissection may also cause hypotension. Hypotension may accompany pericardial tamponade or coronary artery interruption. Tamponade may result in muffled heart tones, elevated jugular venous pressure, and pulsus paradoxus. Compression of the recurrent laryngeal nerve or the superior cervical sympathetic ganglion may cause either hoarseness of voice or Horner syndrome, respectively.

DIAGNOSIS

Abdominal Aortic Aneurysms

The differential diagnoses for abdominal aneurysms include the causes of syncope, abdominal pain, back pain, and shock. The presentation of syncope with back pain or shock should strongly suggest aortic disease. However, the diagnosis will be difficult to make in shock or syncope without a significant complaint of pain. Other cardiac, abdominal, and retroperitoneal diseases need to be considered, including renal disorders, hepatobiliary disorders, and pancreatic disease. Unfortunately, some patients may appear well enough to receive benign diagnoses such as musculoskeletal back pain or enteritis and be discharged from the emergency department (ED).

The diagnosis may be further confused by coexisting pathology. Coronary artery disease and chronic lung disease are often present, and these features may distract the physician from the diagnosis of aneurysmal disease. This is especially true in patients without significant pain.

Aneurysms of large arteries other than the aorta may expand or rupture. Ileac aneurysms are notoriously difficult to diagnose because they may be confused with urologic, bowel, or groin disorders. Splenic artery aneurysms may present as undifferentiated shock or intraabdominal catastrophe. A rupture of the splenic artery has a poor prognosis owing to its intraperitoneal location.

Radiologic studies may be very helpful in confirming a ruptured AAA, but since radiographs often unnecessarily delay operative repair, the decision to obtain confirmatory studies must be made carefully.

Radiologic evaluation may include plain radiography, ultrasound (Fig. 54-1), or computed tomographic (CT). Plain abdominal films may show a calcified, bulging aortic contour implying the presence of an aneurysm. Approximately 65 percent of patients with symptomatic aortic aneurysmal disease will have a calcified aorta. Some propose that a cross-table lateral film of the abdominal aorta will have a higher yield for calcifications.[1] The lateral view will allow the aorta to be visualized without overlying the vertebral column. An AP projection may show an arch of calcification, most commonly on the patient's left. Rarely, a chronic aneurysm may erode into a vertebral body. Plain film cannot exclude the presence of AAA.

FIG. 54-1. Bedside ultrasound image of an abdominal aortic aneurysm. This aneurysm measures 6.5 cm.

Rapid bedside ultrasonography is ideal for unstable patients who cannot undergo CT scanning. A technically adequate ultrasound study has virtually 100 percent sensitivity for demonstrating the presence of an aneurysm and measuring its diameter. [11] Obesity or bowel gas may make the study difficult to perform. Rupture cannot be reliably seen.

CT with intravenous contrast is useful to demonstrate the anatomic details of the aneurysm and associated retroperitoneal hemorrhage. CT should be obtained on stable patients. Should unusual circumstances occur (such as the presence of other prominent acute abdominal conditions) and a CT become necessary, the patient should be accompanied by the surgeon, who could expedite an emergent operation if necessary.

Dissecting Aneurysms

The ischemic end-organ manifestations associated with many dissections may confuse the differential diagnosis, which includes myocardial infarction, pericardial disease, pulmonary disorders, stroke, musculoskeletal disease of the extremities, spinal cord injuries, and intraabdominal disorders. Ischemic manifestations may change with time (as the dissection progresses) distracting the physician from making the correct diagnosis. Rupture of the dissection into the true lumen may cause a cessation of symptoms, and the correct diagnosis may then be inappropriately dismissed.

Thoracic dissecting aneurysms will most commonly (90 percent) have an abnormal aortic contour on chest x-ray. Widening of the mediastinum and deviation of the trachea, mainstem bronchi, or esophagus may also be seen (Fig. 54-2 and Fig. 54-3). Intimal calcium may be visible and distant from the edge of the aortic contour (calcium sign).

FIG. 54-2. Chest x-ray of a descending saccular thoracic aneurysm.

FIG. 54-3. Chest x-ray of a dissecting thoracic aneurysm.

CT scanning may reliably make the diagnosis of aortic dissection (Fig. 54-4).[12,13] Sensitivity for dissection ranges from 83 to 100 percent and specificity ranges from 87 to 100 percent.[12] Spiral CT with rapid intravenous boluses of contrast may be more sensitive. [13] However, CT scan cannot reliably give anatomic details of other arterial branches off the aorta and cannot address aortic valve competence.

FIG. 54-4. Computed tomographic scan of same patient revealing false (double arrows) and true aortic lumens in both ascending and descending aorta.

Angiography can be considered the "gold standard" for diagnosis and will provide more anatomic detail than a CT scan. [12,13] Aortography also will reliably show

complications of dissection, including involvement of branch vessels, aortic valve incompetence, and coronary artery involvement. However, the angiogram is not a perfect study. Erbel[14] found aortography to have a specificity of 94 percent and a sensitivity of 88 percent. Risks of the procedure include the use of intravenous contrast agents and the delay in assembling an angiography team.

In experienced hands, a transesophageal echocardiogram (TEE) may be as sensitive and specific as angiography.[15,16 and 17] Sensitivity for dissection ranges from 97 to 100 percent, specificity 97 to 99 percent.[12] Some 3 percent of patients cannot tolerate the procedure, which should be performed under sedation or general anesthesia. Known esophageal disease is a relative contraindication. Disruption of sound transmission by air in the trachea or left bronchi may cause difficulty in evaluating the ascending aorta. Among the imaging techniques mentioned above, TEE has the highest diagnostic variability between operators or observers. Therefore, the imaging procedure of choice may vary between institutions.[12] In contrast with AAAs, suspected dissections must be confirmed radiologically prior to operative repair.

Thoracic aortic saccular aneurysms are generally uniformly identified on chest x-ray. Rarely, the presence of thoracic, pleural, or parenchymal densities may make the diagnosis more difficult. CT scan will delineate these aneurysms reliably.

EMERGENCY DEPARTMENT TREATMENT

Abdominal Aortic Aneurysm

The emergency physician's role in the care of a patient with an acute rupture of an AAA lies largely in making the diagnosis and assisting with rapid transfer to the operating room.

Any suspected ruptured aneurysm requires immediate operative repair. One-half of patients with a ruptured aneurysm who reach the operating room die.[9] Imaging modalities should be restricted to patients who are considered unlikely to have a ruptured aorta. Standard resuscitative maneuvers (two large-bore intravenous catheters, a cardiac monitor, and supplemental oxygen) are required. The patient suspected of having an AAA may require resuscitation for blood loss. However, overly vigorous fluid resuscitation may be harmful (see Chap. 27), and the appropriate amount of intravenous fluids to be given is controversial.

Aortic Dissection

Patients with suspected aortic dissection will commonly require antihypertensive treatment, which must be provided without increasing the shear force on the intimal flap of the aorta. Therefore, medications with negative inotropic effects must be given initially. b blockers (esmolol, metoprolol, or propranolol) are commonly used for this purpose. The optimal blood pressure is undefined and must be tailored to each patient. However, systolic pressure of 120 to 130 mmHg may be a convenient starting point.

Esmolol may be given as an infusion of 500 μg/kg over 1 min followed by an infusion of 50 to 150 μg/kg per minute. Metoprolol may be given intravenously in three 5-mg doses every 2 min followed by 2 to 5 mg/h. Labetolol, 20 mg (or 0.25 mg/kg) IV over 2 min, repeated q10 min to desired effect or a total dose of 300 mg; or labetolol 2 mg/min to desired effect or total dose 300 mg, can also be given. Calcium channel blockers may be used if a contraindication to b blockers is present.

Vasodilators (such as nitroprusside) may be added for further antihypertensive treatment after the successful administration of a negative inotrope. Nitroprusside may be infused intravenously at 0.3 to 10 μg/kg per minute. Administration should be provided by a pump to ensure precise measurement of drug. Patients should clearly have evidence of adequate b-receptor or calcium channel blockade prior to starting a vasodilator. Close monitoring of the pulse rate is required, as this is a convenient indicator of blockade in most patients. Aortic dissections may cause hypotension, which requires fluid or blood product resuscitation.

Rapid referral to a surgeon is mandatory. Dissections with involvement of the ascending aorta require prompt surgical repair. Patients with dissecting aneurysms of only the descending aorta are worse surgical risks, and indications for repair are controversial.[18]

Asymptomatic abdominal and thoracic aortic aneurysms require prompt outpatient referral. Other interventions are generally not needed.

55 NONTRAUMATIC PERIPHERAL VASCULAR DISORDERS

Anil Chopra

THROMBOPHLEBITIS

Deep venous thrombosis (DVT) is a common, potentially life-threatening condition with an estimated annual incidence of 5 to 20 million cases in the United States. The admission rate for DVT, however, is declining greatly owing to the widespread use of newer outpatient treatments. The most common life-threatening consequence of DVT is pulmonary embolism (PE), which is responsible for approximately 200,000 deaths in the United States every year.[1] The recognition and early treatment of a presumed or known DVT is paramount to reducing the morbidity and mortality from its local and thromboembolic sequelae.

Pathophysiology

The formation of venous clots is related to at least one of Virchow's triad of factors: venous stasis, injury to vessel wall, and hypercoagulable state. Table 55-1 outlines the clinical risk factors predisposing to DVT, which can be remembered by the mnemonic *thrombosis*; Table 55-2 provides a detailed list of associated conditions. Trauma includes multitrauma patients, lower extremity fractures, and burns. Hypercoagulable states include those associated with malignancy; lupus anticoagulant; deficiency of or resistance to protein C, protein S, or antithrombin III; and abnormal plasminogen or plasminogen activators, all of which can lead to clotting. Obstetric risk occurs not only during pregnancy but also in the postpartum period. Medications that predispose to thrombosis include birth control pills and replacement hormones. Major orthopedic, thoracic, abdominal, or gynecologic surgery is a significant risk factor for developing DVT, though the risk is diminished with prophylactic subcutaneous heparin postoperatively. Illness includes cardiovascular diseases—myocardial infarction (MI), congestive heart failure (CHF), and cerebrovascular accident (CVA)—nephrotic syndrome, inflammatory bowel disease, and vasculitis (lupus, Behçet syndrome).

T	Trauma
H	Hypercoagulable, hormone replacement
R	Recreational drugs (iv drugs)
O	Old (age >40)
M	Malignancy
B	Birth control pill, blood group A
O	Obesity/obstetrics
S	Surgery, smoking
I	Immobilization
S	Sickness

TABLE 55-1   Clinical Risk Factors for Deep Venous Thrombosis

TABLE 55-2   Conditions Associated with Deep Venous Thrombosis

Thrombi most commonly form at the venous cusps of deep veins in the lower extremities, where altered or static blood flow initiates clot formation. Blood clots are primarily composed of red cells, fibrin, and platelets. An immature thrombus may propagate, dissolve, or embolize, depending on various local and systemic factors related to thrombogenesis (especially venous stasis and activation of the coagulation pathway) and the body's defenses responsible for clot lysis (antithrombin III, protein C, plasmin, and other factors). The signs and symptoms of DVT are typically due to a partially or totally occluded vein, leading to venous outflow obstruction and/or the variable inflammatory response to a clot adhering to endothelium. PE may sometimes be the first and only clinical indication of an existing DVT in 10 percent of patients.

A postphlebitic syndrome (PPS) may develop following the resolution of a DVT and is related to valvular incompetence and persistent venous outflow obstruction. The true incidence of PPS is unknown, but studies have revealed a range of 20 to 60 percent depending on the criteria used for diagnosis.[2]

Superficial Thrombophlebitis

Thrombosis can occur in any superficial vein, especially in varicosities at the saphenous vein or its tributaries. It is a common, benign, self-limiting process but can cause significant incapacitation. Local pain, redness, and tenderness of a cord along the course of the involved vein are typical findings. Bruising or bleeding may

also be noted at the involved site. Doppler ultrasound may be used to confirm the diagnosis if there is any ambiguity or if an alternative diagnosis such as a DVT, cellulitis, or lymphangiitis is possible. Demonstration of flow within the involved vein reliably excludes superficial venous thrombosis.

Mild cases can be treated with warm compresses, analgesia, and elastic supports for the involved extremity with the patient continuing daily activities as tolerated. Severe thrombophlebitis where the patient is functionally debilitated by symptoms should be managed with periods of bed rest, elevation of the extremity, support stockings, and analgesia. Anti-inflammatory medications are commonly used to treat superficial thrombophlebitis. Antibiotics and anticoagulants are of no proven benefit. The incidence of DVT and subsequent PE due to a superficial thrombus is extremely low. Improvement with aggressive therapy can be painfully slow, and symptoms may persist for weeks. Definitive treatment for refractory or recurrent disease is excision of the involved vein. Patients with recurrent or migratory thrombophlebitis should be investigated to exclude a malignancy or other hypercoagulable state.

Deep Venous Thrombosis

CLINICAL FEATURES   The clinical examination is unreliable for the detection or exclusion of DVT. Assessment of risk factors (Table 55-1 and Table 55-2) may be a stronger predictor whenever the diagnosis is entertained. One study showed that a single risk factor is associated with DVT in 24 percent of patients, while those with four or more risk factors are virtually certain to have the diagnosis established. [3] The constellation of pain, redness, swelling, warmth, and tenderness is present in less than half of patients with confirmed DVT. Swelling and tenderness in the involved extremity are the most common findings, occurring in 80 and 75 percent, respectively, of patients with DVT. Though some patients with DVT may have a low-grade fever, one should be careful to exclude an infectious process such as cellulitis. Differences in calf measurements made 10 cm below the tibial tuberosity of greater than 2 cm have been historically suggested as a screening tool for a DVT, but there is no published scientific evidence to validate this practice. Suspicion of DVT by symptoms alone is sufficient to initiate objective investigations even with a negative physical exam. Pain in the calf with forced dorsiflexion of the ankle and the leg straight (Homans' sign) is not reliable for DVT. The physical findings with DVT depend on its location and the degree of venous obstruction, inflammation, and collateral blood flow. For example, significant iliofemoral vein occlusion can present with minimal to absent clinical findings but can result in a catastrophic PE.

Symptomatic DVT will be in the popliteal or more proximal veins in more than 80 percent of cases. An isolated calf DVT will extend proximally only 20 percent of the time, usually within a week of presentation.[4] Unlike proximal DVT, nonextending calf DVT will rarely cause a PE.

Uncommon presentations of DVT include phlegmasia cerulea dolens (painful blue inflammation) and phlegmasia alba dolens ("milk leg"). In the former, the patient presents with an extensively swollen, cyanotic leg from venous engorgement due to massive iliofemoral thrombosis. This high-grade obstruction can compromise perfusion to the foot from high compartment pressures and lead to venous gangrene. Petechiae and bullae may be present on the skin. Phlegmasia alba dolens is also due to massive iliofemoral thrombosis, but the patient's leg is pale or white secondary to associated arterial spasm. Dorsalis pedis and posterior tibial pulses may be diminished or absent, which can lead to a false diagnosis of arterial occlusion. The arterial spasm with milk leg is transient and often followed by venous engorgement, suggesting the correct diagnosis.

The PPS is manifest by signs and symptoms that can be difficult to differentiate from acute DVT. Pain, swelling, and occasionally ulceration of the skin can occur months to years after the resolution of DVT. Long-term follow-up of patients reveals that the syndrome (PPS) can occur in up to 60 percent of patients who have had a previous proximal DVT and one-third of patients with calf DVT. [2]

Diagnosis

Owing to the poor accuracy of clinical methods in identifying DVT, all patients with any signs or symptoms suggesting DVT must undergo an objective diagnostic evaluation. Less than one-third of patients with clinically suspected DVT are found to have the disease following objective investigation. [4] Several investigative techniques are available to search for a deep thrombus, including plasma D-dimer level, impedance plethysmography (IPG), Doppler ultrasound (duplex), contrast venography, radionuclide scintigraphy, and magnetic resonance imaging (MRI).

Venography has represented the historical "gold standard" for the detection of DVT. It can be useful for patients with a high clinical probability of DVT when noninvasive tests are negative. However, it is an invasive, often painful, and expensive test that may cause contrast-related reactions or iatrogenic venous thrombus in about 1 to 2 percent of patients. It is difficult to perform and requires considerable expertise. When contrast is seen throughout the deep venous system (not possible in 5 to 10 percent of tests), a venogram reliably excludes DVT. Inadequate visualization of the deep venous system can occur due to difficulties with venous access (e.g., obesity, severe edema, cellulitis), dilution of contrast in the proximal lower limb, or a previous thrombus.

The commonest test used to identify a DVT in North America is ultrasonography. B-mode ultrasound gives two-dimensional images of a vein and its surrounding structures and can directly visualize a clot, while Doppler flow capacity when combined with color images provides a visual and audible evaluation of blood flow for venous obstruction. B-mode ultrasonography combined with Doppler flow is termed a *duplex*. A duplex scan with or without color flow is highly sensitive and specific for a proximal DVT (clot proximal to the popliteal veins). The positive predictive value of ultrasound is higher than IPG for DVTs (94 versus 83 percent, respectively). Both of these tests are portable, noninvasive, safe, quick, readily accessible, accurate for proximal DVTs, and provide immediate information. Ultrasound testing requires more expertise (due to subjective interpretation). It is also more expensive than an IPG but is the test of choice when available owing to its higher accuracy. Both tests are insensitive for calf DVTs and serial testing is required to exclude the extension of clot to proximal veins. Some centers will not routinely scan the leg for a calf DVTs, choosing instead to do a more time-limited study looking only for the more significant proximal clots.

All plethysmographs measure a change in volume. An IPG that can be done at the bedside measures changes in electrical resistance in response to changes in calf volume secondary to venous obstruction. The procedure involves a supine patient with a leg externally rotated and knee partially flexed, having an 8-in. pneumatic cuff placed around the thigh and inflated to 37 to 51 mmHg to preferentially obstruct venous return, causing calf enlargement. Measurements are made with two electrodes on the calf after cuff inflation and then rapid deflation within 3 s of cuff release. Measurements are plotted on a graph and, if they lie above an experimentally determined baseline, the test is negative for a DVT. If the measurements lie below this line, the test is repeated, with increasing periods of cuff inflation (45 to 120 s). If several of these repeat measurements lie below the baseline, the test is considered positive for DVT. Several studies have shown that sensitivity and specificity for proximal DVT are about 95 percent.[5] False positives can occur with PPS, abdominal or pelvic neoplasms, CHF, and pregnancy. Plethysmography is insufficiently accurate to be useful for isolated calf DVT.

Several radioisotope techniques are available for investigating for DVT, including ^{111}In- or ^{99m}Tc-labeled antifibrin monoclonal antibodies, ^{125}I-labeled fibrinogen, and ^{99m}Tc-labeled red blood cells or macroaggregated albumin. These radioisotopes may be incorporated into actively forming thrombus and can be detected by scanning the extremity hours or days after injection. There are several disadvantages to radionuclide venography which make it a suboptimal test for detecting a DVT. While sensitivity for detecting calf DVT is about 90 percent, sensitivity for thigh DVT is as low as 60 percent and even lower for pelvic veins. [5] Still, this test has been used to complement a negative or equivocal ultrasound exam in high risk patients such as those who have undergone surgery or have an indeterminate lung scan for PE. Radionuclide venography is expensive, time-consuming and not as accurate as IPG or a duplex for proximal DVTs.

Some authorities advocate MRI as the "gold standard" for imaging the venous system. It is at least as accurate as any other investigational modality and can detect a filling defect in the entire extremity (including calf veins) and pelvic veins, which are sometimes not well visualized by ultrasonography or venography. An MRI visualizes both extremities simultaneously and can identify alternative causes of extremity swelling such as cysts, aneurysms, hematomas, tumors, and other masses. Some of the limitations of MRI include its cost, lack of ready availability, lack of portability, and inability to be used in patients harboring ferromagnetic objects (prostheses, pacemakers).

D-dimer fragments can be measured as an indicator of the presence or absence of DVT or PE. A quantitative enzyme-linked immunosorbent assay (ELISA) D-dimer level less than 250 ng/mL is helpful to exclude a venous thrombosis, but the test takes several hours to perform (latex and immunofiltration techniques are quicker but less sensitive). It is a fairly nonspecific test, as many other conditions such as infections, surgery, trauma, cardiovascular disease, and cancer can elevate a D-dimer level. It follows, then, that despite a sensitivity of over 80 to 90 percent, a D-dimer level is useful only when it is low.[5] The combination of a normal IPG or ultrasound and a low D-dimer level has a negative predictive value of about 99 percent for proximal DVT. [4]

Clinical Approach to Establishing the Diagnosis

Since the diagnosis of DVT is difficult to establish based solely on history or physical exam, some type of imaging modality is necessary. An appropriate initial imaging study would be either duplex scanning or IPG. The choice is more dependent on local availability and expertise, as both are reasonably accurate, noninvasive, and

inexpensive. In patients with risk factors in whom either of these tests are positive, anticoagulation therapy may be initiated if there are no contraindications. If the diagnosis is equivocal or there is potential for false-positive results, either contrast venography or MRI can be performed. A poor IPG study or suspicion of false negative results can be verified by a duplex scan. A good quality duplex scan with adequate compressibility of proximal veins excludes the diagnosis of proximal DVT, but can be repeated in a few days if high clinical suspicion of DVT remains. (There is no evidence that an IPG adds further conformation to a negative duplex scan with good compressibility of the femoral & popliteal vein.) The approach at any given institution is dependent on availability, equipment, and local expertise.

Treatment

Traditional therapeutic measures—including bed rest, continuous leg elevation, and elastic stockings—are of unproven benefit when used with anticoagulation in the management of a DVT. Aggressive anticoagulation will prevent extension of clot and allow for its lysis by the usual fibrinolytic pathways. Early ambulation with appropriate analgesia as needed after adequate anticoagulation with heparin is a practical and safe approach. PPS can be treated with periodic leg elevation, compression stockings, and pain medications as required.

Prevention of PE is the primary objective in treating DVT. Given the potential to propagate, a calf DVT should be followed closely with repeat duplex or IPG in 5 to 7 days after initial examination. (Some authorities suggest two repeat examinations at 2 and 7 days after first test.[7]) The potential morbidity and cost of several months of anticoagulation is not justified for an isolated, nonextending calf DVT except in high-risk groups such as patients with a history of a previous proximal DVT or PE, significant cardiovascular comorbidity, a persistent hypercoagulable state, or poor ambulation.

Several recent studies have documented the accuracy of serial duplex examinations and the safety of withholding anticoagulation in patients clinically suspected of having DVT but with a normal initial ultrasound.[4,7] A repeat duplex should be done in these patients at 5 to 7 days after initial exam or earlier if there is progression of symptoms or signs. The risk of a PE within 7 days of a normal duplex scan in patients with symptoms of DVT of the lower extremity is near zero. The probability of detecting DVT on a second ultrasound when there is a completely normal color-flow duplex scan from a few days earlier is approximately 2 percent.[2,7] Subsequent thromboembolism (typically nonfatal) within 3 months of two normal serial duplex studies occurs in about 0.6 percent of patients, which is comparable to the outcome in patients with normal venograms.[7] It follows that withholding anticoagulation in patients with negative serial ultrasounds is safe, accurate, and cost-effective.

Proven proximal DVT requires immediate anticoagulation to reduce local morbidity and prevent thromboembolism. The initial choice of treatment is becoming a low-molecular-weight heparin (LMWHs), such as dalteparin, enoxaparin, or tinzaparin. These are *weight-adjusted* and given once or twice daily subcutaneously until oral anticoagulation reaches the therapeutic range (100 U/kg q12h or 200 U/kg q24h for dalteparin; 100/mg/kg q12h for enoxaparin; 175 U/kg q24h for tinzaparin based on actual body weight). The available LMWH agents are *not* interchangeable. These drugs have several advantages over unfractionated heparin, including a more predictable anticoagulant effect, ease of administration, longer half-life, lack of a need to monitor the anticoagulation effect, resistance to inhibition by activated platelets, and a lower incidence of major bleeding and heparin-induced thrombocytopenia.[2,8,9] LMWH has a preferential inhibitory effect on factor Xa rather than factor IIa (thrombin) and is at least as effective and safe as unfractionated heparin in the treatment of DVT or PE.[8,9,10] INR or PTT cannot be used to monitor the effect of LMWH and measuring factor Xa levels is expensive, not readily available, and unnecessary given the very predictable effect of these heparins. The ability to discharge most patients home after treatment with LMWH with next-day follow-up makes this the most cost-effective option. The treatment plan must be discussed with the continuing care physician, including follow-up in 24 h and institution of warfarin.

Despite the increasing use of LMWH, some patients will have indications for admission. These include the patient who is unable to ambulate, has poor social supports or unreliable follow-up, has difficulty with education for drug administration, needs lytic or invasive therapy, or needs to have an alternative serious diagnosis investigated or treated (e.g., arterial ischemia, cellulitis, or pelvic mass). The consequences of a suspected or known PE such as hemodynamic instability or significant comorbidity will also require in-hospital treatment. Obviously, there must be a mechanism for providing the patient with the medication before discharge from the ED.

If LMWH is not immediately available, a continuous infusion of unfractionated heparin can be started until LMWH is initiated or oral anticoagulation is therapeutic. Weight-adjusted dosing of 80 U/kg bolus followed by an infusion of 18 U/kg per hour will rapidly achieve a therapeutic activated partial thromboplastin time (aPTT). Traditional dosing of a 5000-U bolus followed by an infusion of 1000 U/h will result in subtherapeutic aPTT at 6 h in two-thirds of treated patients. If weight-adjusted dosing is not used, a higher bolus of 7500 to 10,000 U followed by an infusion of 1250 U/h or greater is recommended. The infusion is altered to keep the aPTT between 55 and 85 s (1.8 to 2.8 times normal). Close monitoring of patients is required to detect bleeding and heparin-induced thrombocytopenia and thrombosis. Serious bleeding due to LMWH is very unusual, but if it occurs, the anti-Xa effect cannot be reversed. Protamine can counteract the minor anti-thrombin effect of LMWH, but is not useful given its inability to effect factor Xa and its own inherent potential to cause bleeding.

Oral anticoagulation with the vitamin K antagonist warfarin should be started on the same day as heparin for the treatment of a DVT. However, before its delayed effect of reducing prothrombin concentrations occurs, warfarin increases coagulability and thrombogenesis in the first 24 to 48 h owing to its early effect on reducing protein C levels.[2] This has prompted some authors to suggest that warfarin should be started well after initiation of heparin when the aPTT is adequately prolonged, though it is common practice to start both drugs simultaneously. It is clear, however, that if heparin is discontinued early, when the International Normalized Ratio (INR) first becomes therapeutic, the patient is at risk of clot extension, since warfarin has induced a transient hypercoagulable state. The usual recommended loading dose of warfarin is 7.5 to 10 mg, which is twice the expected maintenance dose. Then the daily warfarin dose is adjusted to keep the INR between 2 and 3. Heparin can be discontinued when the INR is in the therapeutic range for at least two consecutive days.

Warfarin is associated with some serious adverse effects and should not be used in certain circumstances. The commonest risk of warfarin is bleeding. This is usually related to the degree of anticoagulation and typically responds to dose reduction. Skin necrosis secondary to warfarin occurs primarily in patients with a deficiency of protein C or protein S.[2] The necrosis is due to thrombotic occlusion of small vessels, usually three to eight days after initiation of this drug. Warfarin is contraindicated in patients who are pregnant, have a serious or active bleeding diathesis, or have had very recent major surgery (thoracoabdominal, nervous system, spine, or eye). It causes fetal bleeding and is teratogenic, but neither unfractionated heparin nor LMWH crosses the placenta and both are safe for the fetus. LMWH is the preferred drug for the treatment of a DVT in pregnancy and warfarin can be safely started in the postpartum period even in breast-feeding women.[2]

The duration of warfarin treatment has to be individualized and is dependent on a previous history of DVT or PE, reversibility of previous thromboembolic risk factors, the effectiveness of warfarin to resolve thrombosis, and on the risk of bleeding. Oral anticoagulation for 3 to 6 months is associated with fewer recurrent thromboembolic events than shorter treatment regimens. There is no evidence that a longer course of warfarin is needed for patients with a PE. Despite adequate treatment of a DVT, there is a 6 percent risk of a recurrent DVT or PE during the first year and 13 percent over 5 years. Patients who present with a new or progressive clot despite adequate anticoagulation with warfarin need to be started on LMWH and investigated for a hypercoagulable state on an urgent outpatient basis. Warfarin resistance is not infrequently encountered in patients with metastatic disease.

The issue of initiating anticoagulation and interference with workup of possible hypercoagulability occasionally arises. Since LMWH does not alter the ability to investigate hypercoagulable states, there is no need to procure additional blood samples beyond routine coagulation studies in patients with a straightforward DVT. Further, acute-phase reactants themselves can alter blood results with an acute DVT/PE. Initiation of unfractionated heparin therapy is likely to interfere with the workup of hypercoagulability. However, such investigations for the underlying etiology of a DVT typically do not alter management. Thus, these patients can be investigated in 3 to 6 months, when anticoagulation is stopped. When a patient presents with a refractory or progressive clot despite warfarin and is treated with LMWH, further hematologic studies can still be carried out and extra blood from the ED can be held for further testing (factor V Leiden, antithrombin III, protein C and S levels, and antiphospholipid anticoagulants). If, for some reason, unfractionated heparin is used to treat a patient with DVT, then at least two extra blood tubes should obtained prior to initiation of treatment and held for further testing by the hematologist.

Thrombolytic and Mechanical Therapy

Currently, no controlled clinical trials have shown a survival benefit of thrombolytics over heparin and warfarin. Some randomized trials suggest reduced morbidity from PPS if complete clot lysis is achieved with thrombolytics.[2] However, as the short-term benefits of lytic agents are generally small and the long-term benefits remain to be proved, the use of these drugs has very limited indications. In practice, they are rarely used to treat a DVT. Thrombolytics have a significantly greater bleeding risk, including fatal intracerebral hemorrhage, than heparin or warfarin. Currently, lytic drugs such as streptokinase, urokinase, and tissue plasminogen activator (tPA) should be restricted to extensive iliofemoral thrombosis such as phlegmasia cerulea dolens in patients with a low risk of bleeding. Systemic thrombolysis may fail to lyse iliofemoral clots due to local stagnant blood flow; in such cases, intravascular catheter-directed thrombolysis is recommended.

An inferior vena cava filter can be placed to prevent a PE when oral anticoagulation is contraindicated, a DVT persists or propagates despite adequate medical treatment, embolization occurs after 1 to 2 weeks of therapeutic anticoagulation, or there is significant bleeding with the use of anticoagulants. Given the greater than 95 percent patency rate of a Greenfield filter at 1 year after placement, its indications can be expanded. A free-floating, nonadherent iliofemoral thrombus greater than 5 cm has an up to 60 percent chance of forming a PE; in such cases, filter placement should be considered.

Surgical thrombectomy was enthusiastically received in previous decades, but owing to high rates of rethrombosis and failure to prevent postphlebitic sequelae due to valve incompetency, it is rarely considered today. When conventional therapy for DVT is contraindicated or ineffective, thrombectomy followed by heparin can achieve long-term patency. Surgical treatment of a DVT is typically reserved for patients when limb viability is jeopardized by a massive venous clot, such as a persistently ischemic leg secondary to phlegmasia cerulea dolens.

The ED management of patients who are adequately anticoagulated but present with propagation or a new clot is fairly straightforward. Since LMWH is significantly more effective for treating DVT, these patients should all be started on LMWH with urgent follow-up by hematology (or, if otherwise indicated, admission). If they fail LMWH or have large free-floating thrombi, a Greenfield filter should be emergently placed by radiology. The investigation of these patients for a hypercoagulable state or malignancy need not be initiated in the ED. There is no evidence in the literature that increasing anticoagulation beyond an INR of 3 is at all effective in treating refractory DVT.

Axillary and Subclavian Vein Thrombosis

Though up to 90 percent of all DVTs occur in the lower extremities, a clot can develop in the axillary or subclavian vein. The risk factors for developing a venous thrombus in the upper extremity are like those outlined in Table 55-1 and Table 55-2, a higher incidence being associated with venous catheterization, intravenous drugs, excessive or unusual exercise (effort thrombosis), malignancy, and other hypercoagulable states. A predisposing venous stricture or chronic compression (cervical rib, hypertrophied scalene muscle, congenital web, etc.) is not uncommonly detected as a causal factor. The patient with DVT of an upper extremity can present with an abrupt or gradual onset of swelling in the arm, associated with dilated veins in the hand and forearm. The arm may feel heavy, with pain on physical activity which is relieved with rest. Sudden onset of severe pain and swelling with a change in the color of the arm is a rare presentation. The two primary methods of investigating a suspected venous thrombosis of an upper limb is by duplex ultrasound or venography. Computed tomography (CT) and MRI are occasionally useful in difficult cases.

It is estimated that a PE occurs in 10 to 30 percent of cases involving axillary or subclavian DVT; aggressive therapy is warranted in such instances. Current treatment options include anticoagulation alone or preceded by catheter-directed thrombolysis. The choice of therapy should be discussed with the consulting vascular surgeon and invasive radiologist but should be individualized in every case. The underlying cause, duration of symptoms, comorbidity and contraindications to lytic agents or anticoagulants can help guide the choice of the most appropriate therapy. Resolution of symptoms and signs is dependent not only on therapy but also on the development of collateral flow. Following initial therapy, an underlying compressive abnormality or venous stenosis, if present, must be corrected (e.g., rib resection, balloon angioplasty).

OCCLUSIVE ARTERIAL DISEASE

Acute limb ischemia secondary to thrombosis or embolism is a true emergency requiring immediate therapy to salvage the limb. The ED physician must urgently initiate treatment and investigation of a threatened limb in collaboration with the radiologist and vascular surgeon. A good understanding of the pathophysiology, etiology, and clinical presentation of peripheral vascular disease will help guide management in the effort to restore blood flow to the affected limb.

Epidemiology

Intermittent claudication has a prevalence of between 1 and 7 percent for men above age 50, with symptomless disease existing in up to 25 percent of men scanned with noninvasive testing in this age group.[11] Symptoms of peripheral arterial disease increase with age and are two to four times more common in men than in women. The vast majority of these patients have a history of prolonged smoking. There has been an increase in the incidence of both chronic limb ischemia and arterial embolic disease in the last decade. Given that atherosclerosis is the usual pathology in ischemic limb pain, it is not surprising that at lest half of these patients have coronary or cerebrovascular disease.[11] Embolic occlusion of an artery also occurs primarily in elderly men and postmenopausal women, given the higher prevalence in this group of heart disease, which is the major source of thromboemboli.

Pathophysiology

Acute limb ischemia results from a blood supply that is inadequate to meet tissue oxygen and nutrient requirements. If allowed to persist, it will lead to cell death and irreversible tissue damage. Even after perfusion is partially or completely restored, reperfusion injury can occur as oxygen radicals form and cause further cell injury. Perfusion may not be fully attainable with prolonged arterial obstruction due to distal edema and thrombi forming in the microcirculation. The extent of injury depends on the duration and location of the arterial blockage, the amount of collateral flow, and the previous health of the involved limb. Also, some tissues are more susceptible to anoxia than others, presumably on the basis of differences in cellular respiration and oxygen requirements. Peripheral nerves and skeletal muscle are very sensitive to ischemia; in them, irreversible changes occur within 4 h of anoxia at room temperature.

Nonembolic limb ischemia is secondary to atherosclerosis in the vast majority of patients.[12] Plaque formation within the intima of an artery results from lipid accumulation, proliferation of smooth muscle cells, and fibrogenesis. Narrowing of the vascular lumen occurs with progression of the atheromatous plaque. Complete or high-grade obstruction can occur at this site of stenosis secondary to plaque rupture, hemorrhage, or thrombus formation. An atherosclerotic vessel can give rise to an aneurysm because of its weakened walls. A true aneurysm, involving dilatation of its entire wall, can present clinically with thrombosis, rupture, and hemorrhaging or by its mass effect on adjacent structures.

Etiology

An embolus is the commonest cause of an acute arterial occlusion in the limb and originates from the heart in 80 to 90 percent of cases of embolism. Atrial fibrillation and recent myocardial infarction are the two primary causes of mural thrombus within the heart. Both conditions result in poor wall motion and stagnant blood flow, predisposing to clot formation. The natural history of an embolus is to either fragment and embolize distally or to propagate locally into a larger clot, though associated venous thrombosis can occur possibly secondary to local ischemia, decreased venous flow, and inflammation. Emboli usually lodge where vessels branch or taper, most frequently in the lower extremities. The commonest location for an embolus in the leg is the bifurcation of the common femoral artery and in the brachial artery of the upper limb. Rare cardiac sources of emboli include tumor emboli from atrial myxomas, vegetations from valve leaflets, and parts of prosthetic devices such as mechanical valves.

Noncardiac sources of arterial emboli include thrombi from aneurysms and atheromatous plaques. Mural thrombus in aneurysms of aortoiliac, femoral, popliteal, and subclavian arteries are the most notable sources. Atheroemboli result from plaque fragmentation and cause obstruction of the microcirculation, giving symptoms in the feet ("blue toe syndrome"), hands, or cerebral circulation (transient ischemic attack). These emboli consist of cholesterol-laden debris and platelet aggregates and can be showered to multiple parts of the body.

Thrombosis unrelated to atherosclerotic disease can occur at an area of vessel injury, as with invasive catheters, balloons, sites of bypass grafting or intraarterial drug injection, and with hypercoagulable states. All of these are potential sources of embolization. Femoral artery catheterization for coronary angiography or angioplasty and vascular access can result in ischemia of an extremity secondary to thrombosis or expanding hematoma; symptoms may be altered by preexisting aortoiliac or femoropopliteal plaques. Radial artery injury during blood-gas analysis or the placement of arterial lines rarely leads to tissue ischemia, given the excellent collateral supply from the ulnar artery. Intentional or accidental intraarterial drug injections by medical personnel or for illicit drugs can result in local vasospasm, infectious arteritis, thrombosis, pseudoaneurysms, and mycotic aneurysms. Inert particles or drug crystals can embolize to obstruct end arteries, leading to gangrene of digits, especially as drug addicts tend to delay seeking medical attention.

Peripheral arterial supply can also be obstructed by vasospastic or inflammatory conditions. Raynaud disease involves vasospasm in small arteries and arterioles in response to a stressor such as cold temperature or emotional stress. Symptoms of local pain, pallor followed by cyanosis, numbness, and parasthesias usually involve the fingers and hands and generally resolve within 30 to 60 min, especially with rewarming. Inflammation of arteries in the limb can occur with collagen

vascular diseases such as rheumatoid arthritis, lupus, and polyarteritis nodosa. When clinically active, these vasculitides are often associated with systemic symptoms and multiorgan involvement. Necrosis of blood vessels and loss of limb tissue is always a possibility. Thromboangiitis obliterans (Buerger disease) is an idiopathic occlusive disease resulting from segmental inflammation of arteries in all extremities. It occurs almost exclusively in young smokers (age 20 to 40), predominantly males, and is characterized by painful, tender nodules in the limbs with decreased distal flow.

Limb ischemia may occur with nonembolic central causes. A thoracic aortic dissection can propagate into the carotid, subclavian, and iliofemoral system and present with neurologic and extremity findings. The false lumen created by the dissection occludes flow in the involved artery. Takayasu arteritis, which primarily occurs in Asian females, involves the aortic arch and its branches and has a "pulseless phase" where peripheral ischemia and necrosis can develop.

More commonly, low cardiac output states with cardiogenic or hypovolemic shock may present with extremity ischemia. Severe left ventricular dysfunction—which can occur with ischemic cardiomyopathy, valvular heart disease, and cardiac tamponade—acutely threatens limb blood flow, particularly in elderly patients with preexisting atherosclerosis. Acute hemorrhage similarly reduces perfusion to the limbs, but, with acute intervention, may be reversible.

Clinical Features

Patients with acute limb ischemia will exhibit one or more of the "six P's": pain, pallor, polar (for cold), pulselessness, parasthesias, and paralysis. However, a lack of one or more of these findings does not exclude ischemia. Pain alone may be the earliest symptom. High clinical suspicion is paramount to early intervention to save a limb. Complete arterial obstruction results in visible skin changes, with initial pallor that may be followed by blotchy, mottled areas of cyanosis and associated petechiae and blisters. Severe, steady pain in the involved extremity associated with decreased skin temperature is expected. Hypoesthesia or hyperesthesia due to ischemic neuropathy is typically an early finding, as is muscle weakness. An absent pulse distal is only so helpful. It may be an abrupt new sign of an occlusive clot or a long-standing finding of chronic vascular disease. As ischemic injury progresses, anesthesia and paralysis become evident and foreshadow impending gangrene. Preservation of light touch on skin testing is a good guide to tissue viability. Necrosis of skin and fat is a late finding.

Despite the generally held belief that limb salvage is possible with reperfusion within 4 to 6 h, tissue loss can occur with significantly shorter occlusion times. As important, mild to severe limb dysfunction is possible even with an injury involving only brief anoxia, with potential for lasting disability. The poor predictability of functional outcome after ischemic injury underscores the need to attain rapid reperfusion and not rely on a probable safe time interval until resolution of occlusion. Disability and tissue loss are inevitable after 6 h of occlusive anoxic injury.

Microemboli present clinically with pain and cyanosis in the involved digit, petechiae, and local muscle pain and tenderness at the site of infarction. Several different small areas can be affected with a shower of microemboli originating from a large or unstable source. Though mottling and decreased function may occur, pulses are preserved.

Chronic peripheral arterial insufficiency is characterized by intermittent claudication, which may progress to intermittent ischemic pain at rest. Femoral and popliteal disease often causes reproducible calf pain with activity that is relieved with rest. Pain at rest typically localizes to the foot and is aggravated with leg elevation, improves with standing, and is poorly controlled with analgesics. [11] Shiny, hyperpigmented skin with hair loss and ulceration, thickened nails, muscle atrophy, vascular bruits, and poor pulses is a hallmark of chronic vascular disease. Complete arterial occlusion from thrombosis of a limb in these patients may present subacutely owing to a well-developed collateral circulation.

Diagnosis

A thorough clinical evaluation is the most useful diagnostic tool for the assessment of occlusive arterial disease. A history of an abruptly ischemic limb in a patient with atrial fibrillation or recent myocardial infarction is highly suggestive of an embolus. Acute ischemia in the limb of a patient known to have advanced peripheral vascular disease is more likely due to thrombosis or a low cardiac output state.

At the bedside, blanching the involved extremity with finger pressure and noting a delay in the return of blood as compared with the uninvolved extremity indicates decreased perfusion. However, several factors can influence capillary refill; thus one cannot rely on the presence or absence of this finding alone.

A hand-held Doppler can document the amplitude of flow or its absence when held over the dorsalis pedis, posterior tibial, popliteal, or femoral arteries in the lower limb and over the radial, ulnar, brachial, or axillary arteries in the arm. If time permits or the diagnosis of arterial occlusion is in question, duplex ultrasonography can be undertaken to detect an obstruction to flow. Cardiac monitoring and an electrocardiogram will detect an dysrhythmia and an echocardiogram can be done to look for an intracardiac thrombus if such is clinically suspected.

In consultation with a vascular surgeon and during the period of preoperative and/or medical management, an arteriogram can be done to confirm the diagnosis, define the vascular anatomy and perfusion, and guide aggressive management. A particular advantage of arteriography is the ability to perform this test on the operating room table before and during surgery. Scanning a limb with a spiral CT or MRI, though accurate and noninvasive, is not usually practical, given the time constraints, in the face of an acutely ischemic limb. However, when an aortic dissection or sources of microemboli such as aortoiliac or femoral aneurysms are suspected, an aortogram, CT, or MRI can be useful. Transesophageal echocardiography is gaining acceptance as the choice modality for detecting cardiac or aortic root pathology.

Management

When the diagnosis of acute limb ischemia is known or suspected, immediate intravenous heparinization should be started if no contraindications exist. This may help prevent clot extension, recurrent emboli, venous thrombosis, and the appearance of microthrombi distal to the obstruction. [12] Fluid resuscitation and treatment of heart failure and dysrhythmias is necessary to improve limb perfusion.

Definitive treatment of an obstructing clot should be done in conjunction with a vascular surgeon. Prompt surgical embolectomy is the optimal therapy for an acute arterial embolism causing limb-threatening ischemia. Catheter embolectomy has been the choice technique for removal of clot ever since the development of the Fogarty balloon catheter in 1963. [12] It has reduced mortality from arterial emboli by 50 percent and need for amputation by 35 percent. Overall mortality from an arterial embolus is about 15 percent and is usually due to the underlying cardiovascular disease. The limb salvage rate ranges from 62 to 96 percent. [12]

Intraarterial thrombolysis with streptokinase, urokinase, or tPA infused near or into the clot for a few hours to days is an alternative to surgery, with a rate of successful reperfusion of 50 to 85 percent. [12] It should be considered for distal thromboembolic occlusions in surgically inaccessible small arteries, acute thrombosis in a limb with chronic arterial insufficiency and adequate collateral flow, or in poor surgical candidates. Follow-up balloon angioplasty or surgical grafts may be needed to prevent rethrombosis in patients with atherosclerotic plaques. Systemic thrombolysis has been compared with intraarterial lytic agents in randomized trials and has been shown to produce inferior results. [12]

Since thrombotic occlusion usually occurs in arteries with advanced atherosclerosis and a developed collateral supply, it is often not a dramatic event and is occasionally silent. [12] Management of these occlusions therefore is conservative, with heparin alone. An angiogram is helpful to direct therapy and exclude embolic occlusion (radiologically seen as an abrupt cutoff of blood flow) when limb viability is acutely threatened. It is still unclear whether heparin improves outcome in the clinical circumstances of thrombosis in a plaque-laden artery.

Aneurysms of the Extremity

Over 80 percent of all peripheral arterial aneurysms arise in the popliteal artery and the vast majority are due to atherosclerosis. More than 95 percent of patients with popliteal aneurysms are elderly males. [13] Acute symptoms develop with thrombosis or distal embolization and rupture is rare.

False aneurysms of the femoral artery, consisting of encapsulated hematomas adjoining the vessel lumen, arise from iatrogenic injury and occur more frequently than true femoral aneurysms. Duplex ultrasonography, CT scan, or an MRI can confirm the clinical diagnosis and detect mural thrombus. The risk of ischemic complications from an asymptomatic popliteal aneurysm ranges from 8 to 100 percent (mean 36 percent). Thus, elective surgery following arteriography is recommended for all cases. [13] As 37 percent of patients with a single popliteal aneurysm have an aortic aneurysm and half have a contralateral popliteal aneurysm, a

thorough search is indicated after detection of a single aneurysm.

Subclavian artery aneurysms occur from atherosclerosis, trauma, or thoracic outlet obstruction. Rupture of a proximal subclavian aneurysm can cause death from exsanguination. Thromboembolism gives rise to typical signs and symptoms of distal ischemia, but it may also produce central neurologic deficits from retrograde propagation of clot into the vertebral and carotid circulation. Because of their severe potential morbidity, these aneurysms should be surgically removed promptly after diagnosis.

56 CARDIAC TRANSPLANTATION

Michael R. Mill
Michelle S. Grady

The first clinically successful cardiac transplant was performed in December 1967. Since then, advances in the immunosuppression and postoperative care of these patients have resulted in dramatically improved patient survival. This has been accompanied by a tremendous growth in the number of procedures performed. Data from the registry of the International Society of Heart and Lung Transplantation (ISHLT) and the United Network for Organ Sharing (UNOS) reveals that 45,993 heart transplants were performed at 301 centers throughout the world between January 1, 1983, and March 1, 1998.[1] This total includes more than 2000 heart transplants per year in the United States since 1990. The actuarial survival after transplantation reported by UNOS is 85 percent at 1 year, with 3-year and 5-year actuarial survivals of 76 percent and 69 percent, respectively.[2] Given the increased number of patients undergoing transplantation and their excellent long-term survival, these patients will come to the attention of physicians in the emergency department (ED) with increasing frequency.

TRANSPLANT RECIPIENTS

Cardiac transplantation has been applied successfully to patients of all ages, from newborns through persons in their late sixties. Heart transplantation is indicated for patients with end-stage heart failure not remediable by standard medical or surgical therapy. The etiology of heart failure in transplant recipients as reported by the ISHLT/UNOS registry is listed in Table 56-1.[1] The majority of adult patients have either idiopathic dilated cardiomyopathies or end-stage coronary artery disease. Many in the latter group will have undergone previous coronary artery bypass surgery. The predominant diagnoses in children undergoing transplantation are dilated cardiomyopathies and congenital heart disease. Many of the children with congenital heart disease will have undergone previous palliative or corrective operations. Patients are carefully evaluated to rule out other irreversible end-organ dysfunction and other systemic illnesses that would separately limit survival.

Adult	Occurrence	Pediatric	Occurrence
Coronary artery disease	44.8%	Congenital heart disease	46.4%
Dilated cardiomyopathies	46.2%	Dilated cardiomyopathies	44.3%
Valvular	3.5%	Retransplantation	2.9%
Retransplantation	2.1%	Miscellaneous	6.4%
Congenital	1.8%		
Miscellaneous	1.6%		

TABLE 56-1 Etiology of Heart Failure in Transplant Recipients

CARDIAC PHYSIOLOGY AFTER TRANSPLANTATION

The physiologic basis upon which cardiac transplantation is grounded is the ability of the denervated heart to support normal circulation. The lack of sympathetic and parasympathetic innervation does, however, induce an altered physiologic state. The denervated heart has a normal sinus rhythm with a heart rate between 90 and 100 beats per minute. Denervation results in the absence of the initial centrally mediated tachycardia in response to stress or exercise. The heart remains responsive to circulating catecholamines of either endogenous or exogenous origin. The cardiac response to stress or exertion is therefore blunted. With the onset of exercise, the heart rate initially remains unchanged, then gradually increases to a level of approximately 80 percent of predicted over 10 to 15 min. After termination of exercise, this exercise-induced tachycardia will persist for approximately 20 to 30 min before slowly returning to the patient's baseline rate. Patients may complain of fatigue or shortness of breath with the onset of exercise that resolves with continued exertion as an appropriate tachycardia develops. In order to accommodate this response, patients are trained to perform warmup exercises prior to vigorous exertion to initiate an increase in their heart rate. They are also cautioned to allow appropriate time for recovery at the end of exertion.

Cardiac hemodynamics after transplantation as measured by cardiac catheterization reveal a normal to mildly depressed cardiac output at rest. With exercise, cardiac output increases in response to increased venous return (preload) and circulating catecholamines. Maximal cardiac outputs of 80 to 100 percent of normal have been measured. Patients are able to resume normal activity levels, including vigorous exercise, following transplantation. A number of posttransplant patients have completed marathons and participated in other rigorous physical activities, and at least one such individual has competed as a professional athlete.

Cardiac denervation results in an altered response to some medications used in emergency resuscitation.[3] In patients with supraventricular tachycardias, the lack of sympathetic innervation obviates the utility of carotid sinus massage. Atropine, which acts by abolishing reflex vagal slowing, will have no effect on heart rate in patients with symptomatic bradyarrhythmias. Conversely, denervated hearts are quite sensitive to the chronotropic effects of b-adrenergic agents such as isoproterenol, dopamine, and dobutamine. Because these are normal hearts, they are resistant to the proarrhythmic effects of these drugs. Isoproterenol is used preferentially to increase donor heart rates because it has the greatest chronotropic effects and can easily be titrated to achieve the desired heart rate. The typical dose range is 1 to 4 µg/min administered by continuous intravenous infusion.

CARDIAC EVALUATION OF THE POSTTRANSPLANT PATIENT

Electrocardiograms (ECGs) obtained on transplant recipients should demonstrate normal sinus rhythm. The donor heart is implanted with its sinus node intact to preserve normal atrioventricular conduction. The technique of cardiac transplantation also results in the preservation of the recipient's sinus node at the superior cavoatrial junction. The atrial suture line renders the two sinus nodes electrically isolated from each other. Thus, ECGs will frequently have two distinct P waves (Fig. 56-1). The sinus node of the donor heart is easily identified by its constant 1:1 relationship to the QRS complex, while the native P wave marches through the donor heart rhythm independently. The presence of the two separate P waves may lead to confusion about the patient's rhythm. The ECGs may be interpreted erroneously as showing atrial fibrillation, atrial flutter, or frequent premature atrial complexes. The use of calipers aids in the definition of the two distinct P waves. Sinus node dysfunction in the posttransplant heart occurs in approximately 4 to 5 percent of patients and is manifest by either sinus brachycardia with heart rates of equal to or less than 50 beats per minute or sinus standstill with a junctional escape rhythm with heart rates of 60 to 70 beats per minute. This dysfunction occurs in the early postoperative period and resolves spontaneously in most patients. For patients in whom sinus node dysfunction persists, treatment consists of either theophylline, which accelerates the sinus bradycardia in some patients, or implantation of a permanent transvenous pacemaker. The type of pacemaker implanted varies depending on institutional preference but generally is either an atrial pacemaker programmed in the AAIR mode or a ventricular pacemaker programmed in the VVIR mode. Use of an atrial rate-responsive pacemaker preserves atrioventricular conduction in addition to providing physiologic rate responsiveness.

FIG. 56-1. Electrocardiogram demonstrating donor and recipient P waves. Ñ donor P wave; ↑ recipient P wave.

Posttransplant chest radiographs show evidence of a prior sternotomy but otherwise are generally normal. Some patients may have evidence of "cardiomegaly" related to the transplantation of a heart from a donor who was larger than the recipient (Fig. 56-2).

FIG. 56-2. Chest radiograph of healthy posttransplant patient with typical postoperative changes.

Echocardiography is a useful tool for evaluating cardiac function post-transplantation. Interpretation of the echocardiogram is routine with the exception of the evaluation of the atrial size. Because the atrial anastomoses incorporate the posterior walls of the recipient's native atria, echocardiography will show atrial enlargement, but this has no significant effect on cardiac function. Early rejection results in diastolic dysfunction, although the echocardiographic indices may be subtle and difficult to detect. Severe rejection will be accompanied by signs of biventricular enlargement with global hypocontractility and significant atrioventricular valve regurgitation.

IMMUNOSUPPRESSION FOR CARDIAC TRANSPLANTATION

As with all types of solid organ transplantation, lifelong immunosuppression is required to prevent acute graft rejection. One of the most significant challenges of clinical transplantation is to maintain an adequate level of immunosuppression to prevent rejection while preserving adequate immunocompetence to avoid serious infectious complications. Since the mid 1980s, standard immunosuppression has employed a triple drug regimen consisting of cyclosporine (Sandimmune, SangCya), prednisone, and azathioprine (Imuran). The combination of these agents has resulted in superior graft and patient survival rates, has decreased the mortality from infectious complications, and has minimized the side effects of the individual agents. Recently, the newer immunosuppressive agents tacrolimus (Prograf) and mycophenolate mofetil (Cellcept) have been used in place of cyclosporine and azathioprine, respectively. In addition, some programs use induction therapy in the early postoperative period, employing cytotoxic antibody preparations targeted against the T lymphocytes. The most commonly used agents include OKT3, a murine monoclonal antibody, and polyclonal preparations such as antilymphocyte serum (ALS) and antilymphocyte globulin (ALG).

Cyclosporine remains one of the mainstays of immunosuppressive regimens. This fungal metabolite is a potent inhibitor of T-lymphocyte activity and interferes with the generation of interleukin 2 (IL-2). It is a lipophilic substance that is metabolized in the liver by the cytochrome P-450 system. Cyclosporine is usually taken twice daily, and doses are adjusted based on serial blood levels. Target trough levels vary depending on the specific laboratory assay used. Levels are maintained in the range of 300 to 400 ng/dL early after transplantation and then lowered to levels of approximately 150 ng/dL long term. The list of drugs that interact with cyclosporine (Table 56-2) continues to grow yearly, and careful consideration is required before adding or withdrawing medications for an individual patient. Such changes should always be made with the knowledge and input of the patient's transplant physician. Acute increases in cyclosporine levels may be associated with severe renal dysfunction, and acute decreases may result in the development of acute rejection.

TABLE 56-2 Cyclosporine Drug Interactions

Commonly encountered side effects of cyclosporine are listed in Table 56-3. Hypertension occurs in the majority of patients and frequently requires combination therapy to achieve adequate control. Renal insufficiency is also quite common and is mediated at least in part by the vasoconstrictive effects of cyclosporine on the proximal renal tubule. Management of cyclosporine-induced renal insufficiency requires careful monitoring, because worsening renal insufficiency results in elevated cyclosporine levels, leading to more renal dysfunction, thus creating a vicious cycle. Although early renal insufficiency is frequently reversible, some patients have developed end-stage renal disease requiring dialysis or renal transplantation.

TABLE 56-3   Common Cyclosporine Side Effects

Formally known as FK-506, tacrolimus is a macrolide antibiotic with an immunosuppressive mechanism similar to that of cyclosporine. Tacrolimus prevents rejection of the transplanted organ by inhibiting the expression of IL-2 in T cells and inhibiting T-cell growth and proliferation. Studies show that replacing cyclosporine with tacrolimus as a primary or rescue immunosuppressant may result in fewer episodes of rejection, less clinically relevant hypertension, and lower doses of maintenance corticosteroids.[4] Initial studies with tacrolimus after cardiac transplantation suggest that tacrolimus is a safe and effective immunosuppressant alternative to cyclosporine. Oral doses of tacrolimus are typically 0.15 mg/kg twice daily. Doses are adjusted to achieve a goal trough blood level of 10 to 15 ng/dL for the first several months posttransplant and then 5 to 10 ng/dL long term. The most common side effects of tacrolimus are similar to those of cyclosporine, as shown in Table 56-3, with the exception of hirsutism and gingival hyperplasia, which have not been reported. Based on the mechanism by which tacrolimus is metabolized, drugs known to interact with cyclosporine and erythromycin should be considered potential interactants for tacrolimus until proven otherwise.

Azathioprine is a 6-mercaptopurine derivative that acts as a false metabolite in the proliferation of bone marrow stem cells. The typical dose is 1 to 2 mg/kg per day, adjusted to maintain a white blood cell count greater than 5000/mm^3. The most common side effect is bone marrow suppression manifest as neutropenia. In some patients, anemia and thrombocytopenia may be present. The most common drug interaction is with allopurinol, which may be prescribed to treat acute gouty arthritis, itself a side effect of cyclosporine therapy. If allopurinol is to be prescribed, the dose of azathioprine should be decreased by half and frequent follow-up white blood cell counts should be obtained to avoid profound bone marrow suppression.

Mycophenolate mofetil (MMF), another new immunosuppressant, is a potent inhibitor of de novo purine synthesis inhibiting T- and B-lymphocyte proliferation.[5] MMF has been approved by the Food and Drug Administration (FDA) for the prophylaxis of organ rejection in renal transplantation when used concomitantly with cyclosporine and prednisone. MMF is being promoted as an improvement over azathioprine, replacing it in the standard triple-drug immunosuppressive regimen. Clinical studies of MMF after cardiac transplantation suggest that it is a safe and effective alternative to azathioprine in maintenance immunotherapy and possibly more effective in the treatment of refractory and persistent rejection.[6] Dosing of MMF is typically 1.0 to 1.5 g twice daily. The most common side effects include diarrhea, vomiting, leukopenia, and an increase in opportunistic infections, especially involving cytomegalovirus (CMV), both tissue-invasive disease and viremia. Should neutropenia develop, the MMF dosage should be adjusted or the therapy discontinued. Drugs that interact with MMF include antacids and cholestyramine, which decrease absorption of MMF and therefore should not be taken at the same time.

Steroids remain an integral part of posttransplant immunosuppression. Prednisone is begun initially at high doses (1.0 to 1.5 mg/kg per day) posttransplant and weaned over 6 to 8 weeks to a maintenance dose of 0.2 mg/kg per day (about 15 mg/day in the average adult recipient). Many programs now attempt to wean patients off steroids in an effort to avoid the well-known deleterious effects of chronic steroid therapy. Steroid withdrawal is successful in approximately 50 percent of cases.

REJECTION

Rejection after cardiac transplantation is a lifelong risk, although the incidence of rejection decreases with time. Rejection can be divided into three types, based on mechanism of rejection and time after transplantation. *Hyperacute rejection* is mediated by preformed anti-HLA antibodies directed against the donor tissue. Hyperacute rejection results in immediate and irreversible donor heart failure and is a fatal complication unless the patient can be maintained with a mechanical assist device until a new donor heart is located. With the use of ABO blood group–compatible donors and screening of transplant candidates for elevated levels of preformed anti-HLA antibodies, hyperacute rejection is very rare in cardiac transplantation.

Acute rejection, the most common type of rejection encountered, occurs in approximately 75 percent of all patients at some time after transplantation. The incidence of acute rejection is greatest within the first 6 weeks posttransplantation as immunosuppressive medications are weaned to chronic maintenance levels. Rejection can occur at any time after transplantation. Late episodes can usually be correlated with some change in the patient's immunosuppressive status, such as an acute illness or noncompliance with medications. Acute rejection is a cellular phenomenon resulting in the infiltration of lymphocytes into the myocardium, with subsequent destruction of individual myocytes. Because most episodes of rejection do not cause clinically detectable graft dysfunction, surveillance endomyocardial biopsies are performed on a routine basis after transplantation. Biopsy specimens are examined histologically and graded according to a grading system (Table 56-4) developed by a working group of the ISHLT.[7] Mild to moderate episodes of rejection (grades 0 to 2) are generally not accompanied by clinical symptoms or hemodynamic changes. Severe rejection (grade 4) can result in profound myocardial dysfunction and death. Patients with grade 2 or higher rejection are treated with augmented steroids or cytotoxic therapy, as outlined below.

Grade	Histologic Description
0	No rejection
1	A = focal (perivascular or interstitial) infiltrate without necrosis B = diffuse but sparse infiltrate without necrosis
2	One focus only with aggressive infiltration and/or focal myocyte damage
3	A = multifocal aggressive infiltrates and/or myocyte damage B = diffuse inflammatory process with necrosis
4	Diffuse aggressive polymorphous infiltrate ± edema, ± hemorrhage, ± vasculitis, with necrosis

TABLE 56-4   Standardized Cardiac Biopsy Grading System

Chronic rejection is believed to be manifested in the heart by the development of graft atherosclerosis. This antibody-mediated phenomenon is thought to result in injury to the endothelial lining of the coronary arteries, with the subsequent development of intimal hypertrophy. The lesions may be focal but are more often diffuse and concentric, involving the entire length of the epicardial and intramyocardial vessels. Because the heart is denervated, myocardial ischemia does not present with angina. Instead, recipients present with heart failure secondary to silent myocardial infarctions or with sudden death. Transplant recipients who present with new-onset shortness of breath, chest fullness, or symptoms of congestive heart failure should be evaluated for the presence of myocardial ischemia or infarction. This is done in routine fashion with ECG and serial cardiac enzymes. Echocardiography can be used to look for segmental wall motion abnormalities. If evidence for myocardial ischemia or infarction is found, cardiac catheterization with ventriculography and coronary angiography is indicated. The rate of development of graft coronary disease is quite variable, occurring months to years after transplantation; consequently, cardiac transplant programs employ annual follow-up coronary angiograms to detect its presence. The diffuse nature of graft coronary artery disease generally precludes standard methods of myocardial revascularization such as percutaneous transluminal coronary angioplasty, stent implantation, or coronary artery bypass surgery. Retransplantation is the most effective treatment.

Although most episodes of acute rejection are asymptomatic, symptoms can occur. The most common presenting symptoms are dysrhythmias and generalized

fatigue. The development of either atrial or ventricular dysrhythmias in a cardiac transplant recipient must be assumed to be due to acute rejection until proven otherwise. Arrangements should be made for prompt performance of an endomyocardial biopsy. If patients are hemodynamically compromised by their dysrhythmias, empiric therapy for rejection with methylprednisolone (Solu-Medrol), 1 g IV, may be given. If the diagnosis of rejection is confirmed, standard antirejection therapy should be completed. Atrial dysrhythmias may respond to treatment with digoxin or calcium channel blockers. Ventricular dysrhythmias may respond to lidocaine or other class I-C agents. Frequently the dysrhythmias will be controlled only with antirejection therapy.

Untreated acute cardiac rejection results in progressive myocardial dysfunction. Diastolic dysfunction occurs first, followed by systolic dysfunction as the degree of myocardial damage increases. Diastolic dysfunction causes symptoms of congestive heart failure with shortness of breath, fatigue, and malaise. Progressive myocardial dysfunction results in low-output syndrome, with symptoms including nausea, vomiting, and/or diarrhea. Severe rejection leads to hypotension and circulatory collapse. Symptoms of rejection may be mistakenly attributed to a viral syndrome or gastroenteritis. Physical examination reveals signs of heart failure, including distended neck veins, an S_3 gallop on cardiac auscultation, rales on pulmonary auscultation, and occasionally the presence of ascites or peripheral edema. Chest x-rays show enlargement of the cardiac silhouette and pulmonary vascular congestion. ECGs may demonstrate—in addition to dysrhythmias—a decrease in amplitude and widening of the QRS complex.

Patients with signs or symptoms suggestive of acute rejection should be admitted to the hospital with continuous ECG monitoring. Arrangements should be made for performance of an endomyocardial biopsy at the earliest possible time. If facilities for obtaining and interpreting biopsy specimens are not available, transfer to the nearest transplant center should be arranged. Low-output syndrome and/or hypotension should be treated with inotropic agents such as dopamine or dobutamine while specific treatment for rejection is instituted. Treatment for rejection without biopsy confirmation is contraindicated except when the patient is hemodynamically unstable. This is especially true in patients whose symptoms are due to an occult infection because of the potential adverse consequences of high-dose steroid therapy. Empiric treatment for rejection should be employed only after consultation with the patient's transplant center.

Standard therapy for acute rejection includes intravenous methyl-prednisolone 1 g/day for 3 days. In patients with refractory rejection, treatment with specific T-cell cytotoxic agents such as OKT3, ALS, or ALG is required. Occasionally, patients have been successfully supported with mechanical assist devices for profound circulatory collapse while undergoing therapy for rejection, with resultant complete recovery of normal ventricular function.

INFECTIOUS COMPLICATIONS AFTER CARDIAC TRANSPLANTATION

Infectious complications are fairly common after transplantation, particularly in the early posttransplant period, when the highest doses of immunosuppressive medications are employed. The infectious complications after cardiac transplantation are similar to those following all types of solid-organ transplantation and those in other immunocompromised hosts.[8] The infections most commonly encountered are listed in Table 56-5. Prophylactic regimens are employed by most transplant centers. Pretransplantation, patients are vaccinated with pneumococcal, *Haemophilus influenzae,* and hepatitis B vaccines. Peri-operatively, routine antistaphylococcal antibiotics are used. Postoperatively, mycostatin mouthwash is used to prevent oral and esophageal candidiasis while the patients are on high-dose steroids and is reinstituted when augmented steroid therapy is required to treat rejection. *Toxoplasma gondii* can infect the transplanted heart; it may result from reactivation of a latent recipient infection or be transmitted with the donor organ. *Toxoplasma* titers are measured in all recipients and donors, and pyrimethamine is administered prophylactically for 6 weeks posttransplantation if titers are elevated. Beginning approximately 2 months posttransplantation, trimethoprim/sulfamethoxazole (Septra, Bactrim) is used as prophylaxis against *Pneumocystis carinii* pneumonia (PCP). Antibiotic prophylaxis for any invasive procedure (e.g., dental work, endoscopy, or surgical procedures) is recommended for the lifetime of the patient. Annual flu shots are recommended. Live attenuated virus vaccines such as those for measles, mumps, and rubella are contraindicated in transplant recipients.

TABLE 56-5   Common Infections after Cardiac Transplantation

Any patient with a history of solid-organ transplantation who presents with symptoms of an infection must be evaluated in an aggressive and thorough manner. Appropriate stains and cultures should be obtained to allow identification of bacterial, fungal, and viral pathogens. There should be a low threshold for instituting antimicrobial therapy while awaiting culture results and for admitting patients to the hospital for further evaluation and intravenous antibiotics. Patients with evidence of pulmonary infiltrates but without productive sputum require bronchoscopy with bronchoalveolar lavage and transbronchial biopsy for definitive diagnosis. Pulmonary infections that are frequently encountered include *P. carinii, Nocardia, Legionella pneumophilia,* and *Aspergillus;* these require special stains and studies for accurate diagnosis. Patients with gastroenteritis and nausea, vomiting, and/or diarrhea require special attention. Inability to ingest or adequately absorb immunosuppressive medications may result in the development of an episode of rejection. If there is any question about a recipient's ability to maintain adequate oral intake, the patient should be hospitalized and immunosuppressive medications be administered intravenously.

Antibiotic therapy for documented infections should be guided by appropriate culture and sensitivities and must take into account underlying renal insufficiency and potential interactions with cyclosporine or tacrolimus.

Of special note is the risk of CMV infection after cardiac transplantation. CMV is a common virus to which the majority of adults have been exposed, as demonstrated by the presence of anti-CMV IgG antibodies in the serum. Posttransplantation, CMV infections can occur due either to the reactivation of latent virus in a previously infected recipient or the development of a new infection with a different viral strain transmitted with the donor organ. The latter situation is much more serious and potentially life-threatening, particularly in recipients who were CMV-negative prior to transplantation. Routine posttransplant surveillance for CMV infection is performed utilizing serial IgG and IgM antibody testing and throat, urine, and serum buffy coat cultures. The recent development of CMV antigenemia assays has enhanced the early detection of CMV infection. CMV disease can occur in either a mild or severe form. Mild disease is manifested by a flulike illness with low-grade fever, fatigue, malaise, and nausea. Severe disease may include profound leukopenia; pneumonitis; gastroenteritis including epigastric pain, vomiting, and diarrhea; and hepatitis with elevated transaminases. CMV pneumonitis carries a mortality of greater than 50 percent. CMV infection typically occurs 4 to 12 weeks posttransplantation. The diagnosis is made by the demonstration of cytoplasmic inclusion bodies in biopsy specimens of affected organs. Treatment includes the use of intravenous ganciclovir and, in severe cases, intravenous immunoglobulin infusions. Of particular concern is the documented increased incidence of acute rejection complicating acute CMV infections. Therefore, patients with active CMV disease must be monitored carefully for signs and symptoms of rejection. An endomyocardial biopsy should be performed if there is any suspicion of rejection.

NONINFECTIOUS COMPLICATIONS OF CARDIAC TRANSPLANTATION

In addition to common forms of cancer, those malignancies associated with chronic immunosuppression also occur in cardiac transplant recipients. These include posttransplant lymphoproliferative disorders (PTLDs), which are usually B-cell lymphomas and have been related to the Epstein-Barr virus. PTLDs may occur as early as 1 month posttransplantation and may present with a variety of nonspecific symptoms. If diagnosed in their early stages, they may respond to decreased levels of immunosuppression, chemotherapy, and/or radiation therapy, with long-term survival reported.

Aseptic necrosis of the femoral heads and thoracic and lumbar spine compression fractures are not uncommon manifestations of long-term steroid therapy. The development of hip pain referred to the medial thigh or knee is often indicative of early aseptic necrosis. Magnetic resonance imaging (MRI) is the most sensitive

means of detection, and patients should be referred for orthopedic evaluation if this diagnosis is suspected.

PEDIATRIC CARDIAC TRANSPLANTATION

The care and evaluation of pediatric heart transplant recipients is similar to that of adults, with a few special considerations. Rejection surveillance in infants and small children is done primarily with serial echocardiograms. Difficulties with vascular access and the need for anesthesia make serial endomyocardial biopsy procedures impractical. Acute rejection is more frequently heralded by symptoms in children than in adults. Children will present with a low-grade fever, fussiness, and poor feeding. Echocardiography will demonstrate decreased ventricular contractility, thickening of the posterior wall of the left ventricle, cardiac enlargement, and mitral and tricuspid valve insufficiency. Because the signs of rejection may be subtle and difficult to quantify, serial echocardiographic studies are required throughout the postoperative period in order to establish each patient's baseline echocardiographic characteristics.

Immunosuppression for children is based on standard triple therapy. Because of the more rapid metabolism of cyclosporine and tacrolimus, higher doses and more frequent (thrice daily) dosing is often needed in children. Steroids are withdrawn whenever possible to avoid their deleterious effects on somatic growth.

Childhood infections are frequently encountered and should be treated according to routine practice. Vaccinations with live attenuated virus are avoided. Exposure to chickenpox (varicella) is avoided if possible. If exposure does occur in a recipient without a history of previous infection, treatment with varicellazoster immune globulin (VZIG) is indicated. Recipients who develop chickenpox are treated with intravenous acyclovir (Zovirax).

EMERGENCY DEPARTMENT EVALUATION AND TREATMENT OF THE POSTTRANSPLANT PATIENT

Cardiac transplant recipients are susceptible to all of the acute illnesses that affect the general population. These patients should be treated in the same way as any other acutely ill or traumatized patient. In the assessment of such patients, however, the possibility that symptoms may be due to rejection, infection, or side effects of their immunosuppressive medications must always be considered. Patients on chronic steroids will have adrenal suppression and may need stress coverage if they are severely ill or in need of surgical intervention. Uninterrupted administration of immunosuppressive medications must be assured to avoid the development of acute rejection. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be used with extreme caution because of the potential exacerbation of underlying renal insufficiency secondary to cyclosporine or tacrolimus use.

The evaluation of patients presenting with signs and symptoms of congestive heart failure must include the consideration of rejection, myocardial ischemia, and fluid overload due to renal insufficiency. Echocardiography provides important information regarding cardiac performance and may demonstrate findings suggestive of rejection (global dysfunction) or ischemic dysfunction (segmental wall motion abnormality). Results of routine annual cardiac evaluations are useful in assessing whether echocardiographic abnormalities represent acute changes or chronic conditions. Similarly, the availability of old laboratory test results will aid in assessing the importance and acuity of renal impairment.

Any transplant patient presenting with an acute febrile illness warrants aggressive and complete evaluation. If a specific diagnosis cannot be established by history, physical examination, and readily available laboratory and radiographic tests in the ED, consultation with the infectious disease service is indicated. The patient should be admitted to the hospital for further invasive tests and broad-spectrum intravenous antibiotics until culture results are available and a specific diagnosis is made.

In the event that a transplant recipient presents to the ED in extremis, standard cardiopulmonary resuscitation should be performed. Etiologies for hemodynamic collapse related to the posttransplant state include severe acute rejection and myocardial ischemia due to advanced graft coronary disease. Sudden death due to an dysrhythmia may also result from rejection or ischemia. Because of sympathetic denervation, vagally induced bradycardias do not occur; therefore atropine has no role in the resuscitation of these patients. The empiric administration of high-dose steroids (methylprednisolone 1 g intravenously) may be beneficial if rejection is present. Finally, hyperkalemia due to chronic renal insufficiency may result in acute dysrhythmias and should be corrected with standard pharmacologic intervention.

57 NONINVASIVE MYOCARDIAL IMAGING

David A. Bluemke
Bennett Chin
João A. C. Lima

Diagnostic imaging tests for imaging myocardial disease have grown substantially in sophistication. Recent developments include new scintigraphic diagnostic contrast agents in nuclear medicine, Doppler methods in echocardiography, and rapid magnetic resonance imaging (MRI) of the heart. Since the cost of these diagnostic tests is relatively high, it is essential that the "correct" test be selected. Such a test will lead to the most accurate diagnosis in a short period, with few false positives or negatives. This chapter reviews diagnostic modalities for myocardial imaging, with specific emphasis on basic principles of the techniques. Following this discussion, the use of imaging modalities in an array of cardiovascular disorders is presented.

CHEST X-RAY

The chest x-ray is often the first imaging test obtained for patients with suspected cardiovascular disease. Ideally, lateral and posteroanterior (PA) views of the chest are obtained, with film exposure at a distance of 6 ft (1.8 m). Patients should be upright and have a moderately deep inspiration. For patients who are too ill to stand, semierect x-rays are obtained with an anteroposterior (AP) film exposure. The AP film has two disadvantages: the heart demonstrates magnification, and the pulmonary vessels, which show information regarding the extent of congestive failure, are somewhat blurred because of longer exposure times.

Cardiac size can be measured from the chest x-ray with an error of ± 10 percent. Unfortunately, borderline cases require accurate measurements, and factors such as depth of inspiration, conformation of the chest wall, and pulmonary diseases all may affect the apparent heart size on a chest x-ray. The cardiothoracic ratio is the ratio between the transverse diameter of the heart on a PA chest x-ray and the greatest internal diameter of the thorax. Although there are other formulas for measuring cardiac size, this method is the quickest and easiest. The normal adult heart measures 50 percent or less of the transverse diameter of the chest. Cardiothoracic ratios greater than 50 percent are considered to be cardiomegaly. In children, the normal cardiothoracic ratio is 65 percent in the first year, decreasing to 50 percent by age 5.

On the chest x-ray, the heart and major vessels are visualized in the middle mediastinum and are readily recognized. The heart as well as the great vessels all appear to have the same density, relative to the radiolucent lungs. On the left side, there is usually air around the cardiac border, but, on the right side, the heart blends in with the density of the liver. In normal individuals, two-thirds of the heart lies to the left of the midline.

Chest X-ray Interpretation

On the PA view of the chest, there are three visible cardiac segments (Fig. 57-1a). The lowermost segment, adjacent to the diaphragm, is the lateral and apical walls of the left ventricle. A small rounded density may be lateral to the cardiac apex; this represents the epicardial fat pad. Superior to the left ventricle is a rounded short segment that varies considerably in size. This is the pulmonary artery and its left main branch. Prominence of the pulmonary artery is normal in young women. Just below this level, the left atrial appendage forms a short portion of the lateral portion of the left heart border. Conditions that result in left atrial enlargement will cause a convex bulge in this portion of the cardiac silhouette. The third and most superior portion of the left edge of the cardiac silhouette is formed by the transverse aortic arch. On a properly exposed chest film, the descending aorta can be seen descending behind the heart shadow. Regarding the right side of the cardiovascular silhouette, the lower rounded portion is due to the lateral border of the right atrium. The upper segment is formed by the superior vena cava. In older adults in whom the ascending aorta becomes more rounded and dilated, the upper segment of the right heart border may become convex, representing the lateral border of the ascending aorta.
FIG. 57-1. Normal cardiac size and lung fields. **A.** Frontal view. The lateral wall of the left ventricle (*large black arrow*), the pulmonary artery (*small black arrow*), and the aortic arch (*black arrowhead*) form three visible cardiac segments on the left side. On the right side, the right atrium (*white arrow*) and superior vena cava (*white arrowhead*) form lower and upper borders, respectively. **B.** Lateral view. The left ventricle (*arrow*) forms the lower posterior cardiac border, and the left atrium is superior to this (*arrowhead*.)

On the lateral view of the chest, the anterior and superiormost shadow of the cardiac silhouette is formed first by the ascending aorta, and then the pulmonary artery and the pulmonary artery outflow tract, and then the anterior border of the right ventricle (Fig. 57-1b). Posteriorly, the superior shadow is due to the left atrium, with the left ventricle forming the cardiac silhouette inferiorly.

Early left ventricular failure is reflected on the chest x-ray by a "redistribution" pattern of blood flow. Normally, the most prominent pulmonary veins are at the lung bases. With the redistribution phase, the vascularity in the upper lung fields is increased, relative to that of the lower lung fields.

As pulmonary capillary wedge pressure elevates to 20 to 25 mmHg (Fig. 57-2), fluid moves from the vascular bed into the interstitial spaces of the lung. The chest x-ray appears hazy at this stage, with short lines appearing perpendicular to the pleura (Kerley B lines). Finally, as pulmonary capillary wedge pressure further

increases to 30 to 35 mmHg, frank alveolar edema ensues due to massive fluid movement from the vasculature to the alveolar spaces.

FIG. 57-2. Pulmonary vascular congestion. Bilateral increased lung markings are present, particularly in the lower lung fields, with prominent interstitial lung markings. The pulmonary hila are also enlarged.

CARDIAC CHAMBER ENLARGEMENT **Left Ventricle** Increased workload by the left ventricle initially results in dilatation of the ventricle, but if it is sustained, hypertrophy of the left ventricular wall occurs. Hypertrophy is a normal response to increased workload. Chest x-ray findings at this time are usually normal. As the ventricle begins to fail, dilatation results, and the cardiothoracic ratio increases. The apex of the heart also becomes more rounded in appearance. The most marked increases in size of the left ventricle result from hypertension, aortic insufficiency, and cardiomyopathy. Pericardial effusion results in generalized cardiac enlargement (Fig. 57-3).

FIG. 57-3. Pericardial effusion. Generalized dilatation of the heart is present, with the cardiothoracic ratio measuring more than 50 percent. Although a similar cardiac silhouette would be present in patients with dilated cardiomyopathy, this patient had documented pericardial effusion.

Right Ventricle The right ventricle enlarges from processes that increase the work of this chamber, such as pulmonary diseases or pulmonary artery hypertension. Mitral valve disease will also eventually result in right ventricle enlargement. The outflow tract of the right ventricle enlarges first; chest x-ray findings are subtle but include straightening or convexity of the pulmonary artery segment below the aortic knob in the frontal view. Multichamber enlargement is frequent, so that the relative involvement of each cardiac chamber is not easily distinguished on chest x-ray.

Left Atrium Common cases of left atrial enlargement include mitral valve disease from rheumatic fever, or congenital defects resulting in left-to-right shunts. The normal left atrium is posterior and does not form any portion of the cardiac silhouette in a normal patient. Moderate enlargement causes the left atrial appendage to become larger and causes a bulge or straightening of the left cardiac border below the pulmonary artery segment. Further enlargement may cause the right-sided border of the left atrium to extend beyond the normal upper aspect of the right atrium and superior vena cava. A double cardiac border is seen on the frontal view on the right side. If the left atrial enlargement is less extreme, a double border may still be seen because of the increased radiodensity of the left atrium. On the lateral view, the upper posterior border of the cardiac silhouette projects more posteriorly than normal.

Right Atrium Enlargement of the right atrium causes enlargement of the lower right cardiac contour with increased convexity. Diseases resulting in right atrial enlargement include atrial septal defect, tricuspid stenosis and insufficiency, and right ventricular failure. In multichamber disease, right atrial enlargement is not separately identified.

COMPUTED TOMOGRAPHY

In evaluation of the heart, the primary role of conventional computed tomography (CT) has been to exclude other abnormalities, such as aortic dissection, that may secondarily affect cardiac function. Because of excellent anatomic resolution, CT is also useful in depicting paracardiac disease processes that involve the myocardium.

Advantages of CT examination of myocardial structures include good resolution of 0.1 to 0.5 mm^2 and rapid imaging times of 5 min or less for the chest. The low-density epicardial fat usually provides excellent contrast to the higher density of the cardiac structures. Calcifications, present at the site of ventricular aneurysms, of the coronary arteries or of atherosclerotic change, are easily depicted. With the advent of helical CT scanners, a full three-dimensional (3D) set of images is obtained, allowing multiplanar reconstruction and 3D viewing. Although conventional CT scanners provide only one image slice each 2 to 5 s, helical CT is increasingly available to emergency departments (EDs). Helical CT and spiral CT are synonyms for the same rapid mode of CT scanning, and are described in more detail below.

Helical Computed Tomography

In conventional (nonhelical) CT scanning, the image acquisition is as follows: scan a slice, move the patient, scan a slice, etc. Thus, there are two distinct parts to the process: turn on the x-ray beam, usually for only about 1 to 2 s, and then move the patient to the next table position. Patient motion to the next position may take an additional 2 to 4 s. Therefore, each slice can take approximately 5 s (1-s scan and 4 s of motion), of which only 20 percent (1 s/5 s) is actually imaging time.

In its most basic form, helical CT consists of scanning a patient *continuously* while the patient is being continuously moved through the CT gantry. In this mode, the x-ray beam is on for perhaps 20 s or more, and the patient is moved for this same duration. The efficiency of scanning is 100 percent. During the scanning process, the x-ray beam source is continuously rotating around the patient, tracing a helical, or a helix, along the patient's body. Implementing this is actually quite demanding of the CT scanner, its computer, and the electronic components. For this reason, helical CT remains a relatively new and developing technology.

Helical CT data sets are truly 3D. Instead of scanning a series of *slices,* a *volume* data set is acquired. This results in

- Vastly improved multiplanar and 3D reconstructions. Since data sets are acquired in a breath hold, respiratory misregistration is eliminated. Data appear "smoother" with fewer "stair-step" artifacts in sagittal and coronal reconstructions.
- Reconstruction of slices at arbitrary intervals. Because of the 3D nature of helical scanning, images can be reconstructed at small intervals, e.g., 2 to 3 mm. This reduces stair-step artifacts in 3D reconstructions.
- Rapid acquisition. Complete helical data sets of a patient's examination are typically acquired within 20 to 30 s, and the patient is then done with the

examination.

Electron-Beam Computed Tomography

Electron-beam CT technology (Imatron, South San Francisco, CA) operates by a different technology from helical and conventional CT. With those methods, a large detector array and x-ray unit rotate around the patient. The sheer mass of the x-ray apparatus limits the rate of rotation to about once every 0.75 to 1.0 s. With electron-beam CT, electrons are generated and deflected electromagnetically onto tungsten target rings located in the gantry below the patient. X-rays are generated by the electron bombardment of the target rings. The x-rays are then tightly collimated and directed to pass through the patient onto a double ring of detectors in the gantry above the patient. Since mechanical motion is not involved, imaging times are very rapid: images can be acquired every 58 ms (17 images per second). Similar to helical CT, image resolution is excellent: 0.1 to 0.5 mm^2. At this time rate of image formation, very little blurring of cardiac structures takes place. Calcifications involving the coronary arteries are easily detected, and cine images of the myocardium are available.

Electron-beam CT and helical CT require injection of an iodinated contrast medium to enhance blood in the vessels and myocardial cavities relative to the myocardium itself. With helical CT, approximately 120 mL of iodinated contrast is delivered intravenously at a rate of 3 mL/s. Using electron-beam CT, 40 to 80 mL of contrast is given at 2 to 10 mL/s. In both cases, a power injector is used, necessitating large-bore intravenous access.

Radiation exposure is a consideration with all CT scanning methods. With conventional or helical CT, radiation levels are 2 to 4 cGy (2 to 4 rad) per CT slice. If multiple slices are taken at the same level of the heart, then the radiation increases directly in proportion to the number of slices. Electron-beam CT has less exposure to radiation for the patient: each slice has an exposure of 0.54 cGy (540 mrad). However, more imaging slices are acquired with electron-beam CT in obtaining a cine sequence of the heart, so that 10 cine frames would result in an exposure of 5.4 rad. For comparison purposes, a single x-ray of the lumbar spine is approximately equivalent to 1 cGy (1 rad), whereas radiation exposure from a chest x-ray is 0.06 cGy (60 mrad).

Applications

Electron-beam CT is available at only a very few centers across the United States. A major nonemergent application is the detection of coronary artery calcification. The degree of coronary artery calcification bears a strong relationship to the presence of significant coronary artery stenosis. Cardiac anatomy, the relationship between chambers of the heart and great vessels, is readily determined using this modality. Since electron-beam CT can obtain cine images of the heart, cardiac function and focal wall motion abnormalities can be determined. Due to the limited availability of this modality, however, the remaining discussion will focus on non-electron-beam methods.

Although helical CT offers very rapid scanning, it is unable to assess cardiac function, since cine loops of the heart are not obtained. Cardiac anatomy, however, is well assessed. Focal abnormalities of the myocardial wall are indicative of cardiac tumor or thrombus (Fig. 57-4). Differentiation of these possibilities usually requires cine imaging, so that patients with such masses are referred for echocardiography or MRI.

FIG. 57-4. High-grade malignant neoplasm. Helical computed tomographic scan demonstrates right pleural effusion, pericardial effusion, and thickening of the septum and left atrium (*arrows*). (Reprinted from Bluemke and Boxerman,[19] with permission.)

CT offers a good depiction of pericardial disease (Fig. 57-5). Simple pericardial effusions show low density relative to the myocardium, and the extent of effusion can be readily quantified, if necessary. The presence of calcifications of the pericardium is an important factor in the diagnosis of constrictive pericarditis and, with the correct symptoms, improves the specificity of this diagnosis. High-density pericardial fluid collections are likely to represent localized hematomas, either from trauma or surgery.
FIG. 57-5. Computed tomographic scan after intravenous contrast administration shows pericardial effusion and enhancement (*arrows*) due to pericarditis, with left pleural effusion and left lower lobe atelectasis. (Reprinted from Bluemke and Boxerman,[19] with permission.)

Helical CT following intravenous administration of contrast is an excellent modality for assessing diseases of the pulmonary arteries. Pulmonary artery emboli appear as low-attenuation defects in the opacified pulmonary arteries. Helical CT can demonstrate emboli not only in the main pulmonary arteries but also in the third- and fourth-order branches, because of high spatial resolution and cross-sectional imaging of these vessels.

NUCLEAR MEDICINE

Nuclear medicine examinations of the heart represent the study of cardiac function and physiology, rather than anatomy. Because of higher spatial resolution, MRI and CT are better suited to anatomic evaluation of the heart. Nevertheless, nuclear medicine examinations of the heart still remain a primary means for assessing cardiovascular function and, in particular, gated radionuclide angiography of the heart is a mainstay of cardiovascular imaging.

Radiopharmaceuticals and Imaging Techniques

ASSESSMENT OF CARDIAC PERFUSION   **Thallium-201**   Thallium is a potassium analogue that is transported by the Na$^+$,K$^+$-ATPase system in cells, in direct proportion to regional blood flow. Approximately 85 percent of each "pass" of the contrast agent is extracted from the blood across the capillary bed. Thallium is initially extracted by myocardial cells but then redistributes to maintain an equilibrium with the blood at a rate that is proportional to regional blood flow. Thus, the early

images from a thallium scan reflect blood flow, and the later images (redistribution phase) reflect the intracellular K^+ blood pool. The intracellular K^+ blood pool in turn is reflective of cellular viability. The redistribution phase is usually imaged at from 4 to 24 h after the initial injection of thallium.

In combination with exercise or pharmacologically induced coronary hyperemia (from dipyridamole or adenosine), thallium imaging is able to distinguish normal blood flow, ischemia, infarction, and hibernating myocardium. Myocardial tissues distal to a physiologic coronary artery stenosis are unable to increase their blood supply during stress conditions or hyperemia and thus have low radiotracer activity. On 4-h-delayed images, however, the thallium redistributes to these arrows and the radiotracer activity of the myocardium becomes more uniform. With infarction, delayed images show no evidence of radiotracer redistribution, reflecting the lack of intracellular K^+ blood in the area of infarction. With hibernating myocardium, redistribution occurs by 24 h.

Technetium Technetium radionuclides offer greater ease of use and availability for nuclear medicine departments. Whereas thallium requires a cyclotron to produce, technetium agents are widely available and produced by a generator in each nuclear medicine laboratory. The most commonly used technetium agent is technetium-99m sestamibi (^{99m}Tc-sestamibi). This agent is taken up by the myocardium in direct proportion to myocardial blood flow. At this point, the sestamibi molecule becomes trapped within the myocardium and does not redistribute (contrary to the behavior of thallium). Thus, the initial uptake by the myocardium reflects blood flow at the time of injection. Typically, ^{99m}Tc-sestamibi is initially injected at peak exercise, or during the period of maximum coronary vasodilatation (induced by dipyridamole or adenosine).

Since ^{99m}Tc-sestamibi does not redistribute on delayed images, myocardial infarction and decreased flow from physiologically significant coronary stenosis both appear as myocardial defects on images. To differentiate these two possibilities, a second dose of ^{99m}Tc-sestamibi is given while the patient is at rest. If the rest images show uniform radiotracer distribution, then the defect seen on stress images is due to ischemia. Persistent areas of absent radiotracer on rest images indicate areas of myocardial infarction.

GATED RADIONUCLIDE ANGIOGRAPHY Gated radionuclide angiography (RNA) has remained a clinical gold standard for overall assessment of left ventricular function. This test has the advantage of being applicable to nearly all patients, regardless of body habitus or underlying illness. In addition, unlike echocardiography, RNA is relatively operator independent. Radiation exposure is present but insufficient to prevent serial examination of cardiac function in the same patient.

In RNA, a blood sample is labeled with a technetium-based radionuclide, and a series of images of the heart is acquired. These images are gated to the R wave of the electrocardiogram. Function, and measurement of ejection fraction, involve measuring radioactivity counts at multiple time points throughout the cardiac cycle. The number of radioactive counts is directly proportional to the blood volume in the cardiac chamber. Thus, the method is insensitive to the precise geometry of the left ventricle, since only the overall count rates, and thus volumes, are measured. Other than segmentation of the left ventricle from other cardiac cavities, no geometric assumptions regarding left ventricular anatomy are necessary with the technique. Using gated techniques, with display of images as a cine loop, it is possible to assess segmental function of the heart. However, the resolution of the images is limited, and the strength of the examination relies primarily in accurate quantitation of the global left ventricular function.

Ventricular function is assessed by qualitative evaluation of cardiac wall motion, and quantitative assessment of radionuclide counts as a function of time. Computer-generated curves are verified by an experienced observer's interpretation of regional wall motion determined by gated RNA studies. RNA allows particularly good views of the lateral wall of the left ventricle, where there is no overlap from other cardiac segments. Although systolic function is easily assessed, diastolic function of the left ventricle is more commonly performed by echocardiography.

FIRST-PASS CARDIAC STUDIES If the radionuclide is rapidly injected, and the acquisition speed of the nuclear images is rapid, the "first pass" of the radionuclide can be tracked, as it passes through the heart. This method relies on tracking of the radionuclide bolus as it passes through the ventricular cavities immediately following contrast injection. In this technique, the acquisition time is very rapid (30 s), although very few heartbeats are evaluated, thus limiting spatial resolution.

Left ventricular ejection fraction measurement is determined by following the passage of the radiotracer between the left and right ventricles. The injection of the radiotracer must be rapid, or poor separation of radiotracer between the two sides of the heart occurs. Patients with dysrhythmias, atrial septal defect, or significant regurgitation across the mitral or tricuspid valves will have poor ejection fraction estimates using this method. First-pass studies using ^{99m}Tc-sestamibi enable cardiac function as well as perfusion to be assessed in the same study.

GATED PERFUSION IMAGING Following injection of ^{99m}Tc-sestamibi, images can be collected such that multiple time points, or cine frames, during the cardiac cycle can be independently collected by gating data acquisition to the cardiac cycle. In this manner, a cine loop, or movie of the cardiac cycle, can be generated. The function of the heart can be qualitatively reviewed to assess for wall thickening or segmental dysfunction. Thus, the perfusion of the heart can be assessed in the same setting as cardiac function. Functional imaging aids in discriminating between true mild perfusion defects and imaging artifact, such as due to attenuation from overlying breast tissue or the diaphragm. When severe perfusion defects are present, due to infarct or significant coronary artery narrowing, accurate estimation of ejection fraction is difficult to measure.

Applications

Myocardial perfusion scintigraphy is a noninvasive modality with high sensitivity for the diagnosis and evaluation of coronary artery disease. Physiologically significant coronary stenoses may be evaluated in populations with known or suspected coronary disease, after therapeutic interventions, preoperatively for risk assessment, and for prognostication after acute ischemia or infarction.

A more recent application of this technique has been made to the patients presenting to the ED with chest pain. In a subset of patients with an intermediate or low probability of coronary artery disease and chest pain (unstable angina), the missed diagnosis of coronary artery disease has been reported as high as 5 to 8 percent.[1,2 and 3] As many as a third of patients with acute myocardial infarction do not have electrocardiographic (ECG) changes suggestive or diagnostic of ischemia, many of which have baseline ECG abnormalities.

Several centers around the country have used myocardial perfusion scintigraphy to further classify this subset into high-risk and low-risk categories to reduce the incidence of missed acute ischemic coronary syndromes and the number of unnecessary hospital admissions for noncardiac chest pain. In a large study at the Medical College of Virginia involving 1187 patients, ^{99m}Tc-sestamibi perfusion imaging was used in defining the critical pathways in this population.[4] Used with established clinical criteria, the cardiac event rate at 1-year follow-up for patients with abnormal scan findings was 42 percent versus 3 percent (revascularization) for those with a normal scan findings. In those with abnormal scan findings, 11 percent experienced myocardial infarction and 8 percent suffered cardiac death; in those with normal scan findings, none had myocardial infarction or death. Other centers around the country are reporting similarly favorable results.[5,6]

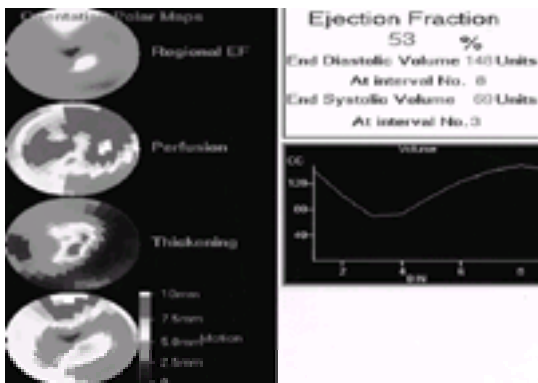
The nuclear perfusion imaging protocol performed in the ED is very similar to conventional myocardial perfusion stress protocols with the exception that the injections are performed at rest during chest pain. Preliminary reports indicate that timing of injection during chest pain may improve diagnostic sensitivity; however, other centers have reported good results with injections performed up to within 12 h of the chest pain.[7] ^{99m}Tc-sestamibi or tetrofosmin are used because of their favorable imaging properties of minimal redistribution and lower radiation dosimetry compared with ^{201}Tl chloride. After intravenous injection, these ^{99m}Tc tracers are highly extracted and retained for several hours within the myocardium in a distribution proportional to coronary blood flow. This permits imaging several hours later after additional ED evaluation or intervention. Because of the more favorable dosimetry of ^{99m}Tc tracers, a higher dosage approaching 7 to 10 times the injected dose of ^{201}Tl is typically used. This permits high-quality tomographic imaging (single-photon emission computed tomograpy or SPECT) and ECG gating, which provides additional information, including assessment of wall motion, wall thickening, and left ventricular ejection fraction. In patients with a normal findings on resting perfusion study, further evaluation with a stress myocardial perfusion study may be performed with them as outpatients. Preliminary studies have shown the cost effectiveness of this risk stratification, and further studies are currently in progress. Figure 57-6, Figure 57-7 (Plate 7), and Figure 57-8 (Plate 8) illustrate the utility of myocardial perfusion scintigraphy in a patient with acute chest pain.
FIG. 57-6. A 59-year-old white hypertensive man who arrived at the emergency department with 6 h of intermittent chest pain. Findings on physical examination and electrocardiography were unremarkable. Initial cardiac enzyme levels (CK-MB, myoglobin, and troponin T) were normal. ^{99m}Tc-sestamibi SPECT perfusion images show a moderate area of hypoperfusion in the middle and proximal inferolateral wall. The patient went directly to catheterization, which showed a 95 percent circumflex marginal stenosis that was successfully treated by angioplasty. (Courtesy of Ethan Spiegler, MD.)
FIG. 57-7. (Plate 7). Three-dimensional representation of gated SPECT data at end diastole.


FIG. 57-8. (Plate 8). Bull's-eye representation of gated SPECT data. Hypoperfusion of the proximal inferolateral wall as well as mild hypokinesis and diminished wall thickening. There is preserved global left ventricular function.

ECHOCARDIOGRAPHY

Echocardiography is the use of ultrasound to image the heart and great vessels. This general term includes the techniques of M-mode, two-dimensional (2D) imaging, pulsed wave, and color Doppler studies. Frequently, an examination of the heart will apply a combination of these ultrasound methods to the clinical problem at hand.

Echocardiography, after the chest x-ray, represents one of the most commonly applied methods for cardiac diagnosis. Applications of this method include assessment of cardiac chamber size and function, patterns of flow within the ventricles, pericardial assessment, and identification of cardiac masses, including tumors, valve vegetations or calcification, and thrombi (Fig. 57-9). Advantages for this technique include its relatively low cost, portability of the ultrasound equipment, good patient comfort, and safety.

FIG. 57-9. Echocardiography of inferior wall pseudoaneurysm, due to prior rupture of the left ventricular wall.(Reprinted from Burton and Lima, [20] with permission.)

Although the use of echocardiography is extremely widespread, there are limitations to the technique. The method is highly operator dependent. Patient positioning relative to the ultrasound probe is crucial, and specific machine adjustments must be made to optimize the examination to a particular patient. These adjustments may substantially alter the diagnostic ability of the examination. Certain patients have poor "acoustic windows," through which the ultrasound beam "looks" to see the cardiac structures. This limits examination quality in patients with chronic obstructive lung disease, obesity, and some musculoskeletal deformities. The use of transesophageal echocardiography, in part, alleviates the limitations of the technique for these patient populations.

Background

Echocardiography is based on the transmission and disruption of sound waves into the body. These sounds waves are much higher than the normal range of human hearing (20 kHz), and range from 1 to 10 MHz. The relationship between the frequency of the sound wave (i), the velocity of wave (n), and the wave length (l) is given by

$$\nu = f\lambda$$

The velocity of sound in the tissues is assumed to be constant, and equal to 1540 cm/s. For typical clinical frequencies of 2 to 5 MHz, the wavelengths are on the order of 0.3 to 0.8 mm. Given the velocity of the wave, pulsed ultrasound methods calculate the distance traveled by the sound wave by measuring the time from the start of the pulse wave to the time taken to reflect from an object and return to the transducer.

ACOUSTIC IMPEDANCE   The signal returning to the ultrasound transducer depends on the reflected ultrasound wave. The reflected ultrasound wave is generated at the acoustic interfaces between tissues of different density or through which sounds travel at different velocities. At these tissue interfaces, sound waves are either reflected back to the transducer (specular interface) or scattered into many different directions. The endocardial border represents a specular interface; sound waves are maximally reflected back from this interface when they are incident upon the interface at a 90° angle. As the sound waves become more parallel to the endocardium, the reflected waves are weakest.

Incident ultrasound waves that are scattered as they reflect from red blood cells may be used to assess the Doppler phenomenon, thus measuring the velocity of the red blood cells. The Doppler phenomenon refers to increased frequency of the ultrasound wave when the motion of the red blood cells is toward the transducer, and decreased frequency when the motion is away from the transducer. The Doppler shift, D f, is related to the velocity of the red blood cells, n, by the equation

$$\Delta f = (2f_0/C)\nu\cos(\vartheta)$$

where f_0 is the frequency of the incident ultrasound beam, C is the velocity of sound in the tissue, and J is the incident angle of the ultrasound beam relative to the blood vessel of ventricle. In Doppler display mode, blood flowing toward the transducer is coded red; blood flow away from the transducer is shown as blue. Further, the intensity of the red or blue is displayed as proportional to the velocity. According to the foregoing equation, velocities are most accurate when the angle between the ultrasound beam and blood flow is close to 0, since the cosine of 0 is equal to 1. Pulsed wave ultrasound techniques may be used to assess blood velocity: a series of rapid pulses is sent into the tissue, followed by a short segment of time for receiving the reflected waves.

M-MODE DISPLAY   M-mode display is unique in medical imaging to echocardiography. The primary advantage of this display mode is that high time resolution, to approximately one-thousandth of a second, can be displayed on the time axis. Compared with this, traditional 2D displays are updated only approximately 30 times per second. Thus, M-mode display has excellent time resolution and can be used to display the periodic motion of, for example, cardiac valves or vegetations. In this display mode, a 2D display is typically first selected. A single line, or slice, of the 2D display is then selected, often across a valve plane. M-mode displays then show the reflected ultrasound signal along this single line, with continual updating every millisecond.

Applications

MYOCARDIAL INFARCTION   Echocardiography is more sensitive and specific than history and ECG findings in diagnosing myocardial infarction in patients presenting with chest pain. In several clinical series, left ventricular wall motion abnormalities were observed in 89 to 100 percent of patients with transmural infarction.[8,9] The sensitivity of echocardiography in detecting a nontransmural infarction is somewhat less and depends on the transmural thickness of the infarcted myocardial segment. In addition, patients who had no echocardiographically detected wall motion abnormalities had smaller infarctions and fewer complications. [8,9]

Echocardiography is also useful in the diagnosis and management of chest pain due to causes other than myocardial infarction. Patients with chest pain due to myocardial ischemia usually have echocardiographically detectable wall motion abnormalities with pain, even in the absence of infarction. Other causes of chest pain, including aortic dissection, hypertrophic cardiomyopathy, valvular heart disease, pericarditis, and pulmonary embolism, can frequently be identified or suspected based on transthoracic echocardiography.

In addition to facilitating diagnosis, echocardiography early in the course of acute myocardial infarction provides information important in guiding early management and determining short-term prognosis. The location and size of wall motion abnormalities correlate well with the coronary artery involved in an infarction. Infarction resulting from obstruction of the left anterior descending coronary artery usually causes abnormal function in the anterior, septal, and apical segments of the left ventricle. Akinesis of the basal anterior segment predicts occlusion of the left anterior descending coronary artery, proximal to the first septal perforator, a finding of prognostic significance. There is overlap in the areas of abnormal wall motion in myocardial infarcts involving the left circumflex and right coronary arteries. Occlusion of either vessel can cause abnormal motion in the middle and basilar segments of the posterior and inferior walls. Wall motion abnormalities confined to the posterior and lateral walls are usually caused by obstruction of the circumflex, whereas abnormalities confined to the inferior basal segment are characteristic of obstruction of the right coronary artery.

A number of factors, including the presence of ischemia, stunning, or overload, confound the relationship between the size of regional wall motion abnormalities and the amount of infarcted myocardium. When compared with pathologic examination, echocardiography tends to overestimate the amount of necrosed myocardium early in the course of myocardial infarction. Despite this limitation, echocardiographic estimation of the extent of myocardial infarction correlates well with infarct size as determined by peak creatine kinase, radionuclide imaging, and contrast ventriculography. Echocardiographic evaluation of left ventricular function early in the course of myocardial infarction has been found to be a better predictor of in-hospital mortality than the prognostically strongest clinical parameters. An echocardiographically determined ejection fraction of greater than 40 percent has correlated with a low short-term mortality and could potentially be used to select low-risk patients for early discharge. [10] By contrast, a tall peaked E wave on Doppler evaluation of left ventricular filling has been correlated with elevated left ventricular end-diastolic pressure and worse prognosis.

Echocardiography has been used to assess the efficacy of thrombolytic therapy. The time required for improvement of left ventricular function after reperfusion is related to the duration of ischemia and size of the ischemic zone. In patients with successful reperfusion induced by thrombolytic agents or direct angioplasty, echocardiographically detectable improvement in contractility can occur in the first 24 h. The delay in recovery of function, even after successful reperfusion, limits the utility of echocardiography in acutely assessing the success of thrombolytic therapy.

The widespread use of echocardiography early in the course of myocardial infarction reflects the clinical utility, availability, and safety of this technique. Echocardiography does have a number of potential shortcomings in the early diagnosis and management of acute myocardial infarction. The quality of echocardiographic images depends on the skill of the operator and the habitus of the patient. Images adequate for evaluation of wall motion can not be obtained in 5 to 15 percent of patients in clinical studies of myocardial infarction. [8,9] Abnormal wall motion can be present in patients with Wolfe-Parkinson-White syndrome, bundle branch block, right ventricular overload, and after cardiac surgery. However, in contrast to patients with myocardial infarction, in these patients, wall thickening is usually preserved. On the other hand, myocarditis may cause regional loss of wall thickening and be indistinguishable from infarction by echocardiography. In addition, it is sometimes difficult to differentiate new wall motion abnormalities from preexisting ones by echocardiography.

ACUTE MITRAL REGURGITATION   This requires emergent surgery, and has a higher mortality rate than that of chronic mitral valve disease. Etiologies include endocarditis, acute ischemia or myocardial infarction, prosthetic valve failure, and chordal rupture due to myxomatous mitral disease or trauma.

Echocardiographic signs in acute mitral regurgitation include the "snake" sign, corresponding to high-frequency fluttering of a ruptured chord in the left atrium. Rupture of the papillary muscle may cause disconnection of the involved tip from the body of the muscle. The direction of the mitral regurgitant jet distinguishes anterior from posterior flail leaflet: anterior leaflet failure is associated with posteriorly directed jet, and posterior leaflet failure shows anteriorly directed jet. Transesophageal echocardiography appears to be superior to transthoracic imaging for determining the size and etiology of the valvular disorder.

ACUTE AORTIC REGURGITATION   Acute aortic regurgitation results from trauma, endocarditis, or aortic dissection. This condition is rapidly fatal and requires immediate surgical repair. Transesophageal echocardiography may be necessary to delineate disruption of valvular or annular architecture in this condition.

For chronic aortic regurgitation, color Doppler demonstrates a regurgitant jet in the left ventricle. In the acute case, however, rapid equilibration of pressures in the aorta and the normal-sized left ventricle causes a small, or no, Doppler jet. The spectral pattern of the continuous wave Doppler will have a low peak velocity and an extremely rapid deceleration slope. These findings correspond to the inaudibility of the murmur of acute regurgitation. In the most severe case, there is little diastolic flow into the ventricle, since the aorta and left ventricle become a continuous chamber. Early closure of the mitral valve or diastolic mitral regurgitation on M-mode or

2D echocardiography are ominous prognostic signs. Early mitral valve closure indicates severe and acute decompensated aortic insufficiency.

MAGNETIC RESONANCE IMAGING

MRI is rapidly becoming the noninvasive gold standard for the assessment of cardiac structure and function. The high contrast between moving blood and the myocardium by MRI, as well as high spatial resolution (Fig. 57-10) and lack of ionizing radiation, results in a superb technique for myocardial assessment. Although availability remains a concern, it is anticipated that major medical centers will increasing have MRI services available for emergency applications in myocardial imaging. Previously, MR machines had been designed to image static areas of the body, specifically, the brain and spine. Currently, all major equipment manufacturers have devoted substantial resources to developing MR equipment specifically for the diagnosis of cardiovascular disorders. This section reviews principles of MRI to provide a basis for emergency medicine professionals in evaluating MR studies. Additionally, the range of emergency medicine applications for cardiac imaging is presented.

FIG. 57-10. MRI of normal short-axis cardiac anatomy. Short-axis images from the base of the heart **(A)** through the cardiac apex **(B)**. Successive images are displayed left to right, top to bottom. *Abbreviations:* LAD, left anterior descending coronary artery; LV, left ventricle; PM, papillary muscles; RVOT, right ventricular outflow tract; RV, right ventricle; S, septum; T, trabeculations in right ventricle. Principles of Magnetic Resonance Imaging

The basic process of MRI involves excitation of hydrogen nuclei (i.e., protons) with radio frequency energy. After sending electromagnetic energy into the patient, protons are excited to a higher-energy state. The radio frequency wave is then turned off, and protons "relax" to their baseline state. As the protons relax, they emit a radio frequency signal that can be picked up by an antenna, amplified, and used to form an image.

Although hydrogen nuclei are typically used in MRI, other atoms, such as phosphorus (particularly important for cardiac energetics and infarction) can also be used for MRI. Hydrogen is particularly useful for biologic tissues: it is extremely abundant (for example, in water and fat) and is extremely sensitive to the MRI process. In addition, with pathologic processes, the water content of tissues often changes. For example, myocardial infarctions have a higher water content than normal tissues. Therefore, pathologic processes can be readily detected by imaging changes in water content of tissues.

To summarize, the basic MR process involves the following:

- The patient is placed in very high field strength magnet
- The magnetic field causes alignment of protons in the patient
- A radio wave is sent into the patient, disturbing the alignment
- The radio wave is turned off
- The patient emits a radio frequency signal
- The signal is picked up by an antenna and used to form an image

The MR signal is a function of multiple tissue parameters, including T1, T2, proton density, and the rate and type (oxygenated or deoxygenated) of flowing blood. *T1* and *T2* parameters are numbers that characterize the response of biologic tissue to an applied magnetic field. *T1-weighted images* are generally those that help define the *anatomy* that is being viewed (Fig. 57-11). *T2 images* are those that better define the *pathology* of the tissue. *Proton-density images* may also be generated, in which the image intensity is proportional to the number of protons present. Finally, images can be generated that are sensitive to flowing blood (*bright blood images* or MR angiograms). It is the unique property and strength of MR imaging that four different physical factors (T1, T2, proton density, and blood flow) may be used to derive a variety of imaging results; this is very different from CT scanning or echocardiography, in which only one factor (x-ray attenuation and acoustic attenuation, respectively) is used to generate contrast in images. Although these multiple factors add to the complexity of understanding MR, it also enhances the power of the technique for detecting subtle changes in pathologic tissues relative to normal tissues.
FIG. 57-11. Paracardiac mass demonstrated by MRI. Axial images of the chest demonstrating a mass posterior to the left ventricle. **A.** T1-weighted image, showing thickening of the posterior wall of the left ventricle. **B.** T2-weighted image, showing bright increase signal in the mass. Biopsy revealed hemangiopericytoma. (Reprinted from Bluemke and Boxerman,[19] with permission.)

Two parameters are particularly helpful in determining MR image contrast: time to repetition (TR) describes the time between radio frequency pulses, and time to echo (TE) describes the time after each radio frequency pulse when the MR scanner "listens" for signal from the patient. By changing the TR and TE values, different types of image contrast are obtained (Table 57-1). For more detailed information regarding MR physics, the reader is referred to standard textbooks on the subject, such as that by Berning and Steensgaard-Hansen.[11]

Image Type	TR (ms)	TE (ms)	Fat Appearance	Water Appearance
T1 weighted	300–600	20–30	Bright	Dark
Proton density	2000–6000	20–30	Intermediate	Intermediate
T2 weighted	2000–6000	80–100	Intermediate*	Bright

*Fat on T2-weighted images are darker than proton-density images. Also, "fat suppression" may often be used with T2 images, resulting in very dark fat signal.

TABLE 57-1   Appearance of Magnetic Resonance Images

Magnetic Resonance Pulse Sequences

CONVENTIONAL SPIN ECHO IMAGING   The most common pulse sequence traditionally used for cardiac imaging is a conventional spin echo sequence, gated to the cardiac cycle. In this technique, the TR is equal to the duration of the RR interval, and the minimum TE time is used (10 to 20 ms). Since the T1 time of the myocardium is on the order of 800 ms, only moderate T1 weighting is achieved using this method. These images are commonly referred to as *black blood* images, since radio frequency saturation bands are placed above and below the imaging planes, causing blood to lose MR signal and become dark (Fig. 57-12). Since the TR depends on the RR interval, imaging times are typically long (e.g., 6 to 8 min). Image quality is only moderate, and highly dependent on consistent ECG gating and lack of patient motion during the relatively long acquisition times. However, the contrast difference between the heart, the epicardial fat, and the ventricular cavities is relatively good.

FIG. 57-12. Magnetic resonance imaging of aortic dissection. Axial T1-weighted image shows the site of prior repair of the ascending aorta, following dissection. There is residual soft tissue thickening around the ascending aorta. A residual dissection remains in the descending aorta. The patient had a history of Marfan disease.

T2 weighting for spin echo images is achieved by gating at several multiples of the RR interval, together with a TE time of 80 to 100 ms. Imaging times are quite long if conventional spin echo techniques are used. The image quality of T2-weighted images is lower than that of T1 images, because of lower signal-to-noise ratios typically associated with T2 images. Also, artifacts due to respiratory and cardiac motion may be pronounced because of long imaging times. T2-weighted images are usually not necessary for *anatomic* evaluation of the heart but are more helpful for characterization of cardiac or paracardiac masses (Fig. 57-11b). In these cases, the mass frequently has somewhat restricted motion relative to the myocardium, so that image quality is often adequate. *Fast spin echo* or *turbo spin echo* T2-weighted pulse sequences are available on most new MR sequences. These methods reduce imaging time for T2-weighted images by a factor of 8 to 16. Because of the high signal intensity of fat on fast spin echo images, an additional radio frequency pulse is often added to cause fat to be very dark. This in turn helps to highlight nonfatty structures.

CINE IMAGING   Cine imaging for cardiac MRI consists of a motion picture loop of various phases of the cardiac cycle (Fig. 57-13). To generate cine images, images must be gated to the cardiac cycle. In cine acquisitions, the imaging pulse is triggered, or gated, to begin based on the R wave of the electrocardiogram. *Segmented k-space* pulse sequences are very rapid, cardiac gated pulse sequences in which a complete cine sequence of the heart is acquired within a breath hold of 12 to 18 heartbeats. This consists of a fast gradient echo acquisition with relatively short TR (e.g., 5 to 10 ms) combined with very short TE (approximately 2 ms), and a flip angle of 10° to 15°. The TR and TE are usually the minimum values achievable by the MR gradient system, so that the system software may automatically set these parameters. The above acquisition parameters result in saturation of background, stationary tissues, while flowing blood has a higher and brighter signal. Breath-hold cine imaging of the heart can be performed in any anatomic plane, e.g., parallel to the long axis and short axis of the heart.
FIG. 57-13. Magnetic resonance imaging of mitral valve dysfunction. Images during systole and diastole show a dark regurgitant jet extending from the valve plane to the left atrium during systole, compatible with mitral valve regurgitation. (Reprinted from Bluemke and Boxerman, [19] with permission.)

The Magnetic Resonance Environment and Safety Considerations

The MR environment for high-field-strength MR scanners is potentially hostile for ED personnel and their patients. Standard support devices necessary for patient monitoring, such as pulse and blood oxygenation monitoring, blood pressure measurement, and electrocardiogram evaluation, are incompatible with operation inside the MR suites. Cardiac disease patients are typically transported with oxygen cylinders: steel oxygen cylinders will act as high-speed projectiles inside the MR suite if allowed near the MR scanner. Finally, electromechanical infusion pumps for delivery of medication are not certified to operate properly near strong magnetic fields. Because of these considerations, the preparation of patients for MR imaging involves the teamwork of both the ED staff and the MR technologists who can advise on device compatibility and provide MR compatible equipment (Table 57-2).

TABLE 57-2   Emergency Department Patients in the Magnetic Resonance (MR) Environment

ED personnel as well as their patients must be "cleared" for MR compatibility prior to entering the MR suite. A number of implanted medical devices are not MR compatible. The most common of these are certain brain aneurysm clips, cardiac pacemakers, cochlear implants, and internally placed pumps or electrical stimulators. Regarding brain aneurysm clips, the specific manufacturer of the clip and the model number should be provided to MR department personnel, who can advise on MR compatibility. Patients are also questioned to determine whether they have had injuries or a typical work history that would place them at risk for having metal fragments in or near the orbit or brain. Because of space limitations, all such devices cannot be reviewed in this chapter, and readers are advised to consult with MR personnel for any implanted device or device transported with the patient. Finally, although there is no known biohazard to humans or fetuses at approved energy levels specified by the Food and Drug Administration, pregnant hospital personnel are advised to stay out of the MR suite. Patients who are pregnant are requested to sign a consent form prior to MR imaging. These consent forms state that the potential benefit of the MR test for that patient greatly outweighs the potential risk to the fetus and mother, which appears to be extremely low or negligible (particularly, for example, compared with known risks of ionizing radiation with nuclear imaging studies or computed tomography). Contrast agents used for MRI are contraindicated during pregnancy.

Specific Applications of Magnetic Resonance Imaging

ACUTE MYOCARDIAL INFARCTION   Infarction can be visualized following intravenous administration of a contrast agent: gadolinium-DTPA. Within the infarct, there is a central "core" of tissue within which there is microvascular obstruction, despite patency of the epicardial vessel (Fig. 57-14). Surrounding this is nonviable tissue, with yet a still larger area of myocardium that remains "stunned." Signal intensity of myocardial territory corresponding to microvascular occlusion is reduced (*hypoenhanced*) compared with normal myocardium immediately after contrast administration. In reperfused infarcts, myocardial image intensity is increased (*hyperenhanced*).[12,13] The ability to discern these changes with fidelity may play a role in the detection of myocardial infarcts and the determination of their size. Large human infarcts, associated with prolonged obstruction of the infarct-related artery, frequently have central areas of hypoenhancement during the first several minutes after myocardial infarction. Smaller, reperfused infarcts tend to demonstrate more uniform signal hyperenhancement. [13]
FIG. 57-14. Magnetic resonance imaging of myocardial infarction. Short-axis images of the heart show a focal area of decreased signal in the circumflex artery territory of the left ventricle. Images were acquired in a breath hold, after injection of a gadolinium contrast agent.

First-pass MRI myocardial perfusion methods may be applied to the assessment of coronary flow reserve. *Coronary flow reserve* is defined as the ratio of blood flow at maximal vasodilatation, divided by flow at rest. Maximal flow is measured under conditions of vasodilatation, as achieved with dipyridamole or adenosine. Typically, coronary flow reserve ranges from 3 to 5 in normal individuals. In the presence of fixed coronary stenoses, coronary flow reserve is markedly reduced. [14] Coronary flow reserve may be measured with an intracoronary Doppler flow ultrasound probe, but first-pass contrast MR has also been found to be useful for flow reserve assessment. In both animal and patient studies, a linear relationship between coronary flow reserve and first-pass MR imaging has been found This indicates that patients with microvascular dysfunction, either from epicardial vascular disease or diseases altering the microvasculature, such as hypertension or diabetes, may be assessed by using these methods.[15]

CHRONIC MYOCARDIAL INFARCTION   This results in thinning of the left ventricular wall (remodeling) that is distinct from the normal myocardial wall thickness. These changes are better seen during systole, because of increased thickness of normal myocardium relative to the region of infarction. This finding is specific for chronic myocardial infarction on MRI. [16,17]

Left ventricular aneurysms may occur following myocardial infarction and are depicted as areas of focally protruding myocardium (Fig. 57-15), with transmural thinning and associated with mural thrombus. Although distinguishing between a true aneurysm and false aneurysm (ruptured myocardium contained by pericardium) is usually straightforward by echocardiography, MR is useful in cases in which an adequate acoustic window is not obtained. Pseudoaneurysms are characterized by a relatively small neck communicating with the left ventricular cavity, whereas true aneurysms have a relatively wide neck. [18]
FIG. 57-15. Magnetic resonance imaging of left ventricular aneurysm. A focal outpouching of the left ventricle is present (*arrow*) during both systole and diastole. The patient had a prior myocardial infarction, with resulting thinning of the ventricular wall and aneurysm formation. (Reprinted from Bluemke and Boxerman, [19] with permission.)

58 RESPIRATORY DISTRESS

J. Stephan Stapczynski

Common respiratory symptoms that bring patients to the emergency department include dyspnea (with the associated findings of hypoxia and hypercapnia), wheezing, and cough. Hiccups are an infrequent presenting symptom but, when persistent, very distressing to the patient. Cyanosis can be associated with pulmonary and vascular, as well as hematologic, pathologic conditions. This chapter discusses these symptoms and signs as they relate to evaluation of emergency patients. It is worth noting that, despite the increasing availability of and reliance on ancillary tests, the assessment of patients still begins with an accurate history and a careful physical examination in order to make the wisest use of ancillary tests. [1]

DYSPNEA

Dyspnea is a subjective feeling of difficult, labored, or uncomfortable breathing. This common emergency department complaint is often described as "shortness of breath," "breathlessness," "not getting enough air," and a variety of other phrases. Dyspnea does not result from a single pathophysiologic mechanism and may result from many disorders. Approximately two-thirds of patients presenting to the emergency department with dyspnea have either a cardiac or a pulmonary disorder. An emergency physician can usually distinguish these on the basis of history, physical examination, and, occasionally, ancillary tests.

Dyspnea must be distinguished from a number of other signs and symptoms. Tachypnea is rapid breathing; it may or may not be associated with dyspnea, and dyspnea is not always accompanied by tachypnea. Orthopnea is dyspnea in the recumbent position. It is most often the result of left ventricular failure and may be associated with diaphragmatic paralysis or chronic obstructive pulmonary disease (COPD). Paroxysmal nocturnal dyspnea is orthopnea that awakens the patient from sleep. Trepopnea is dyspnea associated with only one of several recumbent positions. Trepopnea can occur with unilateral diaphragmatic paralysis, with ball-valve airway obstruction, or after surgical pneumonectomy. Platypnea is the opposite of orthopnea: dyspnea in the upright position. Platypnea results from the loss of abdominal wall muscular tone and, in rare cases, from right-to-left intracardiac shunting, as occurs from a patent foramen ovale. Hyperpnea is essentially hyperventilation and is defined as minute ventilation in excess of metabolic demand. Hyperpnea may not be associated with dyspnea, and dyspnea is not always associated with increased minute ventilation.

Pathophysiology

Dyspnea is a complex sensation that involves both objective and subjective elements. Unlike other noxious sensations, dyspnea does not have a defined neural pathway, and the perceived difficulty probably arises from several pathophysiologic mechanisms. [2] The following processes are involved in the sensation of dyspnea:

1. A sense of voluntary skeletal muscular effort occurs with increased work of breathing. Muscle spindle receptors found in the muscles of respiration, as well as the associated Golgi tendon organ receptors, contribute to the sense of dyspnea when stimulated.
2. Hypercapnic chemoreceptors in the central medulla are stimulated.
3. Hypoxic chemoreceptors, primarily in the carotid body in concert with those in the aortic arch, are stimulated. However, there is a poor correlation between hypoxia and dyspnea, and dyspneic patients with hypoxia often have little improvement after correction of hypoxia.
4. Upper-airway mechanical and thermal receptors are stimulated.
5. A variety of lung receptors respond to various stimuli. They include intraparenchymal pulmonary stretch receptors, airway irritant receptors, and unmyelinated receptors that respond to interstitial edema or a change in compliance. Afferent signals from these receptors reach the brainstem by way of the vagus nerve and supply the majority of neurologic input that results in dyspnea.
6. Peripheral vascular receptors, including the right atrial and left atrial mechanoreceptor and the pulmonary artery baroreceptor, contribute to dyspnea in a poorly defined way.

Input from any or all of these receptors is integrated in a complex manner in the central nervous system (CNS) at both the subcortical and cortical level. Many authors believe that dyspnea results from afferent mismatch, when feedback from these peripheral receptors indicates that the work of breathing is greater than would be expected by the patient's level of activity. [3]

Clinical Features

Dyspnea has many causes but can be divided into general categories (Table 58-1). Because of its mainly subjective component, the presence or degree of dyspnea is difficult to measure, although categorical scales (e.g., the Borg scale) and visual analogue scales can be used in individual patients to gauge changes in the degree of distress in response to therapy. The initial assessment of any patient with dyspnea should be directed toward identifying imminent respiratory failure. The physician should specifically evaluate for tachypnea, tachycardia, stridor, and use of the accessory respiratory muscles, including the sternocleidomastoid, sternoclavicular, and intercostals. Other signs and symptoms of imminent respiratory failure are inability to speak due to the breathlessness, agitation or lethargy due to hypoxia, and

paradoxical abdominal wall movement (abdominal wall retracts inward) with inspiration, indicating diaphragmatic fatigue. In patients with any of these signs or symptoms, oxygen should be administered and the need for airway control and mechanical ventilation must be anticipated. Lesser degrees of dyspnea allow for a more detailed medical history, physical examination, and indicated ancillary tests.

TABLE 58-1   Common Causes of Dyspnea

Diagnosis

A detailed medical history often identifies the primary process resulting in dyspnea. [3,4,5 and 6] Patients often have underlying chronic disorders and can frequently specifically and accurately self-diagnose their exacerbations. The medical history should include recent infectious and environmental exposures that may impair respiratory function. Patients who require daily medications for symptom control should be questioned carefully about compliance and possible drug interactions.

A number of ancillary tests aid in determining the severity and specific cause of dyspnea. Pulse oximetry is a rapid but insensitive screening test for disorders of gas exchange, and results may be normal in acute dyspnea. Arterial blood gas (ABG) analysis is more sensitive for detecting impaired gas exchange, but results may also be normal in acute dyspnea, and ABG analysis cannot evaluate the work of breathing. Rarely, patients who appear dyspneic or tachypneic but who exhibit no evidence of hypoxia or pulmonary disease are shown to be hyperventilating from metabolic acidosis on ABG testing. A chest radiograph may indicate the general category of primary disease (infiltrate, effusion, and pneumothorax) but also may be normal. Bedside spirometric analysis (peak expiratory flow, or PEF) before and after bronchodilator therapy can be used to diagnose and treat dyspnea resulting from asthma or COPD, although it requires voluntary effort that might be difficult for dyspneic patients. Other potentially useful tests include an electrocardiogram and determination of hemoglobin level. Uncommonly, the specific process resulting in dyspnea cannot be identified by the history, the physical examination, and these simple ancillary tests, and specialized testing, including cardiac stress testing, echocardiography, formal pulmonary function testing, computed tomography scanning of the chest, or combined cardiopulmonary exercise testing, is indicated.

Treatment

Just as there is no single cause of dyspnea, there is no single treatment. In severe dyspnea, the primary treatment goal is maintenance of the airway and oxygenation with a Pa_{O_2} greater than 60 mmHg (arterial oxygen saturation, or Sa_{O_2}, approximately 90% or greater). After this is ensured, or for patients with lesser degrees of dyspnea, disorder-specific treatment along with supplemental oxygen can be provided in the emergency department. Patients with unrelieved dyspnea at rest, particularly those with terminal malignancies, may benefit from benzodiazepines and/or opiates. [7]

HYPOXEMIA

Hypoxia is insufficient delivery of oxygen to the tissues. The amount of oxygen available to the tissues is a function of the arterial oxygen content (Ca $_{O_2}$) and blood flow to the tissues.

$$Ca_{O_2} = 0.0031 \times Pa_{O_2} + 1.38 \times Hb \times Sa_{O_2}$$

Tissue hypoxia occurs in states of low cardiac output, low hemoglobin concentration, or low Sa $_{O_2}$. The percent oxygen saturation of arterial hemoglobin is, in turn, dependent on the Pa_{O_2}, as described by the oxygen-hemoglobin dissociation curve. Hypoxemia is an abnormally low arterial oxygen tension. Under most situations, cardiac output is within a normal range, and hypoxemia is the most common cause of hypoxia. Although the terms *hypoxia* and *hypoxemia* are generally used interchangeably, one can occur without the other. For example, in states of low Pa $_{O_2}$ (hypoxemia) with concomitant polycythemia, the patient may have no tissue hypoxia. Alternatively, very anemic patients may suffer tissue hypoxia despite a normal Pa $_{O_2}$. Hypoxemia is arbitrarily defined as a Pa_{O_2} less than 60 mmHg. As noted above, patients with hypoxemia may not necessarily have dyspnea, and patients with dyspnea may not have hypoxemia.

Relative hypoxemia is the term used when the arterial oxygen tension is lower than expected for a given level of inhaled oxygen. The degree of relative hypoxemia can be assessed by calculating the alveolar-arterial (A-a) oxygen partial pressure difference. This A-a gradient measures how well alveolar oxygen is transferred from the lungs to the circulation. Alveolar oxygen partial pressure is determined by the inhaled oxygen concentration (21% for room air), atmospheric pressure (760 mmHg at sea level), and displacement by water vapor (47 mmHg for full saturation) and carbon dioxide. Gas in the alveolus is fully saturated with water vapor, and the amount of alveolar oxygen is further reduced by carbon dioxide that freely diffuses from the pulmonary capillaries in an amount determined by the ratio between oxygen consumption and carbon dioxide production, or the respiratory quotient (R). On a typical diet, the respiratory quotient is 0.8. Thus, alveolar oxygen from breathing room air at sea level has a PA $_{O_2}$ = 0.21 × (760 − 47) − PA_{CO_2}/0.8. The A-a gradient at sea level for room air is P(A-a) $_{O_2}$ = 149 − Pa_{CO_2}/0.8 − Pa_{O_2}. A simplified formula is often used (Ch. 22): PA_{O_2} = 145 − Pa_{CO_2}. A normal P(A-a)$_{O_2}$ is under 10 in young healthy patients and increases with age. The predicted A-a gradient is approximately P(A-a)$_{O_2}$ = 2.5 + 0.21 (age) mmHg, with age in years and a standard deviation of 11 mmHg. This value for the normal A-a gradient is for healthy, asymptomatic individuals measured in an upright or sitting position. The supine position alone, as well as many chronic cardiac or pulmonary diseases, may raise the A-a gradient. Thus, many patients seen in the emergency department already have an elevated A-a gradient due to position or underlying chronic diseases, making it difficult to evaluate increases in the gradient that may be due to an acute pathologic condition.

Pathophysiology

Hypoxemia results from any combination of five distinct mechanisms.

1. *Hypoventilation.* Hypoventilation from a variety of disorders may result in hypoxemia. Regardless of its specific etiology, hypoxemia resulting from hypoventilation without any other cause for hypoxemia is always associated with an increased P $_{CO_2}$, and the P(A-a)$_{O_2}$ is normal. In the case of pure hypoventilation, the additional CO_2 displaces the inhaled oxygen and lowers the amount in the alveolus. This lowered amount, however, diffuses normally and mixes normally into the arterial blood.
2. *Right-to-left shunt.* Right-to-left shunting occurs when blood enters the systemic arteries without traversing ventilated lung. There is always a small degree of right-to-left shunting because of the direct left ventricular return of deoxygenated blood from both the coronary veins and the bronchial arteries. Increased right-to-left shunting occurs in a variety of conditions, including pulmonary consolidation, pulmonary atelectasis, and vascular malformations. Regardless of the specific cause of the right-to-left shunt, there is always an increase in the P(A-a) $_{O_2}$. In addition, right-to-left shunting does not increase Pa $_{CO_2}$. In fact, patients with a right-to-left shunt may have an abnormally low Pa_{CO_2}. A hallmark of significant right-to-left shunting is the failure of arterial oxygen levels to increase in response to supplemental oxygen. Although a small improvement is observed with supplemental oxygen, hypoxemia is never fully eliminated because of the continuing mixture of nonoxygenated blood into the systemic circulation.
3. *Ventilation-perfusion mismatch.* Ideal pulmonary gas exchange depends on a balance of ventilation and perfusion. Any abnormality resulting in a regional alteration of either ventilation or perfusion can adversely affect pulmonary gas exchange, resulting in hypoxemia. A wide variety of etiologies may result in these regional impairments, including pulmonary emboli, pneumonia, asthma, COPD, and even extrinsic vascular compression. Regardless of its specific etiology,

hypoxemia from ventilation-perfusion mismatch is associated with an increased $P(A-a)_{O_2}$ gradient and improves with supplemental oxygen.

4. *Diffusion impairment.* Pulmonary gas exchange also depends on diffusion across the alveolar-blood barrier. Any condition that influences this diffusion (e.g., adult respiratory distress syndrome, pneumonia, or pulmonary edema) may result in hypoxemia. Regardless of the specific cause of the diffusion impairment, the $P(A-a)_{O_2}$ is increased, and hypoxemia improves with supplemental oxygen.

5. *Low inspired oxygen.* Decreased ambient oxygen pressure results in hypoxemia. This is most commonly seen at high altitude or in nonobstructive asphyxia. The $P(A-a)_{O_2}$ is normal, and hypoxemia improves with supplemental oxygen. For example, Denver, at 5400 ft above sea level, has an atmospheric pressure of 620 mmHg and an inhaled oxygen partial pressure of only 0.21 × 620 = 130 mmHg, as opposed to 160 mmHg at sea level.

There are three distinct acute compensatory mechanisms for hypoxemia. Initially, minute ventilation increases. Next, pulmonary arterial vasoconstriction decreases perfusion to hypoxic alveoli. While vasoconstriction balances ventilation and perfusion in order to restore arterial oxygenation, it may also cause acute right heart failure and is ineffective with diffuse lung disease. Finally, sympathetic tone increases and improves oxygen delivery by increasing cardiac output, usually with an increased heart rate. Chronic compensatory mechanisms include an increased red blood cell mass and decreased tissue oxygen demands. These compensatory mechanisms appear to be activated at different levels of hypoxemia for different individuals. However, the acute compensatory mechanisms are always activated when Pa_{O_2} reaches 60 mmHg, and compensatory mechanisms fail when Pa_{O_2} falls below 20 mmHg.

Clinical Features

The signs and symptoms of hypoxemia are nonspecific. CNS manifestations include agitation, headache, somnolence, coma, and seizures. While tachypnea and hyperventilation are often present, at a Pa_{O_2} less than 20 mmHg, there is a central depression of respiratory drive. Cyanosis is not a sensitive or specific indicator of hypoxemia. Patients with chronic compensatory mechanisms may display polycythemia or alterations in body habitus (e.g., pulmonary cachexia).

Diagnosis

The diagnosis of arterial hypoxemia requires objective measurement. Because hypoxemia is defined as a Pa_{O_2} of less than 60 mmHg, formal diagnosis requires ABG analysis. Pulse oximetry is useful in screening for gross alterations in Pa_{O_2}. Although decreased oxygen saturation readings accurately predict significant hypoxemia, normal oxygen saturation readings do not exclude hypoxemia.

Treatment

Regardless of the specific cause of hypoxemia, the initial approach remains the same: ensuring a patent airway and providing supplemental oxygenation with a goal of maintaining a Pa_{O_2} of greater than 60 mmHg. Except in patients with right-to-left shunts, arterial oxygenation responds to supplemental oxygen.

HYPERCAPNIA

Hypercapnia is exclusively due to alveolar hypoventilation and is arbitrarily defined as a Pa_{CO_2} greater than 45 mmHg. Alveolar hypoventilation can be due to a variety of disorders, including rapid shallow breathing, small tidal volumes, underventilation of the lung, or reduced respiratory drive; it is never due to increased CO_2 production (Table 58-2).

Depressed central respiratory drive
  Structural CNS disease
  Sedating drugs
  Exogenous toxins
  Endogenous toxins

Thoracic cage disorders
  Kyphoscoliosis
  Extreme obesity

Neuromuscular diseases

Intrinsic lung disease associated with increased dead space
  COPD

TABLE 58-2   Causes of Hypercapnia

Pathophysiology

A portion of each tidal volume remains in the non-gas-exchange area of the respiratory system—termed the "dead space"—and is usually fixed by the anatomic size of the conducting airways (trachea and bronchi). The portion of the tidal volume that reaches the alveoli is that which remains after the dead space volume is subtracted: Ta = TV − Td. Alveolar ventilation per minute is the volume multiplied by the rate: A = Ta × R = (TV − Td) × R. Alveolar hypoventilation can result from a decrease in respiratory rate, a decrease in tidal volume, or an increase in dead space.

Since the medullary chemoreceptors stimulate both respiratory rate and tidal volume in response to increased CO_2, alveolar ventilation is finely controlled to maintain Pa_{CO_2} within a narrow range under most circumstances. In essence, alveolar ventilation is balanced relative to the production of CO_2 to maintain the Pa_{CO_2} within a narrow range. Decreased respiratory drive is associated with CNS lesions and toxic depression (Table 58-2). Thoracic cage and neuromuscular disorders produce hypoventilation by allowing a slower respiratory rate and/or a decreased tidal volume relative to the production of CO_2. Intrinsic lung diseases, such as COPD, produce alveolar hypoventilation due to an increase in dead space.

Clinical Features

The signs and symptoms of hypercapnia depend on the absolute value of Pa_{CO_2} and its rate of change. Acute elevations result in increased intracranial pressure, and patients may complain of headache, confusion, or lethargy. With severe hypercapnia, seizures and coma can result. Extreme hypercapnia can result in cardiovascular collapse, but this is usually seen only with acute elevations of Pa_{CO_2} to over 100 mmHg. As opposed to acute hypercapnia, chronic hypercapnia, even over 80 mmHg, may be well tolerated.

Diagnosis

Diagnosis of hypercapnia requires ABG analysis. The results of pulse oximetry analysis can be normal, depending on other factors. With acute hypercapnia, the serum bicarbonate level increases slightly due to mass action through the CO_2-bicarbonate equilibrium: bicarbonate increases about 1 meq/L for each increase of 10 mmHg in the Pa_{CO_2}. Patients with chronic hypercapnia have an elevated serum bicarbonate concentration due to the renal response to increased Pa_{CO_2}: the serum bicarbonate concentration increases about 3.5 meq/L for each increase of 10 mmHg in the Pa_{CO_2}.

Treatment

Treatment of hypercapnia requires maneuvers to increase minute ventilation, both the rate and the tidal volume. This involves ensuring a patent airway and may require mechanical ventilation. The disposition of hypercapnic patients depends primarily on the underlying cause and severity. In general, patients with hypercapnia that causes CNS symptoms should be hospitalized. Also, patients with neuromuscular disease—either congenital or acquired—who present with acute hypercapnia should be hospitalized. Some COPD patients have chronic hypercapnia and do not require admission provided they are stable. Conversely, patients with COPD who

display worsening hypercapnia despite maximal therapy require hospital admission.

WHEEZING

Wheezes are adventitious lung sounds that can be best described as "musical," produced by airflow through the central and lower airways. [8] Wheezes have sinusoidal acoustics, over a wide frequency range, typically 100 to 1000 Hz. The duration is prolonged, typically longer than 80 ms. Wheezes differ from the other two main adventitial lung sounds: rhonchi and crackles (rales). Rhonchi are a series of damped sinusoidal sounds, of lower frequency (<300 Hz) and prolonged duration (>100 ms). Crackles are a series of intermittent individual sounds, typically of less than 20 ms duration.

Pathophysiology

The current theory is that wheezes are produced by airway flutter and vortex shedding from the central and distal airways, although movement of airway secretions may play a small role.[9] While flutter and vortex shedding are possible in normal airways, these processes are more pronounced in obstructed airways. Airway obstruction is associated with the processes of bronchial smooth muscle contraction (bronchospasm), smooth muscle hypertrophy, increased mucus secretion, and peribronchial inflammation.

Clinical Features

Wheezing is not synonymous with airflow obstruction, and it must be remembered that

1. Wheezing can occur in normal adults and children without evidence of airflow limitation during quiet inspiration.
2. Forced expiration can produce wheezing in normal individuals, rendering its presence diagnostically useless.
3. Patients with obstruction may not have wheezing; the sensitivity of wheezing in detecting bronchial hyperreactivity with airflow limitation of greater than 20 percent is at best 75 percent, and patients with profound obstruction (<20 percent of normal) may have not enough gas movement to generate a sound.

These facts notwithstanding, wheezing is usually associated with asthma and other obstructive pulmonary diseases characterized by bronchial obstruction due to muscular spasm and inflammation (Table 58-3).

Upper airway (more likely to be stridor, may have element of wheezing)
    Angioedema: allergic, ACE inhibitor, idiopathic
    Foreign body
    Infection: croup, epiglottis, tracheitis
Lower airway
    Asthma
    Transient airway hyperreactivity (usually due to infection or irritation)
    Bronchiolitis
    COPD
    Foreign body
Cardiovascular
    Cardiogenic pulmonary edema ("cardiac asthma")
    Noncardiogenic pulmonary edema (adult respiratory distress syndrome, or ARDS)
    Pulmonary embolus (rare)
Psychogenic

TABLE 58-3   Causes of Wheezing

The duration of wheezing, or, more precisely, that portion of the expiratory phase occupied by wheezing, has been used to quantify the severity of airflow obstruction in moderate-to-severe acute asthma. As noted above, patients with the most profound obstruction may not wheeze, but their condition can be detected by noting markedly decreased lung sounds.

Most patients with bronchospastic disease (either asthma or COPD) relate a history of previous attacks and response to bronchodilators. The finding of wheezing in a symptomatic patient without such a history is a clue that another process may be present. [10]

Diagnosis

Airflow obstruction can be assessed by bedside spirometric analysis using portable machines; either PEF or forced expiratory volume at 1 s (FEV_1) is measured. Accurate measurement requires a cooperative patient and several (usually three) maximal-effort expirations. Severely dyspneic patients are often not able to perform the maneuver. Likewise, children may not understand the directions well enough to give a maximal effort. Since this test is effort dependent, only the maximal value should be reported. The obtained value should be compared to predicted normal values. The predicted value for spirometric measurements is dependent primarily on age, gender, and height, with only a small and clinically inconsequential adjustment for weight and ethnic background. For practical purposes, PEF or FEV_1 values greater than 80 percent of the predicted value are within the normal range. Values between 50 and 80 percent of the predicted value constitute minor airflow obstruction, values between 25 and 50 percent constitute moderate airflow obstruction, and values less than 25 percent constitute severe airflow obstruction. However, the severity of clinical symptoms is dependent as much on the rapidity of the development of obstruction as on its absolute value. Conversely, relief of symptoms is correlated more closely with the relative degree of airflow improvement than with the absolute value.

Spirometric analysis can also be used to monitor response to treatment. Because of variations in effort and measurement, a change in spirometric value of up to 6 percent can be within the error range of the test. Thus, an improvement or decline in PEF or FEV_1 of more than 8 to 10 percent from one measurement to another is significant.

A chest radiograph may be useful in assessing wheezing, particularly for patients without a history of asthma. [10] As noted elsewhere, patients with uncomplicated acute asthma do not require routine chest radiographs during their emergency department assessment and treatment. Conversely, patients with COPD and congestive heart failure who present with dyspnea and wheezing should have chest radiographs to evaluate for severity and complications.

ABG analysis is useful if clinical examination suggests hypoxemia, hypercapnia, or metabolic acidosis. The ABG analysis may also provide baseline values for further testing and treatment. However, most patients with mild-to-moderate asthma and wheezing can be assessed by spirometric analysis and do not require routine ABG analysis.

Treatment

Treatment of wheezing is directed by the underlying disorder and often involves aerosols of b_2 agonists (e.g., albuterol) and/or anticholinergics (e.g., ipratropium bromide). Patients with peribronchial inflammation are often treated with systemic (oral or intravenous) or inhaled steroids.

COUGH

Cough is a common and nonspecific symptom that may bring patients to the emergency department, particularly if the cough interferes with activity or sleep.

Pathophysiology

Cough is a protective reflex that acts to clear secretions and foreign debris from the tracheobronchial tree. [11] Coughing is initiated by stimulation of irritant receptors located largely in the larynx, trachea, and major bronchi. These receptors are stimulated by inhaled irritants (e.g., dust), allergens (e.g., ragweed pollen), toxic

substances (e.g., gastric acid), hypo- or hyperosmotic liquids, inflammation (e.g., asthma), cold air, instrumentation, and excess pulmonary secretions. [12] Minor cough receptors located in the upper respiratory tract (sinuses and pharynx) and chest (pleura, pericardium, and diaphragm) may stimulate coughing. Signals from these receptors travel via the vagus, phrenic, and other nerves to the cough center in the medulla.

Once stimulated, the cough center initiates the stereotypical cough pattern: a deep inspiration followed by attempted expiration against a closed glottis that suddenly opens, providing for a forceful exhalation of gas, secretions, and foreign debris from the tracheobronchial tree. Extremely high peak airway velocities have been measured with coughing. The coughing sound is generated at the larynx and resonates in the nasal cavity and the lungs. [11]

Coughing patterns vary widely according to the underlying pathologic condition of the lung, the presence or absence of secretions, and whether the cough is voluntary or involuntary. Thus, it is not surprising that the frequency, duration, and quality of coughing vary among patients.

Clinical Features

For the purposes of differential diagnosis, cough has been subdivided into acute and chronic, although this distinction is primarily used to separate the self-limited syndromes of acute bronchitis and upper respiratory infection (URI) from other causes. For the purposes of discussion, chronic cough is defined as a cough that is present for more than 3 weeks without any periods of resolution. Cough has also been divided into nonproductive and productive with excess sputum production. That distinction may be artificial because, at least for cases of chronic cough, the same disorders produce both nonproductive and productive coughing; the distinction is without diagnostic utility. [13]

Excluding environmental exposures, acute cough is most often due to URI, lower respiratory tract infection, and allergic reactions. Common URIs are associated with a combination of rhinorrhea, sinusitis, pharyngitis, and laryngitis, with the cough due to drainage from the nasopharynx onto cough receptors in the pharynx and larynx. A productive cough is the hallmark of acute bronchitis. While pneumonia generally produces a cough, pulmonary secretions may be scant; thus, the cough is not productive and the presentation may be dominated by other symptoms (e.g., altered mental status, fever, and dyspnea). Mycobacterial and fungal pulmonary infections may produce cough, but the presentation is usually more subacute or chronic. Acute asthma is often associated with cough, but symptoms of wheezing and dyspnea usually dominate. Occasionally, a patient with asthma may present with coughing, as opposed to wheezing, as a manifestation of airflow obstruction.

Chronic cough is due to a wide variety of disorders, but studies have found that most patients have chronic cough due to (1) smoking, often with chronic bronchitis, (2) postnasal discharge, (3) asthma, (4) gastroesophageal (GE) reflux, and (5) angiotensin-converting enzyme (ACE) inhibitor therapy (Table 58-4).[14,15] and [16] The association of smoking, chronic bronchitis, and persistent cough is so obvious as to merit little discussion, other than to firmly point it out to patients. Smoking-induced coughing is usually worse in the morning and, with chronic bronchitis, usually productive. Rhinitis with postnasal discharge is associated with mucus drainage from the nose, a history of "allergies or sinus problems," and frequent clearing of the throat or swallowing of mucus. Chronic cough associated with asthma is usually worse at night, exacerbated by irritants, and associated with episodic wheezing and dyspnea. Asthma can be exacerbated by b-blocker therapy and present with nocturnal coughing. Cough associated with GE reflux often has a history of heartburn, is worse when lying down, and improves with antiacid therapy (antacids or H_2 blockers).

The incidence of ACE inhibitor cough is approximately 10 to 12 percent, although higher values have been published. [17] All ACE inhibitors have been reported to induce cough; it is not clear whether certain agents have a higher likelihood of inducing cough than others. ACE inhibitor cough is thought to result when the blockade of ACE leads to accumulation of bradykinin and substance P, which stimulate the pulmonary cough receptors and enhance the formation of irritating prostaglandin metabolites. Extreme variability characterizes ACE inhibitor cough: early (1 week) or later (1 year) onset after starting treatment, only slightly bothersome to debilitating symptoms, and variation during the day. The association of pertussis in adults with persistent cough (>2 weeks) was documented from a convenience sample from one emergency department.[18] The therapeutic implication of this finding is unclear; antibiotic treatment of adults with pertussis is controversial, and late treatment has no proven benefit. Table 58-4 lists the major causes of cough.

Acute	Chronic common	Chronic less common
Upper respiratory infection: rhinitis, sinusitis, pharyngitis, laryngitis	Smoking and/or chronic bronchitis	Heart failure
Lower respiratory infection: bronchitis, pneumonia	Postnasal discharge	Bronchiectasis
Allergic reaction	Asthma, reactive airway disease	Lung cancer, other intrathoracic mass lesion
Asthma	GE reflux	Emphysema
Environmental irritants	ACE inhibitor	Pertussis (perhaps more common)
Transient airway hyperreactiveness		Mycobacterial and fungal infection
		Recurrent aspiration
		Foreign body
		Occupational and environmental irritants
		Interstitial lung disease
		Cystic fibrosis

TABLE 58-4   Causes of Cough

Diagnosis

Most causes of acute cough do not warrant routine ancillary tests. A chest radiograph may be used in patients with purulent sputum and/or fever, and spirometric analysis may be used to document the presence of airflow obstruction in patients with asthma,

Patients with chronic cough are usually treated based on clinical assessment first, and ancillary tests are performed only if symptoms persist. [14,15] Nasolaryngoscopy can be used to document the presence of mucosal inflammation and excessive mucus drainage. Sinus radiographs or computed tomography scanning can document the presence of sinusitis. A chest radiograph can detect focal or diffuse lung disease. Spirometric analysis can identify airflow obstruction, although, in cases of asthma-associated cough, the spirometric values are normal between attacks. GE reflux can be documented by a number of methods; esophageal pH monitoring is probably the most useful.

Treatment

In addition to disease-specific therapy, patients with acute cough may occasionally benefit from antitussives, which block the cough reflex at various locations. Mild cough suppressants, such as the antihistamine diphenhydramine, should be tried first. However, the most effective cough suppressants are the opiates: dextromethorphan, codeine, and oxycodone.[7,19] While cough suppressants are usually restricted to patients with a dry cough and avoided in patients with significant sputum production, there is only tradition to support this practice. Demulcents, part of most proprietary cough preparations, soothe the pharynx and somewhat suppress the cough reflex. Inhaled local anesthetics are effective cough suppressants but also suppress protective lung reflexes and may induce bronchospasm; they should be used only with great caution and under careful supervision. [20]

Because chronic cough is most often due to a few common disorders, an algorithmic approach to treatment using sequential steps appears to be effective: [21]

1. Reduce exposure to lung irritants (e.g., smoking) and discontinue ACE inhibitors and b blockers.
2. Treat for postnasal discharge with an oral antihistamine-decongestant and/or an inhaled nasal steroid. If the cough improves, continue treatment and evaluate for sinus disease with imaging studies.
3. Evaluate and treat for asthma.
4. Obtain chest and sinus radiographs if not already done.
5. Evaluate and treat for GE reflux.
6. Refer the patient for bronchoscopy.

Using a sequential approach, tailoring treatment to the clinical symptoms and the patient's responses, over 95 percent of patients achieve resolution of their

cough.[16],[21]

HICCUPS

Hiccup, or singultus, is an involuntary respiratory reflex with spastic contraction of the inspiratory muscles against a closed glottis, producing the characteristic sound. As opposed to coughing, where the reflex serves the useful purpose of expelling secretions and debris from the pulmonary tree, a specific protective purpose has not be elucidated for hiccups.[22]

Pathophysiology

The afferent arm of the hiccup reflex consists of the phrenic and vagus nerves as well as the thoracic sympathetic chain. There is no well-defined central hiccup center; instead, there is an intensive interconnection among the hypothalamus, medullary reticular formation, respiratory center, and cranial nerve nuclei. The efferent limb of the reflux uses the phrenic nerve, the recurrent laryngeal branch of the vagus nerve, and the motor nerves to the anterior scalene and intercostal muscles.

As noted above, hiccups are produced by spasmodic contraction of the inspiratory muscles (diaphragm and intercostals) against a closed glottis, a breakdown in the normal relationship between inspiration and glottic closure. Inspiration normally inhibits glottic closure and maintains an open airway. During swallowing, the stimulation of glottic closure inhibits inspiration, preventing aspiration. In some manner, the hiccup reflex disrupts the connection between these two processes so that 30 to 40 ms after the onset of inspiration, glottic closure is stimulated. [23] In most cases where a specific cause can be assigned, hiccups appear to result from stimulation, inflammation, or injury to one of the nerves of the reflex arc.

Clinical Features

For diagnostic classification, hiccups are divided into benign self-limited and persistent, or intractable (Table 58-5).[22],[24]

TABLE 58-5   Causes of Hiccups

Benign hiccups are generally initiated by gastric distention from food, drinking (especially carbonated beverages), or air. Alcohol ingestion appears to precipitate hiccups by relaxing the relationship between inspiration and glottic closure, making it easier for other stimuli to trigger the reflex. Excessive smoking, a sudden change in environmental temperature, and psychogenic events (excitement or stress) are sometimes associated with hiccups.

Persistent hiccups are usually due to damage or irritation to a branch of the vagus or phrenic nerve. A wide variety of events have been implicated in producing persistent hiccups. One rare but readily treatable stimulus is a foreign body (often a hair) in the external auditory canal that is pressing against the tympanic membrane and stimulating the auricular branch of the vagus nerve. Several drugs—most often steroids and benzodiazepines—have been implicated in inducing hiccups, but a recent review found evidence of etiologic association unconvincing. [25]

Diagnosis

Most patients with benign hiccups resolve spontaneously or with simple maneuvers, do not seek medical attention, and do not require specific diagnosis. Patients with persistent hiccups often seek medical attention, occasionally in the emergency department. [26]

The evaluation of persistent hiccups should start with a history to determine whether a specific event was associated with the onset. Are the hiccups persistent during sleep? Persistence during sleep suggests an organic cause, and resolution during sleep suggests a psychogenic cause, although this distinction is not absolute. [24] Inquiries should be made concerning general anesthesia, surgical procedures, and several metabolic diseases that are associated with persistent hiccups. As noted above, the external auditory canal should be carefully examined. A chest radiograph should be done to evaluate for possible intrathoracic pathology. Fluoroscopy can be useful to evaluate to unilateral versus bilateral diaphragmatic movement during hiccups.

Treatment

A wide variety of physical maneuvers have been used to terminate an acute episode of hiccups. Many of these measures are based on the concept that stimulating the pharynx will block the vagal portion of the reflex arc and abolish the hiccups. [27] No one method appears to be more effective than another. Swallowing a teaspoon of granulated sugar dry is about as effective as others and does not involve the infliction of noxious or painful stimulation.

Drug treatment also works by inhibiting the reflex arc. [27] A large number of agents have been described as effective, but mostly only as case reports. Of the recommended drugs, only chlorpromazine has been tried enough to have achieved US Food and Drug Administration approval for treatment of intractable hiccups. The recommended dose is 25 to 50 mg intravenously, with a repeated dose in 2 to 4 h if needed. If improvement is noted, oral therapy with 25 to 50 mg tid or qid should be given. Metoclopramide 10 mg intravenously or intramuscularly and, if effective, followed by 10 to 20 mg qid for 10 days appears to be effective. The advantage of both these drugs is that effectiveness is usually evident in 30 min, unlike with other agents. The major disadvantages are extrapyramidal symptoms with both drugs and hypotension with chlorpromazine.

For more gradual control and with perhaps less risk of adverse reactions, oral treatment can be initiated with nifedipine (10 to 20 mg tid or qid), valproic acid (15 mg/kg per day taken tid), or baclofen (10 mg tid). Initiation and maintenance of these agents is best done in concert with a primary care physician who will follow up with the patient.

CYANOSIS

Cyanosis is a bluish color of the skin and mucous membranes that results from an increased amount of reduced hemoglobin (deoxyhemoglobin) or hemoglobin derivatives. The detection of cyanosis can be highly subjective and is not considered a sensitive indicator of the state of arterial oxygenation. In fact, cyanosis is determined by the absolute amount of reduced hemoglobin in the blood; the amount of oxygenated hemoglobin is of little influence.

Pathophysiology

Standard teaching has been that cyanosis is usually present when there is 5 g or more of reduced hemoglobin in 100 mL of capillary blood. However, this figure has been questioned recently when it was demonstrated that central cyanosis can be detected when the deoxyhemoglobin concentration is as low as 1.5 g/100 mL. [28] The increase in the amount of reduced hemoglobin in the cutaneous vessels can result from an increase in the quantity of venous blood in the skin, dilatation of the

venules, or a decrease in the oxygen saturation in the capillary blood. In some instances, cyanosis can be detected when the arterial saturation has fallen to 85 percent; in others, it may not be detected until saturation is 75 percent. The absolute, rather than the relative, amount of reduced hemoglobin produces cyanosis. [29]

Various physiologic, anatomic, and physical factors other than the amount of reduced hemoglobin may influence the appearance of cyanosis, making an accurate clinical detection of the degree or even the presence of cyanosis difficult. Physiologic factors include the oxygen content of the blood, level of tissue oxygenation, degree of oxygen extraction, and oxyhemoglobin dissociation curve. Anatomic factors include the status of the cutaneous microcirculation, pigmentation, and thickness of the skin. Physical factors include the lighting under which the patient is examined and the skill of the physician. The tongue is considered one of the most sensitive sites for observing central cyanosis, and the earlobes, conjunctivae, and nail beds are considered much less reliable.

Clinical Features

Clinically, the presence of cyanosis suggests the possibility of tissue hypoxia, and possible causes for hypoxia should be considered. Unexplained cyanosis, particularly in association with normal arterial oxygen tension (Pa o_2), suggests the possibility of abnormal hemoglobin, such as methemoglobin. However, the absence of cyanosis does indicate adequate tissue oxygenation; severe states of tissue hypoxia are possible without the presence of cyanosis

Cyanosis is traditionally divided into two categories: central and peripheral. The central type is seen under conditions with unsaturated arterial blood or abnormal hemoglobin. The mucous membranes and skin are both affected. In contrast, peripheral cyanosis is due to the slowing of blood flow to an area and an abnormally great extraction of oxygen from normally saturated arterial blood. Congestive failure, peripheral vascular disease, shock states, and cold exposure all create states of vasoconstriction and decreased peripheral blood flow. The differentiation between central and peripheral cyanosis may not be possible in conditions where there may be an admixture of mechanisms (Table 58-6).

Central Cyanosis	Peripheral Cyanosis
Decreased arterial oxygen saturation	Reduced cardiac output
Decreased atmospheric pressure: high altitude	Cold exposure
Impaired pulmonary function	Redistribution of blood flow from extremities
Alveolar hypoventilation	Arterial obstruction
Uneven relationships between pulmonary ventilation and perfusion	Venous obstruction
Impaired oxygen diffusion	
Anatomic shunts	
Certain types of congenital heart disease	
Pulmonary arteriovenous fistulas	
Multiple small intrapulmonary shunts	
Hemoglobin with low affinity for oxygen	
Hemoglobin abnormalities	
Methemoglobinemia: hereditary, acquired	
Sulfhemoglobinemia: acquired	
Carboxyhemoglobinemia (not true cyanosis)

TABLE 58-6 Causes of Cyanosis

Diagnosis

The presence of cyanosis suggests the possibility of hypoxemia, and pulse oximetry analysis is readily available to assist the physician in the early diagnosis of hypoxemia and provide continuous oxygen saturation measurements. However, an exception occurs when the hemoglobin is in a state in which it is unable to bind to oxygen (i.e., methemoglobin or carboxyhemoglobin). In such situations, pulse oximetry analysis not only overestimates the oxygen saturation but also reflects a diminished response to any supplemental oxygen. ABG analysis with co-oximetry is still the gold standard in the assessment of any patient with suspected cyanosis. In central cyanosis, the oxygen saturation of the ABGs is decreased due to the underlying hypoxia. In peripheral cyanosis, assuming normal cardiopulmonary and hemoglobin status, the oxygen saturation should be normal. If methemoglobinemia or carboxyhemoglobinemia is suspected, the ABG analysis will show a normal $Pa o_2$ (reflecting a normal amount of dissolved oxygen in the plasma), a normal calculated oxygen saturation (from the normal Pa o_2), and a decrease in measured oxygen saturation (due to decreased number of oxygen binding sites).

Few tests are as vulnerable to errors introduced by improper sampling, handling, and storage as are ABG analyses. The technical difficulties with obtaining an arterial sample via percutaneous puncture accounts for much of the high preanalytic error rate for isolated ABG samples obtained in the emergency department, compared to a low error rate for samples obtained from an indwelling arterial catheter.

Special attention should be given to the following sources of preanalytic error with ABG samples:

1. Heparin is the anticoagulant of choice, and one make sure that the syringe is flushed with heparin and then emptied thoroughly. This will allow adequate anticoagulation of a 2- to 4-mL blood sample with assurance that the results will not be altered by the anticoagulant. Excessive heparin affects the pH, P $_{co_2}$, and Po_2 as well as the hemoglobin determination.
2. Air bubbles that mix with the blood sample will result in gas equilibration, significantly lowering the P $_{co_2}$ values with an increase in pH and Po_2. Any sample obtained with more than minor air bubbles should be discarded.
3. Reducing the temperature of the blood by placing the sample immediately in an ice slush will significantly deter changes in the P $_{co_2}$ and pH for a period of several hours. If the sample is not iced immediately, changes can be significant. As a general rule, arterial blood samples should be analyzed within 10 min or cooled immediately. Failure to properly cool the sample is a common source of preanalytic error.

Hypoxemia, anemia, and polycythemia can be diagnosed by means of hemoglobin and ABG determination. The red cyanosis of polycythemia vera occurs because the increase in the number of red blood cells and the hemoglobin concentration results in sludging of blood flow in cutaneous capillaries and venules. Similarly, cyanosis is enhanced in chronic hypoxemia accompanied by polycythemia.

If the $Pa o_2$ and the hemoglobin concentration are normal, the cyanosis may be due to abnormal skin pigmentation or abnormal hemoglobin. The term pseudocyanosis is used to describe a blue, gray, or purple cutaneous discoloration that may mimic cyanosis. Pseudocyanosis can be caused by heavy metals [e.g., iron (hemochromatosis), gold, silver, lead, or arsenic] or drugs (e.g., phenothiazines, minocycline, amiodarone, or chloroquine). Chrysiasis is a specific type of pseudocyanosis that is characterized by a gray, blue, or purple pigmentation of areas exposed to light. It is a rare dose-dependent complication of gold treatment that tends to cause permanent discoloration of the skin. Another example of pseudocyanosis is argyria, which is a slate blue-to-gray coloration of the skin resulting from either chronic ingestion or chronic local application of silver salts or colloidal silver. In pseudocyanosis the skin does not blanch with pressure, in contrast to true cyanotic skin, which does blanch. Carboxyhemoglobinemia does not cause cyanosis. Occasionally, however, carboxyhemoglobinemia does produce a cherry-red flush of the skin, retina, or mucous membranes.

Cyanosis can be caused by methemoglobinemia and sulfhemoglobinemia. Most cases are due to chemicals or medications. Although a wide range of drugs can produce methemoglobinemia, benzocaine, nitrates, and nitrites are the most common agents implicated in drug-induced methemoglobinemia. Sulfhemoglobinemia most commonly results from either phenacetin or acetanilid (Bromo Seltzer). Industrial aniline compounds may produce either sulfhemoglobinemia or methemoglobinemia.

The incidence of acquired methemoglobinemia secondary to industrial exposure to aniline dyes and aromatic amino and nitro compounds has decreased with improvement in occupational health standards. Hereditary methemoglobinemia is a rare genetic disorder affecting the enzyme NADH-methemoglobin reductase, resulting in structural alterations of the hemoglobin molecule. This enzyme is the major pathway responsible for converting methemoglobin to its reduced state. This pathway plays a clinically significant role in the treatment of methemoglobinemia because it is the pathway by which the antidote, methylene blue, is able to enhance the reduction of methemoglobin. Patients with NADH-methemoglobin reductase deficiency appear cyanotic but are usually compensated and asymptomatic.

Methemoglobinemia produces visible cyanosis with as little as 1.5 g of methemoglobin per 100 mL of blood. Since methemoglobin is incapable of binding with oxygen, the symptoms of methemoglobinemia are secondary to hypoxia, and the severity is related to the quantity of methemoglobin present, the rapidity of onset, and the

patient's cardiopulmonary system. Cyanotic patients without cardiovascular or pulmonary disease should be suspected of having methemoglobinemia, especially if cyanosis is not relieved by oxygen administration. An additional clue is that venous blood will appear chocolate brown. Spectrophotometric analysis is required for identification of the pigment and its quantity.

Sulfhemoglobin is inert as an oxygen carrier and can produce deep cyanosis at a level of less than 0.5 g of sulfhemoglobin per 100 mL of blood. Unlike methemoglobinemia, sulfhemoglobinemia is irreversible. Treatment is directed toward symptomatic and supportive care as well as the identification and removal of suspected agents.

Treatment

Patients with central cyanosis should be started on supplemental oxygen. Failure to improve suggests either impaired circulation (shock), abnormal hemoglobin, or pseudocyanosis.

In acquired methemoglobinemia, no treatment is necessary unless signs of hypoxia (i.e., angina, arrhythmias, hypotension, stupor, or coma) are present. Methylene blue in a dose of 1 to 2 mg/kg of body weight given intravenously over 5 min as a 1% solution (0.1 to 0.2 ml/kg) is the antidote for acquired methemoglobinemia. Caution should be taken whenever methylene blue is used; by itself, at high doses, it can cause hemolysis or even precipitate methemoglobinemia and possibly worsen the patient's condition.

59 BRONCHITIS AND PNEUMONIA

Donald A. Moffa, Jr.
Charles L. Emerman

ACUTE BRONCHITIS

Epidemiology

Acute bronchitis may occur in outbreaks as a respiratory virus spreads through a population, or it may be sporadic. It accounts for more than seven million outpatient physician visits among patients older than age 18. Antibiotics are prescribed more than half of the time to treat this condition even though most cases are self-limited and antibiotic therapy has not been shown conclusively to alter outcomes.

Pathophysiology

Acute bronchitis, an infection of the conducting airways of the lung, produces inflammation, exudate, and sometimes bronchospasm of the involved airways. The majority of acute bronchitis is caused by viruses, including influenza A and B, adenovirus, parainfluenza virus, rhinovirus, respiratory syncytial virus (RSV), coxsackievirus A21 and, less commonly, measles, rubella, herpesviruses, or coronaviruses.[1] Enteroviruses such as coxsackievirus and echovirus may cause acute bronchitis, primarily in the summer, whereas rhinovirus may be suspect year round. Most other viruses cause bronchitis from early fall to spring. Influenza is more prevalent during the winter. Adults who have contact with children may develop acute bronchitis and pneumonia from RSV.[2] Measles and herpes simplex viruses may cause severe cases. Bacteria known to contribute to acute bronchitis include *Bordatella pertussis, Mycoplasma pneumoniae, Chlamydia pneumoniae*, and possibly *Streptococcus pneumoniae*.[3]

Clinical Features

The hallmark of acute bronchitis is cough, usually productive, in patients without evidence of pneumonia, sinusitis, or chronic pulmonary disease. Patients may have rhinitis (nasal congestion and discharge), myalgias, and fever.[1] Sputum may be clear or colored, and the presence of colored sputum does not necessarily indicate a bacterial infection. Patients may complain of dyspnea or wheezing; usually due to bronchospasm.

Acute bronchitis caused by influenza A and B usually includes the abrupt onset of fever, chills, headaches, and myalgias that subside over 3 to 4 days, followed by 1 to 2 weeks of nonproductive cough and malaise. Less commonly, patients present with pharyngitis or tracheobronchitis. One-quarter may have rales or wheezes. Outbreaks occur from October to April.

Bordatella pertussis as a cause of acute bronchitis in adults has been increasing since 1981 and has been implicated as a causative agent in adults with chronic cough.[3] Protection owing to childhood immunization diminishes within 4 to 12 years. Cough is usually preceded by low-grade fever, rhinorrhea, and conjunctivitis, but adults usually lack the characteristic "whoop" heard in children. Commonly, available culture and direct fluorescence antibody test of nasopharyngeal swabs are uniformly negative.[3]

Mycoplasma pneumoniae affects mainly older children and young adults and may occur throughout the year, with epidemics occurring every 4 to 7 years. The incubation period is 16 to 30 days. Given the usual brevity of symptoms and relatively quick resolution of illness, diagnostic tests are usually not warranted unless pneumonia is suspected.

Chlamydia pneumoniae, which may cause wheezing associated with acute bronchitis and chronic asthma, has a 30-day incubation period and is found mainly in the elderly. Patients may be afebrile and produce minimal sputum, and laryngitis may be more common than with mycoplasmal or viral infections. Symptoms may persist even after adequate antibiotic therapy.

Diagnosis

Clinical diagnosis is appropriately made when these findings are present: (1) an acute cough (for less than 1 week), (2) no prior lung disease, (3) normal arterial oxygenation, and (4) no auscultatory abnormalities. As noted previously, wheezing in patients without prior history of asthma indicates bronchospasm stimulated by the bronchitic inflammation.

A chest radiograph is not required for straightforward cases of acute bronchitis. As noted below, the absence of fever, tachycardia, tachypnea, or auscultatory abnormalities reduces the likelihood of a radiographic infiltrate to less than 1 percent. Pulse oximetry is indicated if a patient complains of dyspnea or is noted to be cyanotic or short of breath. Bedside spirometry [peak expiratory flow (PEF) or forced expiratory volume in 1 s (FEV$_1$)] should be done if a patient complains of dyspnea or wheezing or if wheezing is heard on examination. Blood tests are not indicated in routine cases. Sputum cultures are not indicated in immunocompetent patients.

Treatment

Nine randomized, double-blind, placebo-controlled trials were undertaken between 1966 and 1995 to determine antibiotic effectiveness in treating acute bronchitis.[4,5] Whereas two studies reported improvement in symptoms, and a trend toward resolution of cough and clinical improvement at follow-up were noted, systematic review did not find statistical benefit for antibiotic treatment. Most cases of acute bronchitis are self-limited, and patients recover at the same rate regardless of antibiotic treatment. Even if there is evidence of bacterial infection with *B. pertussis, M. pneumoniae, C. pneumoniae,* or *S. pneumoniae,* there is no evidence that antibiotic treatment hastens improvement. There is some evidence that older adults and patients with underlying chronic obstructive pulmonary disease (COPD) benefit from antibiotic treatment for acute bronchitis.[5,6] However, until controlled trials are performed, routine antibiotic use even in these patients cannot be recommended.

There is evidence that bronchodilators are useful in treating acute bronchitis, compared with either placebo or erythromycin. Patients' report decreased cough and faster return to work when treated with oral or inhaled albuterol.[7,8] A significant bronchodilator response, as measured by an improvement in PEF or FEV$_1$ of greater than 10 to 12 percent, may be useful in determining whether outpatient treatment is useful. The administration of inhaled (metered dose inhaler, 2 puffs q 4 to 6 h) or

oral (2 mg tid to qid) albuterol should be considered in acute bronchitis, especially if reversible bronchospasm is present.

Amantadine has been shown to shorten the duration and severity of influenza A in up to half of patients who receive it within 48 h of symptom onset (see Chap. 150, "Common Viral Infections"). Amantadine or rimantadine may be effective in treating acute bronchitis caused by this agent. Aerosolized ribavirin may also be helpful in patients with acute bronchitis due to RSV.

Disposition

Patients with acute bronchitis should be discharged with appropriate instructions for rest, for hydration, and to watch carefully for symptoms of worsening: dyspnea, fever, and lethargy. It usually takes 3 to 4 weeks for cough to resolve completely and for general well-being to return.

PNEUMONIA

Epidemiology

Community-acquired pneumonia (CAP) is a common medical problem accounting for about 4 million visits to physicians and 600,000 adult hospitalizations per year. [9] Pneumonia is the sixth leading cause of death and is particularly lethal among very young children and older adults, in whom the disease is more common. Whereas older studies of pneumonia pointed to pneumococcus as the most common cause of pneumonia, there is an increasing frequency of atypical or opportunistic infections. [10,11] Unfortunately, although the classic presentation of pneumococcal pneumonia is generally apparent, atypical infections, infections in compromised hosts, and infections in extremes of age may present with more subtle findings. [12] Older patients often present with a change in mental status and often do not manifest respiratory symptoms. Pneumonia may occur through a variety of routes of infection. Pathogenic organisms may be inhaled or aspirated directly into the lungs. Alternatively, some bacteria, such as *Staphylococcus aureus* or pneumococcus, may develop as a result of hematogenous seeding. With this in mind, patients most at risk for pneumonia are those with a predisposition to aspiration, impaired mucociliary clearance, or risk of bacteremia (Table 59-1).

TABLE 59-1   Risk Factors for Pneumonia

Pathophysiology

Pneumonia is an infection of the alveolar or gas-exchange portions of the lung. Some types of pneumonia produce an intense inflammatory response within the alveoli that leads to filling of the airspace with organisms, exudate, and white blood cells. Pneumonia can spread throughout the lung by the bronchial tree or through the pores of Kohn. Bacterial pneumonia, with an intense inflammatory response, tends to cause a productive cough, whereas other atypical organisms do not lead to such an intense inflammatory response and may only be associated with mild nonproductive cough.

Most of our knowledge about the etiology of pneumonia has been derived from studies of hospitalized patients where pneumococcus was the overwhelming cause. Prospective studies of both inpatients and outpatients with CAP often (up to 40 to 60 percent of the time) fail to identify a specific pathogen. [10,11] When an etiology is found, pneumococcus is still the most common single agent, followed by viruses and the atypical agents such as *Mycoplasma, Chlamydia,* and *Legionella.* In up to 5 percent, multiple agents are identified. Special populations, including nursing-home residents, chronic alcoholics, and HIV-infected patients, may have a somewhat different spectrum of disease.

Clinical Features

Pneumonia can present with a variety of clinical features, many of which overlap with other entities. There is wide variability in the presence of individual symptoms and physical findings. [13] The typical presentation of pneumococcal pneumonia is a sudden onset of illness with fever, rigors, dyspnea, bloody sputum production, chest pain, tachycardia, tachypnea, and abnormal findings by lung examination. Many other types of pneumonia do not have such a sudden and characteristic presentation. Especially in the elderly, the immunocompromised, and children, dramatic presentations are unusual. Sputum production is not necessarily present, particularly with mycoplasmal or viral agents. Pneumonia may be preceded by symptoms of a viral upper respiratory infection with coryza, low-grade temperature, rhinorrhea, or nonproductive cough. Weight loss, malaise, dizziness, and weakness may be associated with pneumonia. Some of the atypical agents are associated with dramatic presentations of headache or gastrointestinal (GI) illness. Occasionally, pneumonia is associated with extrapulmonary symptoms, including joint pain, hematuria, or skin rashes.

The physical examination may show evidence of alveolar fluid (inspiratory rales), consolidation (bronchial breath sounds), pleural effusion (dullness and decreased breath sounds), or bronchial congestion (rhonchi and wheezing). Tachypnea, tachycardia, fever, and hypotension are associated with severe illness and may not be present in all cases.

PNEUMOCOCCAL PNEUMONIA   The pneumococcus, although it affects all age groups, is particularly prevalent with the extremes of age. [14] Classically, patients present with sudden onset of disease with rigors, bloody sputum, high fever, and chest pain. This presentation commonly occurs in young adults, particularly in those in crowded living situations such as may occur in a military camp. In this setting, patients will frequently have lobar pneumonia, with parapneumonic pleural effusions occurring in about 25 percent of patients. Patients with functional or anatomic asplenism or patients being treated with immunosuppressive drugs, such as transplant patients, may have a very rapid progression of disease, with acute prostration and septic shock progressing to multisystem organ failure. Patients with chronic lung disease, nursing-home patients, or otherwise healthy elderly patients may have a slower progression of the disease. They may present with malaise and dehydration associated with minimal cough or sputum production. Along with the frequent finding of leukocytosis, elevation of the serum bilirubin or other liver enzymes may be seen. In addition, hyponatremia may be a finding in many causes of pneumonia, including pneumococcal pneumonia.

Pneumococcal pneumonia will respond to a variety of antibiotics, although there is an increased incidence of penicillin-resistant pneumococci. The risk factors for penicillin resistance include patients at the extremes of age, day-care attendance, immunosuppression from alcoholism or cancer, or travel to areas where penicillin resistance is common, including the Mediterranean. In addition to penicillin resistance, there is increasing resistance to other common antibiotics, including tetracycline, azithromycin, and trimethoprim-sulfamethoxazole (TMP-SMX). Patients with intermediate penicillin-resistant pneumococci may still be effectively treated with routine antibiotics so long as an adequate dose is administered. Patients with highly penicillin-resistant pneumococci require treatment with either vancomycin, imipenem, or levofloxacin.

STAPHYLOCOCCAL PNEUMONIA   *Staphylococcus aureus* is a consideration in patients with chronic lung disease, patients with laryngeal cancer, immunosuppressed patients, nursing-home patients, or others at risk for aspiration pneumonia. *Staphylococcus aureus* may occur in otherwise healthy patients following viral illness, such as during an influenza epidemic. But even there, pneumococcus is still more common. Patients with staphylococcal pneumonia typically have an insidious onset of disease with low-grade fever, sputum production, and dyspnea. The chest radiograph usually demonstrates extensive disease with

empyema, pleural effusions, and multiple areas of infiltrate.

OTHER BACTERIAL PNEUMONIA *Klebsiella* pneumonia usually occurs in compromised patients: patients at risk of aspiration, alcoholics, the elderly, and other patients with chronic lung disease. In contrast to *S. aureus,* patients with *Klebsiella* have acute onset of severe disease with fever, rigors, and chest pain. Herpes labialis is occasionally associated with *Klebsiella* pneumonia. Patients with *Klebsiella* may develop abscesses, although more commonly they have a lobar infiltrate.

Pseudomonas causes a severe pneumonia with cyanosis, confusion, and other signs of systemic illness. The chest radiograph usually shows bilateral lower lobe infiltrates, occasionally associated with empyema. *Pseudomonas* is not a typical cause of CAP, but may be seen in patients who have had prolonged hospitalization or are nursing-home residents.

Haemophilus influenzae pneumonia may be seen both in pediatric patients and in the elderly and should be considered in patients with chronic lung disease, sickle cell disease, or immunocompromised disorders and in alcoholics and diabetics. Patients may either have a gradual progression of disease with low-grade fever and sputum production or occasionally have the sudden onset of chest pain, dyspnea, and sputum production. Bacteremia may be seen in older adults. Pleural effusions and multilobar infiltrates are common findings in *H. influenza* pneumonia.

Moraxella catarrhalis pneumonia has clinical features similar in spectrum to those of *H. influenzae.*[15] Typically, patients with *M. catarrhalis* present with an indolent course of cough and sputum production. Generally, pneumonia with this organism occurs during the winter. Fever and pleuritic chest pain are common clinical symptoms. The chest radiograph usually shows diffuse infiltrates.

ATYPICAL PNEUMONIA Atypical agents are being recognized more frequently as a cause of pneumonia in older children, in young adults, and in the elderly. Because these agents lack a cell wall, they do not respond to b-lactam antibiotics, and current recommendations for empiric antibiotic treatment of CAP take this into account, using either a macrolide or newer-generation fluoroquinolone.

Legionella can cause a range of illness from benign self-limited disease to multisystem organ failure with acute respiratory distress syndrome. Patients at particular risk include cigarette smokers, patients with chronic lung disease, transplant patients, and immunosuppressed patients. There is no seasonality to *Legionella* pneumonia, making it a more common cause of pneumonia in the summer. *Legionella* pneumonia is commonly complicated by GI symptoms, including abdominal pain, vomiting, and diarrhea. In addition, *Legionella* can affect other organ systems, causing sinusitis, pancreatitis, myocarditis, and pyelonephritis. The chest radiograph frequently shows a patchy infiltrate, with the occasional appearance of hilar adenopathy and pleural effusions.

Chlamydia pneumonia is a common cause of respiratory infection, with about half of the population demonstrating antibodies by the age of 15. Infection with *Chlamydia* usually causes a mild subacute illness with sore throat, mild fever, and nonproductive cough, although occasionally patients have a more severe course. Patients with *Chlamydia* pneumonia frequently have abnormal physical examination findings, with rales or rhonchi. The chest radiograph usually shows a patchy subsegmental infiltrate. Chlamydial infection has been associated with the development of adult-onset asthma.

Mycoplasma pneumonia also occurs year round, although it tends to cluster in epidemics every 4 to 8 years. [16] As is the case with *Chlamydia,* it may cause a subacute respiratory illness with cough, sore throat, and headache. *Mycoplasma* pneumonia is frequently associated with retrosternal chest pain. Unlike *Legionella,* *Mycoplasma* usually is not associated with GI symptoms. The chest radiograph shows patchy infiltrates, with the common occurrence of hilar adenopathy and pleural effusions. *Mycoplasma* occasionally causes extrapulmonary symptoms, including bullous myringitis, rash, neurologic symptoms, arthritis and arthralgia, hematologic abnormalities and, rarely, renal failure.

Diagnosis

Pneumonia is suspected based on a constellation of symptoms and signs, but individual symptoms and clinical findings lack accuracy for precise diagnosis. [13] Attempts have been made to combine some of the symptoms and signs into a scoring system that predicts the probability of pneumonia, and four different decision rules were compared in a study of adult outpatients (Table 59-2). The results of these attempts indicate that clinical criteria are most useful for "ruling out" pneumonia; that is, if a patient has none of the positive predictors, the probability of pneumonia is very low, from 1 to 4 percent. However, clinical criteria are inaccurate for "ruling in" pneumonia; even if a patient has all of the positive clinical predictors, these scoring systems predict pneumonia with a maximal probability of 40 to 50 percent. [13] Thus, for accurate diagnosis, a chest radiograph is required.

TABLE 59-2 Prediction Rules for Pneumonia in Adult Patients with Cough

Patients with complaints of dyspnea or physical signs of respiratory distress (tachypnea, use of accessory muscles, wheezing, etc.) should have oxygen saturation measured by pulse oximetry. In young, otherwise healthy, mildly ill, ambulatory patients, no further ancillary testing may be necessary. If a patient requires admission, additional tests recommended include complete blood count and determination of serum electrolyte, blood urea nitrogen, creatinine, and glucose levels. [9] Evaluation of arterial blood gas is indicated if patients are hypoxic or have moderate to severe respiratory distress. No single set of recommendations for diagnostic testing can encompass all patients, and additional ancillary studies should be obtained according to appropriate indications.

In patients with fever, cough, and radiographic abnormalities, the etiology of the infection is confirmed by identification of a pathogenic organism from the blood, sputum, or pleural fluid. Atypical agents may be demonstrated by a variety of sophisticated laboratory techniques, including evaluation of titers from acute and convalescence sera or by direct fluorescent antibody testing. In hospitalized patients with CAP, about 10 percent will have a positive blood culture, most of which are pneumococcal.[10] The incidence of positive blood cultures in nonhospitalized patients with CAP is lower, pathogen identification does not alter treatment, and the overwhelming majority of patients respond to empiric antibiotic treatment. [11] Thus, blood cultures are recommended only for patients who require hospitalization.

The value of sputum examination in CAP has been debated.[9] The yield of a sputum Gram stain is reduced in the 10 to 30 percent of patients unable to produce sputum, in the 15 to 30 percent of patients who have already received antibiotic therapy, and in the 30 to 65 percent of patients who have a negative Gram stain despite a positive culture. Taken together, the sputum Gram stain is positive in only 10 to 40 percent of cases with CAP. The test is noninvasive and inexpensive, however, so it is often advocated.[9,10 and 11] Pneumococcal pneumonia may be suspected in patients with more than 10 gram-positive, lancet-shaped diplococci from an adequate sputum sample. *Haemophilus influenzae* may also be occasionally demonstrated on Gram stain. There are few indications for performing transtracheal aspiration or bronchial washings in the emergency department.

The differential diagnosis of patients with cough and radiographic abnormality includes a number of disorders, such as lung cancer, tuberculosis, pulmonary embolism, chemical or hypersensitivity pneumonitis, connective tissue disorders, granulomatous disease, and fungal infections.

A chest radiograph may provide clues to the underlying organism. [17] Pneumococcal pneumonia typically presents with lobar segmental pneumonia. Occasionally, patients may present with the so-called round infiltrate of pneumococcal pneumonia. In general, patients with bacterial pneumonia are more likely to have unilobar or

focal infiltrates than patients with viral or atypical pneumonia. Hilar adenopathy is more common in patients with atypical pneumonia. Pleural effusions occur more commonly in patients with bacterial pneumonia, although occasionally patients with viral pneumonia or atypical agents may have small effusions. Cavitary lesions occur in patients with bacterial or tuberculous lesions. Lung abscesses are rare complications of pneumonia in the antibiotic era, but they occur due to *S. aureus* or *Klebsiella.* Pneumonia may mimic the appearance of lung masses particularly when the pneumonia is pneumococcal and staphylococcal. Other atypical pneumonia such as Q fever and tularemia may present with discrete masses.

Specific Issues

PNEUMONIA IN COPD PATIENTS   Patients with COPD have a higher incidence of pneumonia than other outpatient populations who have no identifiable predisposition to pneumonia.[18] Frequent antibiotic use has been blamed for colonization of the respiratory tract by more pathogenic organisms. As a result, there has been more frequent identification of aerobic gram-negative rods and a decline in pneumococcal disease.

Inflammation of large and small airways, bronchial wall distortion, and bullae formation are pulmonary changes affecting patients who have COPD. The lower respiratory tract, which is ordinarily sterile in healthy nonsmokers, in COPD becomes colonized with potentially pathogenic bacteria, and it is assumed that these organisms may cause pneumonia. The risk factors for gram-negative colonization in COPD include advanced age, serious underlying illness, cigarette smoking, recent antibiotic use, endotracheal intubation, malnutrition, viral tracheobronchitis, corticosteroid use, prolonged hospitalization, and advanced pulmonary disease. Patients with stable chronic bronchitis are predominantly colonized with *S. pneumoniae* and nontypeable *H. influenzae.* Although pneumococcal pneumonia occurs more commonly in COPD than in other outpatient groups, its relative frequency appears to be declining. The incidence of pseudomonal pneumonia is low, but certain therapies such as frequent use of broad-spectrum antibiotics and corticosteroids, endotracheal intubation, and instrumentation of the lower respiratory tract may introduce *Pseudomonas aeruginosa* and other bacteria into the lower respiratory tract.

Clinical manifestations of pneumonia in COPD patients may include dyspnea, cough with sputum production, bronchial hyperactivity, or severe fixed airflow obstruction, pleuritic chest pain, and altered mentation. Fever, leukocytosis, and respiratory symptoms are unreliable indicators of pneumonia and may be absent in as many as half of the patients. Physical examination may show signs of lung consolidation. These signs and symptoms are nonspecific in the setting of preexisting lung disease. The classic presentation of pneumococcal pneumonia of acute fever, chills, and pleuritic chest pain may not occur in COPD patients. Instead, symptoms may be more insidious and appear to represent an exacerbation of the underlying disease. The chest radiograph may show a bilateral patchy bronchopneumonia more frequently than lobar pneumonia.

COPD patients with *H. influenzae* pneumonia typically present with gradually increasing cough, sputum production, and shortness of breath. Fever is mild, and arthralgias and myalgias are common. The chest radiograph may initially be considered unchanged, but a patchy bronchopneumonia pattern is common.

COPD patients treated with frequent courses of corticosteroids may develop nonbacterial infections that mimic bacterial pneumonia, including those caused by *Aspergillus fumigatus, Strongyloides stercoralis,* and *Mycobacterium tuberculosis. Aspergillus* causes both a rapidly progressive, necrotizing pneumonia or an indolent form with a less fulminant course. *Strongyloides* can cause bronchospasm, pneumonia, pulmonary infarction, or respiratory failure. The chest radiograph may show alveolar infiltrates, nodular infiltrates, cavitary lesions, or lung abscess.

PNEUMONIA IN DIABETICS   Diabetes is associated with an increased risk of recurrent bacterial pneumonia, more serious infection, and higher hospitalization rates.[19] Diabetic patients with pneumococcal disease are more likely than nondiabetics to develop bacteremia, and bacteremia doubles the mortality rate. Diabetics have a higher risk of developing complications from gram-negative pneumonia, such as empyema, lung necrosis, metastatic infections, and bacteremia.

There are two patterns of susceptibility to lower respiratory tract infections in diabetic hosts. First, pulmonary infections that occur with *increased frequency* include those caused by *S. aureus,* gram-negative bacteria, *M. tuberculosis,* and mucormycosis. These infections may occur from aspiration of bacteria from a colonized pharynx, hematogenous spread from an extrapulmonary infection, or contaminated equipment such as nebulizers. Second, pulmonary infections associated with *increased morbidity and mortality* include those caused by *S. pneumoniae, Legionella,* and influenza. Vascular insufficiency, cardiovascular disease, chronic renal insufficiency, or malnutrition may contribute to increased morbidity and mortality.

As with other populations, diabetic patients with pneumonia are often treated empirically, though treatment should be guided by pathogen isolation whenever possible. An alternative to aminoglycosides should be used whenever possible in diabetics who may already have neuropathy or nephropathy from diabetes.

PNEUMONIA IN PREGNANCY   Pneumonia in the peripartum period poses threats to the developing fetus as well as the expectant mother and is the most common nonobstetric infection to cause maternal mortality during that period. [20] Antepartum respiratory infection is associated with preterm delivery and fetal loss. Studies have shown a decline in antepartum pneumonia from one case per 367 deliveries during the early 1970s to one case per 2288 deliveries in the late 1980s. Preterm labor is more likely when pneumonia occurs between weeks 20 and 36 of gestation.

Physiologic changes during pregnancy and various therapeutic interventions, such as tocolytics that increase lung water, may predispose pregnant patients to pneumonia. Pneumonia in the postpartum period is commonly attributed to aspiration during labor and delivery. Unusual pathogens that may cause pneumonia in pregnancy include mumps virus, Epstein-Barr virus, swine influenza, influenza A, varicella, *Coccidioides immitis,* and other fungi.

Varicella infection in pregnancy is infrequent (0.7 cases per 1000 pregnancies), but as many as 9 percent of primary varicella infections during pregnancy develop varicella pneumonia. Patients with varicella pneumonia may have cough, dyspnea, pleuritic chest pain, and hemoptysis a few days after the onset of fever, rash, and malaise. The chest radiograph typically shows diffuse miliary or nodular infiltrates that resolve within 2 weeks but may show fulminant pneumonitis or acute respiratory distress syndrome. The mortality rate from varicella pneumonia in nonpregnant patients is 11 to 17 percent, but the rate may be higher in pregnancy.

Penicillins, cephalosporins, and erythromycin, excluding the estolate form, are safe in pregnancy. Clindamycin is likely safe. Tetracycline given in the third trimester may cause fulminant hepatitis in the mother or cause bony and dental abnormalities in the developing fetus if given anytime during pregnancy. Sulfonamides may cause fetal kernicteris if given shortly before delivery. Chloramphenicol can cause fetal bone marrow suppression and gray baby syndrome. Aminoglycosides and vancomycin should be used only when absolutely necessary to avoid fetal renal toxicity and ototoxicity.

Bacterial pneumonia complicating influenza or other viral infections should be treated with antibiotics directed at the likely superinfecting organism. Oral amantadine or inhaled ribavirin may be used if viral pneumonia complicates an influenza infection and for prophylaxis in pregnant women at high risk for influenza infection. Ribavirin is active against influenza A and B, whereas amantadine is active only against influenza A. Varicella pneumonia must be treated early and aggressively with hospitalization and intravenous acyclovir 10 mg/kg every 8 h for 5 days. Varicella immune globulin may help prevent pneumonia in pregnant women infected with varicella but who have no prior immunity, but will not prevent prenatal fetal infection or congenital varicella syndrome.

PNEUMONIA IN THE ELDERLY   Pneumonia is the most common infection and represents the fifth leading cause of death among the elderly. [21] The incidence of lower respiratory tract infection in the elderly range from 25 to 44 cases per 1000 in the general population, with the mortality rate approaching 40 percent. COPD, congestive heart failure (CHF), cardiovascular and cerebrovascular disease, lung cancer, dementia, diminished gag reflex, and other disorders that may predispose the elderly to aspiration may make them more susceptible to infection.

The elderly are three times more likely to have pneumococcal bacteremia than younger patients. The mortality from pneumococcal pneumonia is three to five times greater in the elderly (up to 40 percent) than in those younger than age 65. Although becoming more frequent in the elderly, atypical pathogens such as *Mycoplasma* are still more common in younger populations. *Legionella* is the most common atypical agent in the elderly and responsible for up to 10 percent of CAP. Influenza is the most common serious viral infection in the elderly. Postinfluenza bacterial pneumonia is most commonly caused by *S. pneumoniae, S. aureus,* and *H. influenza.*

Instead of respiratory symptoms, elderly patients with pneumonia may complain about falling, weakness, tremulousness, functional decline, or GI symptoms and may exhibit delirium or confusion. Elderly patients are more likely to be afebrile on presentation but are more likely than younger adults to have a serious bacterial infection when temperature is higher than 38.3°C (100.9°F). Tachypnea may predate the diagnosis of pneumonia by 3 to 4 days.

In bacterial pneumonia, the chest radiograph may show a bronchial pattern rather than a classic lobar consolidation. Multiple lung segments are often involved, and patients over age 65 are more likely to show radiographic progression of disease (48 percent) compared with younger patients (11 percent). Early consolidation is more likely to indicate a bacterial etiology than atypical or viral infection. Coexisting conditions such as CHF, lung cancer, or pulmonary embolism may mask

pneumonia.

Up to one-third of elderly patients with CAP will not manifest leukocytosis. Poor prognostic indicators include hypothermia or a temperature greater than 38.3°C (100.9°F), a low white blood cell count, immunosuppression, gram-negative or staphylococcal infection, cardiac disease, bilateral infiltrates, and extrapulmonary disease. Elderly patients with pneumonia frequently require hospitalization and about 10 percent may require intensive care.

PNEUMONIA IN NURSING-HOME PATIENTS   Nursing-home-acquired pneumonia may be considered a distinct clinical entity, intermediate in severity between CAP and nosocomial pneumonia.[22] Pneumonia in nursing-home patients is a leading cause of hospitalization and along with bronchitis accounts for 30 percent of all nursing-home infections. The mortality rate of nursing-home-acquired pneumonia approaches 50 percent.

The major pathogenic mechanism is aspiration of colonizing oropharyngeal organisms with the resultant pneumonia depending on the organism's virulence, inoculum size, and health of the host's defense system. Nursing-home residents have an increased frequency of colonization by gram-negative bacteria. Altered sensorium, swallowing and esophageal disorders, tracheostomy tubes, nasogastric feeding tubes, and sedative medications may promote aspiration in these patients.

Streptococcus pneumoniae is the most common pathogen (20 percent), but gram-negative organisms as a group are more common (30 percent).[16] Outbreaks of *H. influenzae,* influenza A, influenza B, *Chlamydia,* and RSV have been reported. Staphylococcal pneumonia is seen more frequently in the nursing-home setting (7 to 12 percent) than in the general population (1 percent). Pseudomonal, *Legionella,* and *Mycoplasma* pneumonia are rare in the nursing-home environment.

In nursing-home patients, signs and symptoms of pneumonia are frequently atypical, with altered mental status as the presenting complaint more than one-fifth of the time. Other subtle symptoms may include difficulties with gait, bowel or bladder incontinence, decreased appetite, or a new requirement for feeding. Most patients will have a slightly elevated temperature, respiratory rate, and cough. Pulmonary consolidation is often absent, especially if a patient is dehydrated, and the initial chest radiograph will often fail to show the pneumonia, which may be masked by CHF, COPD, malignancy, or prior lung disease.

Frequently, empiric broad-spectrum antibiotic therapy must be started with consideration of sputum Gram stain results, likely pathogen, host comorbid disease, and recent antibiotic use. Antibiotics should cover pneumococcal, staphylococcal, and gram-negative bacillary infection. Depending on the capability of the nursing home, it may be appropriate to manage patients there, where overall function may be better preserved than in the hospital. The most important indicators for hospitalization are tachypnea with a respiratory rate of more than 30 bpm, temperature greater than 38.3°C (100.9°F), and altered mental status. Patients should certainly be admitted if hemodynamically unstable or if hydration, oxygen, nutritional, or respiratory therapy requirements cannot be met at the nursing home. Patients with diabetes or underlying cardiopulmonary disease frequently require admission.

PNEUMONIA IN HIV PATIENTS   Recurrent bacterial pneumonia, pulmonary tuberculosis, and opportunistic pneumonia are AIDS-defining criteria for patients with HIV infection. Although *Pneumocystis carini* pneumonia (PCP) is the most common AIDS-defining infection, bacterial pneumonia is more common.[23] CAP is 10 times more frequent in HIV-positive patients compared with those who are HIV seronegative, but the overall mortality from bacterial pneumonia is no different between HIV-positive and HIV-negative patients.

The incidence of pneumococcal pneumonia ranges from 20 to 95 per 1000 in HIV-positive patients compared with 3 to 4 per 1000 in HIV-negative patients. *Haemophilus influenzae* type B and nontypeable strains also cause pneumonia in HIV patients. Viral pneumonitis may occur independently or more commonly in association with another pathogenic agent.

Opportunistic infections are uncommon when the CD4 count is above 800 cells/μL and bacterial infections are the likely cause of pneumonia. The likelihood of both bacterial and opportunistic pneumonia increases as the CD4 count falls. Between 250 and 500 cells/μL, there is a greater risk of infection from *M. tuberculosis, Cryptococcus neoformans,* and *Histoplasma capsulatum.* Below 200 cells/μL, there is an increased risk of PCP.

HIV patients with bacterial pneumonia typically present with symptoms and findings similar to those in HIV-seronegative patients. PCP usually presents with rapid exacerbation of symptoms, often after weeks of increasing cough and dyspnea. The chest radiograph in PCP usually reveals bilateral alveolar and interstitial infiltrates, but unusual findings, such as nodular densities, cystic lesion, lobar infiltrate, or pneumothorax, may be seen. Extrapulmonary dissemination and atypical radiographic features (upper lobe involvement) have been associated with patients taking aerosolized pentamidine. Knowledge of a patient's CD4 count may help the clinician formulate a differential diagnosis and diagnostic approach. PCP is unusual with CD4 counts greater than 200 cells/μL, but at less than 100 cells/μL increases greatly. For mild cases of PCP (those patients able to take oral medications and with Pa$_{O_2}$ > 70 mmHg) oral treatment with TMP-SMX, trimethoprim-dapsone, clindamycin-primaquine, or atovaquone for 21 days may be used. For moderate to seriously ill patients with PCP, treatment regiments include TMP-SMX orally or intravenously (IV); clindamycin IV plus primaquine orally; or pentamidine isethionate IV for 21 days. Adjunct corticosteroid treatment will most likely benefit patients with a Pao$_2$ < 70 mmHg and reduces the likelihood of respiratory failure, increased oxygen requirement, and death among patients with moderate to severe PCP. Oral prednisone may be used in the following regimen: 40 mg bid for the first 5 days, 40 mg/day for the next 5 days, then 20 mg/day for the next 11 days.

Cryptococcus neoformans is found throughout the world and is the most common fungus causing life-threatening infection in AIDS. Typically causing meningitis, *C. neoformans* may also cause pneumonia presenting with fever, cough, and dyspnea. The chest radiograph may show diffuse or localized infiltrates, cavitation, nodules, miliary disease, lymphadenopathy, or pleural effusions.

Histoplasma capsulatum infection is usually subacute, and chest radiograph may show a diffuse, miliary pattern or a localized infiltrate. HIV patients from endemic areas (the Ohio and Mississippi River valleys, the Caribbean islands, and Central and South America) may present with disseminated disease. *Histoplasma* antigen may be found in urine or blood, and *Histoplasma* may be cultured from respiratory specimens, bone marrow, liver, or blood.

Life-threatening pulmonary aspergillosis may develop in patients with advanced immunosuppression, generally in those patients with absolute neutropenia, CD4 count below 30 cells/μL, or prior corticosteroid use. Disseminated disease is common.

Patients with AIDS from endemic areas may develop disseminated coccidioidomycosis and blastomycosis. Pulmonary disease may present with cough, fever, and dyspnea. Chest radiograph may show nodular, cavitary, or diffuse disease, and antibodies to *Coccidioides immitis* found in the blood may assist diagnosis. Cytomegalovirus (CMV) often can be isolated from lungs of HIV patients but rarely causes clinically significant disease. Patients with CMV pneumonitis may present with dyspnea, nonproductive cough, and fever. The chest radiograph may look similar to that with PCP with diffuse pulmonary infiltrates. Coinfection with CMV does not appear to alter the course of therapy when patients are treated for other pathogens.

PNEUMONIA IN TRANSPLANT PATIENTS   Posttransplantation pulmonary infections may occur with both solid organ and bone marrow transplant patients. Factors such as type of transplant, time after transplant, invasive procedures during hospitalization, and prior travel to endemic areas determine the infection that may occur. Pneumonia may result from a newly acquired pathogen or reactivation of a dormant infection such as *M. tuberculosis, Toxoplasma gondii, H. capsulatum, C. immitis, S. stercoralis,* herpes simplex virus, CMV, and varicella-zoster virus.[24]

Immunosuppression of cellular and humoral immunity, airway colonization, hematogenous spread from distant infection, and liberal use of broad-spectrum antibiotics have been blamed for the development of pneumonia in transplant patients. Other risk factors include intubation, pulmonary edema, blood or blood product transfusion, central venous catheter infections, the use of polyurethane film dressings, intensive care unit admission, and use of agents that increase gastric pH.

Certain infections tend to occur during three time periods after transplantation and are related to a patient's degree of immunosuppression during each. These time periods are the first month, 30 to 120 days, and more than 120 days after transplantation.

Pneumonia that occurs during the first 30 days after transplant is usually bacterial and typically of nosocomial origin similar to that in any immunocompetent host. Gram-positive and gram-negative pathogens (including *S. aureus* and *Legionella* pneumophila) are encountered, and hematogenous spread from central venous catheters or aspiration of oropharyngeal contents during prolonged intubation may be the cause. Opportunistic infections are rare during this time.

Patients are most severely immunocompromised from 30 to 120 days after transplant. Because of marked depression of cell-mediated immunity, patients are susceptible to infection by viruses (CMV, herpes simplex virus, and adenovirus), fungi (*Candida albicans, A. fumigatus,* and mucormycosis), and protozoa (*P. carini* and *Toxoplasma gondii*). CMV is the most common infection after kidney, liver, and bone marrow transplantation, usually occurring 4 to 6 weeks after transplantation.

CMV pneumonitis in lung transplant patients may present like an acute rejection. Pulmonary infections caused by *P. carinii, A. fumigatus,* mycobacteria, and *Nocardia* are more likely during this period.

More than 120 days after kidney transplantation, immune function improves as a result of withdrawing immunosuppressive therapy, and organisms more typical of CAP are seen. Most patients maintain some degree of immune suppression. Therefore, *C. neoformans, P. carinii,* and other opportunistic organisms may be encountered.

Treatment

Emergency physicians will most often initiate empiric treatment for patients who have CAP. Four different specialty societies have developed guidelines for the treatment of adults with CAP: the American Thoracic Society (ATS), the British Thoracic Society, the Canadian Infectious Disease Society, and the Infectious Disease Society of America.[25],[26],[27] and [28] Slight differences exist between the guidelines, particularly regarding etiologic diagnosis and antimicrobial therapy. For emergency physicians, the ATS guidelines are most germane because they take into account the low risk of mortality in otherwise healthy patients under the age of 60, emphasize empiric antibiotic selection, and discourage ancillary testing which has little influence on patient management. All four guidelines recognize that although pneumococcal pneumonia is still the single most common cause of CAP, atypical agents are increasingly more common and empiric therapy should include antibiotics that are active against organisms that lack a cell wall (Table 59-3). Recommended agents include doxycycline, a macrolide, or one of the newer fluoroquinolones orally for 7 to 10 days for treatment of bacterial infection, although there is evidence that treatment for up to 21 days is helpful for atypical infections. Doxycycline is an excellent antibiotic because of its tolerance, bioavailability, low price, and easy compliance with twice-a-day dosing. Erythromycin is a very cost-effective agent for CAP, but is associated with GI side affects in about 25 percent of adult patients. Clarithromycin has fewer GI side effects and the advantage of twice-a-day dosing. Azithromycin has the advantage of once-a-day dosing for only 5 days. Both clarithromycin and azithromycin are many times more expensive than erythromycin or doxycycline. The newer fluoroquinolone agents, including sparfloxacin, levofloxacin, and trofloxacin, have extended coverage that includes both common bacterial agents and atypical agents and the advantage of once-a-day dosing. Because of increasing *S. pneumoniae* resistance to doxycycline and the macrolides (approaching 30 percent in some areas), some societies are revising their recommendations to use a fluoroquinolone, such as levofloxacin, as the initial agent for empiric treratment of CAP.

TABLE 59-3 Antibiotics Used in Adults with Community-Acquired Pneumonia

The ATS guidelines recommend that patients over age 60 or those with concomitant disease should be treated with extended-spectrum antibiotics, such as a second-generation cephalosporin, a combination of penicillin plus b-lactamase inhibitor, or TMP-SMX. Although such agents are considered to have an "extended spectrum," they do not cover atypical agents. Clinical trials indicate that, even in older patients, the inclusion of an antibiotic that is active against atypical agents leads to lower mortality and morbidity rates. This suggests that emergency physicians should use a newer fluoroquinolone alone or a macrolide agent plus an "extended spectrum" cephalosporin or penicillin in older or compromised patients with CAP.

Emergency physicians play a prominent role in the initiation of treatment for patients being hospitalized with CAP. Recent evidence indicates that early administration of antibiotics, within the first 8 h of presentation, leads to a lower mortality rate and a shorter hospital stay. Although the yield is low, admitting physicians may benefit from the results of the sputum Gram stain, sputum culture, or blood culture obtained in the emergency department. For patients hospitalized with CAP, therapy should be initiated with a second- or third-generation cephalosporin or penicillin plus b-lactamase inhibitor, usually with a macrolide to provide coverage against *Legionella* or other atypical agents. Coverage can also be provided by a fluoroquinolone alone with the advantage that the newer quinolones such as levofloxacin achieve very high serum levels after oral administration, matching those achieved with intravenous administration. Patients with severe CAP should receive a macrolide plus an extended-spectrum antibiotic with antipseudomonal coverage (ceftazidime, cefoperazone, cefepime, imipenem, meropenem, levofloxacin, or trovafloxacin).

Disposition

An estimated 75 percent of patients with CAP do not require hospitalization. In young adults, the pathogenic organism is frequently viral or atypical and associated with low morbidity and mortality rates. Many factors influence the prognosis and outcome of CAP.[29] In general, physicians tend to overestimate the risk of pneumonia mortality. Fine and coworkers have developed a decision tree that can be used to estimate the risk of death from pneumonia and predict the need for hospitalization [30] (Table 59-4, Table 59-5 and Table 59-6). With this decision rule, patients are assigned to one of five risk categories, with the lowest category having a mortality rate of around 0.1 percent. Although not a prominent part of this decision rule, patients who are immunocompromised as a result of AIDS or chronic alcohol use may require hospitalization. In addition, a chest radiograph that demonstrates bilateral effusions, bilateral infiltrates, moderately large pleural effusions, or extensive pulmonary involvement is associated with a higher risk of mortality. Patients should be considered for admission to an intensive care unit if they are markedly tachypneic or have high oxygen requirements, evidence of shock, or very extensive pulmonary involvement (more than 50 percent of the lung). For patients in risk category II, admission may be chosen based on the presence of relative hypoxemia, social factors, and the inability to complete a course of oral antibiotics.

TABLE 59-6   Prediction of Mortality from Pneumonia

Emergency physicians play a role in educating patients about their disease. Most patients will achieve some measure of resolution within 3 to 5 days after the initiation of antibiotics. Large population studies have demonstrated, however, that many patients are still symptomatic at 30 days, with a significant minority of patients experiencing chest pain, malaise, or mild dyspnea even 2 to 3 months after treatment. Patients should be educated about the importance of smoking cessation and moderation of alcohol use. Patients should receive instructions about rest, nutrition, hydration, and follow-up. Patients at risk should be educated about the importance of vaccination against pneumococcus and influenza.

60 ASPIRATION PNEUMONIA, LUNG ABSCESS, AND PLEURAL EMPYEMA

Eric Anderson
Maxime Alix Gilles

ASPIRATION PNEUMONIA

Epidemiology

Aspiration pneumonia is an infectious inflammatory condition that results from the inhalation of oral contents into the lungs. The oral contents can be food, vomitus, inedible objects (e.g., toys, screws, etc.), or oral secretions. One of the earliest recorded aspiration deaths was in 475 B.C. when the Greek poet Anacreon died as a result of aspirating a grape seed.[1] Mendelson in 1946, described 66 obstetrical patients who developed respiratory failure as a result of aspiration of stomach contents during obstetric anesthesia.[2] The pulmonary effects of aspiration are due to the presence of foreign bodies, chemical irritants, and bacterial pathogens in the material aspirated.[3]

The true incidence of pathologic aspiration into the lungs is difficult to determine. Small volumes of aspiration that do not lead to infection or pulmonary disease have been documented in approximately 50 percent of normal subjects during sleep.[4]

Such chronic debilitating conditions as stroke, dysphagia, tube feeding, and altered mental status with decreased level of consciousness place patients at increased risk for aspiration (Table 60-1). Of patients studied within 5 days after an acute stroke, 38 percent demonstrated evidence of aspiration.[5] One-third of those who aspirated had silent aspiration without evidence of cough or gag. Risk factors and predictors for silent aspiration included dysphagia, dysarthria, voice change after swallow, and abnormal gag reflex (Table 60-2).

TABLE 60-1   Risk Factors for Aspiration Pneumonia and Lung Abscess

TABLE 60-2   Physical Findings in Patients at Risk for Aspiration

Patients discharged back to long-term care facilities are at persistent risk for aspiration. Patients who aspirate are at three times the risk of dying compared with patients who did not aspirate.[6]

Pathophysiology

Risk factors for aspiration among emergency patients includes transient or permanent altered mental states with depressed glottic reflexes, anomalies of the esophagus, alcohol or illicit drug intoxication, seizure, tube feedings, anesthesia, advanced age, and supine position. It is not uncommon to see more than one of these risk factors in a single patient. For example, an elderly nursing home patient in a persistent vegetative state with a gastrostomy tube arrives for evaluation of fever. Caretakers may not appreciate aspiration, since the event may be occult secondary to the lack of gag or cough reflex at the time of aspiration.

The severity of the symptoms is related to the volume of material aspirated, the amount of bacterial contamination, and the pH of the material aspirated. Liquids with a

pH lower than 2.0 are associated with a much higher mortality rate than are liquids with a higher pH. Aspirated bacteria usually come from oropharyngeal contents, with anaerobic bacteria predominating. Patients in hospitals or long-term care facilities may become colonized by gram-negative bacilli, and these bacteria may make their way into the aspirated inoculum.

Normal mechanisms that protect the airway include the sneeze, gag, and cough reflexes. Particles deposited in the distal nasal epithelium are removed by a sneeze. Lower airways are protected by mucus produced by cells that line the airways. This mucus traps airborne particles of 10-μm diameter. Once trapped by the mucous coating, these larger particles are swept proximally by the mucocillary escalator to the oropharynx, where they are expectorated or swallowed. Alveolar macrophages, polymorphonuclear leukocytes, or lymphocytes destroy infectious particles that are small enough to reach the alveoli.

Many of the symptoms of aspiration pneumonia are elicited by the body's inflammatory response to the infectious or irritative material. Proinflammatory cytokines, which increase capillary permeability and are cytotactic, cause migration of fluids and inflammatory cells into the area of irritation. [7] The inflammatory response is responsible for the symptoms of fever, productive cough, and radiographic findings. These findings may not be present when aspiration occurs in an immunocompromised patient who may not be able to mount the inflammatory responses.

Solid material, such as sand, dirt, toys, and other small objects, can cause rapid asphyxiation secondary to mechanical blockage of the trachea. Patients with total or near-total obstruction of the glottis or trachea will be unable to cough or call for help because of the lack of air movement.

Clinical Features

The typical patient has had problems with oral secretions or coughing with meals, suggesting gastroesophageal reflux. [8] Patients who require tube feedings are at risk for aspiration. [8] In the elderly, localizing symptoms may be minimal, and the complaint may be a change in baseline mental status. There may be a specific witnessed episode of aspiration.

Physical findings include those common to pneumonia: fever; cough; localized rales, wheezes, or rhonchi; tachycardia; and tachypnea. Cyanosis can develop quickly in patients with underlying lung disease or in patients with overwhelming pulmonary bacterial contamination. Aspiration of large volumes of fluid can also precipitate the rapid development of cyanosis.

Chest radiographs may show an interstitial or alveolar pattern. The right lower lobe is the most common area for the development of aspiration pneumonia when aspiration occurs in an upright sitting posture because the right main stem bronchus has a more direct course from the trachea than does the left main stem bronchus (Fig. 60-1). Aspiration in a supine position may produce infection in any lobe, although the posterior pulmonary segments are more susceptible.

FIG. 60-1. Aspiration pneumonia of the right lower lobe.

Laboratory tests may demonstrate an elevated white blood cell count. In elderly patients the typical leukocytosis may be blunted. In these situations it is helpful to assess the differential and look for a left shift with an increased percentage of immature forms. An elevated C-reactive protein level is a nonspecific indicator of an inflammatory process and may be the only indication of an aerobic infectious pulmonary process resulting from an aspiration. [9] Arterial blood gas measurements may reveal hypoxia if the aspiration or inflammatory process is large enough to significantly interfere with alveolar gas exchange. Oxygen content may be normal early in the course of the illness, but evidence of pulmonary injury can be found by detecting hyperventilation (decreased Pa_{CO_2}) and ventilation-perfusion mismatching (elevated A-a gradient).

Treatment

Prevention of aspiration is particularly important for those patients at risk. Treatment of illicit drug use and alcohol addiction will significantly decrease the individual patient's chance of intoxication and subsequent aspiration. Feeding in an upright position will decrease the risk of aspiration in patients with dysphagia, on tube feedings through nasogastric or orogastric tubes, or with gastrostomy or jejunostomy tubes. Increasing the gastric pH by the use of antacids (four times a day) or proton pump inhibitors (omeprazole 20 mg/d orally) will decrease the pulmonary damage from silent serial aspirators. [10]

Prokinetic agents that increase lower esophageal sphincter tone and stimulate gastric emptying are useful in treating gastroesophageal reflux disease and would be useful in preventing aspiration in patients at risk. These agents include bethanecol 25 mg qid, metoclopramide 10 mg before meals and at bedtime, and cisapride 10 mg before meals and at bedtime. These agents are useful in gastroesophageal reflux disease, but they have some troublesome side effects. The side effects of bethanecol are related to its cholinergic effects: abdominal cramps, salivation, urination, and blurred vision. Cisapride has been reported to cause Q-T interval prolongation and ventricular dysrhythmias, including torsade de pointes, in patients receiving other medication (e.g., ketoconazole and other antifungals). In addition to the desirable antiemetic central nervous system effects of metoclopramide, there are also undesirable effects: mild anxiety, nervousness, insomnia, depression, confusion, disorientation, and hallucinations. Other troublesome side effects of metoclopramide include the extrapyramidal effects of tremor; akathisia; tardive dyskinesia, a Parkinson-like syndrome; gynecomastia; and reversible amenorrhea. [8]

For patients who have experienced an acute, symptomatic aspiration, immediate removal of any airway obstruction and rapid assessment of ventilation is needed. Hypoxia should be corrected by oxygenation, ventilation, and intubation if necessary. Aerosolized bronchodilators are useful for aspiration-induced bronchospasm. For patients in shock, aggressive intravenous (IV) fluid administration and, if appropriate, vasopressors are used.

Healthy patients who aspirate but who are not hypoxic and have no infiltrate on x-ray may be observed for development of signs of infection and may not require antibiotic treatment. Elderly or chronically ill patients who present with signs and symptoms of infection should have antibiotic therapy instituted. In general, appropriate cultures of blood, urine, and sputum (if available) should be obtained in the emergency department, and antibiotic therapy should be initiated. Anaerobes predominate in aspiration pneumonia, and antibiotics that are proven effective include clindamycin 450 to 900 mg IV every 8 h, cefoxitin 2.0g IV every 8 h, ticarcillin-clavulanate 3.1 g IV every 6 h, or piperacillin-tazobactam 3.375 g IV every 6 h.

Bronchoscopy may be indicated for patients who aspirate large objects that move into the distal airways. Patients with viscous materials or tenacious secretions may require direct bronchoalveolar lavage for removal. Patients who develop copious hemoptysis may require bronchoscopy for both diagnosis and treatment.

Disposition

Patients who have had a witnessed episode of aspiration and who are otherwise healthy and exhibit no signs of infection or respiratory compromise may be discharged home with instructions to follow up with their primary care physician in 1 to 2 days. They should be instructed to watch for shortness of breath, fever, chest pain, unusual fatigue, or the development of a cough and to return to the emergency department or see their primary care physician promptly if any of these symptoms

develop.

Patients who appear stable but have risk factors for worse or very aggressive disease (diabetes, old age, dialysis, recent stroke, chronic pulmonary disease, active cancer, HIV, etc.) should be admitted to either a hospital or an observation unit. Oxygen, fluids, and possibly antibiotics should be started and the patient followed carefully for 12 to 24 h. If stable after 12 to 24 h of treatment and observation, such patients can be sent home and instructed to follow up as described above and to return if any sign of deterioration develops. Patients with definite evidence of infection should be admitted and antibiotic treatment started. Patients who exhibit hemodynamic or respiratory instability require admission to an intensive care unit.

LUNG ABSCESS

Epidemiology

A pulmonary abscess is a localized area of suppuration and necrosis involving one or more areas of the lung parenchyma and leading to cavity formation and the characteristic radiographic finding of an air-fluid level. [11]

The most common risk factors for lung abscess in adults are a history of alcohol abuse, a history of aspiration pneumonia, dental caries, and poor dental hygiene (Table 60-1). About 90 percent of patients with lung abscess have obvious periodontal disease or some predisposition to aspiration. [11,12]

Limited data exist on lung abscesses in children, especially with regard to bacteriology, diagnosis, and management. In normal children with no known underlying disease, the most common organisms are *Streptococcus pneumoniae,* anaerobic bacteria, nontypable *Haemophilus influenzae,* and *Staphylococcus aureus.*[13] Anaerobic bacteria are the predominant organisms isolated from children with underlying neurologic disorders. [11]

Patients with HIV infection are at risk for lung abscesses, especially those with advanced disease and a low CD4 count (less than 50). [14] The microbiologic etiology of lung abscess in patients with advanced HIV infection differs from that in HIV-negative patients. *Pseudomonas aeruginosa* is one of the most commonly isolated pathogens from patients with advanced HIV infection or AIDS-defining illnesses. Lung abscesses in patients with advanced HIV infection respond poorly to antibiotic therapy.

Pathophysiology

Primary lung abscess usually results from aspiration of anaerobic oropharyngeal bacteria into the dependent portions of the lung. Any breakdown of the normal protective mechanisms predisposes patients to aspiration, which is also the predominant cause of a lung abscess in infants and children. [13] Aspiration of the bacteria leads to pneumonitis, which impairs drainage of fluids and/or aspirated material and results in inflammatory vascular obstruction, leading to tissue necrosis, abscess formation, or empyema. Lung abscesses resulting from bacteremia are usually due to *S. aureus* that enters the blood via skin lacerations, soft tissue infection, and injected drug use.

Clinical Features

Patients typically have an intermittent febrile course, chest pain, cough, tachypnea, dyspnea, weight loss, malaise, and night sweats. [11] Oral examination may reveal gingivitis and poor oral hygiene. Approximately 1 to 2 weeks after the initial aspiration, the lung abscess cavitates, resulting in putrid expectoration in 40 to 75 percent of patients, a finding highly suggestive of an underlying lung abscess. [11]

Diagnosis

The diagnosis and management of lung abscess continues to challenge physicians as more patients present with complex coexisting diseases, often including profound immunosuppression. The diagnosis of a lung abscess is most commonly established by chest radiograph, including both upright and lateral views (Fig. 60-2). These views typically show an inflammatory infiltrate of the pulmonary parenchyma with one or more cavities containing an air-fluid level.

FIG. 60-2. Lung abscess of the left lower lobe.

Analysis of expectorated sputum is an important first step in the evaluation of patients with a lung abscess. [11] Sputum should be cultured for aerobic and acid-fast organisms, and fungi. While sputum analysis is not reliable in determining the anaerobic bacteria causing a lung abscess, it is useful in detecting or excluding alternative diagnoses.

Anaerobic bacteria remain the most frequent cause of lung abscess, followed by polymicrobial infections (63 percent with anaerobes as coisolates) and *S. aureus.* In addition to bacteria, there are several other infectious and noninfectious causes of lung abscess (Table 60-3).

TABLE 60-3 Noninfectious and Infectious Causes of Lung Abscess

Fiberoptic bronchoscopy and/or bronchial alveolar lavage are useful diagnostic adjuncts.

Treatment

The treatment of choice for lung abscesses is conservative medical management, with the length of therapy dictated by the patient's clinical course and documented radiographic improvement. Radiographic resolution of an abscess cavity may take up to 2 months. Current first-line therapy for lung abscess is antibiotic therapy directed at anaerobes or mixed aerobic and anaerobic bacteria. This is effective in 80 to 90 percent of patients. [15]

In earlier studies, most patients with lung abscess responded to oral or parenteral doses of penicillin or tetracycline. [11] However, over the past two decades several strains of anaerobic bacteria have evolved resistance to penicillin and tetracycline. Although penicillin has long been the antibiotic of choice, recent trials show clindamycin to be superior. [11] Clindamycin should now be considered the first-choice therapy for anaerobic lung abscess unless otherwise specified by culture results. The adult dosage for clindamycin is 600 mg IV every 6 to 8 h until a clinical response is achieved. Oral clindamycin 300 mg tid or qid can be started once an initial clinical response is noted. Depending on the microbiologic characteristics of the specimens obtained, other antibiotics, such as aminoglycosides, imipenem, chloramphenicol, antipseudomonal penicillins, and cefoxitin, may be effective.

Patients who display no radiographic improvement, show signs of persistent sepsis, or develop complications, such as hemoptysis, bronchopleural fistula, and empyema, require external drainage or resection. [15] The incidence of operative management of lung abscesses has decreased dramatically over the last 40 years and is now less than 10 percent. [11]

Most lung abscesses communicate with the tracheobronchial tree fairly early in the course of the infection and drain spontaneously. Unfavorable conditions, such as a large cavity (greater than 6 cm), necrotizing pneumonia with multiple small abscesses, an elderly or immunocompromised patient, an associated bronchial obstruction, or aerobic bacterial pneumonia may require surgical management despite adequate medical therapy. [11] External drainage or resection of a lung abscess is indicated if fever and toxicity persist despite adequate antibiotic therapy and internal drainage. External drainage is the preferred method of treatment for pleural-based abscesses, particularly in patients with a high risk of surgical mortality. [15]

Overall, surgical and image-guided percutaneous drainage has been successfully used for treatment of lung abscesses. The patient must be placed in a gravity-dependent position whenever possible in order to avoid soiling the normal lung. Placement of a relatively large-bore catheter (12-French or greater outer diameter) is essential in establishing adequate external drainage and maintaining catheter patency. The catheter is positioned in the abscess cavity, aspirated manually, and subsequently irrigated with saline solution. [15] The drainage catheter is irrigated daily in order to maintain patency and placed at −20 cm of water suction.

Disposition

The treatment of choice for lung abscesses is conservative medical management, with the length of therapy dictated by the patient's clinical course and documented radiographic improvement. Most uncomplicated cases require admission to a hospital and a 2- to 3-week course of parenteral antimicrobial therapy.

Most patients with a lung abscess who respond to conservative medical management usually recover with no adverse sequelae. Patients typically become afebrile in 7 to 10 days with appropriate antimicrobial treatment. If patients respond to therapy, they can complete oral antibiotic therapy over a period of 4 to 8 weeks. If a patient is seriously ill or fails to improve after a course of appropriate antibiotic therapy, other interventions may be required to facilitate drainage. Such interventions, previously discussed, may include thoracentesis and percutaneous drainage of the abscess with computed tomography (CT) or fluoroscopic guidance.

PLEURAL EMPYEMA

Epidemiology

Pleural empyema is gross pus in the pleural space or a parapneumonic effusion, documented by Gram stain or culture to be infected, that requires drainage for definitive treatment. [11] Pleural empyema can be found in all age groups.

Empyema of the chest is associated with considerable morbidity and mortality rates despite treatment. [16] Infected pleural fluid collections develop as a complication of pulmonary abscess, chest trauma, or surgical procedures. Other causes include secondary infection from a preexisting hydrothorax, hemothorax, esophageal perforation, or mediastinitis; or direct extension from vertebral osteomyelitis or subdiaphragmatic abscess. [11] These complications preceding an empyema are usually a result of direct hematogenous or lymphatic spread from the primary source.

Pathophysiology

Most empyemas develop from an underlying pulmonary infection and are thought to be secondary to subclinical aspiration of organisms in the dependent portions of the affected lung. [15] Alcohol abuse is a recognized risk factor for pleural empyema, primarily because of the increased incidence of aspiration pneumonia. [17] *Klebsiella pneumoniae* empyema may occur in alcoholic males with multiple host defense defects that impair containment of or perception of disease until it is well advanced. [18] Immunocompromised patients are prone to pleural involvement with fungal or aerobic gram-negative bacillary infection. In patients with a malignancy, fungal or tuberculous foci may be reactivated, and empyema develops. Fungal or mycobacterial empyema may also develop in transplant recipients and patients with AIDS. The most common organisms in healthy adults, children, or patients who have had chest trauma or surgery include *Streptococcus pneumoniae* and *Streptococcus pyogenes*. [17,18] Other bacterial isolates include gram-negative aerobic bacilli in hospitalized patients and anaerobes such as fusiform bacilli, *Bacteroides*, anaerobic *Streptococcus,* and *Clostridium* species.

Pleural empyema represents a continuum of disease ranging from thin pleural fluid microscopically contaminated by organisms to gross pus in the pleural space. Approximately 20 to 30 percent of patients with bacterial pneumonia develop a radiographically apparent pleural effusion. [11] The stages of a parapneumonic empyema are exudative, fibrinopurulent, and organizing. In the early phase, the effusion is thin, watery, and easily drained by thoracostomy. In the exudative and intermediate fibrinopurulent stages, the lung retains its compliance and capacity to fully expand. As infection progresses, the initially serous fluid becomes thick and purulent with organisms, fibrin, and white blood cells. In the fibrinopurulent stage, the deposition of fibrin on the parietal pleura retards the resorption of blood, preventing access to lymphatics and retarding fluid resorption. [19] Fibrin deposition in the presence of bacteria provides an ideal environment for the development of pleural empyema. Over a period of 4 to 6 weeks after the start of an empyema, the fibrin layer becomes organized and forms a thick peel (the thickened pleura that develops around a pleural empyema) in the chronic organizing phase. [16] Early management of empyema may prevent the progression of this process to the more advanced stages, where multiple loculations and scarring complicate drainage.

Clinical Features

The clinical presentation of empyema generally blends with that of an underlying pneumonia. Community-acquired *S. aureus* pneumonia is usually preceded by a viral upper respiratory infection or right-sided endocarditis in intravenous drug users. Patients with empyema are initially seen by a variety of physicians due to the indolent course of the disease. Typical symptoms include pyrexia, pleuritic chest pain, cough, dyspnea, and general malaise. Atypical presentations may include weight loss and anemia. Patients may have decreased breath sounds and dullness to percussion on examination of the chest. Symptoms are often masked by protracted treatment with antibiotic therapy for upper respiratory tract infections, which may result in the delayed diagnosis.

Diagnosis

The diagnosis of a parapneumonic effusion is usually suggested by typical findings on conventional posteroanterior and lateral chest radiographs. Lateral decubitus radiographic views are extremely valuable in the detection of subpulmonic effusions and can distinguish free from loculated pleural effusions. [11] Other radiographic findings suggestive of a pleural effusion or empyema include lower lung zone opacification, blunting of the costophrenic angle, and elevated hemidiaphragm with subpulmonic effusions. Extension of the air-fluid level to the chest wall, a tapering border of the air-fluid collection, thickened pleura, and the presence of edema in the extrapleural tissues suggest the presence of an empyema rather than a lung abscess. Virtually all patients with a parapneumonic effusion should undergo a

diagnostic thoracentesis. Microbiologic analysis of the pleural fluid provides important information and helps determine whether drainage is necessary. Infected parapneumonic effusions typically have a pH less than 7.20, a lactate dehydrogenase level greater than 1000 IU/L, and a glucose level lower than 40 mg/dL. [17] Neutropenia, neutrophilia, hypoxia, azotemia, anemia, acidosis, thrombocytopenia, disseminated intravascular coagulopathy, or evidence of multiorgan failure are findings associated with severe infection.

Treatment

The presence of infection, as documented by Gram stain or culture, is an indication for admission and drainage. Image-guided drainage is selected by the availability and convenience of the various techniques and by the size and location of the fluid collection. Ultrasonography, CT, and fluoroscopy can all accurately guide drainage catheter placement. Ultrasonography is the technique of choice to guide thoracentesis and pleural drainage. Thoracic ultrasound is rapid and safe, and can differentiate solid from liquid components and detect subpulmonic or subphrenic pathologic conditions. CT is useful for specific characterization of complex intrathoracic processes, including loculated pleural collections associated with underlying parenchymal consolidation. CT can also be used to guide safe catheter placement into the collection. If fluoroscopy is readily available, it can be used to assess free-flowing loculated collections in supine patients. Radiographically guided pleural drainage procedures have shown success rates ranging from 72 to 80 percent. [15]

The optimal method of establishing external drainage remains controversial. [15] Catheters ranging from 8 to 30 French in outer diameter may be placed under imaging guidance. For serous collections, a 10- or 12-French catheter provides adequate drainage. Thicker collections of purulent or bloody material may require catheters 24 to 48 French in diameter. Most empyema drainage tubes have large round or oval side holes to promote drainage of particulate matter.

Therapy for thoracic empyema requires appropriate antibiotics, prompt drainage of the infected pleural space and lung reexpansion. [17] Empirical antimicrobial therapy is initiated on the basis of its anticipated bactericidal activity against the suspected microbial pathogens. Broad-spectrum antibiotic therapy with clindamycin 450 mg to 900 mg every 8 h IV and a third-generation cephalosporin (e.g., ceftriaxone) can be started with the diagnosis of an empyema and modified according to Gram stain and culture results. In general, antibiotics are given in high doses for 2 to 4 weeks, but more prolonged therapy may be necessary if drainage is not optimal. [18]

Successful treatment of empyema is determined by the stage of the disease process. Tube thoracostomy remains the first treatment option despite variable success rates in the treatment of chronic organizing empyema. Tube thoracostomy, image-directed catheterization, intrapleural thrombolytics, thorascopic drainage, decortication, and chronic open drainage have all been used with success rates ranging from 10 to 90 percent. [17] Generally, the initial exudative stage is amenable to antibiotics and thoracentesis or tube thoracostomy. In the fibrinopurulent stage, antibiotics with drainage by a properly positioned chest tube may resolve the empyema. Most patients with chronic empyema are not cured by medical therapy alone and require surgical intervention. A diffuse organized thick fibrous intrathoracic empyema may require thoracotomy, debridement, irrigation, pleurectomy, decortication, and prolonged open drainage.

The use of intrapleural thrombolytics as an adjunct to the evacuation of loculated pleural effusions has a success rate ranging from 50 to 100 percent, [20] and is associated with low morbidity and mortality rates. Fibrinolysis is likely to be more successful in patients with multiloculated empyemas. [21] Both streptokinase and urokinase are commonly used to convert plasminogen to plasmin. Plasmin dissolves fibrin and produces the dissolution of loculations and early peels, allowing complete evacuation of purulent pleural contents. [21] Urokinase is the agent of choice due to the lower risk of anaphylaxis and to the complications typically associated with streptokinase. The optimal doses of streptokinase and urokinase are unknown; however, mean doses of 275,000 IU and 121,000 IU, respectively, have been used. These agents are injected through drainage tubes, which remain clamped for 6 to 8 h, prior to suction drainage. [11]

Recently, thoracoscopy has been used for the evacuation of hemothorax and the drainage of thoracic empyema with a success rate of approximately 60 percent. [17] Video-assisted thoracic surgery can effectively treat pleural empyema by lysing adhesions, draining the abscess cavity, and decorticating the pleural peel. [19]

Disposition

Admission for early and complete drainage is the fundamental step in the management of an empyema. If primary tube thoracostomy fails, thoracotomy with early decortication has gained favor as therapy for empyema because of the realization that surgery can be safely performed at any stage with low morbidity and mortality rates. [17] After the initiation of antibiotic therapy, the clinical and radiographic response is gradual.

61 TUBERCULOSIS

Janet M. Poponick
Joel Moll

EPIDEMIOLOGY

Tuberculosis remains an important infectious disease in the world today. It is the leading infectious cause of death in people older than 5 years and is estimated to cause 6 percent of deaths worldwide.[1] In the United States, new cases of tuberculosis steadily declined from the late 1800s until 1984. From 1984 to 1992, tuberculosis cases increased at alarming rates. Factors believed to be responsible for this resurgence of tuberculosis include an increase in the number of homeless persons, the human immunodeficiency virus (HIV) epidemic, drug abuse, increased immigration, the inability of local and state governments to maintain tuberculosis control programs, and the increase of multidrug-resistant tuberculosis.[2]

From 1993 to 1997, tuberculosis was once again on the decline, primarily due to stronger tuberculosis control programs, which targeted high-risk individuals. During 1997, there was a 7 percent decrease in reported cases compared with 1996, and a 26 percent decrease from 1992, when tuberculosis cases peaked.[3] Tuberculosis remains more common in urban areas. The case rate for foreign-born persons remains four to five times higher than that for US-born persons.[3]

Continued improvement in tuberculosis control and prevention requires recognition and treatment of high-risk populations (Table 61-1), continued funding of programs for surveillance and treatment of noncompliant patients, continued basic research into the pathogenesis and immunologic response, and continued development of new pharmacologic agents.[2,3]

TABLE 61-1   Patients with a High Prevalence of Tuberculosis

PATHOPHYSIOLOGY

Mycobacterium tuberculosis is a slow-growing aerobic rod that has a unique, multilayered cell wall that contains a variety of lipids that account for its acid-fast property. Transmission occurs through inhalation of droplet nuclei into the lungs. Persons with active tuberculosis who excrete stainable mycobacteria in saliva or sputum are the most infectious.[4]

Once the organisms reach the lungs, host defenses are activated.[5] In immunocompetent persons, such defenses may kill off the inhaled mycobacteria and prevent infection. Some organisms may survive, however, and be transported to the regional lymph nodes, where the host's cell-mediated immunity is further activated to contain the infection. Granulomas, known as tubercles, may form as a result of this process, which involves activated macrophages. Tubercles are a sign of primary infection and may progress to caseation necrosis and calcification leading to the Ghon complex.[4] In most cases, the bacteria are contained in the tubercles, but some organisms enter the thoracic duct and spread throughout the body, where they may remain dormant for many years. This is referred to as latent infection and is manifested by a positive tuberculin skin test.[5] In most cases of dissemination in immunocompetent hosts, the organisms do not find a suitable area to proliferate. Survival is favored in areas of high oxygen content or blood flow, such as the apical and posterior segments of the upper lobe and the superior segment of the lower lobe of the lung, the renal cortex, the meninges, the epiphyses of long bones, and the vertebrae.[4] In immunocompromised hosts, hematogenous spread occurs early, as normal host defenses are unable to contain the organisms, and disseminated disease occurs.[4]

The latent infection may reactivate when a host's immune system is no longer capable of containing the foci of previous hematogenous spread. The young, the elderly, or patients with other chronic debilitating diseases are at higher risk for such reactivation disease. For immunocompetent hosts with latent infection, there is a 5 to 10 percent chance of developing reactivation tuberculosis over a lifetime.[5] The population at risk for HIV infection is also at risk for tuberculosis. As the host defense system weakens, latent infection may progress to reactivation tuberculosis. The incidence of reactivation tuberculosis in HIV patients is reported at 7 percent per year.[5]

Current research centers around the basic science involved in the host response to mycobacteria. The key cells are the alveolar macrophages and T lymphocytes, especially the T-helper cells, and the various cytokines and interleukins that are released into circulation. One of the key cytokines released by macrophages is interferon 8 (IFN-8) which seems to correlate with clinical findings.[6] For patients with active tuberculosis, but whose sputum smear is negative and whose chest radiograph is without cavitation, IFN-8 levels are high and there is a lymphocytic cell predominance in the bronchoalveolar lavage fluid. IFN-8 increases in patients who are improving with treatment for tuberculosis. As information on the role of cytokines is revealed by research, more specific new therapies may be developed to enhance or block important mediators.

CLINICAL FEATURES

Primary Tuberculosis

The initial infection is usually asymptomatic and only identified by a positive reaction to purified protein derivative (PPD) . [4] A pneumonitis may result that is similar to a viral or bacterial infection. Hilar adenopathy is present, but rarely massive. In some cases, especially in immunocompromised patients, the primary infection may be rapidly progressive and fatal.

Reactivation Tuberculosis

The majority of cases of tuberculosis are reactivation of latent infection. Symptoms can be divided into systemic and pulmonary. The most common symptom is fever, followed by night sweats, malaise, fatigue, and weight loss. Productive cough, hemoptysis, and pleuritic chest pain develop as the infection grows in the lungs. When the infection is extensive, shortness of breath may develop. The results of a physical examination are generally not helpful, but rales may be noted over areas of pulmonary infection.[4]

While the majority of cases of tuberculosis are pulmonary, up to 15 percent of cases will have extrapulmonary manifestations. [4] Common sites include the adrenal glands, bones and joints, gastrointestinal tract, genitourinary tract, lymph nodes, meninges, pericardium, peritoneum, and pleura.

Miliary tuberculosis is the result of wide hematogenous spread during the primary infection, or secondary seeding of the other organs in an immunocompromised host. Fever, cough, weight loss, hepatomegaly, splenomegaly, lymphadenopathy, and signs of multisystem illness should cause one to suspect miliary disease. Laboratory abnormalities include hyponatremia, anemia, thrombocytopenia, and leukopenia. The chest radiograph shows diffuse nodular infiltrates. [4]

The most common extrapulmonary site of tuberculosis is the lymphatic system and may involve any of the lymph nodes. Tuberculous adenitis causes symptoms at the site of lymph node enlargement. Fever is usually absent, and the lymphadenopathy is painless. The nodes may develop draining sinuses. Diagnosis is made by lymph node biopsy.[4]

A tuberculous pleural effusion usually occurs after primary infection, when a subpleural node ruptures into the pleura. [4] Some cases occur during hematogenous spread. Symptoms are usually fever, shortness of breath, and pleuritic chest pain. The fluid is exudative in nature, and analysis may not reveal the organisms on acid-fast staining. A pleural biopsy reveals granulomas.

Pericarditis and peritonitis as a result of tuberculosis are difficult to diagnose and often require biopsy. Complications of tuberculous pericarditis include tamponade and constrictive pericarditis.[4]

The central nervous system may become seeded during primary infection, leading to several tuberculous (Rich) foci in the meninges, spinal cord, or the brain parenchyma. Rupture of a Rich focus into the subarachnoid space may result in meningitis. In children, the disease is acute, whereas a more indolent course is noted in adults. Fever, signs of meningeal irritation, and cranial nerve deficits are seen. Typical cerebrospinal fluid analysis reveals mononuclear cells and a low glucose level, but early samples may have a predominance of neutrophils. [4]

Pediatric Tuberculosis

Tuberculosis in the pediatric population occurs in the same risk groups as in the adult population (Table 61-1). Primary tuberculosis is usually an asymptomatic disease and generally found during school screening or household screening programs. [4] The classic symptoms of fever, night sweats, and weight loss may be seen in older children, but, in those younger than age 5, presentation may be that of miliary tuberculosis, meningitis, or a pneumonia that does not respond to therapy. [4] The most common radiographic findings include hilar adenopathy, mediastinal lymphadenopathy, or consolidated pneumonia. The most common extrapulmonary presentation is cervical lymphadenitis, but meningitis and bone and joint involvement may also occur.

Tuberculosis and HIV

Tuberculosis (pulmonary and extrapulmonary) often can be the initial clinical manifestation of immunodeficiency and is considered an AIDS-defining illness. HIV infection increases the risk of reactivation disease and the likelihood that initial infection will result in active disease. [7] The incidence of tuberculosis in HIV-infected patients varies according to community prevalence, but is much higher than in the general population. Physicians considering a diagnosis of tuberculosis should offer patients HIV testing, which may provide early diagnosis and therapy.

Pulmonary involvement may be difficult to distinguish from other HIV-associated lung disorders. Tuberculosis must be in the differential of any HIV-associated respiratory disorder and can present atypically on chest radiographs. The incidence of extrapulmonary tuberculosis is higher in patients diagnosed with AIDS (greater than 70 percent) and in those with less advanced HIV infection (24 to 45 percent) than in individuals not infected with HIV. [7] The most common forms of extrapulmonary disease are lymphadenitis and miliary disease. [7]

Treatment of tuberculosis in coinfected individuals is generally effective, but some reports have indicated higher mortality rates in coinfected patients. [7] The incidence of adverse drug reactions to antituberculosis chemotherapy is higher in HIV-infected than in HIV-negative patients. [8] Due to the number of medications taken by patients with HIV, potential drug interactions must also be of concern.

Multidrug-Resistant Tuberculosis

The incidence of multidrug-resistant tuberculosis (MDR TB) peaked during the resurgence of tuberculosis. The majority of cases involved those coinfected with HIV and was associated with a high mortality rate. With the increased surveillance of high-risk groups, the incidence of drug resistance has stabilized. [3] MDR TB continues to be a concern, however, especially to health care workers assigned to patients with resistant strains. *Mycobacterium tuberculosis* becomes resistant by spontaneous genetic mutation, often as a result of inadequate drug therapy or noncompliance with initial treatment. [2,9] The most powerful predictor of drug resistance remains a history of previous tuberculosis. [9]

The vast majority of MDR TB outbreaks have been in the HIV population. Clinically, the most common pattern is resistance to isoniazid and rifampin. [4] Available data suggest no difference in isoniazid resistance among those patients with or without HIV. Rifampin monoresistant tuberculosis has become a problem, especially in those with AIDS.[10] Cases with rifampin monoresistance were more commonly seen in patients who had previously had tuberculosis, a history of diarrhea, rifabutin use, or antifungal therapy.[10]

For those HIV-negative patients who acquire MDR TB strains, or who are noncompliant with therapy, the course is less well defined. A study prior to the HIV epidemic reported a long-term response rate of 56 percent and a mortality rate of 22 percent. [11] The patient population in this study had tuberculosis for a long period and were heavily pretreated for the disease by the community physician prior to referral. A more recent study from New York demonstrated a more promising course. [12] MDR TB was diagnosed more quickly (mean, 44 days) and, therefore, appropriate treatment started earlier. There were 25 HIV-negative patients in this group: eight were health care workers, and eight had a previous tuberculosis history. Overall, 96 percent had a good clinical response, with 64 percent completing a full course of therapy without relapse.[12]

Treatment of MDR TB remains challenging and depends on the sensitivity patterns from culture. The majority of regimens include four to six drugs with treatment as long as 18 to 24 months after sputum conversion. The fluoroquinolones have been used successfully in treatment of MDR TB. [9,12] Side effects of multiple-drug regimens are a common problem. When drug therapy fails, resectional surgery is considered to eradicate the disease.

DIAGNOSIS

The diagnosis of tuberculosis can present a challenge to emergency physicians. In the past, physicians mainly considered the diagnosis when presented with a young

or older patient with reactivation disease. With the increased incidence of tuberculosis and the appearance of multidrug-resistant strains, one must consider the diagnosis in anyone with respiratory complaints or any extrapulmonary symptoms. The variable clinical presentation along with the time required to culture the organism makes emergent diagnosis difficult. A heightened awareness of the disease along with potential new rapid diagnostic tests can ensure that these patients are not returned to the community without proper therapy.

All prehospital and emergency department personnel must be trained to suspect tuberculosis, institute appropriate precautions, and notify health care providers of their suspicions. Triage workers should ask appropriate questions to detect potential cases. Patients with suspected tuberculosis should be placed in separate waiting areas, wear surgical masks, and be instructed to cover the mouth and nose when coughing. Any immunocompromised patient with respiratory symptoms should be isolated until tuberculosis can be excluded. Prompt evaluation will ensure a minimal amount of time spent in the ambulatory care setting and a minimal risk of exposure to health care providers and other patients. [13],[14]

Skin Test

The most common method to detect exposure to *M. tuberculosis* is a skin test. The Mantoux test, which involves the intracutaneous injection of 0.1 mL of PPD in the forearm, relies on a delayed-type hypersensitivity reaction that is triggered if past exposure to tuberculosis has occurred. The test is read between 48 and 72 h after administration by measuring the extent of skin induration at the test site. Erythema or other skin changes are not assessed. Table 61-2 summarizes the American Thoracic Society's standards for interpretation of test results. [15] All persons with a positive PPD reaction or recent conversion should be referred for possible preventive therapy.

1. ≥5 mm in duration is positive in
   a. Patients with HIV infection
   b. Patients with close contact with a tuberculosis-infected individual
   c. Patients with abnormal chest radiograph suggestive of healed tuberculosis

2. ≥10 mm in duration is positive in patients not meeting the above criteria, but who have other risks
   a. Intravenous drug users
   b. High-prevalence groups (immigrants, long-term-care facility residents, persons in local high-risk areas)
   c. Patients with conditions that increase the risk of progression to active disease

3. ≥15 mm in duration is positive in all others

4. Detection of newly infected persons in a screening program
   a. ≥10-mm in duration increase within any 2-year period is positive if younger than age 35
   b. ≥15-mm in duration increase within any 2-year period is positive if age 35 or older

5. If the patient is anergic, other epidemiologic factors must be considered

Note: A positive reaction does not necessarily indicate disease.

TABLE 61-2   Interpretation of Purified Protein Derivative Skin Test

In a few situations, however, the PPD test may be nondiagnostic. Individuals who have received bacille Calmette-Guérin (BCG) immunization for tuberculosis prevention would be expected to have a positive response. Some individuals with remote BCG immunization lose PPD reactivity over time, but if a second PPD is placed within a few weeks of the first, a falsely positive booster effect may be seen. [13] Exposure to nontuberculosis mycobacteria can also result in a false-positive PPD reaction.

A competent immune system is required to yield a positive response to the PPD if there has been exposure to *M. tuberculosis.* Therefore, individuals with abnormal immune systems, such as in HIV, may lose their ability to mount a delayed-type hypersensitivity reaction required to produce a positive PPD reaction. Although the Centers for Disease Control (CDC) no longer recommend routine anergy testing among HIV-positive individuals, [16] some clinicians utilize control agents such as mumps or candida to assess at-risk patients for anergy. Controls are placed on the opposite forearm, and failure to respond with induration may indicate anergy and thus an unreliable PPD. False negatives have also been demonstrated with improper PPD administration. Nonreactivity to a PPD has been occasionally reported in patients with active culture-positive tuberculosis; therefore, a PPD test may occasionally be unreliable in acute stages of the disease.

Chest Radiograph

The chest radiograph is utilized to screen for disease in individuals with positive PPD skin test and for those with signs and symptoms of active infection. In the past, the classic findings of tuberculosis were those associated with reactivation disease. Cavitary or noncavitary lesions in the upper lobe or superior segment of the lower lobe of the lungs are classic findings. Cavitation can be associated with increased infectivity. [4] Calcification of the lesions may be a later finding.

With the resurgence of tuberculosis, radiographic findings of primary disease are becoming more common. In primary infection, parenchymal infiltrates in any area of the lung may be found.[4] Isolated ipsilateral hilar or mediastinal adenopathy is sometimes the only finding. Miliary tuberculosis as either primary or reactivation disease frequently shows small (1 to 3 mm) nodules throughout the lung fields. Pleural effusions, which are usually unilateral, can occur alone or in association with parenchymal disease. Atelectasis, fibrotic scarring, tracheal deviation, and signs of prior thoracic surgery are other findings. Because tuberculosis has a wide variety of appearances on chest radiographs, comparison to previous films is extremely helpful in determining the significance of an abnormal or unusual finding.

Immunocompromised patients, such as those with advanced HIV, are more likely to have radiographs typical of primary infection or with atypical findings. Normal radiographs in the presence of active disease are seen more frequently in HIV-infected patients. [4],[7]

Microbiology

Culture for tuberculosis is the "gold standard" for diagnosis. [4] Sputum is commonly collected to detect the presence of *M. tuberculosis* by both culture and smear. In the absence of a satisfactory sputum sample, gastric aspirates, pleural and other body fluids, and tissue samples may be employed for culture and other diagnostic tests. Bronchoscopy may also be used to obtain more direct respiratory samples for both smear and culture. Staining of the specimen for acid fastness (i.e., Ziehl-Neelsen stain) or a fluorochrome procedure is the quickest and least expensive method to provide a presumptive diagnosis of tuberculosis. Approximately 60 percent of culture-positive cases of tuberculosis will have smears where acid-fast bacilli are detected, although this may be lower in individuals with HIV. [13]

Newer methods are under development to aid in the speed and sensitivity of diagnosing tuberculosis. Although not widely available, techniques that employ radiometric technology, DNA probes, polymerase chain reaction, reverse transcription, or other technologies may someday provide definitive results in a matter of hours.[4]

TREATMENT

Because of the possibility of resistance, the treatment of active tuberculosis involves the use of a combination of antimycobacterial medications. The emergence of MDR TB prompted the CDC recommendation of treating patients with at least four drugs (and in some cases, six drugs) until susceptibility tests are available. [17] Beginning therapy usually includes isoniazid (INH), rifampin, pyrazinamide, and either streptomycin or ethambutol for 2 months. CDC recommended options for treatment include

1. Daily four-drug therapy for 8 weeks and then 16 weeks of daily or two or three times per week. In this case, treatment is continued for at least 6 months and 3 months after culture conversion.
2. Daily four-drug therapy for 2 weeks followed by two times per week for 6 weeks with subsequent INH and rifampin two times per week for the remaining 16 weeks.
3. Four-drug therapy three times per week for 6 months.

More prolonged therapy is recommended for immunocompromised patients, such as those with HIV or those with extrapulmonary disease. Initial therapy may be modified once drug susceptibilities are available. The importance of directly observed therapy (DOT), where patients are observed taking their antituberculosis

medications to ensure compliance, cannot be overstated.[18] The CDC recommends that all two or three times per week regimens should be by DOT.[17]

Although the standard medications used to treat tuberculosis are generally efficacious and safe, occasionally side effects or drug interactions may be significant. INH, the most frequently used antituberculosis agent, has hepatitis as its major toxicity. Although advancing age is thought to be a significant risk factor for the development of hepatitis,[4] the association with age has not always been clear.[8] Preexisting liver disease, pregnancy, ethanol use, HIV, and hepatitis C infection have been associated with an increased risk for hepatotoxicity from INH.[8,15] In addition, those with preexisting medical conditions requiring multiple medications may be at higher risk for drug interactions with antimycobacterial chemotherapy agents. Table 61-3 summarizes commonly used drug dosages and side effects.

TABLE 61-3   Dosages and Common Side Effects of Some Drugs Used in Tuberculosis (Adults)

With the emergence of multidrug resistance, other treatment modalities have been employed to treat infection that does not respond to antimycobacterial chemotherapy. Among them, surgical resection for multidrug-resistant tuberculosis is a treatment modality that has been shown to have good results, with cure rate of up to 90 percent.[9]

Preventive therapy with INH should be considered for patients with recent conversion to PPD-positive status, for persons who have been in close contact with an individual with active tuberculosis, for anergic individuals with known tuberculosis contact, or if the prevalence of tuberculosis is 10 percent or higher in the community.[16] The decision to institute therapy should be based on the likelihood that the positive PPD reaction represents true exposure to *M. tuberculosis,* the risk of progression to active disease, and the likelihood of INH-induced hepatitis. Therapy should continue for a minimum of 6 months for adults, 9 months for children, and 1 year for those with immunosuppression or HIV.[15] Those at risk for INH hepatotoxicity should be closely monitored for its development if treatment is elected. For those exposed to INH-resistant strains, or those who are intolerant to its use, rifampin and other antimycobacterial agents have been used, but experience is limited.

DISPOSITION

Admission

All hospitalized patients with suspected tuberculosis must be placed in respiratory isolation until the diagnosis is certain.[13] Admission is important in cases where the social situation makes it difficult to obtain a proper diagnosis and for therapy to be instituted. When a patient is proven to have active MDR TB, hospital admission is also indicated to institute therapy and observe for drug toxicity. Other indications for admission include uncertain diagnosis or patient noncompliance. Physicians need to be aware of their own state laws regarding involuntary hospitalization and treatment.[19]

Outpatient Treatment

The vast majority of patients with tuberculosis are treated initially as outpatients. Emergency physicians should contact physicians or public health services providing long-term care prior to discharge. Discharge instructions include home isolation procedures and sites of medication (if DOT is used) and ongoing care. Antituberculosis medications should be instituted by health care professionals who will coordinate the treatment and monitor adverse effects of the medication. Such medications should not be routinely instituted in the emergency department without these measures.

PREVENTION

Prevention of tuberculosis transmission in health care facilities is of extreme importance. Guidelines for prevention of transmission have been published and are available through the CDC. These recommendations include early detection and treatment of active cases, education and screening of health care workers, and engineering controls.[13] Ambulatory care facilities that frequently see tuberculosis patients will need isolation rooms available. Personnel who work in emergency or ambulatory settings where patients with tuberculosis are treated should have routine PPD testing to detect occupational exposure and be offered preventative therapy if appropriate.[13,14] Table 61-4 lists some controls that prevent transmission of disease.

1. High air flow (at least six room exchanges per hour) with external exhaust

2. High-efficient particulate filters (HEPAs)

3. Ultraviolet germicidal irradiation

4. Negative-pressure isolation rooms

5. Respiratory protection: HEPA filter masks or respirators

62 SPONTANEOUS AND IATROGENIC PNEUMOTHORAX

William Franklin Young, Jr.
Roger Loyd Humphries

Pneumothorax occurs when air enters the potential space between the visceral and parietal pleura. The cause may be blunt trauma, penetrating trauma, or spontaneous. Iatrogenic pneumothorax occurs secondary to a diagnostic or therapeutic procedure and is really a subset of penetrating traumatic pneumothorax. Primary spontaneous pneumothorax (PSP) occurs in individuals without known lung disease and accounts for two-thirds of spontaneous pneumothoraces. Secondary spontaneous pneumothorax (SSP) occurs in patients with underlying lung disease, especially chronic obstructive pulmonary disease. Emergency department evaluation and management of pneumothorax center on immediate management of complications such as tension pneumothorax or ventilatory failure, eliminating the intrapleural air, optimizing pleural healing, and preventing recurrences.

SPONTANEOUS PNEUMOTHORAX

Epidemiology

An estimated 20,000 new spontaneous pneumothoraces occur each year in the United States, and there is evidence that the rate is increasing. [1,2] However, the true incidence of spontaneous pneumothorax is unknown, with estimates that up to 20 percent of such patients do not seek medical help. [3] Spontaneous pneumothorax is primarily a disease of male smokers who have larger height-to-weight ratios. [4] Male sex carries a 6:1 relative risk compared with the risk for females, although more recent studies show a trend to increased cases among women, perhaps due to smoking trends. [2] Smoking is an important risk factor with an overall greater than 20:1 relative risk compared with nonsmokers. [5] Spontaneous pneumothorax occurs among all age groups, with three peaks: among neonates (due to hyaline membrane disease or aspiration), among 20- to 40-year-olds (such cases tend to be primary), and among those older than age 40 (typically secondary cases). A genetic component is evidenced in the 11 percent of patients who have family members with spontaneous pneumothorax. [6] Contrary to common belief, only 10 to 20 percent of cases occur with exertion. [4] Spontaneous pneumothorax may rarely be associated with menses (catamenial). [4]

Pathophysiology

The pleurae are serous membranes that surround each lung: the parietal pleura lines the thoracic wall continuous with visceral pleura closely applied to the lung surface. At the hilum of each lung, the parietal and visceral pleurae are contiguous. The intrapleural space has sub-atmospheric pressure due to the inherent tendency of the chest wall to expand and the lung to collapse from elastic recoil.

Primary spontaneous pneumothorax seems to result from rupture of a subpleural bleb, usually in an upper lobe. [7] These blebs are multiple and have increased wall tension allowing distention and eventual rupture. The mechanism of bleb formation remains unknown, but higher upper lobe transpulmonary pressure, local ischemia from decreased upper lobe blood flow, and subclinical emphysema-like changes have been postulated. [3,7]

Chronic obstructive pulmonary disease (COPD) accounts for most cases of secondary spontaneous pneumothorax. [4] Other causes include cystic fibrosis, pulmonary infections, interstitial lung disease, AIDS, neoplasms, and drug use. Pneumothorax occurs in 5 percent of AIDS patients, is associated with subpleural necrosis from *Pneumocystis* infection, and carries a high mortality. [8] Because of necrosis of lung tissue and continued air leak, simple aspiration and nondrainage techniques fail in this group of patients. [8]

Once there is a break in the pleura, air travels down a pressure gradient into the intrapleural space until pressure equilibrium occurs with partial or total lung collapse. [9] Altered ventilation perfusion relationships and decreased vital capacity then contribute to dyspnea and hypoxemia.

Clinical Features

Symptoms are related to the size of the pneumothorax and rate of development. Patients with mild symptoms may not come for evaluation, whereas those with underlying lung disease may arrive in extremis. Patients with secondary spontaneous pneumothoraces present more dramatically than those with primary pneumothoraces. Tension pneumothorax is rare in PSP/SSP but requires immediate treatment by needle decompression and expeditious chest tube thoracostomy based on clinical signs. Pneumothorax is an important differential diagnosis in patients with chest pain, since it can mimic ischemia causing ST changes and T-wave inversion on the ECG. [3]

Acute pleuritic chest pain occurs in 95 percent of patients and localizes to the side of the pneumothorax in > 90 percent of cases. [6] Dyspnea occurs in 80 percent and predicts a larger pneumothorax. [6] Patients with COPD may acutely decompensate, with 1 to 17 percent mortality. Decreased breath sounds occur over the affected lung 85 percent of the time, but only 5 percent have tachypnea of more than 24 breaths per minute or tachycardia of more than 120 beats per minute. [6] Hyperresonance occurs in fewer than one-third. Tracheal deviation and hemodynamic compromise are the hallmarks of tension pneumothorax that demands immediate treatment.

Diagnosis

Tension pneumothorax diagnosed on clinical grounds requires immediate treatment by needle decompression and expeditious chest tube thoracostomy before radiographic evaluation. The traditional "gold standard" for diagnosis of pneumothorax continues to be the 6-foot upright posteroanterior chest radiograph, although the sensitivity of this examination is 83 percent. [10] A radiolucent line is seen to separate the parietal and visceral pleurae. Pseudo-pneumothorax due to a skinfold, scapular border, or tubing is differentiated from true pneumothorax by looking for vascular markings outside the confines of the radiolucent line and the blending of these lines into the chest wall rather than following the borders of a collapsed lung. Large bullae have been mistaken for pneumothoraces, but bullae and cysts have concave inner margins and rounded edges. Pneumothorax is much more difficult to detect on a supine anteroposterior radiograph. On the anteroposterior view, a deep sulcus sign, representing a deep lateral costophrenic angle, sometimes is a clue to a pneumothorax. [10] Expiratory radiographs by themselves are no more sensitive than inspiratory films and provide inferior evaluation of lung parenchyma. [10] However, comparison of paired inspiratory and expiratory films may be more sensitive than either view alone. [11] Chest computed tomography (CT) may be more sensitive than plain radiographs in detection of pneumothorax, but most studies compare supine chest x-ray film (CXR) with chest CT in the setting of trauma. This is useful if the plain film is equivocal. Ultrasound, although portable and easy to perform, is not useful for the diagnosis of pneumothorax, because ultrasound sensitivity is 73 to 95 percent and its specificity is 68 to 91 percent. [12]

Spontaneous pneumothorax should be included in the differential diagnosis of acute chest pain or acute deterioration in a patient with COPD. ST-segment and T-wave changes may be mistaken for ischemia. Occasionally, severe bullous COPD may mimic pneumothorax, and careful review of the CXR is needed with confirmatory CT if the patient is stable. A thoracostomy with the chest tube inserted into a bulla mistaken for a pneumothorax results in a large pneumothorax, associated bronchopulmonary fistula, and its complications. [3]

The size of the pneumothorax may be calculated, and some physicians use size as a guide to therapy. Radiologist "best guess" estimates show substantial

interobserver disagreement and lack of reproducibility. [13] Using the lung area ($x_1 \times y_1$) to hemithorax area ($x_2 \times y_2$) ratio to estimate the size of the pneumothorax has a poor correlation ($r = 0.7$) with actual size[14] (Fig. 62-1). Estimating the amount of collapse by using the ratio of the cube of the pneumothorax diameter (x_1) to the cube of the hemithorax diameter (x_2) also shows poor correlation ($r = 0.7$).[14] Rhea and colleagues[13] describe a nomogram by using the average intrapleural distance, and Collins and coworkers[15] describe a formula using three intrapleural distances measured in centimeters:

$$\% \text{ pneumothorax } = 4.2 + 4.7 \ (A + B + C) \ \text{(Fig. 62-1)}$$
FIG. 62-1. Measurements used in pneumothorax size evaluations.

Whatever method is chosen, the same formula should be used so that sequential calculations are consistent. Chest CT volume measurements represent the current "gold standard," but the patient's clinical status and not the pneumothorax size should determine treatment options. [1]

Treatment

Treatment goals are the elimination of intrapleural air, optimization of pleural healing, and prevention of recurrences. However, there is marked practice variation, and no consensus exists, although attempts have been made.[1,16] Observation, oxygen, catheter aspiration (either single or sequential), tube thoracostomy (either minicatheter or standard chest tube), pleurodesis, video-assisted thorascopy (VAT), and thoracotomy are all options, but only the latter three procedures reduce the risk of future pneumothorax recurrence.

Since 1.25 percent of intrapleural air is reabsorbed each day, stable patients with an asymptomatic primary small spontaneous pneumothorax who have ready access to health care may be observed as outpatients after a 6-h period of observation and a repeat chest radiograph showing no increase in pneumothorax size. Extended outpatient observation is needed because a 25 percent pneumothorax would take about 20 days to resolve. Critics of this treatment plan point to the 23 to 40 percent of patients treated by observation who eventually require tube thoracostomy. [1]

Observation may be a reasonable approach for those patients with a contraindication to invasive therapy, such as coagulopathy. Concomitant oxygen administration at 3 to 4 L/min increases pleural air resorption three- to fourfold and should always be used in the emergency department. [1]

Catheter aspiration is underutilized for treatment of spontaneous pneumothorax. Multiple techniques, equipment, and protocols are described, making a consensus statement difficult. Success rates from 37 to 75 percent are described with the greater success seen in PSP. [1] Techniques include simple one-time aspiration with small plastic 16- to 18-gauge intravenous catheters, repeated aspirations through the same catheter, and small-caliber chest tube with aspiration. Minicatheter tube placement uses a specially designed catheter with multiple side ports eliminating the problem of single-lumen obstruction seen with intravenous catheters. The technique involves placing a small catheter either into the second anterior intercostal space in the midclavicular line or laterally at the fourth or fifth intercostal space in the anterior axillary line after local anesthesia and sterile preparation. A three-way stopcock is applied, and a 60 mL syringe is used to aspirate the pleural space until resistance is met and the patient coughs. The stopcock is closed, the tube is secured, and a chest radiograph is obtained to assure reexpansion. Aspiration of more than 4 L suggests continued air leak and failure of simple aspiration. Failure to fully expand warrants another aspiration attempt. If the procedure is successful, patients should be observed for 6 h and, if no recurrence is seen, discharged to close follow-up within 24 h. If the procedure is not successful, a Heimlich valve is attached, with an improved success rate for failed simple aspiration. [17]

Patients who fail to reexpand even with the Heimlich valve can be placed on low suction or undergo formal large-bore chest tube thoracostomy. These patients require admission, although outpatient chest tube management has been described. Standard chest tube thoracostomy with underwater seal drainage is the most commonly used therapy and remains the standard in many hospitals. Proponents point to a low complication rate and a high success rate of 95 percent. [17] Patients with secondary spontaneous pneumothorax, those with recurrent pneumothorax, and those who fail simple catheter aspiration with Heimlich valve require formal large-bore, >28 French chest tube thoracostomy.[17] A proposed treatment algorithm is presented in Fig. 62-2.

FIG. 62-2. Treatment summary (see the text).
*Symptoms of tension pneumothorax demand immediate decompression.
†Secondary: chronic obstructive pulmonary disease (COPD), AIDS, cystic fibrosis, asthma, or other known prior lung disease.

Short-term complications of spontaneous pneumothorax include tension pneumothorax, failure to reexpand, persistent air leak, and complications related to the removal of intrapleural air, such as infection, technical errors, and reexpansion pulmonary edema. Reexpansion pulmonary edema is multifactorial, poorly studied, and reports are largely anecdotal. [1] Younger patients with larger pneumothoraces rapidly expanded with suction are at most risk. Pulmonary edema generally occurs on the side of the reexpanded lung. Treatment is supportive.

Disposition

After successful emergency treatment of a spontaneous pneumothorax, referral or consultation regarding definitive management with pleurodesis with or without VAT or thoracotomy should be done. Some authors recommend VAT for the first spontaneous pneumothorax due to the relative high rate of pneumothorax recurrence, lower overall cost, and success rate of the procedure, but this seems overly aggressive. [17] Recurrence after VAT requires open thoracotomy with pleurectomy or

pleural scarification.[8]

Recurrence of the pneumothorax is the major long-term complication and the reason that all patients with spontaneous pneumothorax require referral for potential definitive therapy. Primary spontaneous pneumothorax recurs in about 30 to 40 percent and is independent of the method chosen to remove the intrapleural air.[6] Two-thirds of such cases occur within the first year.[6] Smoking cessation reduces this risk by half.[2] Secondary spontaneous pneumothorax recurs in 40 to 50 percent of patients.

IATROGENIC PNEUMOTHORAX

Iatrogenic pneumothorax occurs more than spontaneous pneumothorax and is a subset of traumatic penetrating pneumothorax. Transthoracic needle procedures (transthoracic needle biopsy and thoracentesis) account for more than 50 percent of cases, and subclavian vein catheterization accounts for 22 percent.[18] Given that one central venous line is placed every minute in the United States, and pneumothorax occurs after 1 to 12 percent of subclavian line attempts, iatrogenic pneumothorax must be common.[18,19 and 20] Some of the factors increasing the frequency of iatrogenic pneumothorax include the patient population, underlying disease, body habitus, and experience of the operator.[18] Ultrasound guidance for thoracentesis has been shown to reduce the pneumothorax complication rate from 18 to 3 percent[21] and appears promising to reduce the incidence of pneumothorax with central venous line placement.[22]

Chest radiograph is standard after central line placement or transthoracic needle procedures, but may miss an iatrogenic pneumothorax because of the use of a supine technique or inadequate time for the pneumothorax to develop. Delayed pneumothoraces are common after subclavian line placement; up to 4 percent are delayed for up to 96 h.[23] Emergency department experience with other penetrating chest trauma recognizes the risk of delayed pneumothorax of up to 6 h.[24]

Treatment for iatrogenic pneumothorax parallels that for spontaneous pneumothorax, with some important caveats. Patients on mechanical ventilation require large-bore chest tube thoracostomy.[20] Conversely, patients sustaining a small pneumothorax after a needle puncture and not receiving positive pressure ventilation can be initially treated with simple catheter aspiration, which will be adequate in up to 60 percent of patients. These patients need to be admitted to the hospital, with the catheter in place for observation, because prolonged air leak may occur in some patients.[25] Recurrence is not an issue in these patients, but deaths have occurred from iatrogenic pneumothorax.[20]

63 HEMOPTYSIS

William Franklin Young, Jr.
Michael W. Stava

Hemoptysis is expectoration of blood from the respiratory tract below the level of the larynx. Hemoptysis presents a diagnostic dilemma due to its multiple causes, ranging from minor to life threatening. Up to 25 percent of cases remain undiagnosed even after extensive evaluation. Priorities in the evaluation of hemoptysis are (1) ensuring adequate oxygenation and ventilation, (2) confirming a pulmonary source of bleeding, (3) looking for neoplasia and systemic disease (e.g., pulmonary embolism or Wegener granulomatosis), (4) appropriate radiographic imaging, and (5) appropriate disposition.

EPIDEMIOLOGY

Hemoptysis may be defined as mild, moderate or massive. The precise degree of hemoptysis required for each categorization is arbitrary and not standardized. Despite lack of clinical utility, mild hemoptysis is usually defined as less than 5 mL of blood in 24 h, moderate hemoptysis is defined as 5 to 600 mL in 24 h, and massive hemoptysis is greater than 600 mL in 24 h.[1] Often patients are unable to accurately estimate the degree of bleeding, and the emergency department time frame requires a more appropriate time categorization. A reasonable amount of hemoptysis considered massive in volume would be greater than 50 mL in a single expectoration.

In a retrospective meta-analysis of six prior studies of hemoptysis, Marshall found an infectious nontubercular cause in approximately 25 percent of cases, tuberculosis in 5 percent, neoplasia in 28 percent, miscellaneous and multiple causes in 13 percent; and an undetermined cause in 28 percent. [2] In another study, cardiovascular causes account for 3 percent of total hemoptysis cases, most due to congestive heart failure, and trauma accounts for less than 3 percent. [3] In summary, out of every four cases of hemoptysis, one neoplasm, one nontubercular infectious case, one miscellaneous case, and one idiopathic case may be expected.

Hemoptysis is described in both sexes, with a 60:40 male predominance, and in all age groups. [4] It is rare in children and increases in frequency with age. The true incidence is unknown, since many cases are unreported. Lifestyle activities, such as smoking, predispose patients to lung disease and an increased risk of hemoptysis. Male gender, age over 40, and history of smoking are risk factors for a neoplastic cause of hemoptysis. [2]

PATHOPHYSIOLOGY

The lung has a dual blood supply: (1) bronchial vessels under systemic circulatory pressure supply the supporting structures of the lung, and (2) pulmonary vessels under low pressure perform the specialized oxygen-carbon dioxide exchange in the alveoli. [5] Bleeding may be from either source by three mechanisms: (1) increased intravascular pressure, (2) erosion by an inflammatory process into a pulmonary or bronchial blood vessel, and (3) a complication of a bleeding diathesis.

Hemoptysis due to increases in pulmonary vascular pressure most often arise from primary cardiac abnormalities, such left-sided congestive heart failure (constituting 75 percent of cases) or mitral stenosis. Hemoptysis is usually well tolerated and scant in rheumatic heart disease.

Inflammatory causes of hemoptysis include bronchitis, bronchiectasis, mycetoma, foreign-body aspiration, pulmonary embolism, pneumonia, and malignancy. Fifty percent of malignant lesions are metastatic; the other half are primary lung neoplasms. [4] Erosion into the bronchial vessels under systemic circulatory pressures, with resultant severe hemoptysis, appears to be more common in tuberculosis, bronchiectasis, and mycetomas from fungal infection. [6] Although classically associated with pulmonary embolism, hemoptysis is seen in only 3 to 20 percent of cases and has a sensitivity of only 14 percent for a positive finding on radionuclide scanning. [7] Hemoptysis from vasculitis is usually alveolar in location and part of a larger systemic vasculopathy, such as systemic lupus erythematosus, Wegener granulomatosis, polyarteritis, or Goodpasture syndrome. Extrapulmonary symptoms, especially hematuria, are often seen.

Hemophilia, thrombocytopenia, anticoagulants, and thrombolytics may cause hemoptysis. Thrombolytic-induced hemoptysis occurs in less than 1 percent of patients receiving thrombolysis and is usually self-limited. [8] However, its occurrence should prompt investigation for an underlying cause.

Hemoptysis without a discovered cause tends to resolve spontaneously within 6 months in 90 percent of cases. [2]

CLINICAL FEATURES AND DIAGNOSIS

A history of underlying lung disease provides important clues to the underlying cause of hemoptysis. An abrupt onset of cough with bloody purulent sputum, with or without fever, may indicate acute pneumonia or bronchitis. A chronic productive cough may reflect chronic bronchitis or bronchiectasis. Although typically seen with tuberculosis, fevers, night sweats, and weight loss may represent other infections. Anorexia, weight loss, and change in cough may reflect bronchogenic carcinoma. While some tumors present with new-onset cough and hemoptysis, 80 percent of neoplastically caused hemoptysis had duration of greater than 1 week. Smoking, male gender, and age over 40 are the predominant risk factors for neoplasm. Alveolar hemorrhage syndromes from vasculitis present with dyspnea and mild hemoptysis associated with renal disease and hematuria. As noted earlier, hemoptysis is an insensitive marker for pulmonary embolism and the symptom of hemoptysis is usually overshadowed by anxiety, dyspnea, and chest pain.

The physical examination is useful in determining the severity of hemoptysis, but is unreliable in localizing the site of bleeding. Fever usually suggests an infectious cause. Tachypnea may reflect respiratory compromise with hypoxemia due to the interference of intrapulmonary blood with gas exchange or from underlying lung disease with altered ventilation-perfusion relationships. Blood pressure is usually not changed, except in massive hemoptysis. The nasal cavity and oropharynx should be carefully examined for extrapulmonary causes of hemoptysis (termed pseudohemoptysis) as well as signs of extrapulmonary vasculitis. The cardiac examination may reveal the diastolic murmur of mitral stenosis. The pulmonary examination may reveal fine inspiratory rales associated with alveolar blood or inspiratory and expiratory rhonchi associated with airway secretions and blood. There may be wheezing from bronchial narrowing. Digital clubbing suggests chronic lung disease. Supraclavicular adenopathy and muscle wasting suggest neoplasia.

Upon initial contact, the patient's ventilatory stability should be assessed to the ensure adequate oxygenation and ventilation. The airway may be inadequate and require intubation. Pulse oximetry is necessary to assess oxygenation. Ventilation is assessed by the clinical appearance of tidal volume and mental status. For patients with ongoing massive hemoptysis, immediate intervention with supplemental oxygen, intravenous access, and typing and cross-matching of blood, and urgent consultation with a pulmonologist or thoracic surgeon for emergency bronchoscopy are indicated. Patients who are stable (no respiratory distress and lesser degrees of hemoptysis) should have their sputum evaluated to differentiate true hemoptysis from pseudohemoptysis due to an ear, nose, throat, or gastrointestinal source. A bright red color, frothy appearance, alkaline pH, and presence of macrophages indicating a pulmonary source suggest true hemoptysis. Gastrointestinal blood typically is acidic and dark red, although swallowed epistaxis may be mistaken for gastrointestinal bleeding. Ten percent of pseudohemoptysis is due to lesions of the upper aerodigestive tract.[3]

The laboratory evaluation should be guided by clinical indications. For example, a healthy young person who presents with an acute cough and streaky hemoptysis does not require routine laboratory testing. A complete blood count should be obtained and serum electrolytes, blood urea nitrogen, creatinine, and glucose measured in patients with massive hemoptysis and in the setting of chronic illnesses. Coagulation studies are indicated in patients with liver disease or using anticoagulants. Arterial blood gas analysis should be performed on patients with respiratory distress or altered mental status. Bacterial sputum cultures are indicated with clinical or radiographic evidence of pneumonia. Mycobacterial sputum cultures are indicated with fever, weight loss, night sweating, and cavitary lung masses.

It is generally agreed that all patients with true hemoptysis require radiographic imaging, starting with a chest x-ray, for evaluation. [2,9] Up to 90 percent of individuals with neoplasm as a cause of hemoptysis have abnormal chest x-rays. However, 20 to 30 percent of patients presenting with hemoptysis have a normal chest radiograph, and details of further workup of these patients remains controversial. [2] No definitive diagnosis is reached in up to 90 percent of patients who have normal chest x-rays. Conversely, hemoptysis with a normal chest radiograph carries a small (less than 5 percent) risk of neoplasm.

Chest computed tomography (CT) is felt to have a greater sensitivity than plain radiography in detecting carcinoma or bronchiectasis. [2] Bronchoscopy or laparoscopic biopsy may also be needed. Fiberoptic bronchoscopy and chest CT have complementary roles. Close consultation with the follow-up physician is important to coordinate the timing of these evaluations.

Bronchoscopic evaluation continues to have a pivotal role in the evaluation of ongoing hemoptysis. Patients who are unstable with airway problems or have massive hemoptysis generally require rigid bronchoscopy to evacuate clots and determine the source of bleeding (Fig. 63-1).

FIG. 63-1. Evaluation of hemoptysis.
* Massive, >50 mL per single expectoration.
† Age >40, smoker, male gender, and weight loss (two or more risk factors).
FOB = fiberoptic bronchoscopy.

TREATMENT

Treatment in the emergency department depends on the severity of the hemoptysis and the likelihood of a malignant cause. All patients with massive hemoptysis, and some patients with minor hemoptysis due to tuberculosis, mycetoma, or bronchiectasis, who are at significant risk of developing massive hemoptysis in the near future, require urgent management and hospitalization. All such patients require intravenous access, supplemental oxygen to ensure adequate arterial saturation, and typing and cross-matching of blood.

Patients with ongoing massive hemoptysis from one lung should be positioned with the bleeding lung dependent to minimize soiling of the contralateral lung. Tracheal intubation with a large-diameter endotracheal tube (8 French or larger to allow for bronchoscopy) is indicated if there is respiratory failure or if the patient is unable to clear the blood from the airways. Double-lumen endotracheal tubes have smaller lumina, which limit suctioning and ventilation. [2] If bleeding persists despite initial measures, the endotracheal tube may be advanced to the main-stem bronchus of the nonbleeding lung to minimize further aspiration of blood. The right main-stem bronchus is easily entered by advancing a standard orotracheal tube. This procedure will occlude the right upper lobe tertiary bronchus and ventilate the right middle and right lower lobes only. [2] The left main-stem bronchus is more sharply angled from the trachea, and selective intubation usually requires special equipment and technique. Mechanical ventilation should be instituted as necessary to support ventilation.

Fresh-frozen plasma should be administered to correct coagulopathy, and platelet transfusions are indicated for thrombocytopenia. Cough suppression with codeine or opioids might be helpful to prevent dislodging of hemostatic clots but carries the risk of suppressing ventilation and increases the risk of aspiration.

Emergency consultation is indicated with a pulmonologist or thoracic surgeon who may arrange for bronchoscopy, high-resolution chest CT scan, or bronchial artery angiography to localize the specific bleeding site. [10] Patients with massive hemoptysis that has subsided are at high risk of recurrence and require similar intensive management and hospital admission, usually to an intensive care unit. Massive hemoptysis is less common in children, but similar evaluation and management are appropriate.

Patients with minor hemoptysis due to bronchitis should be treated for the underlying disease as appropriate. Smoking cessation, oral antibiotics, and inhaled b-agonist bronchodilators have a role in the treatment in acute bronchitis. Patients at high risk for neoplasm should have a follow-up consultation with their primary care physician or a pulmonary subspecialist.

64 ACUTE ASTHMA IN ADULTS

Rita K. Cydulka
Sorabh Khandelwal

Asthma is a chronic inflammatory disorder characterized by increased responsiveness of the airways to multiple stimuli. Many cells and cellular elements, such as mast cells, eosinophils, T lymphocytes, macrophages, neutrophils, and epithelial cells, play a role in the development of the inflammatory response. In susceptible individuals, the inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread, but variable, airflow obstruction, that is often reversible either spontaneously or with treatment.

Most acute attacks are reversible and improve spontaneously or within minutes to hours with treatment. Although patients appear to recover completely clinically, evidence suggests that asthmatic patients develop chronic airflow limitation. [1] The recognition that asthma is a chronic inflammatory disorder of the airways has significant implications for the diagnosis, management, and potential prevention of its acute exacerbation.

EPIDEMIOLOGY

Asthma affects approximately 4 to 5 percent of the population in the United States. [2] It is the most common chronic disease of childhood, with a prevalence of 5 to 10 percent. [3] On the other end of the spectrum, asthma affects 7 to 10 percent of the elderly, accounting for 68,000 admissions to hospitals in 1991. [4] About one-half of cases of asthma develop before the age of 10 and another one-third before the age of 40. The 2:1 male to female preponderance of asthma in childhood equalizes by age 30. Self-reported prevalence rates for asthma in the United States increased by 75 percent from 1980 to 1994, with the most substantial increase occurring among children aged 0 to 14 years. [2] Similar prevalence rates are reported in developed nations throughout the world. [5] During the same period, the estimated annual number of office visits for asthma in the United States more than doubled from 4.6 million to 10.4 million, hospitalization rates increased from 386,000 to 466,000, and mortality rates associated with asthma, which had been decreasing from 1960 through 1962 and again from 1975 through 1977, increased in all race, gender, and age strata. [2] Death rates were consistently higher among blacks and among the elderly. The economic implications of asthma are substantial despite advances in treatment. In the United States alone, the estimated direct and indirect cost of asthma in all age groups was 6.2 billion dollars in 1990. [6]

PATHOPHYSIOLOGY

The pathophysiologic hallmark of asthma is a reduction in airway diameter caused by smooth muscle contraction, vascular congestion, bronchial wall edema, and thick secretions. These changes are reflected in pulmonary function changes, increased work of breathing, and abnormal distribution of pulmonary blood flow (Table 64-1). Both large and small airways often contain plugs composed of mucus, serum proteins, inflammatory cells, and cellular debris. On a microscopic level, airways are infiltrated with eosinophils and mononuclear cells. Evidence of microvascular leakage, epithelial disruption, and vasodilation is frequently noted. The airway smooth muscle is hypertrophied and characterized by new vessel formation, an increased number of epithelial goblets cells, and deposition of interstitial collagen beneath the epithelium. [7] Subepithelial fibrosis, an increase in the thickness of the reticular layer of the basement membrane, is characteristically increased in both the large and small airways. [7] Recent data collected from transbronchial biopsy, alveolar lavage, and specialized airway imaging techniques suggest that inflammation affects all bronchial pulmonary structures. [8]

Increased airway resistance

Decreased maximum expiratory flow rates

Air trapping

Increased airway pressure
  Barotrauma
  Adverse hemodynamic effects

Ventilation-perfusion imbalance
  Hypoxemia
  Hypercarbia

Increased work of breathing
  Pulsus paradoxus
  Respiratory muscle fatigue with ventilatory failure

TABLE 64-1   Physiologic Consequences of Airflow Obstruction

Current hypothesis states that airway inflammation may be acute, subacute, or chronic. The acute response is determined by early recruitment of cells to the airway. Antigens come in contact with mast cells in the submucosa and cause elaboration of mediators, such as histamine, leukotrienes (including leukotriene B$_4$), chemokines, tryptase, interleukin 5 (IL-5), IL-8, proinflammatory cytokines, and IL-4, which produce an intense inflammatory reaction, with bronchoconstriction, vascular congestion, edema formation, increased mucus production, and impaired mucociliary transport. Eosinophils, platelets, and polymorphonuclear leukocytes are recruited to the site, activated, and contribute further to the inflammatory cycle that has already been initiated. The immunoglobulin E (IgE) response is controlled by T and B lymphocytes and activated by the interaction of antigen with the mast cell-bound Ig-E molecules. [9] In the subacute or late phase, recruited and resident cells are activated, causing a more persistent pattern of inflammation.

Chronic inflammation is characterized by a persistent cell damage and an ongoing repair process, contributing to some of the microscopic changes seen in the airway. Mediators target ciliated airway epithelium to cause injury or disruption. As a consequence, epithelial cells and myofibroblasts, present beneath the epithelial layer, proliferate and begin to deposit interstitial collagen in the lamina reticularis of the basement membrane. Fibroblasts contribute to the process by releasing cytokines and chemokines, which may be important in both initiating and maintaining the level of airway inflammation and may explain the apparent basement membrane thickening and irreversible airway changes seen in some asthmatics. [10] Clearly, the inflammatory process is multicellular, redundant, and self-amplifying.

Allergic asthma is frequently associated with a personal or family history of allergic diseases such as rhinitis, urticaria, and eczema. Idiosyncratic, or nonallergic,

asthma is associated with no family history or personal history of allergy and normal serum levels of IgE. Many stimuli have been noted to provoke an increase in airway responsiveness. Viral respiratory infections are the most common of the stimuli that invoke acute asthma exacerbation.[11] Increased airway responsiveness secondary to infection may last anywhere from 2 to 8 weeks.[11] Exercise is another common precipitant of acute asthma. Unlike other precipitants of acute exacerbation, long-term sequelae and airway reactivity are not noted as a result of exercise. Environmental conditions, such as atmospheric pollutants and antigens noted in heavy industrial or densely populated urban areas, are associated with higher incidence and severity of asthma. In addition, indoor antigens such as mold, house dust mites, cockroaches, and animal dander, are also associated with acute asthma. Occupational exposures, such as metal salt, wood and vegetable dust, pharmaceutical, industrial chemical and plastic, biological enzyme, vapors, gases, and aerosol, may also stimulate an asthma attack. Multiple pharmaceutical agents, such as aspirin, b blockers (including topical b blockers), nonsteroidal anti-inflammatory agents, sulfating agents, tartrazine dyes, and food additives and preservatives have been implicated in acute asthma. As in exercise-induced asthma, exposure to cold air alone can induce acute bronchospasm. Recent evidence indicates that endocrine factors, such as changing levels of estradiols and progesterone during the normal menstrual cycle and pregnancy, may contribute to the level of airway reactivity.[12,13] Finally, emotional stress can produce an asthma attack.

CLINICAL FEATURES

The symptoms of asthma consist of a triad of dyspnea, wheezing, and cough. Many patients will relay the history of asthma upon presentation, but some will not. Early in the attack, patients will complain of a sensation of chest constriction and cough. As the exacerbation progresses, wheezing becomes apparent, expiration becomes prolonged, and accessory muscle use may become evident. Key historical points should be obtained on asthmatics presenting with exacerbation to emergency departments (EDs) (Table 64-2). Acute asthma exacerbation can be categorized based on clinical features (Table 64-3).

TABLE 64-2   Key Historical Elements When Obtaining a History from Patients with Acute Asthma Exacerbation

TABLE 64-3   Classifying Severity of Asthma Exacerbations

Physical examination findings are variable. Patients presenting with a severe asthma attack may be in obvious respiratory distress, with rapid breathing and loud wheezing, whereas patients with mild exacerbation may present with cough and end-expiratory wheezing. At times, wheezing may be audible without a stethoscope. Other conditions may present with wheezing and mimic asthma (Table 64-4). The use of accessory muscles of inspiration indicates diaphragmatic fatigue, while the appearance of paradoxical respirations reflects impending ventilatory failure. Alteration in the mental status—e.g., lethargy, exhaustion, agitation, or confusion—also heralds respiratory arrest.

Congestive heart failure ("cardiac asthma")
Upper airway obstruction
Aspiration of foreign body or gastric acid
Bronchogenic carcinoma with endobronchial obstruction
Metastatic carcinoma with lymphangitic metastasis
Sarcoidosis with endobronchial obstruction
Vocal-cord dysfunction
Multiple pulmonary emboli (rare)

TABLE 64-4   Asthma Mimickers

Directed physical examination reveals hyperresonance to percussion, decreased intensity of breath sounds, and prolongation of the expiratory phase, usually with wheezing. Although wheezing results from the movement of air through narrowed airways, the intensity of the wheeze may not correlate with the severity of airflow obstruction. The "silent chest" reflects very severe airflow obstruction, with air movement insufficient to promote a wheeze. A pulsus paradoxus above 20 mmHg is also indicative of severe asthma. Although tachycardia and tachypnea are usually seen with acute asthma, vital signs normalize very quickly as airflow obstruction is relieved. Therefore, a normal heart rate, respiratory rate, and the absence of a pulsus paradoxus do not indicate complete relief of airway obstruction.

DIAGNOSIS

Bedside spirometry provides a rapid, objective assessment of patients and serves as a guide to the effectiveness of therapy. The forced expiratory volume in 1 s (FEV_1) and the peak expiratory flow rate (PEFR) directly measure the degree of large airway obstruction.[14] Patient cooperation is essential in order for these tests to be reliable. Sequential measurements help emergency physicians determine response to therapy. Signs on physical examination and a patient's report of symptoms of asthma do not necessarily correlate well with the severity of airflow obstruction. When possible, management decisions should be based on a patient's personal best PEFR or FEV_1 or, if unknown, percent of predicted. Initial spirometry and response to initial treatment can be used to predict the need for hospitalization with 86 percent sensitivity and 96 percent specificity.[15]

Pulse oximetry is a useful and convenient method for accessing oxygenation and monitoring oxygen saturation during treatment but does not aid in predicting clinical outcomes.[16]

Determination of arterial blood gas (ABG) is not indicated in the majority of patients with mild to moderate asthma exacerbation. The main reason to determine ABG during an asthma attack is to assess for hypoventilation with carbon dioxide retention and respiratory acidosis. Such patients almost always have clinical evidence of severe attacks or spirometry demonstrating a PEFR or FEV_1 of less than 25 percent predicted. With acute attacks, ventilation is stimulated, resulting in a decrease in partial pressure of carbon dioxide (P_{CO_2}). Therefore, a normal or slightly elevated P_{CO_2} (e.g., 42 mmHg or more) indicates extreme airway obstruction and fatigue and may herald the onset of acute ventilatory failure.

A chest radiograph is indicated in patients with asthma exacerbation if there is clinical indication of a complication such as pneumothorax, pneumomediastinum, pneumonia, or other medical concern. Routine radiography is unnecessary, but up to one-third of patients requiring admission will demonstrate an abnormality on chest radiograph.

A routine complete blood cell count is rarely indicated and will likely show modest leukocytosis secondary to administration of b-agonist therapy or corticosteroid treatment. In patients taking theophylline prior to ED presentation, a serum theophylline level should be determined. Routine electrocardiogram is also unnecessary but may reveal right ventricular strain, abnormal P waves, or nonspecific ST-T-wave abnormalities, which resolve with treatment. Older patients, especially those with coexisting heart disease, should have cardiac monitoring during treatment. Asthma index scores have failed to predict outcome better than clinical judgment.

TREATMENT

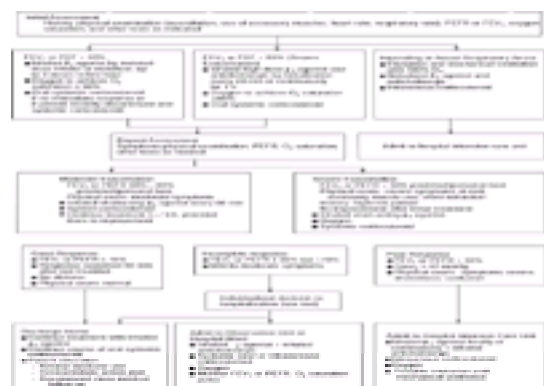
The goal of treatment of acute asthma in the ED is to reverse airflow obstruction rapidly by repetitive or continuous administration of inhaled b_2 agonists, ensure adequate oxygenation, and relieve inflammation. The National Asthma Education and Prevention Program (NAEPP) Expert Panel has developed guidelines for emergency treatment of asthma (Fig. 64-1).[17] The Canadian Association of Emergency Physicians and the British Thoracic Society have developed similar treatment guidelines.[18,19] The following categories of medications are used in the treatment of acute asthma: b-adrenergic agonists, anticholinergics, and glucocorticoids. Magnesium, heliox (helium-oxygen mixture), and ketamine may be considered when the aforementioned medications fail to relieve bronchospasm. Mast cell-stabilizing agents, methylxanthines, and leukotriene modifiers are currently reserved for maintenance therapy only.


FIG. 64-1. Management of Asthma Exacerbations: Emergency Department and Hospital-Based Care. *Abbreviations:* FEV_1, forced expiratory volume in 1 s; PEFR, peak expiratory flow rate.[17] (Adapted from National Asthma Education and Prevention Program Expert Panel, with permission.)

Adrenergic Agents

b-adrenergic agonists are the preferred initial rescue medication for acute bronchospasm. b-adrenergic receptors are divided into two types: b_1 and b_2. Stimulation of b_1 receptors increases rate and force of cardiac contraction and decreases small intestine motility and tone. b_2-adrenergic stimulation promotes bronchodilation, vasodilation, uterine relaxation, and skeletal muscle tremor.

The mechanism of bronchodilator action of b-adrenergic drugs involves stimulation of the enzyme adenyl cyclase, which converts intracellular adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). This action enhances the binding of intracellular calcium to cell membranes, reducing the myoplasmic calcium concentration, and results in relaxation of bronchial smooth muscle. In addition to bronchodilation, b-adrenergic drugs inhibit mediator release and promote mucociliary clearance.

The most common side effect of b-adrenergic drugs is skeletal muscle tremor. Patients may also experience nervousness, anxiety, insomnia, headache, hyperglycemia, palpitations, tachycardia, and hypertension. Despite earlier concerns over potential cardiotoxicity, especially when these drugs were used in combination with theophylline, clinical experience has not revealed significant problems. Arrhythmias and evidence of myocardial ischemia are rare, especially in patients without prior history of coronary artery disease.

The b-adrenergic agonists used today are analogues of naturally occurring sympathomimetics (Table 64-5). The ideal bronchodilator in this class of drugs would possess pure b_2-receptor activity—bronchodilation without cardiac effects. The older catecholamine bronchodilators—isoproterenol and epinephrine—are not b_2 specific and have a short duration of action. Isoetharine is more b_2 selective but still has a short duration of action. These drugs have nearly been replaced by newer agents produced by chemical modification of the parent compound. The resorcinol bronchodilators (metaproterenol, terbutaline, and fenoterol) and saligenin bronchodilators (albuterol and carbuterol) share greater b_2 specificity, as well as longer duration of action and effectiveness through the oral route due to resistance to intestinal sulfatases.

TABLE 64-5   Dosages of Drugs for Asthma Exacerbations in Emergency Medical Care or Hospital

Aerosol therapy with b_2-adrenergic drugs produces excellent bronchodilation and is favored over both the oral and parenteral routes. The aerosol route achieves topical administration of a relatively small dose of drug, producing local effects with minimum systemic absorption and fewer side effects. Aerosol delivery may be achieved with a metered dose inhaler (MDI) with spacing device or a compressor-driven nebulizer. A spacing device attached to the inhaler can improve drug

deposition when patient technique is inadequate. Even with optimum technique, however, a maximum of 15 percent of the drug dose is retained in the lungs, regardless of the aerosol method used. Dry-powder delivery devices and MDIs using hydrofluoralkane as propellant have recently replaced chlorinated fluorocarbon (CFC)-driven devices.

Aerosol treatments may be administered every 15 to 20 min or on a continuous basis. Epinephrine or terbutaline may be administered subcutaneously to patients unable to coordinate aerosolized or MDI treatments but their use should generally be avoided in patients with a history of cardiovascular disease. Intravenous b-agonist infusions offer no advantage over aerosolized or MDI-delivered agents and carry potential risk. [20]

Salmeterol xinafoate is a b_2-adrenoreceptor agonist that binds with greater affinity to the b-receptor site than does albuterol. *It is indicated for twice-daily maintenance therapy, should never be used more frequently, and is to be avoided for treatment of acute exacerbation.* Its bronchodilator effect lasts at least 12 h, and tachyphylaxis has not been reported with long-term use. It is an effective treatment for long-term control of asthma, especially nocturnal asthma. Short-acting b_2-adrenoreceptor agonists are generally added for symptoms that occur despite the use of salmeterol.

Corticosteroids

Corticosteroids are highly effective drugs in asthma exacerbation and form one of the cornerstones of treatment. Although the mechanism of action is unknown, many believe that steroids produce beneficial effects by restoring b-adrenergic responsiveness and reducing inflammation. The onset of anti-inflammatory effect is delayed at least 4 to 8 h following intravenous or oral administration.

Corticosteroids should be administered to asthmatics in whom airway obstruction is not immediately relieved after the first nebulized bronchodilator treatment. Although there is considerable disagreement over what constitutes the optimal dose in acute asthma, an initial oral dose of 40 to 60 mg prednisone or an intravenous bolus of 60 to 125 mg methylprednisolone, in patients unable to tolerate oral medications, is sufficient. [21] High-dose corticosteroid therapy offers no advantage. [22] Additional doses should be given every 4 to 6 h until significant subjective and objective improvement is achieved. Patients may be discharged on a 3- to 10-day nontapering burst of oral steroids, 40 to 60 mg prednisone per day, or its equivalent. [23]

Although the role of both oral and inhaled steroids in the long-term prevention of relapse is yet to be identified, all patients with an FEV_1 or PEFR of less than 70 percent predicted after aggressive ED treatment should be prescribed oral steroids. [17]

Anticholinergics

Plants containing anticholinergic alkaloids have been smoked for hundreds, if not thousands, of years to treat respiratory disorders. In recent years, anticholinergics have been rediscovered as potent bronchodilators in patients with asthma and other forms of obstructive lung disease. Although comparisons of bronchodilator response between anticholinergics and b-adrenergic agonists have produced conflicting results, the effects of the drugs used in combination may be additive. [24] This is plausible, because anticholinergics affect large, central airways while b-adrenergic drugs dilate smaller airways.

Anticholinergic drugs competitively antagonize acetylcholine at the postganglionic, parasympathetic effector-cell junction. This process blocks the bronchoconstriction induced by vagal cholinergic-mediated innervation to the larger central airways. In addition, concentrations of cyclic GMP in airway smooth muscle are reduced, further promoting bronchodilation.

Because of significant systemic side effects, atropine sulfate, once the major nebulized anticholinergic used in the United States, has been virtually replaced by the synthetic quaternary derivative: ipratropium bromide (Atrovent, Boehringer Ingélheim). This drug causes far fewer systemic side effects and is very well tolerated. Ipratropium is currently available as both a nebulized solution and an MDI (18 mg/puff) (Table 64-5).

Aerosolized ipratropium bromide, 0.5 mg, should be administered to patients with severe exacerbation. [17] Potential side effects with nebulized anticholinergics include dry mouth, thirst, and difficulty swallowing. Less commonly, tachycardia, restlessness, irritability, confusion, difficulty in micturition, ileus, blurring of vision, or an increase in intraocular pressure are noted.

Theophylline

Theophylline is no longer considered a first-line treatment for acute asthma. [17] Studies have shown that theophylline, in combination with inhaled b_2-adrenergic drugs, appears to increase the toxicity, but not the efficacy, of treatment. [25] Theoretically, theophylline may be a useful adjunct by providing a more sustained bronchodilator effect, contributing to small airway bronchodilation, improving respiratory muscle endurance, and improving resistance to fatigue. Recent data suggest an anti-inflammatory mechanism of action. [26]

The mechanism of action of theophylline remains unknown; 90 percent of theophylline metabolism is hepatic and the remainder is excreted unchanged through the kidneys. A serum theophylline level should be determined for patients who regularly use theophylline. The most common side effects of theophylline are nervousness, nausea, vomiting, anorexia, and headache. At plasma levels greater than 30 µg/mL, there is a risk of seizures and cardiac arrhythmias.

Magnesium

Intravenous magnesium sulfate is being used with increasing frequency in the management of acute, very severe asthma, i.e., FEV_1 of less than 25 percent predicted. [27,28] Its usefulness in mild and moderate exacerbation has not been established. Although the bronchodilating properties of magnesium sulfate can be helpful, it should not be substituted for standard therapy regimens. The dose is 1 to 2 g intravenously over 30 min.

Heliox, Ketamine, and Halothane

Several studies have demonstrated that an 80:20 percent mixture of helium and oxygen (heliox) can lower airway resistance and act as an adjunct in the treatment of very severe asthma exacerbation. [29] At present, heliox is not indicated for use in mild or moderate bronchospasm. Several investigators have reported success with ketamine and halothane in cases where all other treatment modalities have failed. Controlled trials substantiating these claims are lacking.

Mast Cell Modifiers

Both cromolyn and nedocromil exert their anti-inflammatory action by blockage of chlorine channels, thus modulating mast cell mediator release and eosinophil recruitment. These agents also inhibit early and late responses to allergen challenge and exercise. Neither is indicated for treatment of acute bronchospasm.

Leukotriene Modifiers

Leukotrienes are potent proinflammatory mediators that contract airway smooth muscle, increase microvascular permeability, stimulate mucus secretion, decrease mucociliary clearance, and recruit eosinophils into the airway. [1] Two leukotriene modifiers—zafirlukast and zileuton—are currently available as oral tablets for the treatment of asthma. Leukotriene modifiers improve lung function, diminish symptoms, and diminish the need for short-acting b_2 agonists. They are being investigated as an alternative to low-dose inhaled corticosteroid therapy and as steroid-sparing agents. There is currently no indication for the use of leukotriene modifiers in the treatment of acute bronchospasm.

Mechanical Ventilation

When in spite of the emergency physician's best effort to treat an acute asthma exacerbation, when the patient begins to exhibit signs of acute ventilatory failure, noninvasive positive-pressure ventilation may be attempted. [30] However, if the patient manifests progressive hypercarbia and acidosis or becomes exhausted or confused, intubation and mechanical ventilation are necessary to prevent respiratory arrest. Mechanical ventilation does not relieve the airflow obstruction; it merely

eliminates the work of breathing and enables the patient to rest while the airflow obstruction is resolved. Fortunately, fewer than 1 percent of asthmatics ever require mechanical ventilation. Direct oral intubation is preferred over the nasotracheal route.

The potential complications of mechanical ventilation in asthmatic patients are numerous. Increased airway resistance may lead to extremely high peak airway pressures, barotrauma, and hemodynamic impairment. Mucous plugging is frequent, often leading to increased airway resistance, atelectasis, and pulmonary infection. Due to the severity of airflow obstruction during the early phases of treatment, the tidal volume may be larger than the returned volume, leading to air trapping and increased residual volume [intrinsic positive end-expiratory pressure (intrinsic PEEP)]. These effects may be partially avoided by utilizing rapid inspiratory flow rates at a reduced respiratory frequency (12 to 14/min), and allowing adequate time for the expiratory phase. One can achieve the goal of ventilatory support—maintenance of an adequate arterial oxygen saturation (90 percent or more)—without concern for "normalizing" the hypercarbic acidosis.[31] This approach is called *controlled mechanical hypoventilation* or *permissive hypoventilation.* All patients requiring mechanical ventilation must be admitted to an intensive care unit.

SPECIFIC ISSUES THAT IMPACT DIAGNOSIS, EVALUATION, AND TREATMENT

Age

Diagnosis, evaluation, and treatment of children with asthma are discussed in Chapter 120, "Asthma and Bronchitis." Although newly diagnosed asthma in older populations is not uncommon, differentiation of the etiology of wheezing in older asthmatics may present a challenge. Historical data may help differentiate between congestive heart failure, pulmonary malignancy, and obstructive airway disease, but distinguishing between chronic obstructive pulmonary disease and acute asthma is often difficult.[4]

Treatment of older asthmatics should proceed in the same manner as treatment of younger asthmatics. Age-related changes in pulmonary function must be considered when determining response to treatment in older asthmatics, and care should be taken to avoid medication interactions.

Gender

Recent evidence suggests that men and women interpret changes in pulmonary function differently. Women express a sensation of dyspnea at higher percent predicted PEFR than do men.[32] In addition, cyclic hormonal changes may influence pulmonary function in women.[33]

Pregnancy

Asthma complicates approximately 4 percent of pregnancies. Studies indicate that as many as 42 percent of pregnant asthmatics require hospitalization and that an additional 11 to 18 percent have one or more visits to the ED for exacerbation.[34] In 1993, the NAEPP Expert Panel developed guidelines for the treatment of asthma exacerbation during pregnancy.[34] The principles of managing acute asthma exacerbation are similar to those of managing exacerbation in a nonpregnant state. They consist of repetitive lung function measurements, maintenance of oxygen saturation at greater than 95 percent, administration of repetitive inhaled b_2-agonist and early administration of systemic corticosteroids, along with fetal monitoring. Early intervention during acute exacerbation is key to the prevention of impaired maternal and fetal oxygenation. Uncontrolled asthma is associated with a variety of maternal and fetal complications, including hyperemesis, hypertension, toxemia, vaginal hemorrhage, complicated labor, intrauterine growth retardation, preterm birth, increased perinatal mortality, and neonatal hypoxemia. Although no asthma medication labeled to date qualifies for an FDA use-in-pregnancy category A rating (adequate well-controlled studies in pregnant women have failed to demonstrate risk to the fetus), problems as a result of routine treatment of asthma in the ED have not been reported.

Hyperventilation of pregnancy leads to a higher Pa_{O_2} and a diminished Pa_{CO_2}. Thus, a Pa_{O_2} of less than 70 mmHg in a pregnant women with acute asthma represents fairly severe hypoxemia, and a Pa_{CO_2} of greater than 35 mmHg represents respiratory failure.[35] During asthma exacerbation, the normal alkalosis of pregnancy is aggravated, leading to a decrease in placental blood flow. Hypoxemia is usually more severe in the fetus than in the mother.

b_2 agonists and inhaled corticosteroids are considered safe during pregnancy and are recommended as a routine part of asthma management. As in nonpregnant patients, a short burst of oral steroid (40 to 60 mg prednisone per day) or its equivalent, should be considered for pregnant asthmatics discharged from the ED after treatment for an exacerbation.

DISPOSITION

Disposition decisions should take into account a combination of subjective parameters, such as resolution of wheezing and improvement in air exchange, as assessed by auscultation and patient opinion, and objective measures, such as normalization of FEV_1 or PEFR. The ideal combination of elements needed for successful discharge without risk of early relapse has not yet been determined.[36] Some degree of residual airflow obstruction, airway lability, and inflammation persists after treatment and discharge from the ED.

No single treatment program can be recommended for all patients discharged home from the ED following treatment of exacerbation. Although several studies have demonstrated that a short course of oral steroids and b_2-agonist bronchodilators reduce relapse rates among discharged patients,[37] other studies have reported high relapse rates regardless of ED management and use of steroids.[36] Patients with a history of previous ED visits and hospitalization are at highest risk of relapse, regardless of management.[36]

Current guidelines help to determine hospitalization and discharge criteria based on response to aggressive treatment. A good response to treatment is demonstrated by complete resolution of symptoms and a PEFR or FEV_1 of greater than 70 percent predicted. Such individuals can be safely discharged home. Patients with a poor response to treatment are defined as those with persistent symptoms and FEV_1 or PEFR of less than 50 percent predicted. Such patients are likely to have persistent wheezing and dyspnea at rest despite intensive treatment in the ED and should be admitted. An incomplete response to treatment—the midground—is defined as some persistence of symptoms and a PEFR or FEV_1 between 50 to 70 percent predicted. Most asthmatics treated in the ED fall into this category. They may be discharged home safely, provided they have no risk factors for death from asthma (Table 64-2).[17] Patients who fail to improve adequately over a several-hour period because they are in the late phase of their exacerbation and those with significant risk factors for death from asthma should be admitted to either an observation unit or the hospital.[15,17]

The role of observation units in the care of acute asthma exacerbation is currently being determined. Although early studies indicated no reduction in hospitalization rates after treatment in ED observation units, more recent studies indicate that 59 percent of asthmatics admitted to observation units where strict care protocols are followed are successfully treated and discharged.[38,39]

Follow-up care must be arranged following an acute exacerbation to ensure resolution and to review the long-term medication plan for the chronic management of asthma. High relapse rates, despite the routine use of steroids, strongly suggest the need for follow-up within days of the ED visit.[36] Patients with asthma must have an appropriate written plan of action that addresses both routine care and care of worsening symptoms.

Education of patients must become an integral part of ED care. ED personnel should provide basic education on asthma and help link patients with a primary care providers or asthma specialists while providing discharge instructions. Review of patient's discharge medication, use of inhaler technique, and the use of peak flow monitoring are just some of the issues ED physicians can teach and emphasize (Table 64-6).

65 CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Rita K. Cydulka
Sorabh Khandelwal

Individuals with chronic obstructive pulmonary disease (COPD) frequently develop severe respiratory distress and are among the most frustrating, frightening, and challenging patients to manage. In a fearful state of mixed anxiety, intense physical effort, and disoriented fatigue, such people face a constant battle against asphyxiation. At other times, presentation is prompted by otherwise uncomplicated medical or surgical disease, which becomes more serious or catastrophic as the impact of chronic respiratory disease is unmasked.

The American Thoracic Society (ATS) defines COPD as a disease state characterized by the presence of airflow obstruction due to chronic bronchitis or emphysema. The airflow obstruction is generally progressive, may be accompanied by airway hyperactivity, and may be partially reversible. Chronic bronchitis is defined as the presence of chronic productive cough for 3 months in each of 2 successive years in a patient in whom other causes of chronic cough have been excluded. Emphysema is defined as abnormal permanent enlargement of the airspaces distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis. Note that chronic bronchitis is defined in clinical terms and emphysema in terms of anatomic pathology. [1]

EPIDEMIOLOGY

COPD is a major worldwide respiratory health problem. In North America, COPD is rare in persons younger than age 40, but very common among older individuals, with a prevalence of approximately 10 percent in those aged 55 to 85 years. The disease is more common in men than in women, but is predicted to decrease in incidence in men but not in women, a reflection of gender-based differences in smoking behavior. The World Health Organization estimates that COPD was the sixth leading cause of death in the world in 1990. [2] In the United States, COPD is the fourth most common cause of death, the third most common cause of hospitalization, and the only leading cause of death that is increasing in prevalence. [3]

The mortality of patients hospitalized for a COPD exacerbation is approximately 5 to 14 percent. [4,5] Mortality of COPD patients admitted to an intensive care unit for exacerbation is 24 percent. [6] For patients aged 65 years or older discharged from the intensive care unit after treatment of a COPD exacerbation, the 1-year mortality is 59 percent, nearly double the expected 30 percent. [6]

COPD is an expensive public health problem in terms of direct economic costs (such as hospital admissions and outpatient treatments), indirect economic costs (such as lost years of life, disability, and loss of working capacity), and reduction in quality of life. [1,5,6,7,8,9 and 10] The utilization of health care resources by elderly patients with COPD is immense, both during hospitalization and after discharge. [4]

PATHOPHYSIOLOGY

Cigarette smoking accounts for an estimated 80 to 90 percent of the risk of developing COPD. Age of starting, total pack-years, and current smoking status are predictive of COPD mortality. [1] Of note, only 15 percent of smokers develop clinically significant COPD. A variety of other environmental risk factors, such as respiratory infections, occupational exposures, ambient air pollution, passive smoke exposure, and diet, have been suggested, but supporting data is lacking. The only proven genetic risk factor is a $_1$-antitrypsin deficiency. Airway hyperresponsiveness, which may relate to environmental factors, genetic factors, or both, is a potential risk factor that has received significant attention. However, although airway hyperresponsiveness predisposes individuals to decline in pulmonary function and is a defining component in asthma, the relationship of asthma to COPD is unclear.

The earliest objective changes in the evolution of COPD are clinically imperceptible and are measured as small increases in peripheral airway resistance or lung compliance. The slow, insidious appearance of dyspnea and hypersecretion often requires several decades of disease. The sedentary life habits of many cigarette smokers result in failure to unmask exertional dyspnea, and denial results in suppression of symptoms or attribution of such symptoms to aging, poor conditioning, obesity, or allergies. Further, the respiratory consequences of cigarette smoking are a continuum of slowly evolving and latent effects, unique to each individual, in a complex dose-response relationship. Early in disease evolution, abstinence from smoking may eliminate symptoms and result in physiologic improvement. Once well established, however, abnormalities persist and may still progress despite abstinence.

Pathologic specimens from the patients with early disease demonstrate minor metaplasia of bronchial epithelium and an increase in bronchial gland number and size. [11] As disease evolves, such findings are exaggerated, acute and chronic inflammatory changes in the epithelium are more notable, and acinar expansion, destruction, and coalescence are seen. Elements of emphysematous disease are invariably present in concert with those of bronchitic disease, though one often predominates.

Despite recognition of causative factors, what determines the clinical onset and rate of progression of chronic airflow obstruction, and the direction toward either emphysematous or bronchitic patterns, is uncertain. Clearly, there is a great deal of variability in disease pattern and severity among individuals with seemingly similar predisposition to disease.

The central element in the pathophysiology of chronic airflow obstruction is impedance to airflow, especially expiratory airflow, due to increased resistance or decreased caliber throughout the small bronchi and bronchioles. Airflow obstruction results from a combination of airway secretions, mucosal edema, bronchospasm, and bronchoconstriction from impaired elastance. Impedance to airflow alone accounts substantially for the abnormal physiology of the disease. Exaggerated airway resistance either reduces total minute ventilation or increases respiratory work. To the degree that alveolar hypoventilation occurs, hypoxemia and hypercarbia result. Even without hypoventilation, hypoxemia occurs due to ventilation-perfusion mismatching.

In addition to obstruction of peripheral airways, all forms of advanced chronic airflow obstruction involve other pathophysiologic elements to complete the overall picture. Particularly in dominantly emphysematous disease, destruction and coalescence of alveolar architecture results in reduction of total "matched" alveolar-capillary surface area for diffusion of gas, while vascular destruction results in "unmatched" regions where ventilation is wasted.

Neurochemical and proprioceptive ventilatory responses in chronic airflow obstruction may be aberrant. For example, ventilatory response to hypercarbia may be blunted during sleep, and ventilatory drive and dyspnea may be exaggerated in spite of normal pulmonary inflation. The composition of muscle fiber types, breathing patterns, and resistance to fatigue of respiratory muscles are also altered in advanced chronic airflow obstruction. Finally, pulmonary arterial hypertension supervenes as chronic airflow obstruction progresses. The right ventricle transiently hypertrophies, and then dilates with the evolution of overt cor pulmonale. A low-output state in the pulmonary circulation translates into low left ventricular output. Arterial hypoxemia increases as the effects of right-to-left shunt on poorly oxygenated mixed

venous blood are exaggerated. Right ventricular pressure overload is clinically poorly tolerated and associated with atrial and ventricular arrhythmias.

Even though COPD is becoming increasingly recognized as a chronic inflammatory disease of the lower airways, the role of inflammation in its pathogenesis remains a matter of debate. In current COPD guidelines, there is no mention of lower airway inflammation in the definition of COPD. [1,6,7,8,9 and 10]

CLINICAL FEATURES

Chronic, Compensated COPD

Despite the pathophysiologic segregation of chronic airflow obstruction into categories of pulmonary emphysema, chronic bronchitis, and bronchiectasis, none of these exist as a pure entity in clinical medicine. Most patients demonstrate a mixture of symptoms and signs. The hallmark symptom is exertional dyspnea. Chronic, productive cough is common, and minor hemoptysis is frequent, especially in chronic bronchitis and bronchiectasis.

Physical findings include tachypnea, accessory respiratory muscle use, and pursed-lip exhalation. Airflow obstruction causes wheezing during exhalation, especially during maximum forced exhalation, and prolongation of the expiratory time. In dominantly bronchitic disease, coarse crackles are heard as uncleared secretions move about the central airways. In dominantly emphysematous disease, there is expansion of the thorax, impeded diaphragmatic motion, and global diminution of breath sounds. Weight loss is frequent due to poor dietary intake and excessive caloric expenditure for the work of breathing. Plethora due to secondary polycythemia, and cyanosis; tremor, somnolence, and confusion due to hypercarbia may be seen in advanced disease. Findings of secondary pulmonary hypertension with or without cor pulmonale may be present. The physical signs of left ventricular dysfunction are often disguised or underestimated by the seemingly more overwhelming signs of respiratory disease, or because pulmonary hyperinflation prohibits adequate auscultation.

Acute Exacerbations of COPD

Decompensation is usually due to worsening of airflow obstruction resulting from increased bronchospasm, superimposed respiratory infection or other respiratory pathology, interference with respiratory drive, cardiovascular deterioration, smoking, noncompliance with medications, noxious environmental exposures, use of medications that prevent bronchorrhea, and adverse responses to medication (e.g., anaphylactoid responses or b-adrenergic blockade). Disordered ventilatory drive most commonly arises from misuse of oxygen therapy, hypnotics, or tranquilizers. Metabolic disturbances, as well as inadequate oxygen delivery independent of respiratory function, may cause decompensated COPD.

Exacerbations of COPD usually involve progressive hypoxemia due to bronchospastic worsening of ventilation-perfusion matching. Signs of hypoxemia include tachypnea, cyanosis, agitation and apprehension, tachycardia, and systemic hypertension. The most life-threatening feature of decompensation is hypoxemia where arterial saturation falls below 90 percent. With increased work of breathing, muscle production of carbon dioxide increases and alveolar ventilation is often unable to increase to prevent carbon dioxide retention and respiratory acidosis. Signs of hypercapnia include confusion, tremor, stupor and, finally, hypopnea and apnea.

Patients usually complain of dyspnea and orthopnea. The intensified effort to ventilate is further dramatized by sitting-up-and-forward position, pursed-lip exhalation, accessory muscle use, and diaphoresis. Pulsus paradoxus may be noted during blood pressure recording. Complications such as pneumonia, pneumothorax, or an acute abdomen may be neglected or minimized by the patient's generalized respiratory distress, tachypnea, or global diminution of breath sounds.

DIAGNOSIS

Chronic, Compensated COPD

The most valuable tool in characterizing disease severity is pulmonary function testing, including examination of lung mechanics, analysis of arterial blood gases, description of ventilatory response patterns, tests of respiratory muscle performance, metabolic assessment, and noninvasive survey of hemodynamic reserve. The ratio of forced expiratory volume in 1 s (FEV_1) to forced vital capacity (FVC) should be used to diagnose mild COPD. However, once the disease progresses, the percentage of predicted FEV_1 is a better measure of disease severity. [1,7,8,9 and 10] Various guidelines characterize COPD severity as mild, moderate, or severe, although agreement on precise FEV_1 standards remains arbitrary. [1,8,9]

In the early stages of COPD, arterial blood gas measurements reveal mild-to-moderate hypoxemia without any evidence of hypercapnea. As the disease progresses in severity (especially when the FEV_1 falls below 1 L), hypoxemia becomes more severe and the development of hypercapnia becomes more evident. Not only do arterial blood gas measurements worsen during acute exacerbations, they also may worsen during exercise and sleep. [1]

Radiographic examination is often misleading; mild chronic airflow obstruction is not likely to be radiographically apparent. Dominantly bronchitic disease may be associated with subtle or absent x-ray findings. On the other hand, dominantly emphysematous disease may be associated with remarkable signs of hyperaeration, such as increased anteroposterior diameter, flattened diaphragms, increased parenchymal lucency, and attenuation of pulmonary arterial vascular shadows, despite only mild-to-moderate physiologic alterations. Right or left ventricular enlargement may not produce relative enlargement of the cardiac silhouette. Certainly, radiography is of unquestionable value in diagnosing complications such as pneumothorax, pneumonia, pleural effusion, and pulmonary neoplasia.

Diagnosing heart failure and assessing ventricular function in patients with COPD is difficult. Echocardiography or gated nuclear scans to estimate ejection fractions may prove invaluable. ECGs are useful to identify arrhythmias or ischemic injury but do not accurately assess the severity of pulmonary hypertension or right ventricular dysfunction.

Acute Exacerbations of COPD

Bedside pulmonary function tests provide a rapid, objective assessment of patients and serve as a guide to the effectiveness of therapy. The FEV_1 and the peak expiratory flow rate (PEFR) directly measure the degree of large-airway obstruction. Patient cooperation is essential in order for these tests to be reliable. Sequential measurements help the emergency physician determine response to therapy. Signs on physical examination and physician estimates of pulmonary function are highly inaccurate. [12] Measurement of FEV_1 is preferred over PEFR, because FEV_1 allows comparison with baseline studies and published guidelines. [13]

Although pulse oximetry may identify hypoxemia, it cannot identify hypercapnia or acid-base disturbances. Spirometric criteria that have been used to eliminate the need for arterial blood gases in asthmatic patients cannot be safely applied to patients with COPD. The finding of an arterial pH below that consistent with renal compensation for chronic respiratory acidosis implies either acute exaggeration of hypercapnia or acute metabolic acidosis.

Radiographic abnormalities are common in COPD exacerbation; therefore, radiographs should be strongly considered. [14] ECGs may reveal concurrent disease processes such as ischemia/acute myocardial infarction and signs of cor pulmonale, as well as arrhythmias such as multifocal atrial tachycardia. The theophylline level should be determined in patients whose regimen includes this mediation. Finally, other tests may be indicated to determine the etiology of the exacerbation.

TREATMENT

Chronic, Compensated COPD

The appropriate and optimal management of decompensated chronic airflow obstruction in an emergency department setting requires an appreciation of chronic day-to-day therapy. Specific management limits further insults to the respiratory system, treats reversible bronchospasm, and prevents or treats complications.

HEALTHY LIFESTYLE   Elements include regular exercise, weight control, and smoking cessation. Smoking cessation is the only therapeutic intervention that can reduce the accelerated decline in lung function. [15] Smoking cessation (along with long-term oxygen therapy) has been shown to reduce COPD mortality. [1,7,8,9 and 10] Pulmonary rehabilitation can improve exercise capacity and quality of life and is recommended in those patients with moderate to severe COPD. [16] All COPD guidelines recommend yearly influenza vaccination. [1,7,8,9 and 10] Although there is some controversy regarding the pneumococcal vaccine in COPD patients, it is

currently recommended by the ATS.[1,7,8,9 and 10,17]

OXYGEN   Both the British Medical Research Council (MRC) study and the National Heart, Lung, and Blood Institute's Nocturnal Oxygen Study have demonstrated that long-term oxygen therapy reduces COPD mortality. Oxygen must be started after arterial blood gases document a Pa_{O_2} of 55 mmHg or less, or a Pa_{O_2} between 56 and 59 mmHg when signs of cor pulmonale are present.[1]

PHARMACOTHERAPY   There is no evidence that pharmacotherapy can alter the progression of COPD. Inhaled b_2-adrenergic agents used on an as-needed basis may be prescribed for mild to moderately obstructed patients with intermittent symptoms. In those patients with persistent symptoms or in those patients refractory to b_2-adrenergic agents or bothered by side effects, ipratropium bromide is the drug of choice. With increasing symptoms, even after optimization of the above two classes of bronchodilators, theophylline may be helpful. Only about 20 to 30 percent of patients with COPD improve when given chronic oral steroids. [18] Initiating corticosteroid therapy requires careful analysis so as not to subject a nonresponder to the side effects unnecessarily. The European Respiratory Society Study on COPD showed no benefit of inhaled steroids—budesonide 400 μg twice daily—on the annual rate of decline of lung function. [19] Although some subgroups of patients with milder disease may benefit from inhaled steroids, even high doses were of no physiologic or functional benefit in patients with advanced COPD who were nonresponders to oral steroids.[20] Results from other studies using inhaled steroids in COPD are pending. Although some studies support the use of theophylline in stable COPD patients, most current COPD guidelines consider it only an adjunct therapy. [1,7,8,9 and 10]

MOBILIZATION OF SECRETIONS   Assurance of generous oral fluid intake and atmospheric humidification, avoidance of antihistamine/decongestant agents, and limitation of antitussive use help mobilize respiratory secretions. The efficacy of specific expectorant products is dubious.

Acute Exacerbations of COPD

The primary goal of emergency therapy in decompensated chronic airflow obstruction is to correct tissue oxygenation. This requires the restoration of the lungs as gas-exchange organs, assurance of hemodynamic efficiency, repletion of red blood cell mass where deficient, and limitation of excessive oxygen demands and carbon dioxide production. Factors that influence drug therapy in the emergency department include (1) the degree of reversible bronchospasm, (2) prior therapy of the patient, (3) recent drug usage and evidence of potential toxicity, (4) the ability of the patient to cooperate in taking inhaled medications, (5) the presence of contraindications to any drug or class of drugs, and (6) specific causes or complications related to the exacerbation.

OXYGEN   The first goal in the treatment of COPD is to correct or prevent life-threatening hypoxemia. The goal of oxygen therapy is correction of hypoxemia to an arterial oxygen pressure (Pa_{O_2}) of greater than 60 mmHg or an arterial oxygen saturation (Sa_{O_2}) of more than 90 percent. This can be accomplished in the emergency department through several devices, including the standard dual-prong nasal cannula, simple face mask, a Venturi mask, and finally a non-rebreathing mask with reservoir and one-way valve. The need to increase Pa_{O_2} must be balanced against the possibility of producing hypercapnia either by one of two suggested mechanisms: respiratory center depression or, more likely, ventilation-perfusion mismatching. [21] Hypercapnia in the face of insignificant acidosis can be tolerated. Improvement after administration of supplemental oxygen may take 20 to 30 min to achieve a steady state after a change in percent of oxygen administered (Fi_{O_2}) in patients with COPD. If adequate oxygenation is unachievable without progressive respiratory acidosis, then assisted ventilation may be required.

b_2-ADRENERGIC AGONISTS b_2-Adrenergic agonists remain the first-line therapy in the management of acute, severe COPD. Aerosolized forms are preferred because they minimize systemic toxicity. Limited data exist regarding the optimal dose and frequency of administration. According to ATS guidelines, b_2-adrenergic agents may be administered every 30 to 60 min, if tolerated.[1] Nebulized aerosols administered every 20 min may result in more rapid improvement of FEV_1, but the incidence of side effects is greater.[22] The use of subcutaneous epinephrine or terbutaline in patients with COPD should proceed with great caution because many COPD patients suffer from concurrent coronary artery disease.

Side effects of b_2-adrenergic agonists include tremor, anxiety, and palpitations, so such agonists should be used with care in elderly patients known to have coexisting heart disease. Pa_{O_2} may fall slightly after use of these agents, due to pulmonary vasodilation and resultant ventilation-perfusion mismatch.

ANTICHOLINERGICS   Anticholinergics have not yet been adequately assessed as first-step therapy in COPD. However, they are often favored when the history indicates poor responsiveness to b_2 agonists. Ipratropium bromide given by metered dose inhaler with a spacer or as an inhalant solution by nebulization (0.5 mg or 2.5 mL of the 0.02% inhalant solution) is the agent of choice. [18] Evidence suggests that the combination of a b_2-adrenergic agent and an anticholinergic agent may be more effective than albuterol alone in relieving bronchospasm during COPD exacerbation. [23] Repeat doses need not usually be given more often than every 4 to 8 h. Side effects are minimal and appear to be limited to dry mouth and an occasional metallic taste.

CORTICOSTEROIDS   There is no firm consensus for the use of systemic steroids in the treatment of COPD exacerbation. [1,7,8,9 and 10] The use of a short course (7 to 14 days) of systemic steroids appears effective in severe exacerbations of COPD with respiratory failure, but their role in mild-to-moderate exacerbations needs to be further delineated. [24] ATS guidelines acknowledge the lack of supporting evidence for the use of steroids in COPD exacerbation, but state that steroids can be useful when an asthmatic component is present.[1] A poor bronchodilator response does not preclude a good response to steroid therapy. Current theory holds that steroid responsiveness is on a continuum rather than an all-or-nothing phenomenon. If used, the optimal effective dose ranges between one and three times the maximal physiologic adrenal secretion rate (i.e., the equivalent of 60 to 180 mg prednisone).

ANTIBIOTICS   All current guidelines recommend antibiotics for the treatment of COPD exacerbation, especially if there is evidence of infection (e.g., fever, leukocytosis, change in the chest radiograph, abnormal mucus production). [1,7,8,9 and 10] Recent meta-analysis demonstrates a small, but statistically significant, benefit for antibiotics. [25] Proponents of antibiotic use believe antibiotics have both short-term benefits (i.e., rapid resolution of the symptoms of exacerbation, a rapid return of peak flow rates, avoidance of hospitalization, an early return to work, and prevention of progression of severe airway infection into pneumonia) and long-term benefits (i.e., breaking the vicious cycle of airway infection, inflammation, and loss of lung function; prolonging the time between exacerbations; and preventing secondary infection by resistant organisms). They argue further that differentiating infected from noninfected patients is difficult. Antibiotic choices include macrolides, cephalosporins, trimethoprim-sulfamethoxazole, and the latest-generation fluoroquinolones.

METHYLXANTHINES   The role of aminophylline in the treatment of COPD exacerbation remains controversial. ATS guidelines suggest adding theophylline if aerosol therapy cannot be given or proves inadequate.[1] The bronchodilation effect of aminophylline is limited, and its therapeutic range is narrow. A review of the literature reveals a significant effect on spirometry, respiratory muscle strength, resting blood gases, improvement in the sensation of dyspnea, quality of life, cardiac output, and pulmonary vascular resistance, as well as an anti-inflammatory effect. [26] Other study data suggest that aminophylline increases the toxicity but not the efficacy when treating patients with b_2-adrenergic agonists.[27]

In most patients, a serum level of 8 to 12 μg/mL is appropriate. The intravenous loading dose usually required to obtain an initial serum concentration of 10 μg/mL (10 mg/L) is 5 to 6 mg/kg ideal body weight in patients not currently receiving the drug. In patients regularly taking theophylline, a miniloading dose may be alternatively selected: (target concentration – currently assayed concentration) × volume of distribution (i.e., 0.5 times ideal body weight in liters). With the miniload method, the target concentration should be between 10 to 15 μg/mL. The intravenous maintenance infusion rate is 0.2 to 0.8 mg/kg ideal body weight per hour. Lower maintenance rates are given to patients with congestive heart failure or hepatic insufficiency with low clearance rates, whereas higher rates are given to smokers with rapid clearance.

Maintenance theophylline infusion in patients on chronic oral therapy is complex (whether or not a miniloading dose has been given), particularly in attempting to account for enteric drug yet to be absorbed. Both loading and maintenance doses may need to be reduced to minimize the risk of "summation toxicity" due to continued enteric absorption. Standard-release preparations may continue to be absorbed for up to 6 h, and sustained-release preparations may require up to 12 h. Therefore, maintenance infusion rates should be reduced for 6 h after ingestion of a standard-release formulation and 12 h after ingestion of a sustained-release preparation (including 24-h-release forms). Theophylline and aminophylline should not be given orally in an emergency setting unless decompensation is not severe, alimentary motility is assured, and forthcoming ambulatory care is imminent.

ASSISTED VENTILATION   Mechanical ventilation is indicated in patients with COPD exacerbation if there is evidence of respiratory muscle fatigue, worsening respiratory acidosis, deteriorating mental status, and in those with clinically significant hypoxemia refractory to supplemental oxygen by usual techniques. The main goals of assisted positive-pressure ventilation in acute respiratory failure complicating COPD are the resting of ventilatory muscles and the restoration of gas

exchange to a stable baseline.[1]

Mechanical ventilation is uncomfortable and is associated with a variety of complications including nosocomial pneumonia, sinusitis, pneumothorax, and injury to the trachea and larynx. There are three specific pitfalls in ventilating patients with COPD: (1) overventilation resulting in acute respiratory alkalosis, (2) initiation of complex pulmonary and cardiovascular interactions that may result in systemic hypotension, and (3) creation of intrinsic positive end-expiratory pressure (PEEP), especially if expiratory time is inadequate or if dynamic airflow obstruction exists. [1] The three ventilatory modes most widely used for managing patients with COPD are assist-control ventilation (ACV), intermittent mandatory ventilation (IMV), and pressure support ventilation (PSV). There are some clinical reports that PSV provides increased patient comfort, promotes patient synchrony with the ventilator, and may accelerate weaning, but there is no direct evidence that patient outcome is improved with pressure support modes compared with volume-cycled modes of mechanical ventilation.[1]

Noninvasive positive-pressure ventilation (NPPV) is a term used to describe delivery of gas under positive pressure to the airways and lungs without insertion of an endotracheal tube. It can be delivered via a nasal mask, full face mask, or mouthpiece. NPPV can provide positive pressure to the airways only during inspiration (inspiratory positive airway or IPAP), or the airway pressure can be maintained continuously at the same level (continuous positive airway pressure or CPAP), or NPPV can be delivered so that the airway pressure is higher during inspiration than during expiration, with end-expiratory pressure maintained above atmospheric (bilevel ventilation or BiPAP). [28] NPPV can be delivered using assist-control volume-cycled ventilation, assist-control pressure ventilation, and pressure support ventilation, with or without end-expiratory positive pressure. No particular mode of ventilation or ventilatory device has been shown to be clearly superior. [29] Disadvantages of NPPV include slower correction of gas-exchange abnormalities, risk of aspiration, inability to control airway secretions directly, and possible complications of gastric distension and skin necrosis. [29] Contraindications to the use of NPPV include an uncooperative or obtunded patient, inability of the patient to clear airway secretions, hemodynamic instability, and major gastrointestinal bleeding. [28] Studies suggest a pooled success rate of 76 percent in patients with acute respiratory failure complicating COPD, but the studies consist of small numbers, and failure rates of up to 40 percent have been reported in some studies. [1]

OTHER   Tissue oxygen delivery must be maximized by correcting left ventricular failure or arrhythmia to improve cardiac output, replacing red blood cell mass and intravascular fluid to increase arterial oxygen content, and suppressing fever to decrease oxygen consumption.

Future Considerations/New Therapies

Bronchodilators play an important role in the long-term management of patients with COPD, but they do not alter the progression of COPD. Major advances include the development of long-acting b_2-adrenergic agents, such as salmeterol and formoterol, and anticholinergic agents, such as tiotropium bromide. Tiotropium bromide has the benefit of once-daily dosing. Inflammation is being investigated more closely in the pathogenesis of COPD, especially the role of neutrophils. [30] Corticosteroids, chemokine (interleukin 8) inhibitors, leukotriene B $_4$ inhibitors, adhesion molecule inhibitors, and phosphodiesterase inhibitors are being studied with the goal of inhibiting neutrophil activity. Surfactant replacement is also under investigation. Evidence suggests that the imbalance between proteases in COPD patients may be restored either by inhibiting proteolytic enzymes, such as neutrophil elastase inhibitors, cathepsin inhibitors, matrix metalloproteinase inhibitors, and secretory leukoprotease inhibitors, or by increasing antiproteases, such as a $_1$-antitrypsin. Evidence also exists that oxidative stress is increased in patients with COPD, and that reactive oxygen species are involved in the pathogenesis of COPD. Therefore, antioxidants such as N-acetyl cysteine and spin-trap antioxidants such as a-phenyl-N-tertbutyl nitrone may be useful. Pulmonary vasodilators, such as prostacyclin analogues, nitric oxide donors, endothelial antagonists, and angiotensin antagonists, are being studied in the hope of preventing the progression of pulmonary hypertension and cor pulmonale. Mucoregulators, such as tachykinin antagonists, sensory neuropeptide-release inhibitors, mediator and enzyme inhibitors, MUC gene suppressors, and mucolytic agents, may inhibit the hypersecretion of mucus, without affecting normal mucus secretion and normal mucociliary clearance.

DISPOSITION

Admission Criteria

Patients with acute exacerbation of COPD require admission to the hospital if they fail to improve adequately or deteriorate in spite of medical therapy, if they have significant comorbid illnesses, or they are without an intact social support system at home. The primary goals of hospitalization are to manage the acute exacerbation, prevent further deterioration, and educate patients on the nature the disease, current use of medications, and how to deal with the limitations presented by the disease and future exacerbations.

Objective criteria regarding hospital admission, observation unit stay, and emergency department discharge are lacking. Patients with an FEV $_1$ of 40 percent or more predicted or no clinical evidence of respiratory distress after treatment have a low rate of relapse and may be safely discharged home. [31] The ATS has developed consensus indications for hospitalization of patients with COPD (Table 65-1).

TABLE 65-1   Indications for Hospitalization for COPD Exacerbation

Discharge

Patients with acute exacerbation of COPD have less pulmonary reserve, are more likely to have comorbid diseases, and respond less readily to treatment than patients with acute exacerbations of asthma. Thus, more patients with COPD will likely require admission and, if discharged, more likely relapse. Thus, efforts should be made to ensure success with individuals being discharged with outpatient treatment: (1) adequate supply of home oxygen, (2) adequate and appropriate bronchodilator treatment, and (3) arranged follow-up with their physician.

66 THE LUNG TRANSPLANT PATIENT

Thomas P. Noeller

Since the first successful single-lung transplant in 1983 followed by the first successful double-lung transplant in 1986, lung transplantation has become a viable therapeutic modality for end-stage pulmonary disease. Currently 89 centers perform lung transplants in the United States, and in 1997, a total of 942 patients underwent lung transplant nationally.[1] On December 31, 1997, the United Network for Organ Sharing listed 2664 patients on a waiting list for lung transplantation and noted that 409 patients had been removed from a waiting list owing to death during that year. For the most recent year that full data are available, the median waiting time for lung transplantation during 1996 was 566 days after being placed on a waiting list.[2] Overall, survival rates as of September 1997 were 91 percent at 1 month and 77, 58, and 43 percent at 1, 3, and 5 years, respectively.[2] The long-term survival rates were slightly higher at centers performing more than 30 lung transplants per year. Single and double lung transplants as well as heart-lung transplants are most commonly performed for cystic fibrosis, idiopathic pulmonary fibrosis, and emphysema, including alpha$_1$-antitrypsin deficiency. Congenital heart disease and Eisenmenger complex may also be indications for heart-lung transplantation.

MANAGEMENT OF PRETRANSPLANT PATIENTS

Pretransplant patients are likely to present with exacerbations of their underlying disease; assessment and management should be targeted to these processes. The transplant coordinator should always be contacted early in the course of evaluation and treatment to aid in timely disposition (Table 66-1).

Pretransplant patients
  Respiratory failure
  Infiltrate
  Systemic infection
  Congestive heart failure or pulmonary edema
  Pneumothorax

Posttransplant patients
  Respiratory failure
  Acute rejection
  Rapidly progressive airflow limitation
    (FEV, fall of >10% over 48 h)
  Infiltrate
  Systemic infection
  Febrile neutropenia
  Pneumothorax

TABLE 66-1   Indications for Hospital Admission

The patient's vital signs, particularly the respiratory rate, should be assessed immediately, along with pulse oximetry and physical examination for the presence of cyanosis, diaphoresis, use of accessory muscles, signs of congestive heart failure, and adequacy of peripheral perfusion. Supplemental oxygen should be applied, intravenous access obtained, and the patient placed on a cardiac monitor. A chest radiograph should be obtained to identify infiltrates or pneumothorax and arterial blood gases may also have to be tested. b$_2$ Agonists, anticholinergics, and antibiotics should be given as indicated.

Although the perioperative use of corticosteroids was formerly considered to be a contraindication to transplantation, this is changing somewhat. A maintenance dose of 0.2 to 0.3 mg/kg/day of prednisone is acceptable to most centers. If it is felt that a patient requires a corticosteroid burst or an increase in the maintenance dose to treat an acute exacerbation, the transplant coordinator should be contacted. A dose of prednisone greater than 20 mg/day may result in the patient being suspended from the transplant list until such time that the dose can safely be tapered down to 20 mg/day or less. In primary pulmonary hypertension (PPH) and Eisenmenger complex, consideration should be given to therapies that may help to decrease pulmonary vascular resistance, such as morphine sulfate, nitrates, and furosemide. For patients with respiratory failure, noninvasive ventilation or endotracheal intubation with mechanical ventilation may be required, increasing the risk of barotrauma. Ventilator dependence has generally been regarded as a relative contraindication to lung transplantation. Successes have been reported, but ventilator-dependent patients have a much higher mortality after transplantation.

Idiopathic pulmonary fibrosis (IPF) is a common indication for lung transplantation and carries with it the most dismal prognosis. Patients presenting with exacerbations of their disease in the pretransplant phase generally have a worse prognosis. Treatment with high-dose steroids is rarely successful at achieving a remission, and supportive therapy is the mainstay of acute management. The transplant team may recommend cytotoxic drugs such as cyclophosphamide and azathioprine for their steroid-sparing effect.

Chronic infection, especially common in patients with cystic fibrosis (CF), is a major issue with regard to eligibility for transplantation. CF patients tend to be infected with multiple organisms by the time transplantation is considered. The most common organisms include *Pseudomonas* sp., *Burkholderia cepacia, Aspergillus,* and nontuberculous mycobacteria. *Aspergillus* and mycobacterial infections have not been associated with worse outcomes in posttransplant patients. However, infection with *B. cepacia* and panresistant *Pseudomonas* sp. has been associated with poor outcomes and is considered a contraindication to transplantation in some centers. Therefore, emergency physicians need to pay particular attention to infection-control measures and antibiotic selection in pretransplant CF patients. Generally, those patients requiring antibiotics for acute infections require admission for broad spectrum, multiple-drug regimens to prevent the development of panresistant strains.

In patients with PPH, survival correlates with New York Heart Association (NYHA) classification. Recently, prostacyclin was approved for treatment of NYHA class III or IV patients, in whom it has been shown to improve hemodynamics, exercise tolerance and survival. Calcium-channel blockers have been the mainstay of treatment for NYHA class I and II patients for some time. Those patients who fail medical therapy are subsequently listed for transplant. In the acute setting, treatment with agents that may reduce pulmonary vascular resistance—including morphine, nitrates, and furosemide—may help provide stabilization in addition to other supportive measures and identification of precipitating factors.

MANAGEMENT OF POTENTIAL DONORS

Identification and early management of potential donors has become part of the practice of emergency medicine. The establishment of brain death is generally not done in the emergency department (ED); however several steps need to be taken to maximize organ retrieval in appropriate patients. Most organ procurement organizations (OPOs) work closely with their local EDs, providing education in the various facets of organ procurement. Early communication with the OPO is encouraged, as it can help to identify factors that may qualify or disqualify a potential donor, provide assistance in speaking with families about organ donation, and guide the clinicians through the entire complicated process.

Initial management is centered around maintaining the integrity of potential donor lungs by optimizing hemodynamics and preventing aspiration. Accepting centers generally require a clear chest radiograph, Pa$_{O_2}$>450 mmHg on 100% Fi$_{O_2}$, and no obvious infection on bronchoscopic evaluation. Mechanical ventilation should maintain arterial P$_{O_2}$>80 mmHg, P$_{CO_2}$ between 35 and 45 mmHg, and a pH between 7.30 and 7.45. Hemodynamics should be monitored, with a desirable central venous pressure >10 mmHg. If systemic blood pressure cannot be maintained with fluid resuscitation alone without causing pulmonary edema, then dopamine may be

used. Transfusions may be used to maintain a hematocrit >30% to optimize tissue oxygenation. However, it is crucial to specify the use of blood that is cytomegalovirus (CMV)-negative blood so as not to infect a CMV-negative recipient.

MANAGEMENT OF POSTTRANSPLANT PATIENTS

Transplant patients are managed by a multidisciplinary team comprising transplant surgeons, pulmonologists, nurse coordinators, pharmacists, physical therapists, dietitians, psychologists, and social workers. At each transplant center, a nurse coordinator is on call to address concerns regarding the care of posttransplant patients in the ED. Patients tend to be well educated and well informed about their disease, but the nurse coordinator may be able to provide additional information regarding recent infection history, medication doses, rejection history, and potential complications in a specific patient. Coordinators should always be called early in the course of patient assessment and management.

Posttransplant patients are at risk for several complications related to their underlying disease, medication side effects, and immunocompromised state. Most centers use cyclosporine, azathioprine, and prednisone for maintenance immunosuppression. In addition, prophylaxis against *Pneumocystis carinii* pneumonia is undertaken with trimethoprim-sulfamethoxazole (TMP-SMX). Prophylaxis against herpes simplex virus (HSV) and CMV is indicated based on the specific immunologic status of the donor and recipient. Patients learn to measure their pulmonary function (FEV_1 and FVC), systemic blood pressure, and temperature daily. They carry a diary with daily vital signs, present medications and doses, names of hospital contacts, and guidelines for contacting the nurse coordinator. Bronchoscopy is necessary to diagnose subclinical rejection and infection. Each transplant center has a protocol concerning bronchoscopy indications. Common warning signs of a fever (>37°C), cough, sputum, or FEV_1 decline >10 percent for over 48 h would prompt a call or visit to the transplant center. Since most patients return to their home communities 2 to 3 months following surgery, they may initially be treated and stabilized in their hometown ED prior to transfer back to the transplant center.

The most frequent complications in the lung transplant patient presenting to the ED are infection and rejection, and they are difficult to differentiate clinically. The patient should be placed in respiratory isolation. Initial assessment is similar to that in the pretransplant patient with regard to stabilization and supportive care. In addition to the standard evaluation of airway, respiratory, and circulatory status, initial assessment should include a chest radiograph, arterial blood gas, complete blood count with differential, serum electrolytes, magnesium, creatinine, and cyclosporine level.

Early Complications

REJECTION   Acute rejection is common and may occur three to six times in the first postoperative year. After the first year, the frequency of acute rejection is decreased, but rejection can still be seen several years after transplant. Early after transplant, the diagnosis of rejection is based on clinical parameters. Signs of rejection include cough, chest tightness, fever (>0.5°C above baseline), hypoxemia, decline in FEV_1 (>10%), and the development of infiltrate on the chest radiograph. Radiographic abnormalities are less common more than 6 weeks posttransplant, and an acute rejection episode may actually be "radiographically silent" after this time period. Clinically, acute rejection may be difficult to distinguish from infection. Therefore, bronchoscopy with transbronchial biopsy is frequently necessary to make the definitive diagnosis. During episodes of acute rejection in patients with single-lung transplants, there is a proportional decrease in blood flow to the transplanted lung, which can be monitored with radionucleotide perfusion scans.

Acute rejection is treated with large doses of intravenous methylprednisolone, 500 to 1000 mg on day 1, followed by 500 mg IV qd for 2 days. Clinical response is gauged by improvements in oxygenation, spirometry and radiographic appearance and can be expected to occur within 24 to 48 h after treatment is initiated. Failure to do so should suggest infection as an alternative diagnosis. Following clinical improvement, the maintenance dose of prednisone is increased, with a slow taper back to baseline.

INFECTION   Infectious complications are the most common cause of morbidity and mortality in lung transplant patients. Infections may be due to bacteria, fungi, or viruses and most commonly affect the allograft. Bacterial pneumonia is the most common complication in the first 3 months after transplant due to decreased mucociliary clearance, diminished cough reflex, disrupted lymphatics, reperfusion injury, and immunosuppression. Late or recurrent infections are associated with an increased risk of developing obliterative bronchiolitis. Besides airborne transmission, a common route of transmission is from the donor lung. The vast majority of washings from a donor before retrieval will grow at least one organism. Perioperative antibiotics based on culture and sensitivity results have decreased the rate of invasive infection significantly. Infection with panresistant *Pseudomonas* sp. or *B. cepacia* is associated with increased morbidity and mortality and is generally associated with a higher risk of obliterative bronchiolitis. *P. carinii* pneumonia is now rare due to common prophylaxis with TMP-SMX. Other commonly encountered infectious agents include gram-negative and gram-positive bacteria, *Mycobacterium* sp., *Aspergillus*, CMV, HSV, and Epstein-Barr virus (EBV).

CMV is the most commonly encountered viral agent implicated in posttransplant pulmonary infection. Its clinical spectrum is broad, ranging from asymptomatic shedding to CMV pneumonitis. The risk of infection is directly related to the donor's and recipient's pretransplant immune status. Donor-positive, recipient-negative status is universally associated with the development of CMV infection in the recipient unless aggressive prophylaxis is undertaken with ganciclovir, acyclovir, and intravenous immunoglobulin. If the recipient is CMV-positive, a regimen of ganciclovir followed by acyclovir is used. If the donor and recipient are CMV-negative and either the donor or recipient is HSV-positive, acyclovir only is used. CMV matching has not altered long-term outcome in lung transplant patients, so most centers will transplant regardless of CMV status.

CMV infections occur most commonly between 14 to 100 days posttransplant and manifest as anything from a flulike syndrome to severe multisystem disease including pneumonitis, hepatitis, bone marrow suppression, gastritis, and colitis. Key laboratory features include neutropenia with or without thrombocytopenia, conversion of anti-CMV IgM to positive, and positive CMV cultures from urine, buffy coat, or bronchoalveolar lavage. Definitive diagnosis of CMV pneumonitis requires histopathologic confirmation of tissue obtained by transbronchial biopsy. After confirmation of diagnosis, treatment with ganciclovir or foscarnet is indicated. CMV pneumonitis may be complicated by acute rejection or by bacterial or fungal pneumonia.

Other viral agents, particularly HSV and EBV, have been implicated in posttransplant infections. HSV has a similar presentation to CMV, with diagnosis based on viral culture and differential staining of biopsy specimens. Treatment is with acyclovir. EBV may present as a mononucleosis-type syndrome but is also associated with the development of posttransplant lymphomas.

Fungal infections are less common, but carry a relatively high risk of associated morbidity and mortality. *Candida albicans* is a common airway colonizer but a much less common pathogen. Systemic candidiasis is usually associated with prolonged courses of broad-spectrum antibiotics. The treatment for *C. albicans* is fluconazole, but other *Candida* species may require treatment with amphotericin *B. Aspergillus* sp. may also colonize the airways; this does not require treatment unless associated with invasive disease, evidenced by ulcerations, or histologic evidence of invasion. Itraconazole with amphotericin B is frequently successful in treating early infections, but disseminated disease is usually fatal.

Lung transplant patients are subject to bacterial endocarditis because during the transplant operation the donor pulmonary veins are attached to the atrium by the establishment of a cuff. Therefore, antimicrobial prophylaxis is necessary before dental and other invasive procedures.

OTHER PULMONARY COMPLICATIONS   Airway dehiscence and stenosis are now uncommon postoperative complications. Airway dehiscence, if it occurs at all, is likely to appear within 3 weeks of transplantation, while the patient is still in the hospital. It can be managed expectantly if an omental wrap was used and the omentum is intact. Bronchial stenosis can occur, limiting clearance of secretions and leading to pneumonia. Treatment is with stenting or laser therapy. Spontaneous pneumothorax necessitates the placement of a thoracostomy tube and evaluation of the airways by bronchoscopy.

MEDICATION EFFECTS   Various induction agents are used in the perioperative and immediate postoperative period. These include high-dose corticosteroids and T-cell lytic therapy with equine-derived antithymocyte globulin (ATGAM), a polyclonal thymocyte preparation, or OKT-3, a murine monoclonal antibody. The most common posttransplant immunosuppressives include cyclosporine, azathioprine, and prednisone. Major side effects of these medications are summarized in .

Cyclosporine
  Nephrotoxicity
  Neurotoxicity
  Hyperkalemia
  Hyperuricemia
  Hypertension
  Anemia
  Hyperbilirubinemia
  Cholestasis
  Gastric dysmotility
  Hirsutism
  Hypercholesterolemia

Prednisone
  Cushing syndrome
  Osteoporosis
  Adrenal suppression
  Hypertension
  Hyperglycemia
  Peptic ulcer disease
  Myopathy
  Cataracts
  Poor wound healing

Azathioprine
  Leukopenia
  Thrombocytopenia
  Cholestatic jaundice
  Alopecia

*Avoid NSAIDs and drugs metabolized by the P-450 system.

TABLE 66-2   Medication Side Effects*

Both glucocorticoids and cyclosporine can exacerbate glucose intolerance, worsen osteoporosis, and cause myopathy and systemic hypertension. Commonly, chronic cyclosporine use at the levels employed in lung transplant immunosuppression results in renal insufficiency by decreasing renal blood flow and by a direct effect on the renal tubules, causing in hyperkalemia and hypomagnesemia. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided, since these will act synergistically with cyclosporine to further reduce glomerular filtration. The major side effect of azathioprine is bone marrow suppression. Neutropenia may often result from either azathioprine or CMV infection.

Drugs that are metabolized by the P-450 system will interact with cyclosporine metabolism. Drugs that induce these enzymes (e.g., phenytoin, rifampin, and phenobarbital) may lower cyclosporine levels acutely, possibly precipitating rejection. Drugs that inhibit cyclosporine metabolism (e.g., erythromycin, ketoconazole, cimetidine, and the calcium-channel blockers) may lead to elevation of cyclosporine levels into the toxic range and should be avoided unless appropriate changes in cyclosporine dosing are made to compensate.

Late Complications

OBLITERATIVE BRONCHIOLITIS   The most frequent cause of death after the second posttransplant year is obliterative bronchiolitis (OB), characterized by chronic allograft dysfunction and airflow limitation. Current evidence suggests that chronic rejection plays the most important role in the development of OB, but other factors such as CMV infection, toxic fume inhalation, and chronic foreign-body exposure caused by abnormal mucociliary clearance may contribute as well. Diagnostically, the yield from bronchoscopy and biopsy is low. Therefore, diagnosis rests on clinical criteria (i.e., > 20 percent fall in FEV_1 without any other identifiable cause). Since the large airways become bronchiectatic as the small airways are obliterated, episodes of bacterial bronchitis are common. Typically the chest radiograph is clear of infiltrates. Current treatment is augmentation of immunosuppression and high-dose steroids. The prevalence of OB syndrome in long-term survivors is 20 to 50 percent. The course of the disease is highly variable, with some patients stabilizing at a lower level of pulmonary function and others progressing to respiratory failure and death.

Posttransplant Lymphoproliferative Disease (PTLD)

PTLD can be a consequence of T-cell suppression with long-term cyclosporine use. The overall incidence in lung transplant patients is approximately 8 percent. The disease tends to occur with primary EBV infection following lung transplant. Because younger patients are more likely to be EBV-negative at the time of transplantation, they tend to develop EBV infection and PTLD at a higher rate. Presenting features include isolated lymphadenopathy, painful otitis media (secondary to tonsillar involvement), or a viral-like syndrome. PTLD within 1 year of transplantation is usually localized and can be successfully treated with reduced immunosuppression and high-dose acyclovir, with a relatively good prognosis. In contrast, PTLD after 1 year tends to be disseminated, unresponsive to treatment, and usually fatal.

67 PULMONARY IMAGING

Janet M. Poponick

Imaging of the chest is common practice in the emergent evaluation of patients with dyspnea, chest pain, or trauma. This chapter reviews the indications and limitations of various techniques useful in emergency medicine, including the plain chest radiograph, ventilation-perfusion scans, computed tomography, and echocardiography. The value of a study depends on the technical quality of the procedure and the ability of the physician to interpret the image. Although many studies and findings may have excellent interobserver reliability, others do not. Thus, clinical decisions should be based on knowledge of the value and limitations of image interpretation.

PLAIN RADIOGRAPHY

Chest radiography, which is the most commonly ordered radiologic examination, evaluates the lung parenchyma, cardiac and mediastinal size, and the bony structures of the chest wall. The examination is preferably done in the radiology department with the patient in the standing position. This is the standard posterior-anterior (PA) view (the beam of the x-ray passes posterior to anterior). The patient must be able to take a deep breath and hold while the picture is taken. A "good inspiration" is defined as visualizing the ninth rib above the diaphragm. Adding the lateral film visualizes the posterior lung bases and the retrosternal area, and also helps to localize infiltrates and masses anatomically.

For unstable patients, portable chest radiography is performed at the bedside, with patients sitting upright. Portable chest radiography is limited by the low power of the equipment and variations in radiographic technique. The bedside study is obtained as an anterior-posterior (AP) view (the x-ray beam passes anterior to posterior) and thus magnifies the mediastinal structures. For a trauma victim on a backboard, the portable film may be more difficult to interpret. Skinfolds and clothing under a patient may mimic a pneumothorax. Supine chest radiographs will detect only 40 percent of pneumothoraces,[1] because air rises anteriorly, making the diagnosis of a small pneumothorax very difficult. Likewise, fluid collections layer posteriorly in supine patients, causing a diffuse haziness in the lung fields, which can be confused with infiltrate or contusion. Therefore, chest radiographs are limited by a patient's overall condition, the patient's ability to cooperate with directions, and the technique chosen. The PA and lateral chest radiographs remain the best views.

The chest radiograph should be systematically analyzed so as not to miss key information. To ensure that the radiograph is of the correct patient, always identify the study by patient name. Assess the technique and the quality of the study. In a good-quality study, the trachea is visible in the midline, the medial borders of the clavicle are centrally located over the superior mediastinum, and the thoracic spine is visible through the mediastinal structures. Note the positioning of all lines, the endotracheal tube, and the nasogastric tube. The trachea should be followed to the left and right main-stem bronchi and to the mediastinal structures. Look at the mediastinum for evidence of free air, for density behind the heart, and for cardiac size (which should be less than 50 percent of the thoracic size). Assess position of the diaphragms, looking at position, contour, and subdiaphragmatic free air: the right hemidiaphragm should be slightly elevated compared with the left (0.5 to 2.5 cm is normal). Assess the lung fields and pleura, looking for masses, infiltrates, free air, or effusions. Finally, assess the soft tissue and bones, looking for subcutaneous air or fractures.

Other views may be obtained. The most useful is the *expiratory* film, which may accentuate a free air-lung interface, enabling a small pneumothorax to be diagnosed. Up to 10 percent of small pneumothoraces may be missed in inspiratory film alone.[2] In foreign-body aspiration, the expiratory film shows hyperinflation on the affected side as air is trapped behind the foreign body. The *lateral decubitus* film may be useful to assess a pleural effusion, because free fluid will layer along the dependent portion of the chest.

Specific abnormalities to note on the chest radiograph are pulmonary edema, infiltrates, lung nodules and masses, hilar size and contour, cardiac size and configuration, pleural effusions, and pneumothorax.

VENTILATION-PERFUSION SCANS

The ventilation-perfusion ($\dot{V}/\dot{Q}$) scan is performed on patients with suspected pulmonary embolism (PE). The study has a low incidence of adverse reactions, is noninvasive, and requires no advance preparation.[3] However, it is performed outside of the ED, limiting its use in unstable patients.

The $\dot{V}/\dot{Q}$ scan is a two-step process. First, the ventilation portion of the examination is performed with the patient breathing an aerosolized solution of technetium 99m (^{99m}Tc) diethylenetriaminepentaacetic acid (DTPA). The aerosol is deposited deep into the lungs in proportion to alveolar ventilation. Images are obtained from different projections. The second step is the perfusion study in which ^{99m}Tc-macroaggregated albumin is injected intravenously and becomes trapped within the pulmonary circulation. Again, images are obtained with the patient in multiple positions. Usually, the procedure is quite simple and the test can be finished in 1 h. Procedural problems arise when a patient is unable to lie still. The ventilation study may be limited if a patient cannot take a deep breath or follow instructions or is on a ventilator.

Diagnosis of PE on $\dot{V}/\dot{Q}$ scan is based on documenting perfusion defects in an area of normal ventilation, a *mismatched defect*. Perfusion defects in areas of associated ventilation abnormalities are probably due to vasoconstriction secondary to hypoxia. Such *matched defects* may be due to pneumonia, asthma, or chronic obstructive pulmonary disease. Underlying pulmonary pathology causes abnormalities in both ventilation and perfusion, making interpretation difficult.

The $\dot{V}/\dot{Q}$ scan is reported in terms of probability, correlating the findings of the $\dot{V}/\dot{Q}$ scan with the chest radiograph. Clinicians should understand the definitions for high, intermediate, and low probability used by radiologists when reporting the results of a $\dot{V}/\dot{Q}$ scan (Table 67-1).[4,5] The PIOPED study found that the clinical utility of a $\dot{V}/\dot{Q}$ scan was enhanced when used in conjunction with clinical suspicion of embolism (Table 67-2).[6] For example, if the clinical suspicion for PE is high but the $\dot{V}/\dot{Q}$ scan interpretation is low probability, the probability that a patient may still have PE is 40 percent. Many emergency department patients fall into the intermediate category for clinical suspicion, where a low probability scan does not exclude PE. In this category, 16 percent of the PIOPED study patients had angiographically proven embolism.[6]

High probability	Two or more large segmental mismatches
	One large plus two or more moderate mismatches
	Four or more moderate mismatches
Intermediate probability	One moderate segmental mismatch plus one large mismatch
	Up to three moderate mismatches
	One moderate mismatch
	Unable to categorize as low or high probability
Low probability	Multiple matched defects with some areas of normal perfusion
	Nonsegmental perfusion defect
	Chest radiograph abnormality larger than the perfusion defect
	Normal chest radiograph with small perfusion defects
Normal	No perfusion defects
	Perfusion outlines the shape of the lungs seen on chest radiograph

TABLE 67-2   Prevalence of Pulmonary Embolism as Compared with Angiographic Results or Outcome in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) Trial (Percent)

The $\dot{V}/\dot{Q}$ scan is most useful when it is either normal or high probability. A normal lung scan has a 4 percent overall probability of a PE; 96 percent of the PIOPED study patients did not have the condition.[6] Unfortunately, normal findings on a $\dot{V}/\dot{Q}$ scan are unusual; only 14 percent of patients in the PIOPED study had normal scan findings. A high-probability scan had an 87 percent overall probability of a PE; the 13 percent of high-probability scans that were later found to have normal pulmonary angiograms were false positive, possibly due to vasculitis or neoplasm.[3,6] Again, a high-probability $\dot{V}/\dot{Q}$ scan is uncommon; only 13 percent of the PIOPED patients had a high-probability scan.[6] The majority of patients undergoing $\dot{V}/\dot{Q}$ scanning will have intermediate- and low-probability scans. The major difficulty in interpreting a $\dot{V}/\dot{Q}$ scan occurs in those with underlying pulmonary disease, such as asthma and emphysema, which alters both ventilation and perfusion. Pretest chest radiographs aid radiologists in such cases. For example, patients with matched defects on $\dot{V}/\dot{Q}$ scan and a corresponding infiltrate on plain chest film may have pneumonia or pulmonary infarct. There is some literature comparing the size of matched defects with the size of the infiltrate on chest radiograph to classify the likelihood of embolism.[7]

Although $\dot{V}/\dot{Q}$ scans remain a common initial test for PE, many patients require further testing, especially those with intermediate or high clinical suspicion and intermediate- or low-probability $\dot{V}/\dot{Q}$ scans.

PULMONARY ANGIOGRAPHY

Pulmonary angiography remains the gold standard for accurately diagnosing PE. The disadvantages include patient discomfort, cost, and complications. Pulmonary angiography has excellent interobserver reliability: the PIOPED study found that review of study angiograms by another radiologist reached the same diagnosis in 96 percent of cases.[8] Complications of pulmonary angiography include (1) fatalities in 0.5 percent, (2) major nonfatal complications such as renal failure, significant hematoma, or respiratory distress in 17 percent, and (3) minor complications such as angina, urticaria, or bronchospasm in 5 percent.[8]

A pulmonary angiogram is performed by a flexible catheter advanced from a peripheral large vein (typically the femoral vein) through the right atrium and ventricle, and into the pulmonary artery. Selective injections of contrast media are made into the lobar pulmonary arteries by using the results of the $\dot{V}/\dot{Q}$ scan to guide which lobar arteries should be inspected first.

A PE is identified by either an abrupt cutoff of dye with a meniscus or contrast media traveling around an intraluminal thrombus. Narrowing or luminal irregularities can be caused by other processes and are not considered diagnostic for PE. Pulmonary angiography can identify emboli out to the subsegmental divisions, beyond the reliability of either $\dot{V}/\dot{Q}$ scanning or dynamic computed tomography (CT).

COMPUTED TOMOGRAPHY

CT provides sharp cross-sectional anatomic displays, which enable identification of fluid collections and distinction between soft tissue structures. It eliminates overlap of tissues and thus delineates mediastinal structures very well. A recent upgrade in technology has allowed the scans to be completed more quickly and has the added advantage of being able to evaluate the vasculature by using dynamic and helical techniques.

In the ED, CT scans are useful in assessing the mediastinum to exclude a mediastinal hematoma or aortic injury after blunt trauma, in assessing acute chest pain to exclude the diagnosis of aortic dissection, or in investigating larger pulmonary emboli in unstable patients.

The disadvantages of chest CT include cost, radiation exposure, and adverse reactions to intravascular contrast media. Transporting unstable patients is never easy, but can usually be done safely with monitoring and appropriate personnel accompanying the patient.

Blunt trauma to the chest and abdomen often requires further evaluation by CT. With chest radiographs of supine patients, pneumothorax may be difficult to visualize and be seen only on the upper cuts of the abdominal CT scan.[1] The abdominal CT is done with windows through the lower chest and delineates the air-lung interface very well, identifying even a small pneumothorax.

Aortic injury in the setting of decelerating trauma is suspected by findings on the initial AP chest radiograph of supine patients. Criteria found suggestive of aortic injury include mediastinal widening (greater than 8 cm at the T_4 level), deviation of the nasogastric tube or endotracheal tube to the right, loss of the aortic knob contour, apical capping, or fractures of any of the first three ribs.[9,10] However, the most sensitive finding for aortic injury was the subjective impression of mediastinal widening by the physician viewing the radiograph.[9] When these findings are noted on the chest radiograph, emergent aortography has been used to accurately visualize the aorta and define any injury. However, using sensitive criteria to avoid missing this catastrophic injury means that about 90 percent of aortograms performed to evaluate patients for potential aortic injury are normal. To reduce the incidence of normal studies, some clinicians will attempt to sit the patient up and perform an upright AP or PA chest radiograph before deciding whether there are findings of mediastinal injury.[11] Not all patients can be sat upright, however, and a decision has to be made regarding another imaging study. Two studies have come into clinical practice: transesophageal echocardiography (TEE) and dynamic CT scan.

Dynamic CT scanning with intravenous contrast can be useful, especially in stable patients with possible aortic injury.[12,13 and 14] The major advantages of CT are that it is less invasive than aortography and, while on the CT table, the patient can have multiple parts of the body imaged. The major disadvantage is the logistical difficulty in transporting patients who are unstable or on a ventilator to the CT suite. Intravascular contrast media is used with dynamic CT, so a history of a serious reaction remains a contraindication. With appropriate equipment and physicians who can perform and properly interpret the studies, aortography, TEE, or dynamic CT scan are acceptable tests to evaluate aortic injury after blunt trauma.

Dynamic CT scan of the chest may also be helpful in patients with signs and symptoms of aortic dissection: an accurate diagnosis of dissection will be obtained in more than 90 to 94 percent of such patients.[15,16] Dynamic CT scan can accurately identify dissection by visualizing an intimal flap with opacification of the true and

false lumens. In patients with type B (descending aorta) dissection, no other study will be necessary. A disadvantage of dynamic CT scan is that, in type A (ascending aorta) dissection, aortography will still be required to assess the aortic valve and major arterial vessels prior to surgery.

Dynamic CT scan has recently been used to diagnose PE. Currently, the $\dot{V}/\dot{Q}$ scan remains the initial imaging modality used, but, with added experience, the dynamic CT scan may replace it. Recent articles report 86 to 91 percent sensitivity and 78 to 95 percent specificity for contrast-enhanced spiral CT in detecting PE out to the segmental divisions of the pulmonary arteries.[17,18 and 19] Although dynamic CT can occasionally visualize subsegmental arteries, reliability and interpretation are problematic. Patients must be able to hold their breath, typically for 20 to 24 s, as the CT scan table is moved through the gantry, although scans can be done in 10 to 12 s with thicker image slices. Breath holding may be difficult for dyspneic patients.[19] Another variation is contrast-enhanced electron-beam CT, which has the advantage of a 100-ms scanning time, no need for a breath-holding maneuver, and minimal respiratory or cardiac motion artifact.[20] As radiologists become more familiar with these tests and gain more expertise, the CT scan may become the important noninvasive test for the diagnosis of PE.

TRANSTHORACIC ECHOCARDIOGRAPHY

Echocardiography brought to the bedside of an ED patient is noninvasive, portable, and provides immediate bedside images. Although the techniques of echocardiography are beyond the scope of this chapter, the viewing windows are easy to identify and to access.[21] The subcostal view, at the left intercostal margin at its junction with the xiphoid process, yields information regarding presence of fluid, wall motion, and chamber size. The parasternal view, at the left upper intercostal spaces, gives images of the aorta, cardiac chambers, and heart valves.[22]

Emergency bedside echocardiography is usually performed to detect two conditions: pericardial fluid (in the setting of possible pericardial tamponade) and cardiac wall motion (in the setting of cardiac arrest with maintained electrical activity—pulseless electrical activity or PEA). In both of these settings, the interpretation provided by emergency physician bedside echocardiography has been accurate for clinical decision making.[23,24] Both conditions can be evaluated by performing a limited examination using the subcostal view. A pericardial effusion is identified as fluid following the contour of the heart with the surrounding hyperechoic image of the pericardium. The findings of fluid, hyperdynamic heart, and diastolic collapse of the right atrium and ventricle suggest tamponade.[22] In a pulseless patient with electrical activity on the monitor, echocardiography may accurately identify treatable causes.[24]

Other indications for emergency bedside echocardiography include hypotension of unknown cause, suspected cardiac trauma (blunt or penetrating), and suspected ischemic heart disease. Hyperdynamic wall motion without pericardial fluid suggests hypovolemia. Pericardial fluid suggests cardiac injury. Tension pneumothorax can be suggested by difficulty in visualizing the heart due to an air interface.

Evaluation of patients with possible ischemic chest pain requires a more thorough echocardiographic examination than is usually possible using the equipment and training available to most emergency physicians. Additional training and specific equipment are required to accurately assess cardiac wall motion, cardiac chamber size, and valve function. If the appropriate equipment and physician (usually a cardiologist) are available, though, echocardiography can be very useful in evaluating patients with chest pain.[25] Early echocardiography in the emergency department is more sensitive than an electrocardiogram (ECG) (91 percent versus 40 percent) in predicting acute infarction or revascularization.[25] Echocardiography can identify and assess complications of ischemia: pump failure, mitral valve insufficiency, and pericardial effusion. Along with the medical history, ECG, and serologic markers, echocardiography may aid in the triage process of patients with chest pain.[25]

Other diagnoses that can be made with echocardiography include acute PE, aortic dissection, and cardiac contusion; however, advanced training is necessary to diagnose these conditions accurately.[22]

CHEST ULTRASONOGRAPHY

Ultrasound is not routinely performed to image the thoracic cavity, and does not substitute for the chest radiograph in trauma assessment. However, bedside ultrasound performed by trained emergency physicians was a sensitive as the initial chest radiograph (96 percent) in detecting traumatic hemothorax.[26] The viewing areas used were the right and left intercostal oblique views. Fluid in the pleural space was identified as an anechoic space distal to the hyperechoic line representing the diaphragm.

TRANSESOPHAGEAL ECHOCARDIOGRAM

TEE is useful to image the heart and aorta,[27] and is most commonly used in an emergency department when aortic trauma or dissection is suspected. In both of these conditions, TEE performed by trained physicians has a sensitivity of over 95 percent and specificity over 95 percent.[16,28,29,30,31,32 and 33] will also evaluate cardiac function and may disclose unexpected injury.[26] TEE requires extensive training and is usually performed by a cardiologist.

68 ACUTE ABDOMINAL PAIN

E. John Gallagher

Most investigators in this field have arbitrarily defined "acute" abdominal pain as pain of less than 1 week's duration. [1,2] In keeping with this convention and the American College of Emergency Physicians' Clinical Policies Committee guidelines, this chapter restricts the discussion to postpubescent patients only, excluding individuals with *known* antecedent trauma and women beyond the twentieth week of pregnancy. [2]

EPIDEMIOLOGY

One large cross-sectional study of adults living in the community found that about one individual out of every three reported at least one episode of "abdominal pain or discomfort" during the preceding 3 months. [3] The population-based annual incidence of adults presenting to the emergency department (ED) for acute abdominal conditions is approximately 44/1000.

Data from the U.S. National Center for Health Statistics indicate that abdominal pain was the single "most frequently mentioned" reason offered by patients for visiting the ED in 1996 (annual incidence approximately 57/1000 adult ED visits. [4] Admission rates for abdominal pain vary markedly, ranging from 18 to 42 percent, with rates as high as 63 percent reported in patients over 65 years of age. [5]

PATHOPHYSIOLOGY

Abdominal pain is traditionally divided into three categories: visceral, parietal, and referred. In general, the visceral (autonomic) and parietal (somatic) types are considered the two basic "causes" of abdominal pain. Referred pain can be considered separately as a cortical misperception of either visceral or parietal afferent stimuli. Although each type of pain is thought to have a different neuropathophysiology, the categories are not entirely discrete. For example, visceral pain often blends with parietal pain as a pathologic process evolves. Their shortcomings notwithstanding, these distinctions are clinically useful ways of thinking about abdominal pain.

Visceral Pain

Visceral abdominal pain is usually caused by stretching of fibers innervating the walls or capsules of hollow or solid organs, respectively. Less commonly, it is caused by early ischemia or inflammation. Severity ranges from a steady ache or vague discomfort to excruciating or colicky pain. Because the visceral afferents follow a segmental distribution, visceral pain can be localized by the sensory cortex to an approximate spinal cord level determined by the embryologic origin of the organ involved. For example, foregut organs (stomach, duodenum, and biliary tract) produce pain in the epigastric region; midgut organs (most of the small bowel, appendix, and cecum) cause periumbilical pain; and hindgut organs (most of colon, including the sigmoid) as well as the intraperitoneal portions of the genitourinary system tend to cause pain initially in the suprapubic or hypogastric area.

Because intraperitoneal organs are bilaterally innervated, stimuli are sent to both sides of the spinal cord, causing intraperitoneal visceral pain to be felt in the midline, independent of the right- or left-sided anatomic location of the involved organ. For example, stimuli from visceral fibers in the wall of the appendix enter the spinal cord at about T10. When obstruction causes appendiceal distention in early appendicitis, pain is initially perceived in the midline periumbilical area, corresponding roughly to the location of the T10 cutaneous dermatome.

Parietal Pain

Parietal or somatic abdominal pain is caused by irritation of fibers that innervate the parietal peritoneum, usually the portion covering the anterior abdominal wall. Because parietal afferent signals are sent from a specific area of peritoneum, parietal pain—in contrast to visceral pain—can be localized to the dermatome directly above the site of the painful stimulus. As the underlying disease process evolves, the symptoms of visceral pain give way to the signs of parietal pain, with tenderness and guarding. As localized peritonitis develops further, rigidity and "rebound" appear.

Referred Pain

Referred pain is felt at a location distant from the diseased organ. Like visceral pain and in contrast to parietal pain, referred pain produces symptoms, not signs. Unlike visceral pain, referred pain is usually ipsilateral to the involved organ and is felt in the midline only if the pathologic process is also located in the midline. This is because referred pain, in contrast to visceral pain, is not mediated by fibers providing bilateral innervation to the cord. Like those of visceral pain, patterns of referred pain are based upon developmental embryology. For example, the ureter and the testes share the same segmental innervation because these structures were once anatomically contiguous. Both therefore supply afferent fibers to the same lower thoracic and upper lumbar segments of the spinal cord. Thus, acute ureteral obstruction is often associated with ipsilateral testicular pain. Other sites of referred pain reflect similar dermatomal sharing, providing explanations for otherwise puzzling associations between supra- or subdiaphragmatic irritation and ipsilateral supraclavicular/shoulder pain; gynecologic pathology and back/proximal lower extremity pain; biliary tract disease and right infrascapular pain; and myocardial ischemia and midepigastric/neck/jaw/upper extremity pain.

CLINICAL FEATURES

Conceptual Framework

CLASSIFICATION   A conceptual framework encompassing undifferentiated acute abdominal pain is summarized in Table 68-1. The classification scheme divides abdominal pain into two main categories: Intraabdominal, i.e., arising from within the abdominal cavity or retroperitoneum, and extraabdominal. Intraabdominal causes are then divided by organ system into the "3G's": GI (gastrointestinal), GU (genitourinary), and GYN (gynecologic), plus a fourth, less common but often catastrophic group of *vascular* emergencies. Each of these four organ systems is further subdivided into specific diagnoses within that organ system. Pain of extraabdominal origin, which is substantially less common, is similarly divided into four broad etiologic categories of cardiopulmonary, abdominal wall, toxic-metabolic, and

neurogenic.

TABLE 68-1   Conceptual Framework: Undifferentiated Acute Abdominal Pain

Broadening the scope of abdominal pain beyond the intraabdominal reminds us that the clinical focus of the ED physician is quite different from that of his or her surgical colleagues. Surgeons, quite appropriately, approach abdominal pain seeking a binary answer to the question "Does this patient need an operation?" ED physicians, in contrast, must first identify sick or possibly sick patients as early as possible in the course of their illness. Once this determination is made clinically, the ED physician must rapidly decide which additional diagnostic tests, if any, are needed. Although ED physicians may quickly arrive at the same dichotomous question as their surgical counterparts, because they encounter undifferentiated abdominal pain, they must first cast a much broader net that considers causes located both within and outside of the abdominal cavity.

Finally, nonspecific abdominal pain (NSAP), which is the most common "cause" of undifferentiated abdominal pain among ED patients, is listed as a third category. NSAP stands alone since it is unknown to what extent it may represent an underlying intra- versus extraabdominal problem.

ABDOMINAL TOPOGRAPHY   By combining the four-quadrant approach traditionally used by U.S. physicians with selected aspects of a strategy widely employed throughout Europe and Asia,[1] a simple model of abdominal topography can be developed. In addition to the standard four quadrants—right upper quadrant (RUQ), right lower quadrant (RLQ), left upper quadrant (LUQ), and left lower quadrant (LLQ)—this model includes four areas of the abdomen that are not discrete but rather constitute combinations of all or part of two or more quadrants: (1) upper half of abdomen (UHA), which includes an area of pain as small as the midepigastrium or as large as the RUQ plus LUQ combined; (2) lower half of abdomen (LHA), which similarly includes an area of pain as small as the midhypogastrium or as large as the RLQ and LLQ combined; (3) central (CTL), which includes an area of pain comprising the centermost "quarters" of all four discrete quadrants, such that carving out these areas from each quadrant defines a periumbilical or "central" quadrant and (4) generalized (GEN), which includes poorly localized pain encompassing much or perhaps most of the abdomen, including at least some portion of all four discrete quadrants.

This topographic configuration is particularly relevant to the broad spectrum of undifferentiated abdominal pain seen in emergency practice. It incorporates both the early (visceral, poorly localized) and late (parietal, better localized) pain of an evolving intraabdominal pathologic process, as well as the more generalized pain associated with toxic-metabolic derangements.

Of greater importance, however, is the inherent limitation in any approach to abdominal pain that relies principally on abdominal topography. Following the first critical examination of the association between the location of overlying pain/tenderness and underlying surgical disease, Staniland and colleagues concluded that "the most striking feature" of their findings was the observation that "the 'stereotype' site of pain is seen to be little more than an *approximate guide to the diagnosis of the disease concerned* [italics added]."[6] Their seminal observation that about one-third or more of cases of abdominal pain that come to operation present in a fashion that clinicians mistakenly regard as "atypical" may represent the largest single reason that the error rate in the clinical diagnosis of abdominal pain is so high. A corollary to this is that one cannot exclude a particular diagnosis based solely on the location of abdominal pain or tenderness.

Historical Features

What follows assumes that the patient is sufficiently stable to allow for a detailed history and goal-directed examination.

Historical data can be conveniently divided into attributes of pain, associated symptoms, and past history.

PAIN ATTRIBUTES   The principal characteristics of abdominal pain include location, quality, severity, onset, duration, aggravating and alleviating factors, and change in any of these variables over time.

ASSOCIATED SYMPTOMS   These can be subdivided into one of the four main organ systems that are involved in intraabdominal pain, as shown in Table 68-1.

Gastrointestinal Symptoms   Anorexia, nausea, and vomiting (unless bloody) are among the least helpful symptoms for specific diagnosis. For example, vomiting has been reported in over 40 percent of patients with salpingitis, and in over 60 percent of patients with renal colic. Lower gastrointestinal (GI) symptoms such as nonbloody diarrhea or constipation are similarly too insensitive and nonspecific to significantly alter the probability of a GI cause of abdominal pain.

Genitourinary Symptoms   The hallmark of abdominal pain of genitourinary (GU) origin is the concomitant development of some, often subtle, alteration in micturition—e.g., dysuria, frequency, urgency, hematuria, incomplete emptying, or incontinence (usually overflow). On occasion, non-GU pathology develops in organs contiguous to the GU system, giving the appearance of an intrinsic GU problem. For example, an inflamed appendix lying across the bladder might cause urinary frequency.

Gynecologic Symptoms   Distinguishing GI from gynecologic (GYN) causes of acute abdominal pain is one of the most challenging clinical dilemmas in emergency practice. A thorough gynecologic history is indicated, including menses, mode of contraception, fertility, sexual activity, sexually transmitted diseases, vaginal discharge, recent dyspareunia, and a past gynecologic history, including pregnancies, deliveries, abortions, ectopic pregnancies, cysts, fibroids, pelvic inflammatory disease, and laparoscopy.

Vascular Symptoms   History of myocardial infarction (MI), other ischemic heart disease or cardiomyopathy, atrial fibrillation, anticoagulation, congestive heart failure, peripheral vascular disease, or a family history of aortic aneurysm are all pertinent historical features in older patients.

PAST MEDICAL HISTORY   This includes a history of recent/current medications (including nonsteroidal anti-inflammatory drugs and antibiotics), past hospitalizations, in- or outpatient surgeries, diabetes, other chronic diseases [including human immunodeficiency virus (HIV) status and risk factors], central nervous system (CNS) disease (such as multiple sclerosis), and any history of recent trauma. A social history that includes habits (tobacco, alcohol, and other drug usage), occupation, possible toxic exposures, and living circumstances (e.g., homeless, residing in an unheated dwelling, with no access to running water, living alone, other family members ill with similar symptoms) provides important background and a context within which to place the presenting complaint of acute abdominal pain.

Physical Examination

GENERAL   The patient's general appearance—including facial expression, diaphoresis, pallor, and degree of agitation—provides information about the severity of pain. Although this is helpful in determining the immediacy of need for analgesia, severity of abdominal pain bears no necessary relationship to illness severity. For example, the pain of early mesenteric ischemia may be a vague discomfort, in contrast to the sudden onset of the excruciating pain of ureteral colic. Nevertheless, kidney stones have virtually no acute mortality associated with them, while the majority of patients with ischemic small bowel go on to die.

Patients with colicky pain, which is characteristically visceral due to distention of a hollow organ, are often unable to lie still, while those with peritonitis prefer to remain immobile.

VITAL SIGNS   A reliable means of obtaining a core temperature is important, although absence of fever, especially in the elderly, has virtually no predictive value. Careful counting of rate and observation of depth of respirations for 15 s is often overlooked. However, it can provide crucial information about tachypnea or hyperpnea, which may be subtle. Pulse and blood pressure should include orthostatic changes if, after obtaining the history, there is any reason to suspect intravascular volume contraction. A pulse change of 30 points lying to standing at 1 min (or the development of presyncope) has been shown to be highly specific for the loss of 1 L of blood or its roughly 3-L equivalent of isotonic solute. Changes in blood pressure have not been shown to be discriminatory, probably because they are late findings that represent failure of the tachycardic response to maintain cardiac output. This threshold does not apply to patients on medications that block a tachycardic response or to the elderly, owing to the effects of aging on the cardiac conducting system.

ABDOMEN   **Inspection**   The abdomen should be inspected for distention (with air or fluid), scars, and masses.

Auscultation   Contrary to conventional teaching, absent or diminished bowel sounds provide little clinically useful information. This is supported by the observation that, in a series of 100 patients with operative confirmation of peritonitis due to perforation of peptic ulcer, about half were noted to have normal or increased bowel sounds.[6] Hyperactive/obstructive bowel sounds, although of limited value, are somewhat more helpful, as reflected by their presence in about half of 100 patients with small bowel obstruction (SBO), in contrast to only 5 to 10 percent of patients with 500 other surgical diagnoses. However, fully 25 percent of those with SBO had absent or diminished bowel sounds.[6] It appears, therefore, that only hyperactive/obstructive bowel sounds have some clinical utility, increasing the likelihood of SBO by about fivefold; however, normal or absent bowel sounds appear very nearly valueless, as evidenced by their occurrence with roughly the same frequency in both SBO and perforated peptic ulcer.

Palpation   The vast majority of clinical information obtained from examination of the abdomen is acquired through gentle palpation, using two or three fingers, beginning at a distance from the area of maximum pain. Voluntary guarding (contraction of the abdominal musculature in anticipation of or in response to palpation) can be relieved somewhat by asking patients to flex their knees. Those who remain guarded following this maneuver will often relax if the clinician's hand is placed over the patient's and the patient is then asked to use his or her own hand in palpating the abdomen. In contrast to the symptom of pain, tenderness is a *sign* in which pain is produced by palpation. If tenderness can be confined to a single quadrant, this is preferable. However, this is often not possible, in which case one may have to settle for tenderness encompassing one of the four combined areas noted above. Rigidity (involuntary guarding or reflex spasm of abdominal muscles) is suggestive of underlying peritoneal inflammation, as is pain referred to the point of maximum tenderness when palpating an adjacent quadrant.

"Rebound" tenderness, often regarded as the clinical criterion standard of peritonitis, has several important limitations. In patients with peritonitis, the combination of rigidity, referred tenderness, and especially, "cough pain"[7] usually provides sufficient diagnostic confirmation that little is gained by eliciting the unnecessary pain of rebound.[8] False positive rebound tenderness occurs in about one patient in four without peritonitis,[8] perhaps because of a nonspecific startle response. Indeed, more recent work has led some authors to conclude that rebound tenderness, in contrast to cough pain, is of "no predictive value."[9]

Enlargement of the liver or spleen and other masses, including a distended bladder, should be sought. The examiner should also examine for hernias, particularly those that are tender, suggesting incarceration or strangulation. Men with abdominal pain should have a GU exam, and it is wise to maintain a low threshold for performing a pelvic examination in the evaluation of abdominal pain, particularly in women of reproductive age, regardless of where in the abdomen the pain is localized.

Although the rectal examination is widely regarded as an essential component of the evaluation of abdominal pain, particularly in suspected appendicitis, there is little evidence that rectal tenderness in patients with RLQ pain provides any useful incremental information beyond what has already been obtained by other, less uncomfortable components of the physical examination.[10] The appearance of the stool—if grossly melanotic, maroon, or frankly bloody—is of value. The test for occult blood, although routinely done, loses sensitivity if not performed serially over several days; similarly, repeated rectal examination by several examiners over a period of hours tends to reduce specificity, presumably due to local trauma. In one series of patients with NSAP, 10 percent were found to have a stool positive for occult blood.[11]

COMPLETE BLOOD COUNT   The limited clinical utility of the complete blood count (CBC) can be demonstrated most readily by examining its performance characteristics in the three most common causes of abdominal pain: Appendicitis, biliary tract disease (principally cholecystitis), and NSAP (Table 68-2 and Table 68-3). Based upon three studies containing a total of over 1800 patients, a white blood cell (WBC) exceeding the threshold value of 10,000 to11,000/mm^3 only doubled the odds of appendicitis, while a WBC below this cut the odds in half. As noted below in the discussion of likelihood ratios (LRs), an LR(+) less than 2 and an LR(−) greater than 0.4 are of very little clinical value. For acute cholecystitis, the LRs of the WBC count are virtually identical to those seen in appendicitis and are of equally limited clinical value.

Final Diagnosis	Proportion of >10,000 Patients		
Nonspecific abdominal pain	34%		
Appendicitis	28%		
Biliary tract disease	10%		
Bowel obstruction	4%		
Acute gynecologic disease	4%	Salpingitis	68%
		Ovarian cyst	21%
		Ectopic	6%
		Incomplete abortion	5%
		Subtotal, gynecologic	100%
Pancreatitis	3%		
Renal colic	3%		
Perforated peptic ulcer	3%		
Cancer	2%		
Diverticular disease	2%		
Other (≤1% each)	6%		

TABLE 68-2   Most Common Causes of Acute Abdominal Pain[1,16,34]

Final Diagnosis	≥50 Years Old (N = 2406)	<50 Years Old (N = 6317)
Biliary tract disease	21%	6%
Nonspecific abdominal pain	16%	40%
Appendicitis	15%	32%
Bowel obstruction	12%	2%
Pancreatitis	7%	2%
Diverticular disease	6%	<0.1%
Cancer	4%	<0.1%
Hernia	3%	<0.1%
Vascular	2%	<0.1%
Acute gynecologic disease	<0.1%	4%
Other	13%	13%

TABLE 68-3   Causes of Acute Abdominal Pain Stratified by Age[1,16,34]

In one large, well-conducted series of NSAP, 28 percent [95% CI 22 to 34%] of patients were reported to have WBC counts >10,500/mm^3.[11] In an effort to develop a decision rule for the identification of NSAP, it was found that the CBC, or indeed any laboratory test, was not of value in distinguishing patients with NSAP from other, more serious diagnoses. Because of the design of studies on NSAP, it is not possible to calculate a specificity or likelihood ratio for the performance of the WBC

count in this setting. However, using 28 percent as the sensitivity of the test, it is possible to estimate that, in order for leukocytosis to be of any value in NSAP (defined as producing LRs that deviate significantly from 1), the WBC count would have to demonstrate substantially better specificity than was seen in either appendicitis or cholecystitis.

All of the above refers only to individual WBC counts. There is some evidence that serial counts may assist in the identification of appendicitis. [12] However, in this setting, it would seem wiser to obtain a more definitive test, such as a CT (see Table 68-4) rather than risk a perforation or other complication while obtaining serial WBCs and waiting for development of a leukocytosis.

TABLE 68-4   Diagnostic Tests for Appendicitis

As suggested above, perhaps the only way to obtain some utility from the CBC is to use it only for its LR(+), i.e., to pay some attention to it only if elevated, and to recognize that the elevation must be substantial before it is likely to have much meaning. The term *substantial* is purposely left undefined in order to avoid what has been aptly referred to as the "single-cutoff trap," i.e., the binary thinking that is engendered when continuous data, such as the WBC count, are converted into dichotomous categories of normal and abnormal. Entirely consistent with their test performance characteristics, "normal" WBC counts should be regarded as not helpful.

PLAIN ABDOMINAL FILM   The plain abdominal radiograph (PAR) is often ordered as an "abdominal series," the meaning of which is not clearly defined. In some institutions, this includes an upright abdomen, in others an upright chest; in still others, only a single supine film is obtained. In a prospective study of 102 consecutive patients admitted with acute abdominal pain, the utility of the erect abdominal film when added to the combination of the supine abdominal and erect chest film was examined. The low yield, misleading findings, and lack of impact on management lead to the conclusion that routine use of the erect abdominal film in the acute abdomen was unnecessary. A similar prospective study of over 250 consecutive patients came to the same conclusion.

In one review of over 1500 abdominal films in patients presenting with suspected appendicitis, NSAP, or urinary tract infection, the authors concluded that "any positive information from these radiographs was less likely to be helpful than incidental or inconsistent (and hence potentially misleading)."

Perhaps the limited utility of the PAR is in part related to the difficulty in interpretation, even among experienced radiologists. One study found that about 40 percent of commonly used radiographic signs and diagnoses showed poor agreement among four qualified diagnostic radiologists when the same 140 films were viewed independently by each.

Recent work has concluded that plain films continue to be markedly overutilized. One study concluded that restriction of the PAR to patients with suspected obstruction, perforation, ischemia, peritonitis, or renal colic would have had no impact on management, and the use of PARs would have been reduced by 80 percent.[13] The authors go on to suggest that more liberal use of ultrasound would decrease unnecessary utilization of plain films. There is evidence that ultrasound is superior to plain chest/abdominal films in the detection of free air, [14] which may be one of the principal uses for the PAR and upright chest film. Still other authors note the superior performance of computed tomography (CT) in identifying virtually any abnormality that can be seen on plain films, particularly SBO and renal colic, in addition to many other findings that can only be seen when the technology of computerized, collimated-beam, tomographic imaging is utilized. Although ultrasound can be extremely helpful, particularly as a screening measure that can be implemented quickly at the bedside, it is highly operator-dependent and limited by overlying gas and obesity. The CT, on the other hand, has none of these technical limitations and would seem to be the key to obviating the need for continued use of the PAR in the future—with or without the aid of sonography.

Just as skull films were once obtained "routinely" in head trauma, were almost always nondiagnostic, and told us virtually nothing about what was going on within the intracranial cavity, the PAR is almost always normal or nonspecific in abdominal pain and similarly tells us very little about what is going on within the abdominal cavity and retroperitoneum. Over time, it seems reasonable to speculate that some extension of the helical abdominal CT, or its magnetic resonance imaging (MRI) analog, may replace the abdominal plain film in the very same way—and for the very same reasons—that the head CT/MRI replaced skull films.

DIAGNOSIS

Diagnosis versus Disposition

It is axiomatic in emergency medicine that appropriate disposition and management of acute illness takes precedence over diagnostic accuracy. However, extraordinary technological advances have made rapid, noninvasive diagnosis of many causes of abdominal pain widely available. This has occurred in parallel with the development of an equally sophisticated array of therapeutic options. The net effect of this phenomenon has been to tie diagnosis more closely to disposition and treatment than was the case when the only interventions in abdominal pain were laparotomy vs. observation with medical management.

Diagnostic Error

As accurate diagnosis—as opposed to a discharge or admission decision—becomes more pertinent to emergency medicine, a striking feature of abdominal pain becomes apparent: It is extremely difficult to make the correct diagnosis using only clinical findings and basic laboratory tests. When initial and final diagnoses are compared, diagnostic accuracy is reported as falling somewhere between 50 and 65 percent overall. [15] It is clear that diagnostic error in adults with abdominal pain increases in proportion to age, ranging from a low of 20 percent if only young adults are considered, [15] to a high of 70 percent in the very elderly. [16]

In spite of a high diagnostic error rate, the discharge error rate (proportion of patients mistakenly sent home from the ED) is substantially lower, reported to be 1 percent or less in two series, increasing to 4 percent in patients >65 years old. [5]

Performance Characteristics of Diagnostic Tests

Table 68-4, Table 68-5, Table 68-6, Table 68-7, Table 68-8, Table 68-9, Table 68-10, Table 68-11, Table 68-12, Table 68-13 and Table 68-14 provide a summary of the properties of diagnostic tests used for common or serious causes of abdominal pain encountered in the ED. These test properties are displayed as the traditional sensitivity and specificity, accompanied either by confidence intervals or a range of values if the studies from which the data were drawn were too heterogeneous to be combined.

TABLE 68-14   Diagnostic Tests for Ischemia of the Small and Large Bowel

DEFINITION OF LIKELIHOOD RATIOS (LRs)[17]   In the far right-hand columns of Table 68-4, Table 68-5, Table 68-6, Table 68-7, Table 68-8, Table 68-9, Table 68-10, Table 68-11, Table 68-12, Table 68-13 and Table 68-14, test performance is expressed using positive and negative likelihood ratios (LRs). LRs are defined as the likelihood that a particular test result would be found in a patient *with* the target disorder, relative to the likelihood of that same test result occurring in a patient *without* the target disorder.

Likelihood ratios (LRs) are often divided into positive and negative LRs, expressed as follows: LR of a (+) test = (TPR/FPR) = [(true-positive rate)/(false-positive rate)] = [sensitivity/(1-specificity)]. LR of a (−) test = (FNR/TNR) = [(false-negative rate)/(true-negative rate)] = [(1-sensitivity)/specificity].

The formal definition of an LR(+) is simply a special case of the general definition of LRs: An LR(+) is the likelihood that a *positive* test result would be found in a patient *with* the target disorder, compared with the likelihood of a *positive* test result occurring in a patient *without* the target disorder. The definition of an LR(−) is the likelihood that a *negative* test result would be found in a patient *with* the target disorder, compared with the likelihood of a *negative* test result occurring in a patient *without* the target disorder.

INTERPRETATION OF LRs[17]   In general, an LR(+) of 1 to 2, or an LR(−) of 0.5 to 1, alters disease probability by a small and clinically insignificant degree. In contrast, LR(+)s >10, or LR(−)s <0.1 may have a very substantial impact on clinical decision making through meaningful revision of disease probability. LR(+)s of 2 to 10, or LR(−)s of 0.5 to 0.1 may still make some small contribution to management, depending upon their magnitude and the clinical context in which they are applied. Because LRs are odds, a diagnostic test with an LR(−) = 0.1 is as powerful as a diagnostic test with an LR(+) = 10.

CLINICAL APPLICATION OF LRs[17]   Likelihood ratios (LRs) combine the stability of sensitivity and specificity with the utility of predictive values, resulting in an index of test performance that can be applied directly to a particular patient at the bedside. This is done by multiplying an LR(+) or LR(−) times the pretest odds of disease,

resulting, respectively, in an increased or decreased posttest odds of disease. The larger the LR(+) or the smaller the LR(–), the more powerful the test is.

The performance characteristics of the various tests shown in Table 68-4, Table 68-5, Table 68-6, Table 68-7, Table 68-8, Table 68-9, Table 68-10, Table 68-11, Table 68-12, Table 68-13 and Table 68-14 are incorporated into the discussion of specific diagnoses below.

Specific Diagnoses

Table 68-2 is drawn from a combined series of over 10,000 cases of acute (<1 week duration) abdominal pain presenting to over 200 EDs in 17 countries during a 10-year period. The data were collected on a highly standardized instrument.

In virtually all large series of acute abdominal pain, the substantial majority of final diagnoses include nonspecific abdominal pain (NSAP), appendicitis, and biliary tract disease (usually cholecystitis), in that order, accounting for nearly 75 percent of all acute abdominal pain. However, as shown in Table 68-3, as patients age, the triad remains but the order changes to biliary tract disease (again, usually cholecystitis), followed by NSAP and appendicitis.

INTRAABDOMINAL DIAGNOSES (BY ORGAN SYSTEM) **Gastrointestinal** APPENDICITIS In spite of a large number of algorithms and decision rules incorporating many different clinical and laboratory features, an accurate preoperative diagnosis of appendicitis has remained elusive for more than a century. In at least 20 percent of patients with appendicitis, the diagnosis is missed; conversely, normal appendices are found in 15 to 40 percent of all operations performed for suspected appendicitis. Thus, the diagnosis of appendicitis turns out to either be a false positive or false negative just about as often as it turns out to be correct. [18]

Among patients presenting to an ED with acute abdominal pain, the pretest probability, or prevalence, of appendicitis is roughly 10 to 25 percent. [19] Converting this to odds to facilitate multiplication by LRs, the pretest odds of appendicitis in acute abdominal pain is roughly between 0.1 and 0.3. Five clinical features appear to have sufficiently powerful LR(+) values that the presence of *any one* should drive up the clinical odds to the point that an imaging procedure is indicated. Of those radiographic procedures available, appendiceal CT appears to be the best, [20] although there are many imaging alternatives, as listed in Table 68-4. Those clinical features with some predictive value include pain location in the RLQ [LR(+)=8]; pain migration from the periumbilical area to the RLQ [LR(+)=3]; rigidity [LR(+)=4]; pain before vomiting [LR(+)=2 to 3]; and a positive psoas sign [LR(+)=2]. [19] The widely held belief that anorexia is an essential prerequisite of appendicitis is unsupported by evidence. In fact, about one patient in three with surgically documented appendicitis is *not* anorectic preoperatively.[19]

In excluding the diagnosis of appendicitis, the absence of several of the following features is moderately helpful: The absence of RLQ pain [LR(–)=0.2], presence of similar previous pain [LR(–)=0.3], and absence of typical pain migration to the RLQ [LR(–)=0.5]. [19] Therefore, clinical exclusion of the diagnosis of appendicitis depends upon a persuasive aggregate of absent features or a strong competing alternative diagnosis. Lacking either of these two conditions, a CT should be seriously considered in the interest of avoiding missed appendicitis. In support of this strategy, a recent report of the impact of targeted appendiceal CT on treatment in suspected appendicitis showed that CT altered management in the majority (59 percent) of cases and represented a substantial cost savings. [20,21]

BILIARY TRACT DISEASE This is the most common diagnosis in ED patients above age 50.[1] Among patients found to have pathologically confirmed acute cholecystitis, the majority lack fever and a significant minority lack a leukocytosis (about 40 percent). [22,23 and 24] Pertinent diagnostic tests are shown in Table 68-5.

Recognition that the diagnoses of cholecystitis, "biliary colic," and symptomatic common duct obstruction may represent pathologically distinct entities that cannot be reliably distinguished from one another clinically has led some authors to redefine the *clinica* target disorder as simply "biliary tract disease." Although there is an association between symptomatic biliary tract disease and steady, postprandial upper abdominal pain radiating to the upper back, the likelihood ratios of individual signs, symptoms, and combinations of signs and symptoms are "relatively weak discriminators."[25] Just over one-third of patients have pain isolated to the RUQ, although about two-thirds have tenderness in that location. Most of the remainder complain of diffuse pain in the upper half of the abdomen; among those with pain in the lower abdomen, it is almost invariably in the RLQ. Among the one-third who do not have RUQ tenderness, the distribution is about equally divided between the upper half, the right side, and generalized tenderness throughout the abdomen. [6]

Looking specifically at the common bile duct (CBD), overall clinical accuracy for the identification of obstruction is about 60 percent [95%CI 49 to 70%]. Accuracy is defined here as the proportion of all clinical diagnoses that were correctly identified as obstructed or nonobstructed CBDs.

SMALL BOWEL OBSTRUCTION The central issues in small bowel obstruction (SBO) are diagnosis of the primary disorder and early detection of secondary strangulation or ischemia when present. Only two historical and two physical findings appear to have predictive value: previous abdominal surgery and intermittent/colicky pain plus abdominal distention and abnormal bowel sounds. Although about two-thirds of patients with SBO present with generalized or central abdominal pain and about half have generalized tenderness, the LRs of these findings alone or in combination are such that SBO is another diagnosis that requires imaging confirmation. The general limitations of bowel sounds has been noted previously. As shown in Table 68-6, and also discussed above, the abdominal flat plate is hampered by the large number of indeterminate readings, leaving it with LRs that are of limited usefulness. The CT, however, has an excellent LR(–), indicating that a negative result makes SBO highly unlikely. The LR(+) of CT is not as powerful as the LR(–), but probable SBO on CT increases pretest odds of this diagnosis by about sixfold (which is slightly better than the abdominal plain film).

Those patients with ischemic bowel secondary to strangulation are extremely difficult to detect clinically or by using plain radiographs. Here again the CT may be of substantial assistance in exclusion of the diagnosis of SBO with ischemia. Unfortunately, there is as yet no radiographic means to confirm the *early* diagnosis of ischemia due to SBO.[26]

ACUTE PANCREATITIS About 80 percent of acute pancreatitis in the United States is caused by alcohol or gallstones, with one etiology predominating over the other depending upon the population studied. [27] The pain and tenderness of acute pancreatitis are limited to the anatomic area of the pancreas in the upper half of the abdomen in only a minority of instances.[6] Most patients' pain and tenderness includes this area; in about half, however, it extends well beyond the upper abdomen to cause generalized tenderness. This may be related to the absence of a capsule that might otherwise contain the inflammation and to the difficulty of localizing pathology that—much like the pathology of an abdominal aortic aneurysm—resides deep in the belly and includes the retroperitoneum. Other features of the history and physical examination—such as the quality of the pain, which is steady and graded as severe in the majority of patients, or vomiting—have not been shown to have sufficient discriminatory power to make them clinically useful. Thus, most patients with upper, central, or generalized abdominal pain and tenderness who lack an alternative explanation for their presentation will require further testing.

As lipase assays have improved in accuracy and speed over the last several years, serum lipase has largely replaced amylase as the best "everyday" screening test for suspected acute pancreatitis. By setting the threshold for a positive test at twice the upper limit of normal serum lipase, the likelihood ratios for lipase are better than twice as powerful as those of serum amylase in making or excluding the diagnosis of acute pancreatitis. [28] As shown in Table 68-7, there are other biochemical markers for acute pancreatitis that have superior test properties, but these are not yet widely available. Early evidence that ratios of urine to serum amylase or of lipase to amylase improve diagnostic accuracy has not been validated.

Depending upon institutional custom, a diagnosis of acute pancreatitis may be sufficient to determine the appropriate admitting service. However, in settings where not all pancreatitis is admitted to the department of surgery or where it is expected that the ED will make a decision regarding admission to a monitored versus an unmonitored floor bed, it may be necessary for the ED to assess the patient for biliary pancreatitis and, perhaps, for the likelihood of complications. While ultrasound is nearly as good as CT for assessment of common bile duct obstruction (see Table 68-7), CT with contrast enhancement by intravenous bolus is far superior for identifying peripancreatic fluid collections and the extent of glandular necrosis. Both of these findings are associated with increased need for surgery and increased mortality (Table 68-7).

DIVERTICULITIS In one large study, the clinical accuracy of a diagnosis of colonic diverticulitis among patients with abdominal complaints was only 34 percent [95%CI 26 to 42%]. When the "possible/equivocal" clinical diagnoses were removed from analysis and only those patients with a pretest diagnosis of either "highly suspected" or "very unlikely" were included as clinical positives and negatives, respectively, the LR(+) was 2 to 3, and the LR(–) was 0.4, neither of which offers much help in the revision of disease probability. Of those patients with diverticular abscesses, diagnostic performance was somewhat better, with 70 percent categorized as "highly suspected" and the remainder as "possible/equivocal." No documented abscesses were categorized clinically as "very unlikely." [29]

Pain in diverticulitis was confined to the LLQ in less than one-quarter of the documented cases and to the lower half of the abdomen in only an additional one-third of patients. With respect to tenderness, it was as likely to be generalized as it was to be limited to the lower half of the abdomen or to the LLQ. About 10 percent of

patients with operatively confirmed diverticulitis did not complain of abdominal pain and 20 percent had no abdominal tenderness whatsoever. [6] Elderly patients are at risk for a severe and often fatal complication of diverticulitis that is only rarely seen in younger age groups: perforation of the colon. [16] Diagnostic imaging tests for acute diverticulitis are shown in Table 68-8.

Genitourinary   RENAL COLIC   As in appendicitis, a number of clinical decision rules have been developed in an effort to identify patients with the preimaging diagnosis of ureterolithiasis. Most algorithms include features of the pain—e.g., location (unilateral flank), onset (abrupt), quality (colicky), radiation (groin/testicle/labia). Hematuria appears as the only laboratory test in most algorithms. The utility of plain abdominal radiographs, as in other causes of abdominal pain, is highly questionable, as shown in Table 68-9.

A critical examination of ureteral stones documented on intravenous pyelography (IVP) reveals that, in one series, just over half reported colicky pain and groin radiation, with microscopic hematuria seen in about two-thirds. [30] An examination of Table 68-9 shows that the IVP has a specificity comparable to that of helical noncontrast CT; however, because of the IVP's poor sensitivity, CT shows far better LRs, thus making noncontrast helical CT the current criterion standard in the diagnosis of ureteral stones. In older patients, any presentation that resembles renal colic, with or without hematuria, mandates the exclusion of an abdominal aortic aneurysm (AAA) [reported in 18 percent (95% CI 11 to 24%) of suspected AAAs in one series]. This is yet another reason to obtain a noncontrast helical CT, since it performs extremely well in the detection of both ureteral stones and AAAs.

Because the GU tract is mostly retroperitoneal, it uncommonly causes significant anterior abdominal tenderness. One notable exception to this is an impacted stone at the ureterovesical (UV) junction, where the ureter enters the bladder, producing ipsilateral lower-quadrant pain and tenderness. Because stones at the UV junction [like those at the ureteropelvic (UP) junction] are less likely to produce the typical pain of renal colic than are stones located between the top and bottom of the ureter, impaction of a stone at the UV junction on the right may easily mimic appendicitis and will require a noncontrast CT to identify stone disease (Table 68-9). If this shows neither a stone nor evidence of other intraabdominal pathology, an appendiceal CT should be considered to confirm or exclude the diagnosis of appendicitis. [20]

ACUTE URINARY RETENTION   Another situation in which GU disease may cause abdominal tenderness is in the setting of acute urethral obstruction, producing a distended bladder. When the obstruction is truly acute, the bladder often feels like a solid mass rather than a fluid-filled hollow viscus. However, if one always considers this common entity when confronted with a midline mass of variable tenderness arising from the lower half of the abdomen, insertion of a urethral catheter easily makes the diagnosis and treats the acute problem.

ACUTE SCROTUM   Testicular torsion is the only cause of acute scrotal pain that must either be confidently excluded from the differential or treated within hours of onset. Consequently, the single target of all diagnostic strategies developed to determine the cause of acute scrotal pain is aimed at identification or exclusion of testicular ischemia. Although the etiology of acute scrotal pain in adults is usually either torsion or epididymitis, there are other causes—including inguinal hernia, acute hydrocele, and torsion of the appendiceal epididymis—none of which threatens testicular survival. Although the pain may radiate upward into the ipsilateral groin and lower quadrant, physical examination in adults leaves little doubt that the primary problem resides in the scrotum and not in the abdominal cavity itself (with the notable exception of torsion in an undescended testis).

Some of the features that favor epididymitis over torsion include the presence of fever, chills, dysuria, pyuria, and, most important, localization of the painful area to a swollen, tender epididymis, located posterior to and palpably separate from the testicle itself. The time course over which the pain began—its onset is characteristically more gradual in epididymitis than in torsion—may be helpful. However, it can also be misleading in patients who torse, detorse, and retorse.

The two diagnostic tests for torsion in common use are radionuclide scrotal scanning (RSI) and color Doppler imaging (CDI) (see Table 68-10). Although CDI appears slightly superior to RSI, particularly in younger patients, these findings are not consistent across studies. Both tests have incorrectly identified normal blood flow to testes later found to be ischemic or necrotic at operation. It is difficult to determine to what extent these errors reflect technologic limitations versus operator skill and experience with CDI. With RSI, the problem appears to be one of image resolution in children whose prepubescent testicles represent smaller targets. Because of these limiting features, most authors suggest that imaging be used adjunctively and not as the criterion standard for deciding which patients require exploration. The most conservative indication for surgery, which is likely to result in the fewest missed torsions and the largest number of negative explorations, is inability to distinguish a normal testis and normal epididymis on physical examination. In many institutions, the time required to obtain a nuclear scan is prohibitive, and unless the urology consultant is rapidly available and proficient at Doppler imaging, torsion will, for the present, remain among the steadily dwindling causes of "abdominal" pain in which the diagnosis is made at surgery.

Gynecologic Pain   ACUTE PELVIC INFLAMMATORY DISEASE   Absence of a criterion standard has further confounded the already clinically difficult diagnosis of acute pelvic inflammatory disease (PID). Laparoscopic and histopathologic findings, both of which have been proposed as the criterion diagnostic standard, are discordant. Because gross laparoscopic findings have historically been used as the standard in most well-designed studies, [31] the LRs of clinical features, laboratory results, and sonographic findings that follow, unless otherwise noted, have been measured against direct macroscopic inspection of the adnexa.

Symptoms such as lower abdominal pain, which would be expected to have a high LR(–) for PID, have not been studied because they typically represent inclusion criteria for study enrollment. To date, there have been no historical features associated with laparoscopic PID that demonstrate clinically useful LRs in more than one study population. [31] Signs—such as adnexal tenderness (unilateral on laparoscopy in only 5 to 10 percent of cases) and cervical motion tenderness—like lower abdominal pain, have not been well studied because they have been used as inclusion criteria in most investigations. The only physical finding associated with laparoscopic PID across more than one study population is an abnormal vaginal discharge. [31] In spite of this statistical association, the LRs of vaginal discharge range from 0.5 to 2.5, representing very limited power to alter disease probability. Elevated temperature and a palpable mass have been inconsistently associated with PID. The WBC count has not been found to be helpful in any of the studies that examined it. For the performance characteristics of other laboratory tests that have been associated with PID—e.g., the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), see Table 68-11. As in the evaluation of ectopic pregnancy (see below), the role of culdocentesis in the diagnosis of PID is *not* supported by evidence.

ECTOPIC PREGNANCY   In ruptured ectopic pregnancy, abdominal pain is almost universally present. However, as emphasis in ectopic pregnancy has shifted to identification of patients prior to rupture—with the goal of preserving fertility—pain may be absent at this earlier stage, with vaginal bleeding as the only sentinel complaint. Therefore, any woman of childbearing age who presents to the ED with abdominal pain *or* abnormal vaginal bleeding generally receives a qualitative pregnancy test as a screening measure.

The poor predictive performance of historical features, such as "risk factors," and of the physical examination [sensitivity 19 percent, LR(–)=0.8 among women with a positive hCG], argue strongly that ectopic pregnancy is not a diagnosis that can easily be excluded on clinical grounds.

For this reason, the results of the pregnancy test, independent of most other data, will determine if further testing is indicated to exclude an ectopic pregnancy. If the qualitative hCG is positive, the preferred test is a bedside transvaginal sonogram (TVS). See Table 68-12.

Vascular   ABDOMINAL AORTIC ANEURYSM   Although abdominal aortic aneurysms (AAAs) have little in common with aortic dissections, these two major forms of catastrophic disease of the aorta are often lumped together. Dissections are uncommon causes of abdominal pain and, because they almost invariably originate in the thoracic aorta, usually produce chest or upper back pain before migrating into the abdomen as the dissection moves distally.

AAAs, on the other hand, tend to enlarge, become aneurysmal over years, and—rather than dissect—leak and rupture. Fewer than half of AAAs present with the triad of hypotension, abdominal/back pain, and a pulsatile abdominal mass. Over three-quarters appear normotensive. Spontaneous containment of bleeding is the principal determinant of prehospital survival. Extent of containment further determines the degree of hypotension, if any, on presentation. The absence of abdominal pain or tenderness is entirely compatible with a contained leak extending into the retroperitoneum. Because the aorta is deep in the abdomen, it is extremely difficult to confirm by palpation that it is too small to represent an AAA, even in thin patients. Neither absence of femoral pulses nor an abdominal bruit have LRs that deviate very far from 1 and therefore lack the power to alter disease probability. Thus, a patient in the retirement-age group presenting with recent onset of abdominal, flank, or low back pain is likely to require either a normal aortic sonogram (performed by an experienced operator) or, preferably, a noncontrast helical CT (criterion standard test) before a AAA can be removed from the working differential diagnosis. Because the direction and extent of leakage or rupture—which can occur anywhere in the abdomen or retroperitoneum—determines the location of pain and tenderness, knowledge of aortic anatomy is not of much help in the diagnosis of AAA. The technology of magnetic resonance angiography (MRA) has not yet reached the stage where MRA can serve as an emergency procedure and conventional angiography has been supplanted by the superior, faster, noninvasive images of the helical CT. As noted earlier, the appearance of renal colic in this age group should be regarded as representing an AAA until the helical CT proves otherwise. See Table 68-13.

MESENTERIC ISCHEMIA   Mesenteric ischemia can be divided into arterial and venous disease [mesenteric venous thrombosis (MVT)]. Arterial disease can be subdivided into occlusive and non-occlusive (NOMI or low-flow state). Finally, occlusive arterial disease (generally understood to mean superior mesenteric artery occlusion) may be further categorized into thrombotic or embolic. Several features combine to produce a very high mortality associated with mesenteric ischemia:

1. Unless relatively young patients have an arrhythmia (usually atrial fibrillation causing embolization) or a hypercoagulable state (causing MVT), patients with mesenteric ischemia tend to have a substantial degree of age-related comorbidity.
2. The small bowel, which is supplied by the superior mesenteric artery, has a warm ischemia time of only 2 to 3 h.
3. The clinical picture is characterized initially by poorly localized visceral abdominal pain, without tenderness.
4. Patients may become transiently better after a few hours of ischemia, at the time of onset of mucosal infarction, only to later develop peritoneal findings as full-thickness necrosis of the bowel wall becomes apparent.
5. Timely diagnosis requires that an angiogram be obtained very early in the evolution of the pathologic process—so early, in fact, that it may seem clinically premature to order such an invasive test on an elderly patient who may not appear ill.

Elevation of serum phosphate was initially thought to be a sensitive marker for mesenteric ischemia, but this was not confirmed by later work showing a preoperative sensitivity for the diagnosis of acute mesenteric ischemia in the range of only 25 to 33 percent. In contrast, as shown in Table 68-14, serial serum lactates that remain *persistently* normal reduce the clinician's pretest likelihood of diagnosing mesenteric ischemia by more than tenfold. Unfortunately, lactate is elevated in many abdominal and extraabdominal conditions and therefore lacks specificity in the diagnosis of mesenteric ischemia.

There are some distinctions that can be made among the four major forms of mesenteric ischemia: (1) embolic disease is the most abrupt in onset, MVT the most indolent, with the temporal profile of arterial thrombosis somewhere in between; (2) NOMI is usually accompanied by clinical evidence of a low-flow state, typically due to cardiac disease and responding to improvement in cardiac output;[32] (3) MVT may be more amenable to noninvasive diagnosis with CT,[33] occurs in younger patients, has a lower mortality, and can be treated with immediate anticoagulation; (4) following diagnosis, arteriography with papaverine infusion may be an important component of treatment in patients with splanchnic vasoconstriction.

ISCHEMIC COLITIS   Ischemic disease of the large intestine has as little in common with mesenteric ischemia as aortic dissection does with AAA. As is the case with all vascular diseases, ischemic colitis is predominantly a disease of older patients. About 80 percent of individuals have diffuse or lower abdominal visceral pain, accompanied by diarrhea in about 60 percent, often mixed with blood. In contrast to mesenteric ischemia, ischemic colitis is not generally due to large-vessel occlusive disease, angiography is not usually indicated, and, if performed, is typically normal. Not surprisingly, the severity of the presentation appears to be related to the extent of ischemia. In the majority of cases, only segmental portions of the mucosa and submucosa slough. These then go on to heal uneventfully with conservative management. At the opposite end of the spectrum is full-thickness infarction of the colon, occurring in about 10 percent of cases. Bowel necrosis, whether segmental or pancolitic, causes peritonitis, requiring partial or complete colectomy. The mortality in this latter group approaches that of mesenteric ischemia.

In between mucosal/submucosal involvement and full-thickness infarction is an intermediate form of ischemic colitis involving portions of the muscular layer of the large bowel. These areas of deep but incomplete ischemia may later heal with stricture formation, placing the patient at risk for subsequent obstruction of the large bowel. In many instances, the attack of ischemic colitis that lead to the stricture may have been so mild that medical care was not sought at the time and the episode forgotten entirely by the patient. See Table 68-14.

EXTRAABDOMINAL   **Cardiopulmonary**   If the patient is complaining of pain in the upper half of the abdomen, particularly if the pain is confined to the RUQ or LUQ (with or without tenderness), the chest should be examined for basilar involvement of lung parenchyma or pleura. Because the stethoscope is neither sensitive nor specific for the diagnosis of pneumonia, pulmonary infarction, small pleural effusions, or small pneumothoraces, a chest film should be obtained. Whether a decubitus or expiratory film is requested depends upon clinical suspicion of effusion or pneumothorax, respectively. A negative film, especially if the pain is pleuritic in quality, introduces the differential diagnosis of pulmonary embolism.

If the pain is epigastric and the patient is in an age/gender group where coronary artery disease is prevalent, a further cardiac history and electrocardiogram (ECG) should be obtained. Ischemic cardiac pain referring to the epigastrium is not associated with significant tenderness, although cutaneous dysesthesia may be present, like that found in the upper extremity in other patterns of ischemic cardiac pain.

Abdominal Wall   Pain originating from the abdominal wall may be confused with visceral pain because superficial innervation from the lower thoracic roots enters the spinal cord via the same dorsal horn as the deeper visceral afferents. A useful and underutilized test is the sit-up test, also known as Carnett's sign. Following identification of the site of maximum abdominal tenderness, the patient is asked to fold his or her arms across the chest and sit up halfway. The examiner maintains a finger on the tender area, and if palpation in the semi-sitting position produces the same or increased tenderness, the test is said to be positive for an abdominal wall syndrome. The logic of this is that tensing of the abdominal muscles would be likely to protect the underlying organs, thus reducing tenderness if the cause of pain were deep. In patients unable to perform the maneuver, just raising the head and shoulders off the bed may be sufficient.

Abdominal wall syndromes overlap with hernias, neuropathic causes of abdominal pain, and NSAP.

HERNIAS   Hernias represent a special type of abdominal wall syndrome characterized by a defect through which intraabdominal contents protrude, often only intermittently during transient increases in intraabdominal pressure. Hernias are ordinarily asymptomatic or, at worst, moderately uncomfortable, but they do not generally cause significant pain unless they have become incarcerated or strangulated. Although the vast majority of hernias are inguinal, there are many other types that must be considered, including incisional, periumbilical, and—especially in women—femoral hernias. In a series of 120 cases, sonography of the abdominal wall was shown to be very helpful in identifying hernias and other causes of abdominal wall pain.

OTHER ABDOMINAL WALL SYNDROMES   Other causes of abdominal wall pain include rectus sheath hematomas and trauma to other portions of the abdominal wall. In older patients or in those on anticoagulants, the trauma may be very minor and forgotten. In circumstances where the injury is due to stretching causing tearing of muscle fibers, the overlying skin will not show any evidence of bruising that might provide a clue to the presence of bleeding into the abdominal wall.

Toxic-Metabolic   TOXIC   INFECTIOUS A large number of infectious agents irritate the GI tract, producing pain that is usually crampy. Concomitant vomiting or diarrhea suggests a gastroenteritis or enterocolitis, respectively. Many agents cause both upper and lower tract symptoms; in adults, however, one symptom complex usually predominates over the other. The hallmark of these infections, because most are confined to the lumen (mucosa) of the GI tract, is an absence of significant tenderness. This is because the parietal peritoneum is not irritated by luminal disease. If infarction, penetration, or perforation of the bowel wall occurs, as may happen with some of the invasive dysenteries—e.g., salmonellosis—peritoneal tenderness follows. This is why abdominal tenderness of any significance should never be attributed to uncomplicated "gastroenteritis." Furthermore, because the overall incidence of symptomatic GI infections declines markedly with age, the prior probability of "gastroenteritis" as the basis for abdominal complaints, particularly pain, in the elderly is very low indeed.

Other infections are associated with abdominal pain, although the pathophysiology is less clear. These include group A beta-hemolytic streptococcal pharyngitis (with or without associated scarlet fever), Rocky Mountain spotted fever, and early toxic shock syndrome.

POISONINGS The toxicologic causes of abdominal pain are also legion; they tend to be nonspecific and nondiagnostic in most instances. Some exceptions to this include envenomation by the female black widow spider, which is said to mimic peritonitis. This might represent a diagnostic dilemma if no history was taken and only the abdomen was examined. However, because the rigid abdomen following envenomation is due to muscular spasm, which begins at the site of the bite and gradually spreads to involve other large muscle groups of the back and proximal extremities, the prominence of extraabdominal signs and symptoms, as well as their historical evolution, should point the clinician away from a primary intraabdominal process. Isopropanol-induced hemorrhagic gastritis may be associated with cramping pain from this ingestion. Cocaine-induced intestinal ischemia, progressing to infarction and perforation, has been reported. The first stage of iron poisoning produces abdominal pain and may cause hematemesis due to the direct corrosive effects of iron on the GI tract. Large amounts of iron left in the stomach may also cause perforation. Mercury salts cause severe corrosion of the GI tract, associated with shock. *Acute* inorganic lead toxicity is typically associated with severe, crampy abdominal pain. This is in contrast to *chronic* lead toxicity, in which abdominal pain is minimal or absent. The development of abdominal pain following electrical injury suggests a potentially serious complication and the need for admission. Opiate withdrawal produces abdominal pain, usually crampy in character, associated with diaphoresis and piloerection. In some individuals, the abdominal skin appears dysesthetic to light touch, but significant tenderness should not be present. Mushroom toxicity, though rarely fatal, is commonly accompanied by a chemical gastroenteritis and severe abdominal pain out of proportion to tenderness.

METABOLIC **ACIDOSIS** These causes of abdominal pain include acute anion-gap metabolic acidoses, commonly seen in diabetic ketoacidosis (DKA) and alcoholic ketoacidosis (AKA) and less frequently in lactic acidosis. Although the pain associated with DKA and AKA has been attributed to gastric distention and paralytic ileus, this has not been clearly substantiated. In DKA or AKA, it is critical to consider the possibility that an underlying abdominal problem may have triggered the DKA or AKA, rather than the reverse. This is a particularly challenging clinical problem when amylase or lipase levels are elevated, since both AKA and DKA can be a consequence or a cause of acute pancreatitis. If the acidosis is difficult to "break" or the pain persists after normalization of the pH, intraabdominal disease should be sought.

ENDOCRINOLOGIC Of the endocrinopathies associated with abdominal pain, adrenal crisis is the most striking. Patients are often shocky and may exhibit peritoneal signs. The syndrome appears to be principally related to hypocortisolism rather than hypoaldosteronism. Without a history of similar prior episodes following reduced intake or absorption of adrenal steroids, these patients may be indistinguishable from those with an intraabdominal catastrophe in need of urgent exploration. Other endocrinopathies and electrolyte abnormalities associated with abdominal pain include thyroid storm, hypo- and hypercalcemia. This pain is generally crampy, and tenderness is absent unless the hyperthyroid state has caused acute hepatomegaly and distention of the liver capsule. Hypoglycemia has been reportedly associated with abdominal pain, but the evidence supporting this is unconvincing.

SICKLE CELL CRISIS A painful sickle cell crisis is a common cause of abdominal pain, second only to musculoskeletal pain as the most common manifestation of a vasoocclusive crisis in homozygous (SS) sickle cell disease. Occasionally, patients with sickle cell disease and other symptomatic heterozygous forms may present with abdominal pain due to splenomegaly or splenic infarct. Those with heterozygous sickle trait (SA) are almost invariably asymptomatic. The most reliable means of determining whether the abdominal pain is part of a crisis or secondary to an underlying intraabdominal problem is to ask the patient whether or not this is the pain of a "typical crisis" or whether it represents a pattern break. If the latter, the problem is usually localized to the RUQ, either secondary to biliary tract disease (about 75 percent of those with SS have bilirubin stones due to chronic hemolysis) or hepatomegaly due to sinusoidal sludging of sickled cells. Additional considerations for SS patients include pancreatitis, salmonellosis, and mesenteric venous thrombosis.

Less common "metabolic" entities associated with abdominal pain include virtually all forms of vasculitis, especially systemic lupus and Henoch-Schönlein purpura, porphyria, and familial Mediterranean fever. Each of these may produce peritonitis.

Neurogenic The hallmark of neurogenic abdominal pain is a dysesthetic sensation, particularly in response to light touch in the area of discomfort. This has been characterized by one author as the "hover" sign, in which the patient shows signs of discomfort when the examining hand is passed very lightly across the area of dysesthesia. A positive hover sign may be mistakenly interpreted as indicating a generally hyperreactive patient rather than a normal physiologic response to a dysesthetic stimulus.

Because deep and superficial nerve fibers from the same area of the abdomen may enter the cord together, dysesthesias have also been reported with other, more serious intraabdominal disease, such as appendicitis. In the latter, however, the problem is usually more acute, and either upon presentation or subsequently is accompanied by tenderness (in contrast to dysesthesia alone, defined here as an abnormal sensation in response to light touch). This category includes nerve entrapment syndromes, such as rectus nerve entrapment, and iliohypogastric entrapment following a Pfannenstiel incision. A number of other incisional entrapment syndromes have been described. Many of these patients will have a positive Carnett test, but the hover sign is probably more indicative of neurogenic abdominal pain.

Radicular problems causing abdominal pain include diabetic or zosteriform radiculopathy, the latter being characterized by dysesthesias outlining a dermatome, usually with some "spillover" into contiguous dermatomes on either side of the involved root. The dysesthesias may present as lancinating, ticlike bouts of shooting pain or continuous burning. Accompanying vesicles confirm the diagnosis, although the pain may precede the cutaneous eruption by several days. Diabetic neuropathic involvement of a root, plexus, or nerve can be confirmed by electromyography.

There is some evidence that greater attention to the examination of the abdominal wall might reduce the frequency with which the diagnosis of nonspecific abdominal pain (NSAP) is made. In one report, about 25 percent of patients with the diagnosis of NSAP were found to have significant tenderness confined to the abdominal wall.

NONSPECIFIC ABDOMINAL PAIN Despite a thorough evaluation, the largest single group of patients seen in the ED will have no definite diagnosis and will receive the designation of NSAP. As Lukens et al. point out, the term *undifferentiated abdominal pain* (UAP) would be preferable to *nonspecific,* since the cause of the patient's pain may turn out to be very specific.[11] Unfortunately, the term *NSAP* is relatively entrenched in the English literature. It is essential that diagnostic terms with specific meanings, such as *gastroenteritis* or *gastritis,* not be used as catch-all phrases to describe patients with NSAP.

Although NSAP is a diagnosis of exclusion, there are some clinical features characteristically associated with it. Nausea, present in nearly half the patients, is the most common symptom after abdominal pain. Pain location is often midepigastric or in the lower half of the abdomen. Tenderness is not usually severe, is absent in about one-third of the patients, and localized to the RLQ or midepigastrium in another third. Laboratory tests are usually normal, although a mild leukocytosis is entirely compatible with NSAP. Abdominal radiographs are virtually always normal or nonspecific.[11]

The key to confirming NSAP is reexamination within 24 h (see below).

Special Considerations

THE ELDERLY ABDOMEN In a large combined series of >40,000 patients presenting with acute abdominal pain (<1 week duration), about one patient in four was >50 years old. Diagnostic accuracy in this group fell below 50 percent, reaching a low of about 30 percent in octogenarians, whose corresponding mortality was about 70 times that of patients <30 years old.[16]

Reasons for Increased Diagnostic Error in the Evaluation of the Elderly Abdomen DIFFERENT PREVALENCE OF DISEASE The causes of abdominal pain in elderly patients occur with a substantially different frequency than in younger persons, requiring that the emergency physician approach older patients with a different weighting of prior probabilities than those in younger adults. For example, as shown in Table 68-2, the most common cause of abdominal pain in virtually all consecutive series of adults presenting to the ED is NSAP.[16] When ED patients are dichotomized by age at 50 years, NSAP remains at the top of the list of diagnoses among the younger cohort; however, among the older patients, prevalence is markedly diminished to <20 percent, as shown in Table 68-3.[34]

DIFFERENT KINDS OF DISEASE Another explanation for the increased error and mortality in elderly abdominal pain is that, in addition to an age-related shift in the frequency of certain diseases, there are a number of serious causes of abdominal pain that only rarely arise among younger patients. Specifically, older patients are at risk for vascular causes of abdominal pain—e.g., mesenteric ischemia, AAA, and myocardial infarction.[16,34]

DIFFERENT EVOLUTION OF DISEASE Among common causes of abdominal pain in both young and old, the nature of the presentation and evolution of the same illness is often very different. Using appendicitis as the most common example, those >50 years of age are much more likely to have generalized pain and tenderness (about 14 percent) than are younger patients (about 2 percent).[12] This failure to localize to an area of maximum pain/tenderness may help to account for the nearly 10-fold difference in perforation rate (4 versus 37 percent) in those >60 years of age as compared with their younger counterparts. Later presentation in the course of illness may also contribute to the increased perforation rate (75 percent of the elderly with appendicitis have >24 h of symptoms before seeking care), as may the higher frequency of distention in older patients, making the physical examination more difficult.

DIFFERENT THRESHOLD FOR INTERVENTION An additional contributor to the high incidence of perforation in all causes of elderly abdominal pain is the understandable reluctance to operate upon frail elderly patients without clear-cut signs of peritoneal irritation. This is reflected in the well-established inverse association between negative laparotomies and perforated appendices. At about the age of 45 years, the negative laparotomy rate begins to decrease in parallel with the increase in perforations until each plateaus at about 80 years.[16] Thus, the negative laparotomy rate for appendicitis is lowest in the oldest, who are the group most likely to perforate and therefore most in need of early, expedient surgery.

General Strategies for Evaluation of the Elderly Abdomen ANTICIPATE THE NEED FOR SURGICAL INTERVENTION Assume that the elderly patient with abdominal pain has surgical disease. About 40 percent of all patients >65 years of age presenting to the ED with this complaint ultimately require surgery.

ABDOMINAL AORTIC ANEURYSM   Apparent renal colic is an abdominal aortic aneurysm (AAA) until proven otherwise. Do not be misled by the presence of hematuria.

MESENTERIC ISCHEMIA   Consider the diagnosis of mesenteric ischemia in all elderly patients with abdominal pain, especially if the pain appears out of proportion to tenderness. The presence of atrial fibrillation, cardiovascular or peripheral vascular disease, especially recent MI, increases the likelihood of mesenteric ischemia. Bloody diarrhea will not be seen until mucosa begins to slough and is far more common in ischemic colitis, which is a relatively benign disease in comparison with mesenteric ischemia.

IMAGING   Be liberal with imaging in the elderly who have abdominal pain of unclear etiology. If there is a serious question about important underlying abdominal disease in the setting of a relatively "well-looking" elderly patient, one should have a low threshold for performing an abdominal CT.

GASTROENTERITIS   Attributing vomiting or diarrhea in the elderly to gastroenteritis is inadvisable, particularly in association with abdominal pain.

CONSTIPATION   Because the prevalence of constipation is so high in the elderly, it is a risky explanation for abdominal pain of sufficient severity to bring an older person to an ED. As a corollary to this, apparent resolution of abdominal pain in the elderly with an enema (which is itself a questionable intervention) should not be taken as evidence of a causal relationship between constipation and abdominal pain.

HIV/AIDS   There are several features of patients with HIV and/or acquired immunodeficiency syndrome (AIDS) presenting to the ED with abdominal pain that merit special attention.[35] Abdominal pain is rarely the index event that identifies a patient with HIV disease. Rather, most patients presenting with HIV-associated acute abdominal pain will have previously met criteria for AIDS.

Enterocolitis is the most common cause of abdominal pain in AIDS patients. It is typically accompanied by profuse diarrhea and dehydration. If associated with fecal leukocytes, it is more often accompanied by bacteremia than in immunocompetent patients. Perforation, when it occurs, tends to be large bowel perforation, often caused by *Cytomegalovirus* (CMV).[35] Obstruction presents typically but may be due to an atypical cause such as Kaposi's sarcoma, lymphoma, or atypical mycobacteria.

Biliary tract disease is very common in AIDS patients, presenting in one of two unique forms: (1) AIDS-related cholangiopathy, caused principally by CMV or *Cryptosporidium* sp., which can be treated with sphincterotomy, and (2) AIDS-associated cholecystitis, which is usually acalculous and has a propensity for early perforation.

TREATMENT

General Strategies

HYPOTENSION   Clinically important decreases in cardiac output are commonly underdiagnosed in the elderly. This is because many older patients have chronic systolic hypertension, making the traditional threshold value of 100 mmHg systolic an insensitive marker for declaring hypotension or shock in the elderly. Thus, in the setting of abdominal pain, the blood pressure must be interpreted in a clinical context if it is to provide meaningful information.

In abdominal pain with relative hypotension, management depends upon the presumed etiology. In the absence of heavy GI bleeding, which is not typically accompanied by abdominal pain, younger patients are most likely to be volume-contracted from vomiting, diarrhea, decreased intake by mouth, or third-spacing into the GI tract. Treatment is isotonic crystalloid.

In a smaller number of young patients, hypotension may be the result of abdominal sepsis. In this setting, in addition to appropriate antibiotics (see below) and isotonic crystalloid, pressors may be necessary to sustain blood pressure until more definitive intervention can be undertaken. Vasoconstrictors are indicated in septic (vasodilatory) shock, with levophed or high-dose dopamine as the usual choice of agent.

In older patients, in addition to volume contraction and a higher incidence of abdominal sepsis, associated cardiovascular disease represents a third possible cause of decreased cardiac output. Indeed, in the setting of nonocclusive mesenteric ischemia, the diminished cardiac output may be a cause rather than a consequence of the presenting abdominal pain. In this circumstance, if the problem is acute myocardial ischemia, an aortic balloon pump may be used to buy time until the underlying problem can be corrected with angioplasty. Or, if the decreased cardiac output is secondary to congestive heart failure (CHF), appropriate treatment for CHF is indicated.

ANALGESICS   In the United States, analgesia is usually withheld from patients with acute abdominal pain until a firm treatment plan is formulated. There is no evidence to support this long-standing practice, which has been attributed to Sir Zachary Cope. More than 75 years ago, Dr. Cope wrote that provision of analgesia to patients with abdominal pain might obscure the diagnosis. However, much has changed since that time in both the diagnosis and treatment of abdominal pain: (1) there have been major advances in diagnostic technology, which is largely independent of the patient's degree of evolving pain and tenderness, and (2) there have been parallel advances in therapeutic technology, including the universal availability of antibiotics and sophisticated intra- and perioperative monitoring.

The most recent edition of Cope's text on the acute abdomen by Silen has softened this recommendation somewhat, but it notes that "it will take many generations to eliminate it [withholding analgesia in abdominal pain] because the rule has become so firmly ingrained in the minds of physicians." [36]

There are four published randomized clinical trials in the English literature, each compatible with the hypothesis that administration of opioids to patients with abdominal pain is at least safe.[37,38,39 and 40] Although none of these trials answers the question definitively, at least one of them suggests that diagnosis and management of abdominal pain may, if anything, be facilitated by opioids. The plausibility of this is supported by an improved ability to obtain a history from a patient relieved of severe pain and the enhanced localization of tenderness through reduction of guarding. These data on opioids cannot be extrapolated to nonsteroidal anti-inflammatory drugs (NSAIDs), such as parenteral ketorolac, because NSAIDs are not pure analgesics and have the potential to mask evidence of early peritoneal inflammation.[41] Pending the definitive study, at the present time available evidence favors judicious use of opioid analgesia in the ED management of acute abdominal pain.

ANTIEMETICS   Although metoclopramide (Reglan) appears to be a more effective antiemetic, prochlorperazine (Compazine) is theoretically preferred for control of vomiting in acute abdominal pain because it is less likely to increase motility. Most patients will respond within 10 min to 2.5 mg IV of prochlorperazine, given over 1 min, to be repeated once. Although higher doses have not been tested in the ED setting, 10 to 40 mg prochlorperazine by slow intravenous infusion has been administered to patients receiving chemotherapy, demonstrating a therapeutic dose-response in emesis control with minimal toxicity. Antiemetics may obviate the need for insertion of a nasogastric tube, whose therapeutic value in abdominal pain has never been convincingly demonstrated.

ANTIBIOTICS   Antibiotics are indicated in suspected abdominal sepsis and in most patients with localized and all patients with diffuse peritonitis. Endogenous gut flora cause abdominal infections in the GI or GU tract. Primary gynecologic infections, of which PID is the prototype, behave differently and are discussed separately under the treatment of suspected PID (see Chap. 105). In all intraabdominal (nongynecologic) infections, coverage should be targeted at anaerobes and facultative aerobic gram-negative organisms. An exception to this generalization is the need to provide additional coverage for gram-positive aerobes, e.g., *Pneumococcus*, in spontaneous bacterial peritonitis (SBP). SBP, also known as primary peritonitis, occurs in patients with cirrhosis and ascites, probably owing to spontaneous bacteremic seeding of ascitic fluid. The modifier *primary* is used to distinguish SBP from the more common secondary peritonitis of intraabdominal organ inflammation, ischemia, leakage, or perforation.

Historically, a two-drug regimen, attacking gram-negative aerobes with an aminoglycoside (gentamicin or tobramycin, 1.5 mg/kg IV q8h, or amikacin 5 mg/kg IV q8h) and anaerobes with metronidazole (1 g IV loading dose, followed by 500 mg IV q6h, given slowly) or clindamycin (900 mg IV q8h) was used to obtain the requisite coverage for intraabdominal infections. While dual therapy may still be necessary for sicker, older, immunocompromised, or hypotensive patients, monotherapy with a second-eneration cephalosporin, such as cefoxitin (2 g IV q6h) or cefotetan (2 g IV q6h), should be adequate for those who are less ill. Alternative "combined" monotherapy includes ampicillin-sulbactam (3.0 g IV q6h) or ticarcillin-clavulanate (3.1 g IV q6h). For patients requiring a more potent regimen but in whom one is reluctant to use an aminoglycoside, the combination of piperacillin-tazobactam (3.3 g IV q6h) appears to be at least as effective as imipenem-cilastatin (1 g IV q6h,

maximum dose), particularly in the treatment of suspected biliary sepsis, and is less likely to cause seizures.

For patients with a history of severe allergy to penicillins/cephalosporins, aztreonam (2 g IV q6h, maximum dose) and clindamycin/metronidazole is a safe alternative. In SBP, monotherapy with a third-generation cephalosporin, such as ceftriaxone (2 g IV q12h, maximum) or cefotaxime (2 g IV q4h, maximum), broadens the spectrum sufficiently to cover for *Pneumococcus* in addition to the gram-negative enteric bacteria, such as *E. coli*.

Perhaps the most persuasive reason to forgo use of an aminoglycoside is not the renal or vestibular toxicity but rather the frequent underdosing of patients because of the fear of toxicity, causing emergence of antimicrobial resistance, particularly of *Enterococcus* species.[42]

DISPOSITION

General Indications for Admission

In addition to those with a specific diagnosis requiring admission, the following patients should be seriously considered as candidates for hospitalization: Those who appear ill; any elderly or immunocompromised (including HIV-positive) patient (with or without comorbidity) in whom the diagnosis is unclear; younger, healthy patients in whom the diagnosis is unclear and any potentially serious cause of abdominal pain has not been comfortably excluded; intractable pain or vomiting; acute or chronic altered mental status; inability to follow discharge or follow-up instructions; undomiciled, living in shelter, or otherwise lacking social supports; excessive alcohol or other drug use.

NONSPECIFIC ABDOMINAL PAIN   A substantial number of patients who are discharged with the diagnosis of NSAP are initially admitted as suspected appendicitis. This may be the reason that there appears to be an unexplained predominance of RLQ pain among patients discharged with the diagnosis of NSAP.

Although this entity is poorly understood pathophysiologically, follow-up among patients discharged from the ED with this diagnosis has found that nearly 90 percent are better or asymptomatic at 2 to 3 weeks.[11] Similarly, follow-up of patients discharged from inpatient services with the diagnosis of NSAP has shown that about 80 percent have no further problems and are asymptomatic at 5 years. Of the remainder, about one-third are rehospitalized, of whom one-third have appendicitis. Some of these individuals probably had early appendicitis on their prior admission, with spontaneous resolution due to disimpaction of the appendiceal lumen. [43] Among this group, it is plausible that some later developed recurrent appendicitis that did not resolve and went on to appendectomy. The remaining two-thirds of patients who were neither rehospitalized nor asymptomatic turned out to have "benign" gynecologic and colonic problems, most commonly irritable bowel. [44,45]

The key to confirming NSAP as a working diagnosis is reexamination in 24 h, repeated as necessary if patients remain symptomatic. Whether this occurs on the inpatient service, in the ED observation unit, or at home depends upon the culture of the institution, the clinician's degree of uncertainty about the diagnosis, and the presence of facilities for reliable outpatient follow-up.

69 ABDOMINAL PAIN IN THE ELDERLY

Robert McNamara

EPIDEMIOLOGY

There are limited data on the number of emergency department (ED) visits for abdominal pain in the elderly. Patients aged 65 or older accounted for 9 percent of ED visits for abdominal pain in an adult ED population (age > 15). [1] A recent study from a rural ED reported that abdominal pain in those age 65 and greater represented 0.23 percent of all ED visits. [2] In the United States, abdominal pain is the most frequent reason for an ED visit, accounting for 5.1 million of the 96 million ED encounters in 1996. [3] The preceding figures would create estimates ranging from 230,000 to 450,000 elderly patients presenting to U.S. EDs per year with abdominal pain.

Regardless of the current frequency of ED visits for abdominal pain in the elderly, one can count on a steadily rising volume of such cases. The U.S. population is rapidly aging. Current projections predict that those aged 65 and older will rise from 13 percent of the population in the year 2000 to approximately 20 percent by the year 2030. [4] Since the elderly use the ED more frequently than their proportionate numbers in the general community would indicate, this trend will affect emergency care significantly. [5] Practicing emergency physicians rate abdominal pain as the most challenging clinical situation in this population. [4] Over half of the patients aged 65 or greater who present to the ED with abdominal pain require admission, and one-third or more will require surgical intervention at some point during their hospital stay. [1,3] The mortality rate across all causes of abdominal pain in the elderly is 11 to 14 percent, justifying its anxiety-provoking reputation. [6] The role of the emergency service in the care of these patients is critical, as the mortality rate doubles if the diagnosis rendered in the ED is incorrect. [6,7]

PATHOPHYSIOLOGY

The approach to acute abdominal pain in all age groups requires an understanding of the visceral and somatic pathways of pain perception. Neural pathways are not rerouted as we age; however, it is an accepted axiom that the perception of abdominal pain or at least the reporting of it is altered in the elderly. [7] There is limited proof of this axiom for abdominal pain; however, it is fairly clear that ischemic heart disease is associated with altered pain perception or reporting in the elderly. Other factors such as fear, stoicism, and communication problems may affect the reporting of abdominal pain in older persons. [7,8]

Aging is associated with several factors that influence the prevalence and spectrum of abdominal conditions encountered in this population (Table 69-1). For example, older patients have a statistically increased frequency of abdominal aortic aneurysms that could potentially rupture and present to the ED. The presence of comorbid diseases and their associated therapy certainly contributes to the complexity of care in older patients with abdominal pain. Other important pathophysiologic features to keep in mind regarding this age group include decreased cardiopulmonary reserve, lowered tolerance for hypovolemic shock, and the treatment issues of altered pharmacodynamics and pharmacokinetics.

Increased Risk in the Elderly	Resultant Disease
ASCVD	AAA, mesenteric ischemia, ischemic colitis
Cholelithiasis	Cholecystitis, pancreatitis
Carcinoma	Large bowel obstruction, intussusception
Immobility	Colonic volvulus, Ogilvie syndrome
Medications	Peptic ulcer disease, pancreatitis
Prior surgery	Small bowel obstruction

Key: ASCVD, atherosclerotic cardiovascular disease; AAA, abdominal aortic aneurysm.

TABLE 69-1   Influence of Aging on Abdominal Pain

CLINICAL FEATURES

The History

History taking in older patients with abdominal pain should follow the same general sequence and rules as in younger patients. Unfortunately, an accurate history may be difficult to obtain in this age group. Serious abdominal disease may cause an acute mental status change or distract the patient's attention. Memory deficits or underlying dementia can obscure important aspects, such as the time and nature of the onset of pain. [8] The noise and pace of the ED are often inconsistent with the needs of the older patient who is attempting to relay historical information about his or her abdominal pain. The following historical aspects should be covered:

- *Time of Onset:* Pain awakening the patient from sleep should always be considered significant.
- *Mode of Onset:* A sudden, severe pain should alert the physician to the possibility of serious disease, including a ruptured abdominal aortic aneurysm, aortic dissection, superior mesenteric artery embolus, perforation of a peptic ulcer, or volvulus. It is equally important to remember that these entities may present without a sudden onset. For example, in one prospective series of patients over the age of 70 with perforated ulcers, only 47 percent reported a sudden onset of pain. [6]
- *Progression since Onset:* Steady improvement is reassuring, worsening is not.
- *Location of the Pain:* In general, this seems to be reliable in the elderly. For example, appendicitis in this age group, although diagnostically difficult, generally presents with right-lower-quadrant pain. [9]
- *Character of the Pain:* Severe pain should be taken as an indicator of serious disease. Think of mesenteric ischemia, perforation of a gastric ulcer, vascular accidents, and volvulus.
- *Referral or Radiation of the Pain:* As with location, this aspect of abdominal pain should not change with aging. For example, the referral pattern is helpful in

diagnosing older patients with biliary tract disease. [8]

- *Precipitating and Relieving Factors.* Pain with movement suggests irritation of the parietal peritoneum. The results of any self-treatment should be determined.
- *Prior Episodes:* This generally suggests a medical cause with the notable exceptions of mesenteric ischemia (intestinal angina) and cholecystitis. [10]
- *Associated Symptoms:* Anorexia, vomiting, bowel habits, and urinary symptoms are key areas to cover. In general, pain almost always precedes vomiting in surgical causes of abdominal pain, while the converse is true in 75 percent of patients with gastroenteritis or a nonspecific cause of abdominal pain. [1]
- *Further History:* A detailed review of systems is desirable to seek other causes of abdominal pain, especially those of a cardiopulmonary nature. Do not neglect a careful review of medications including over-the-counter nonsteroidal anti-inflammatory agents. Underlying alcohol abuse must also be a consideration in this age group.

The Physical Examination

As with the history, the abdominal examination in the older patient proceeds in the same manner as for younger patients. Complicating factors may include the patient's stoicism or inability to report pain and the less pronounced muscular response to inflammation. [7,8] The following should be addressed:

- *General Appearance:* An ill-appearing older patient with abdominal pain should cause immediate concern, given the high mortality rate in general case series of elderly patients with abdominal pain. [1,6] On the other hand, the clinician can be misled by a deceptively "well" appearance in the face of serious underlying disease. [8]
- *Vital Signs.* Reflexively think of a ruptured abdominal aortic aneurysm in the hypotensive older patient with abdominal pain. [11] Determination of a core temperature is advisable; however, lack of fever commonly occurs with serious infectious causes of abdominal pain. Tachypnea and tachycardia are nonspecific findings but should raise the possibility of a cardiopulmonary disorder.
- *Inspection and Auscultation:* Distention is common in large bowel obstruction, including sigmoid and cecal volvulus. [12] High-pitched "rushes" suggest small bowel obstruction.
- *Abdominal Palpation:* In general, the location of tenderness is generally reliable in the older patient. Appendicitis usually manifests right-lower-quadrant tenderness, [6,9,13] while cholecystitis and pancreatitis generally cause tenderness in the expected location. [8] Unfortunately, abdominal guarding or muscular rigidity may be lacking despite the presence of chemical or infectious peritoneal irritation. This is partially attributed to the relatively thin abdominal musculature of older patients. [7,8] Disturbingly, of patients over the age of 70 with a perforated ulcer, only 21 percent had epigastric rigidity. [6]
- *Rectal Examination:* This should be performed routinely, and the detection of occult blood should receive follow-up evaluation. In one series of patients over the age of 50, some 10 percent of those discharged from the ED with a diagnosis of nonspecific abdominal pain were diagnosed with cancer, principally of the large bowel, within a year. [14]
- *Further Examination:* There should be careful inspection for hernias, particularly of the femoral canal in the older female patient. Aortic dissection may manifest with unequal femoral pulses. The back should be inspected for herpes zoster. Genital and pelvic examinations may reveal the cause of pain. Assessment of the heart and lungs may yield clues to a nonabdominal cause of the pain.

SPECIFIC DIAGNOSES AND ISSUES

This section reviews the major diagnostic causes of abdominal pain in the older patient and points out specific diagnostic issues to consider in this population. The frequency of each particular disease varies in the reported case series of elderly patients presenting to the ED with abdominal pain. Cholecystitis (12 to 41 percent) is generally the most frequently encountered disease of a surgical nature, followed by bowel obstruction (7 to 14 percent). Nonspecific abdominal pain is also a frequent diagnosis (10 to 23 percent). Perforated viscus, appendicitis, diverticulitis, and pancreatitis each generally represent around 4 to 7 percent, depending on the case series. Aortic aneurysms and mesenteric ischemia are less common.[3,6,8] General coverage of the following conditions can also be found in other chapters.

Appendicitis

Diagnostic problems surrounding appendicitis in the elderly are well known in emergency medicine (see Chap. 74) In one series, only 51 percent of patients over the age of 60 with proven appendicitis had that diagnosis made during the ED phase of their care. [13] Delayed presentation is common and contributes to the higher perforation and complication rate. One must be careful to not exclude appendicitis because of prolonged symptoms, as a small but significant percentage of the elderly will wait more than a week to seek care for this condition.

The abdominal pain is generally reported to be in the right lower quadrant; however, the description may be vague or the pain poorly localized. [9,13] In one study, migration was recorded in only 35 percent of elderly patients with appendicitis. [8] Anorexia, an expected finding in younger patients, may be lacking, while nausea and vomiting are reported in roughly half of elderly patients with appendicitis. [8,9,13] Diarrhea and urinary tract symptoms do not exclude the disease.

Fever may be absent in one-third or more. Tenderness in the right lower quadrant is a frequent finding occurring in 80 to 90 percent of these patients. The presence of peritoneal signs such as rigidity and rebound tenderness have been reported to range from 20 percent to more than 80 percent. [8] Laboratory assessment is potentially misleading, as 20 percent will have a white blood cell count below 10,000. [9,13] Abdominal radiographs rarely add to the diagnostic process and can lead one astray by suggesting small bowel obstruction. [8,9]

It is prudent to include appendicitis in the differential diagnosis of any elderly patient with abdominal pain who has not undergone an appendectomy. The clinician must not expect a neat diagnostic package. In one series, only 20 percent of older patients with appendicitis had all of fever, nausea or vomiting, tenderness in the right lower quadrant, and an elevated white blood count. [13]

Acute Cholecystitis

Acute cholecystitis (see Chap. 81) is the most common surgical emergency in older patients with abdominal pain. Fortunately, physicians have a record of high diagnostic accuracy for this condition in the elderly. [6] The presenting features of acute cholecystitis in the older population are similar to those in younger patients. Right-upper-quadrant or epigastric pain is present in most patients, while radiation to the back or shoulder area occurs in about one-third. Roughly half will report nausea or vomiting, and jaundice will occur in 10 to 30 percent. Fever may be absent in over half of these patients. Laboratory testing may be misleading, as 30 to 40 percent can have a normal white blood cell count. Plain radiographs are of little value; the diagnostic study of choice is ultrasonography. Computed tomography is generally of limited usefulness. [8,10,15]

Conservative management is generally unsuccessful and operative delay increases the complication rate. The older patient can appear deceptively well with acute cholecystitis; however, the overall mortality rate approximates 10 percent. [16] Additionally, a clinical picture of fever, jaundice, and altered mental status without significant abdominal findings has been described in a subset of elderly patients with acute cholecystitis.

Small Bowel Obstruction

The diagnosis of small bowel obstruction is usually straightforward in the older patient (see Chap. 75). Colicky pain, distention, and vomiting that progresses from gastric contents to bile-stained to feculent are the cardinal features. Prior surgery is still the principal risk factor in this age group, and the physician should conduct a careful search for hernias. A missed hernia can lead to a fatal outcome. The mortality rate for small bowel obstruction in the elderly ranges from 14 to 45 percent. Errors in management most frequently relate to misinterpretation of radiographic studies and excessive delays in operative management. [7]

Perforated Peptic Ulcer

Although peptic ulcer disease most frequently presents as gastrointestinal bleeding, perforation is an important cause of abdominal pain in the older patient (see Chap. 73). The expected description of a sudden, acute onset of epigastric pain is reported in only one-half of patients over age 70 with a perforated ulcer. [6] The pain has usually been present only for a matter of hours and is generally severe, constant, and present to some degree in the epigastrium. Free intraperitoneal perforation can cause generalized pain or lower-quadrant symptoms. [8] Vomiting is infrequent. The physical examination is expected to reveal epigastric tenderness, although

muscular guarding is variable. In one study, only 21 percent of the elderly with a perforated ulcer had epigastric rigidity. [6] Fever is generally not present early on.

The key diagnostic mistake is excluding this diagnosis because of a lack of "free air" on plain radiographs. Roughly 40 percent of patients with perforated ulcers will not have this finding on their initial radiographs. The left lateral decubitus view or the lateral view of the upright chest radiograph may help to detect the presence of free air. Repeat radiographs after installation of 500 mL of air by a nasogastric tube increases the diagnostic yield of plain radiographs. Computed tomography is capable of detecting small amounts of air in the peritoneal cavity. In one series, missed perforated ulcer was the leading cause of death in elderly patients with abdominal pain, and in each case the plain radiographs did not reveal free air. [7]

Large Bowel Obstruction

A carcinoma is the leading cause of large bowel obstruction, while volvulus and diverticulitis account for most of the remaining cases. All of these precipitating conditions are more common in the elderly. The overall mortality rate approximates 40 percent. Distention is common, vomiting and constipation are reported in about half the patients. Importantly, a significant percentage (up to 20 percent) will report diarrhea. A history of rectal bleeding, altered bowel habits, or weight loss may be present with underlying carcinoma.[12] The pain is usually gradual in onset; however, cecal volvulus can present with the acute onset of severe, colicky pain. [17] Sigmoid volvulus is two to three times more frequent than cecal volvulus and more commonly presents with a gradual onset of pain. [18] Fever or the presence of peritoneal irritation suggests a perforation or gangrenous bowel.

The principal diagnostic study is plain abdominal radiography; however, cecal volvulus may appear as small bowel obstruction and require a barium enema to make the diagnosis.[17] In one large series, a cecal diameter of 10 cm was not useful in predicting perforation. In fact, cecal diameters of up to 20 cm responded to routine decompression methods.[12] Colonic pseudoobstruction, also known as Ogilvie's syndrome, can present in a manner similar to that of large bowel obstruction. This is massive gaseous distention of the colon, generally occurring in chronically ill, immobilized older patients. The abdomen is distended and tympanitic but usually nontender. A cavernous rectal vault is an important clue on physical examination. Old medical records frequently reveal several such presentations. It is important to avoid surgery in these patients as there is no underlying mechanical blockage. [19]

Diverticulitis

The presence of diverticulae increases with age and acute inflammation, diverticulitis, is a common cause of abdominal pain in the older patient (see Chap. 77). This is covered in a separate chapter, however, there are a few important points worth emphasizing. First, computed tomography is the diagnostic study of choice, as a barium enema or colonoscopy can precipitate perforation. Second, diverticulitis can be mistaken for a pelvic mass of gynecologic origin in the older female.

Acute Mesenteric Infarction

The management of mesenteric ischemia is complicated by diagnostic delays that are often associated with a fatal outcome. An aggressive approach is necessary, as early diagnosis markedly improves the chances of survival. [20] The key to making the correct diagnosis is to consider this possibility in the elderly patient with abdominal pain and risk factors for the disease. Superior mesenteric artery occlusion accounts for roughly half of the cases, with embolus and thrombus nearly equal as the source. Nonocclusive infarction accounts for another quarter of the cases, with inferior mesenteric artery occlusion, venous thrombosis, arteritis, and dissection making up the remainder.[21]

The specific risk factors to be aware of are listed in Table 69-2. The principal manifestation of mesenteric infarction is severe abdominal pain, often refractory to narcotic analgesics. Such severe pain combined with a relatively normal abdominal examination is considered the sine qua non of early mesenteric infarction. Despite its vascular nature, the overall spectrum of mesenteric ischemia involves a gradual onset of abdominal pain. If an embolus is the cause, sudden, severe pain may be reported.[20] Prior episodes can be reported, particularly if mesenteric arterial thrombosis is the cause. Associated gastrointestinal symptoms are very common and should not lead the physician astray. Nausea, anorexia, and vomiting are common, and up to half of these patients will report diarrhea. Objective findings on physical examination are inevitable and should be considered an indication of intestinal necrosis and possible perforation. Theoretically, the stool should be guaiac-negative early on. Approximately 60 percent will present with guaiac-positive stools. [21] Laboratory abnormalities such as metabolic acidosis and extreme leukocytosis are likewise indicators of advanced, perhaps irreversible disease.

Mesenteric Condition	Risk Factors
SMA embolus	Atrial fibrillation, recent MI
SMA thrombosis	Atherosclerosis, low-CO states
Nonocclusive infarction	Low-CO states (esp. CHF), digoxin therapy
Venous thrombosis	Hypercoagulability, prior DVT, liver disease

Key: SMA, superior mesenteric artery; MI, myocardial infarction; CO, cardiac output; CHF, congestive heart failure; DVT, deep venous thrombosis.

TABLE 69-2   Risk Factors for Mesenteric Ischemia

The critical aspect of care is to pursue mesenteric angiography based on the history and physical examination without waiting for "hard" evidence on the exam or diagnostic studies. One series reported a 90 percent survival rate when angiography was performed prior to the onset of peritonitis. [20] The usual survival rate is 30 percent or less.

Abdominal Aortic Aneurysm

Rupture of an abdominal aortic aneurysm is a lethal condition that will be more frequently encountered as the population ages (see Chap. 54). The incidence of abdominal aortic aneurysm in men increases rapidly after age 55 and peaks at the age of 80 at 5.9 percent. In women, the incidence rises quickly after age 70, peaking at 4.5 percent at age 90. [22] Early detection and elective repair are associated with a mortality rate of about 4.0 percent. The mortality rate among those who reach the hospital is generally on the order of 50 percent or higher. A favorable outcome depends on a rapid diagnosis and early operative intervention. Unfortunately, initial misdiagnosis is common, occurring in 30 percent of patients in one series. [11]

The most common symptom is abdominal pain, occurring in 70 to 80 percent, and not back pain, which is noted by just over half. The typical pain is sudden and significant. Atypical locations include the hips, inguinal area, and external genitalia. Syncope may be part of the presenting picture with or without significant blood loss from the aneurysm. Because of the lethal nature of this condition, the diagnosis should be considered in any older patient, especially male, with back, flank, or abdominal pain. Hypotension occurs at some point in the majority of these patients. Palpation of a tender, enlarged (>5 cm) aorta is the key physical finding. Unfortunately, the size of the aorta is often difficult to determine on examination.

Management of the unstable patient with a clinically suspected ruptured abdominal aortic aneurysm involves immediate operative intervention without confirmatory testing. A supine plain radiograph of the abdomen will often reveal a clue to the diagnosis, such as a calcified aortic outline or loss of the renal or psoas outline. In the stable patient, ultrasonography can delineate the size of the aorta, while computed tomography gives more information regarding actual rupture. [22] Any such testing should be expeditious and must include careful monitoring of the patient's condition, with appropriate alerting of the operating theater and surgical team.

The most common diagnostic mistake is to diagnose renal colic in these patients. This is understandable given the severe pain and the location of the pain. Furthermore, abdominal aortic aneurysm may present with hematuria. It should be axiomatic that aortic aneurysm be strongly considered in any patient over the age of 50 suspected of having renal colic. An episode of hypotension is often wrongly ascribed to developing sepsis or a "vagal" reaction in patients initially misdiagnosed

as having renal colic.[11]

Other Conditions and Causes

The list presented above is certainly not comprehensive for abdominal pain in the elderly. Aortic dissection is common in this age group and may cause abdominal pain directly or by causing ischemia of intraabdominal organs, including the bowel. The diagnosis of pancreatitis in this age group is generally straightforward. Tumors can serve as lead points for intussusception in elderly patients. Acute gastric volvulus should be considered in the older patient with sudden epigastric pain, repetitive nonproductive retching, and inability to pass a nasogastric tube. Older patients with underlying vascular disease may develop ischemic colitis, which can be difficult to distinguish from other forms of colitis.

The list of other conditions that can cause abdominal pain in the older patient is extensive, highlighting the need for the comprehensive evaluation of such patients. The most important disease to suspect is acute myocardial ischemia. Some 1 to 2 percent of elderly patients with abdominal pain will be having a myocardial infarction.[10] Virtually all other "chest" diseases can cause abdominal pain, including pneumonia, pulmonary embolism, empyema, tuberculosis, congestive heart failure, esophageal rupture, and endocarditis. Genitourinary disease including renal colic, pyelonephritis, epididymitis, and testicular torsion is a possible cause of abdominal pain in the elderly. Diabetic ketoacidosis, herpes zoster, hypercalcemia, addisonian crisis, hemochromatosis, and retroperitoneal or rectus sheath hematomas secondary to anticoagulant therapy are examples of "medical" causes of abdominal pain in the elderly.

DIAGNOSTIC CONSIDERATIONS

A comprehensive review of diagnostic testing is available in the individual chapters covering the above conditions, however, certain general and specific points regarding the elderly patient are useful. The most critical axiom is to not let the results of diagnostic testing change your diagnostic thinking in the face of strong clinical evidence of a disease. Laboratory testing can be problematic in this age group. A normal white blood cell count cannot be used to exclude serious intraabdominal diseases, including those with an infectious component. For example, a normal total white blood cell count is found in 20 percent of elderly patients with appendicitis and 30 percent or more of those with cholecystitis. Serum amylase levels are frequently normal in the setting of pancreatitis. Serum lipase is more helpful but still not completely accurate. For the patient's sake, one should hope to see little or no evidence of lactic acidosis in mesenteric ischemia. An elevated bilirubin suggests hepatobiliary disease; however, in the ill older patient, this can be a nonspecific elevation. For example, up to 17 percent of elderly patients with appendicitis can have hyperbilirubinemia.[13] Since undiagnosed cancer is a frequent cause of "nonspecific" abdominal pain in older patients, the clinician must be careful not to ignore a low hemoglobin or microcytic indices on the blood count.

Radiographic studies can be equally problematic. Plain radiographs in the setting of perforated ulcer do not show free air in up to 40 percent of the patients. In appendicitis, the abdominal series is often interpreted as supporting the diagnosis of small bowel obstruction. Ogilvie's syndrome will commonly include a radiographic picture consistent with true large bowel obstruction.

Bedside ultrasound in capable hands can assist in rapidly securing the diagnosis of abdominal aortic aneurysm. It can also help clarify the clinical picture in acute cholecystitis and renal colic. Computed tomography is an important diagnostic modality in the older population with abdominal pain. The physician must remember that the unstable patient with a suspected abdominal aortic aneurysm belongs in the operating room and not in the computed tomography suite.

Treatment of the specific entities is covered more thoroughly elsewhere. General measures for the elderly patient with an acute abdominal condition overlap those of younger age groups. Specific useful measures include nasogastric decompression, fluid and blood component resuscitation as indicated, judicious use of narcotic analgesia, and tailored antibiotic coverage.

A period of observation with serial examinations should be considered in the elderly patient with undifferentiated abdominal pain. Depending on the circumstances, this could occur either in the ED, an observation unit, or in an inpatient unit. Patients with severe pain or worsening pain while in the ED should generally not be sent home. Resolved pain is generally reassuring, and such patients who are discharged should receive routine follow-up with their primary care providers. Biliary tract disease and underlying cancer are possibilities in this circumstance. [14]

If an older patient is to be discharged with abdominal pain, the patient should be instructed to return if the symptoms worsen or do not resolve in a brief period of time (6 to 8 h). Similarly, a time limit should be placed on vomiting, as this will quickly resolve in most benign causes. New vomiting after discharge should prompt reevaluation.

70 GASTROINTESTINAL BLEEDING

David T. Overton

Gastrointestinal (GI) bleeding is a common problem in emergency medical practice and should be considered potentially life-threatening until proven otherwise.

Acute upper GI bleeding in adults has an overall annual incidence of approximately 100 per 100,000. It is more common among males and markedly more common among the elderly. Its associated mortality rises with age.[1,2] Lower GI bleeding is somewhat less common, with an annual incidence of approximately 20 per 100,000. It, too, is more common among males and among the elderly.[3]

As with all true emergencies, the traditional triad of medical history, physical examination, and diagnosis often must be accomplished simultaneously with resuscitation and stabilization. Factors associated with a high morbidity rate are hemodynamic instability, repeated hematemesis or hematochezia, failure to clear with gastric lavage, age over 60, and coexistent organ system disease.

PATHOPHYSIOLOGY

Causes of Upper Gastrointestinal Bleeding

Upper GI bleeding is defined as that originating proximal to the ligament of Treitz, whereas lower GI bleeding originates more distally.

PEPTIC ULCER DISEASE   Peptic ulcer disease, including gastric, duodenal, and stomal ulcers, remains the most common etiology for upper GI hemorrhage, encompassing approximately 60 percent of all cases.[2] Duodenal ulcers, approximately 29 percent of the total, will rebleed in approximately 10 percent of cases, usually within 24 to 48 h. Gastric ulcers, approximately 16 percent of all cases, are more likely to rebleed. Stomal ulcers are uncommon (less than 5 percent of all upper GI bleeds) and are present in only one-third of bleeding patients with a history of prior peptic ulcer surgery.

EROSIVE GASTRITIS AND ESOPHAGITIS   Erosive gastritis, esophagitis, and duodenitis together are responsible for approximately 15 percent of all cases of upper GI hemorrhage. Irritative factors, such as alcohol, salicylates, and nonsteroidal anti-inflammatory agents, are predisposing factors.

ESOPHAGEAL AND GASTRIC VARICES   Esophageal and gastric varices result from portal hypertension and, in the United States, are most often a result of alcoholic liver disease. Although varices account for only about 6 percent of all cases of upper GI hemorrhage, they are highly likely to rebleed and carry a high mortality rate. Despite this, many patients with end-stage cirrhosis never develop varices, many patients with documented varices never bleed, and many patients with a documented history of varices presenting with upper GI bleeding will be bleeding from nonvariceal sites.

MALLORY-WEISS SYNDROME   The Mallory-Weiss syndrome is upper GI bleeding secondary to a longitudinal mucosal tear in the cardioesophageal region. The classic history is repeated retching followed by bright red hematemesis, but coughing and seizures have also been reported as etiologic factors.

OTHER ETIOLOGIES   Stress ulcer, arteriovenous malformation, and malignancy are other etiologies of upper GI hemorrhage. ENT (ear, nose, and throat) sources of bleeding can also masquerade as GI hemorrhage. An aortoenteric fistula secondary to an aortic graft is an unusual but important cause of bleeding to keep in mind. Classically, this will present as a self-limited "herald" bleed preceding a subsequent massive hemorrhage.

Causes of Lower Gastrointestinal Bleeding

The most common cause of what initially appears to be lower GI bleeding is actually upper GI bleeding. Thus, proximal etiologies should be sought.

Among patients with an established lower GI source of their bleeding, the most common etiology is hemorrhoids. Among nonhemorrhoidal bleeding, angiodysplasia and diverticular disease are most common, followed by adenomatous polyps and malignancies.[4]

DIVERTICULOSIS   Diverticular bleeding is usually painless and is thought to result from erosion into the penetrating artery of the diverticulum. Diverticular bleeding may be massive. Patients are often elderly with underlying medical illnesses that contribute to both the morbidity and the mortality rates.

ANGIODYSPLASIA   Arteriovenous malformations (angiodysplasia), usually of the right colon, are a common etiology of obscure lower GI bleeding, particularly in the elderly population. They are thought to be more common in patients with hypertension and aortic stenosis.

OTHER ETIOLOGIES   Numerous other lesions may result in lower GI hemorrhage. Although carcinoma and hemorrhoids are relatively common causes of bleeding, massive hemorrhage is unusual. Similarly, inflammatory bowel disease, polyps, and infectious gastroenteritis rarely cause severe bleeding. Finally, Meckel diverticulum is an unusual but important etiology to keep in mind.

DIAGNOSIS

Medical History

Although the medical history may suggest the source of bleeding, it is often misleading. Thus, clinicians should strive to maintain a broad differential and clinical approach. Although most patients will volunteer complaints of hematemesis, hematochezia, or melena, GI bleeding may have more subtle presentations. Patients who present with hypotension, tachycardia, angina, syncope, weakness, confusion, or even cardiac arrest may harbor occult, underlying GI hemorrhage.

Historical features such as hematemesis, coffee-ground emesis, melena, or hematochezia should be sought. Classically, hematemesis or coffee-round emesis suggests a source proximal to the right colon, and hematochezia indicates a more distal colorectal lesion. However, exceptions to these rules occur. Weight loss and changes in bowel habits are classic symptoms of malignancy. Vomiting and retching, followed by hematemesis, is suggestive of a Mallory-Weiss tear. A history of an aortic graft should suggest the possibility of an aortoenteric fistula. A history of medication use should be determined, particularly salicylates, glucocorticoids, nonsteroidal anti-inflammatory agents, and anticoagulants. Alcohol abuse is strongly associated with a number of causes of GI bleeding, including peptic ulcer disease, erosive gastritis, and esophageal varices. Ingestion of iron or bismuth can simulate melena, and certain foods, such as beets, can simulate hematochezia. In such instances, stool guaiac testing will be negative. Finally, a prior history of GI bleeding should be sought, although recurrent bleeding episodes often originate from

different sources.

Physical Examination

The vital signs may reveal obvious hypotension and tachycardia, or more subtle manifestations such as a decreased pulse pressure or tachypnea. Clinicians should remember that some patients can tolerate substantial volume losses with minimal or no changes in vital signs. Similarly, paradoxical bradycardia can occur in the face of profound hypovolemia.

Skin findings should be noted. Cool, clammy skin is an obvious sign of shock. Spider angiomata, palmar erythema, jaundice, and gynecomastia suggest underlying liver disease. Petechiae and purpura suggest an underlying coagulopathy. Skin findings may be suggestive of the Peutz-Jeghers, Rendu-Osler-Weber, or Gardner syndromes. A careful ENT examination may occasionally reveal an occult bleeding source that has resulted in swallowed blood and subsequent coffee-ground emesis or melena. The abdominal examination may disclose tenderness, masses, ascites, or organomegaly. A rectal examination is indicated to detect the presence of blood, its appearance (bright red, maroon, or melanotic), and the presence of masses.

Laboratory Data

In patients with significant GI bleeding, the most important laboratory test is to type and crossmatch blood. Another important laboratory test is the complete blood count. Additionally, blood urea nitrogen (BUN), creatinine, electrolyte, glucose, and coagulation studies, as well as liver function studies, should be considered. The initial hematocrit level often will not reflect the actual amount of blood loss. Upper tract hemorrhage may elevate the BUN through digestion and absorption of hemoglobin. Coagulation studies, including prothrombin time, partial thromboplastin time, and platelet count, are of obvious benefit in patients taking anticoagulants or those with underlying hepatic disease. An electrocardiogram should be considered in patients in the coronary artery disease age group. Silent ischemia can occur secondary to the decreased oxygen delivery accompanying significant GI bleeding and, thus, supplemental oxygen is advised for such patients.

Diagnostic Studies

Routine abdominal radiographs are often obtained in patients with GI bleeding. In the absence of specific indications, they are of limited value. Similarly, routine admission chest x-rays for patients with acute GI hemorrhage, even those admitted to the intensive care unit, have been shown to be of limited utility in the absence of known pulmonary disease or abnormal findings on lung exam.[5] Barium contrast studies are similarly of limited diagnostic value in an emergency setting. Furthermore, barium limits the use of subsequent endoscopy or angiography.

Angiography can sometimes detect the site of bleeding, particularly in cases of obscure lower tract hemorrhage. Moreover, angiography permits therapeutic options such as transcatheter arterial embolization or the infusion of vasoconstrictive agents. However, to be diagnostic, angiography requires a relatively brisk bleeding rate (0.5 to 2.0 mL/min).

Technetium-labeled red cell scans have also been used to localize the site of bleeding in obscure hemorrhage. Such localization can be used to map the therapeutic approach, whether via angiography or operatively. Scintigraphy appears more sensitive than angiography and can localize the site of bleeding at a rate of 0.1 mL/min.

Another approach is colonoscopy, which may be not only diagnostic, but through the use of endoscopic hemostasis, also therapeutic. In most circumstances, endoscopy is more accurate than arteriography or scintigraphy.

Controversy in the literature remains as to whether scintigraphy, angiography, or colonoscopy, and in which order, should be the initial diagnostic procedure of choice in the evaluation of lower GI bleeding. [6,7,8 and 9] Thus, these decisions are often based on local availability and consultant preference.

TREATMENT

Primary

Immediate resuscitative measures take priority. Patients with profuse upper GI hemorrhage may require definitive airway management to prevent aspiration of blood. Oxygen should be administered, and cardiac monitoring is indicated. Volume replacement should be initiated with crystalloids via large-bore intravenous lines. The decision to administer blood should be based on the clinical findings of volume depletion or continued bleeding, rather that on initial hematocrit values. General guidelines for initiation of blood transfusion are continued active bleeding and failure to improve perfusion and vital signs after the infusion of 2 L of crystalloid. The threshold for blood transfusion should be lower in the elderly. Coagulation factors should be replaced as needed. A urinary catheter is indicated in patients with hypotension.

A nasogastric (NG) tube should be placed in all patients with significant GI bleeding, regardless of the presumed source. Concerns that NG tube passage may provoke bleeding in patients with varices are unwarranted. Bright red or maroon blood per rectum unexpectedly originates from upper GI sources approximately 14 percent of the time.[10] A negative gastric aspirate does not conclusively exclude an upper GI etiology and may result from intermittent bleeding or from pyloric spasm or edema preventing reflux of duodenal blood. If bright red blood or clots are found on NG aspiration, gentle gastric lavage should be performed. To be effective, a large-bore tube, usually oral, must be used. Room temperature water is the preferred irrigant, as iced solutions have no proven benefit and have theoretical disadvantages.[11] The addition of levarterenol to the lavage solution is similarly of unproven benefit. Overvigorous suction should be avoided, because it may produce gastric erosions that can confuse findings on subsequent endoscopy.

Secondary

ENDOSCOPY   Upper GI endoscopy is the most accurate technique for the identification of upper tract bleeding sites. It predicts morbidity, and, with the advent of therapeutic endoscopy, is associated with improved outcomes. Early therapeutic endoscopy, where available, should be considered the treatment of choice for significant upper GI bleeding. Thus, early consultation for potential endoscopy should be considered in patients with significant hemorrhage.

Esophageal varices can be endoscopically treated by either band ligation or injection sclerotherapy. Sclerotherapy, which controls acute hemorrhage in up to 90 percent of patients, may decrease the duration of hospitalization and amount of blood transfused when compared with portal-caval shunting. However, complications of sclerotherapy include perforation, sepsis, stricture formation, and portal and mesenteric venous thrombosis. Endoscopic band ligation appears to be as effective as sclerotherapy, but with a decreased incidence of complications, particularly rebleeding and esophageal stricture formation. [12] In addition, band ligation appears superior to sclerotherapy in the long-term management of varices. [13]

Endoscopic hemostasis (with injection sclerotherapy, electrocoagulation, heater probes, and lasers) has been used successfully in a variety of nonvariceal etiologies of upper GI bleeding, as well.

In lower GI bleeding, proctoscopy is often diagnostic in patients with anorectal sources of bleeding, such as hemorrhoids. If an anorectal source is suspected, the patient should be carefully evaluated for significant volume loss or more dangerous proximal sources of bleeding mimicking anorectal bleeding. Colonoscopy can be diagnostic in other forms of lower tract hemorrhage, such as diverticulosis or angiodysplasia, and may also allow ablation of bleeding sites by using the aforementioned technologies.

DRUG THERAPY   Infusions of somatostatin and its synthetic, longer-acting derivative, octreotide, have been shown to be effective in reducing bleeding from both varices and peptic ulcer disease. Octreotide has been shown to be as effective as sclerotherapy in acute variceal bleeding. [14] Both agents, when used in addition to sclerotherapy, are more effective than sclerotherapy alone. [15,16] These agents possess the advantages of vasopressin, with considerably fewer side effects. They should be considered useful adjuncts, either before endoscopy or when endoscopy is unsuccessful, contraindicated, or unavailable. [17]

Vasopressin has been used in the past to control GI bleeding, most commonly from varices. However, adverse reactions are common, including hypertension, dysrhythmias, myocardial and splanchnic ischemia, decreased cardiac output, and gangrene from local infiltration. Although the concomitant use of nitroglycerin has

been shown to reduce the incidence of these side effects, the use of vasopressin has been largely supplanted by the use of somatostatin, octreotide, and therapeutic endoscopy.

Studies have also suggested that the proton-pump inhibitor omeprazole may be useful to reduce rebleeding, transfusion requirements, and the need for surgery in the treatment of bleeding peptic ulcers.[18],[19]

Other drugs may be of benefit in patients with GI hemorrhage, but are of less concern in the initial emergency department management. For instance, b-blocker therapy has been shown to be beneficial in patients with varices, in preventing both initial variceal bleeds and rebleeding.[20],[21] Additionally, the treatment of *Helicobacter pylori* infection with antibiotics reduces the recurrence of peptic ulcer and rebleeding.[22] However, the use of H_2 antagonists in acute upper GI hemorrhage remains of unproven benefit,[23] with no conclusive evidence for reduction in the rates of rebleeding, surgery, or death.

BALLOON TAMPONADE   Balloon tamponade with the Sengstaken-Blakemore tube or its variants can provide therapeutic benefit and presumptive diagnostic information. It can control documented variceal hemorrhage in 40 to 80 percent of patients. The device consists of gastric and esophageal balloons and, depending on the variation, may include gastric and/or esophageal aspiration ports. The gastric balloon should be inflated first. If bleeding does not cease, the esophageal balloon should then be inflated, using a manometer to ensure that the pressure does not exceed 40 to 50 mmHg. Radiologic confirmation of proper balloon placement is suggested. The device should be kept in place 24 h after bleeding has ceased. Some authors recommend deflating the esophageal balloon for 30 to 60 min every 8 h to prevent mucosal ulceration.

Like vasopressin therapy, balloon tamponade is frequently associated with adverse reactions, often severe. Mucosal ulceration, esophageal or gastric rupture, asphyxiation from dislodged balloons, tracheal compression secondary to balloon inflation, and aspiration pneumonia have all been reported. Many authors recommend routine prophylactic endotracheal intubation to prevent pulmonary complications. Because of the incidence of adverse reactions, the use of balloon tamponade has decreased considerably and should be considered an adjunctive or temporizing measure supplementing the more definitive modalities of band ligation or sclerotherapy.

SURGERY   With patients who do not respond to medical therapy, and in whom endoscopic hemostasis, if available, fails, emergency surgical intervention is indicated. Surgical consultation on any patient admitted to the hospital for GI bleeding is prudent, in case uncontrollable rebleeding occurs.

DISPOSITION

Patients with GI hemorrhage will require hospital admission, and early referral to an endoscopist is advisable. Corley and colleagues [24] found five variables to be independent predictors of adverse outcomes in upper GI bleeding: initial hematocrit less than 30 percent, initial systolic blood pressure lower than 100 mm Hg, red blood in the NG lavage, history of cirrhosis or ascites on exam, and a history of vomiting red blood. Such patients are more likely to require a higher intensity of inpatient care.

On the other hand, other authors have attempted to identify a low-risk subset of patients who might be managed as outpatients. Rockall and coworkers [25] developed a risk score for upper GI bleeding, based on age, presence of shock, comorbidity, diagnosis, and endoscopic findings, to identify a low-risk population. Longstreth and Feitelberg[26] developed similar guidelines. Of note, both of these recommendations are based on the performance of endoscopy prior to discharge to classify patients accurately.

71 ESOPHAGEAL EMERGENCIES

Moss H. Mendelson

Patients develop a wide variety of problems related to the esophagus. The complaints of dysphagia, odynophagia, or ingested foreign body immediately point to the esophagus as a source of disease. But the esophagus can be the site of pathology in patients presenting with chest pain, upper gastrointestinal bleeding, malignancy, and mediastinitis. Many esophageal processes can be evaluated over time in an outpatient setting, but several, such as variceal bleeding and esophageal perforation, can be fulminant and rapidly fatal, requiring a unique knowledge base for emergent intervention.

ANATOMY AND PHYSIOLOGY

The esophagus is a muscular tube approximately 20 to 25 cm long. The majority of the esophagus is located in mediastinum, posterior and slightly lateral to the trachea, with smaller cervical and abdominal components as well, as shown in Fig. 71-1. There is an outer longitudinal muscle layer and an inner circular muscle layer. The upper third of the esophagus is made up of striated muscle. Distal to the upper third, smooth muscle appears as well, and the esophagus is all smooth muscle from the lower half down [including the lower esophageal sphincter (LES)]. The cells lining the esophagus are stratified squamous epithelial cells that have no secretory function.
FIG. 71-1. Anatomic relations of the esophagus (seen from the left side). The esophagus is about 25 cm (10 in.) long. The distance from the upper incisor teeth to the beginning of the esophagus (cricoid cartilage) is about 15 cm (6 in.); from the upper incisors to the level of the bronchi, 22 to 23 cm (9 in.); to the cardia, 40 cm (16 in.). Structures contiguous to the esophagus that affect esophageal function are demonstrated.

Two sphincters on either end regulate the passage of materials into and out of the esophagus. The upper esophageal sphincter (UES) prevents air from entering the esophagus and food from refluxing out of the esophagus into the pharynx. The LES regulates passage of food into the stomach and prevents stomach contents from refluxing into the esophagus. The UES is composed primarily of the cricopharyngeus muscle. Additional tone is variably provided by the inferior pharyngeal constrictor and the cervical esophagus.[1] The UES has a resting pressure of around 100 mmHg. The LES is not discretely identifiable anatomically. The smooth muscle of the lower 1 to 2 cm of the esophagus, in combination with the skeletal muscle of the diaphragmatic hiatus, functions as the sphincter, with a resting pressure of 25 mmHg.[2] The pressure within the resting esophagus itself closely approximates intrathoracic pressure.[3] Dysfunction of the LES is a major source of esophageal symptoms and is discussed below.

Three major anatomic constrictions exist within the esophagus and are important when considering esophageal foreign bodies and food bolus impaction, discussed below. They are located at the cricopharyngeus muscle, at the level of the aortic arch/left main-stem bronchus, and at the gastroesophageal junction. An empty, collapsed esophagus has no apparent constrictions: only with esophageal filling do the narrowings become apparent.

Innervation of the esophagus is mediated by both the sympathetic and parasympathetic systems and local nerve networks. Both Auerbach's and Meissner's plexuses are present in the esophagus, in the same distribution noted throughout the gastrointestinal tract. Reflex activity and homeostasis are also mediated by parasympathetic afferents and efferents, carried by the vagus nerve. Pain sensation from heat, spasm, distension, or chemical irritation of the esophagus travels exclusively through sympathetic nerve fibers. The heart has a pattern of innervation mirroring that of the esophagus, and there is a convergence of visceral and somatic stimuli within the sympathetic system. This is the anatomic basis that makes esophageal and cardiac chest pain notoriously similar, as discussed below.[4]

The esophageal blood supply is derived from several arterial sources. The inferior thyroid artery, small branches of the thoracic aorta, and ascending branches form the left gastric and inferior phrenic arteries supply the esophagus throughout its length. The esophageal venous circulation includes a submucosal plexus of veins that drains into another plexus of veins surrounding the outside of the esophagus. Blood flows from this plexus into the inferior thyroid, azygos, coronary, and gastric venous systems. The last is one link between the portal and systemic venous systems. Variceal dilatation of the submucosal system can be responsible for massive upper gastrointestinal (GI) bleeding, reviewed below.

Swallowing is initiated voluntarily, then becomes reflex controlled. Control of the swallowing mechanism is provided by both central nervous system (CNS) input and local reflex feedback. As food is moved to the posterior pharynx during the pharyngeal stage of swallowing, the UES relaxes and the bolus passes into the esophagus. Generally this occurs within the first 2 s of swallowing. The food bolus in the upper esophagus subsequently reinitiates constriction of the UES. Peristalsis moves the food bolus down the esophagus (5 to 6 s) to the LES. The LES relaxes (but remains closed) with the onset of swallowing, remains relaxed for the 5 to 10 s it takes for the food bolus to make the trip down, and then recontracts with the peristaltic wave.[5] Simultaneous reflexes outside of the esophagus help to protect the pharynx and larynx from inadvertent reception of food. Impairment of the swallowing mechanism is reviewed below.

DYSPHAGIA

Dysphagia is defined as difficulty with swallowing. The vast majority of patients experiencing dysphagia will have an identifiable, organic process causing their symptoms.

The literature suggests an approach to patients with dysphagia that recognizes two broad pathophysiologic groups, patients with transfer dysphagia and patients with transport dysphagia.[6] Transfer dysphagia occurs very early in the swallowing process as the food bolus moves from the oropharynx through the UES and is often reported as difficulty in initiating a swallow. In transport dysphagia, there is impaired movement of the bolus down the esophagus and through the LES. Transport

dysphagia is perceived later in the swallowing process, usually 2 to 4 s or more after swallowing is initiated, and most commonly results in the feeling of food "getting stuck." This initial differentiation between transfer and transport dysphagia provides valuable information regarding the likely underlying esophageal pathology, as noted in Table 71-1. Another useful classification scheme divides dysphagia into obstructive disease versus motor dysfunction. Functional or motility disorders usually cause dysphagia that is intermittent and variable. Mechanical or obstructive disease is usually progressive (solids, then liquids).

Transfer Dysphagia (Oropharyngeal)	Transport Dysphagia (Esophageal)
Discoordination in transferring bolus from pharynx to esophagus	Improper transfer of the bolus from the upper esophagus into the stomach
Swallowing symptoms—gagging, coughing, nasal regurgitation, inability to initiate swallow, need for repeated swallows	Swallowing symptoms—food "sticking," retrosternal fullness with solids (and eventually liquids), possibly odynophagia
Risk of aspiration present	Risk of aspiration present, generally less pronounced than in transfer dysphagia
Long term—weight loss, malnutrition, chronic bronchitis, asthma, multiple episodes of pneumonia	Long term—malnutrition, dehydration, weight loss, systemic effects of cancer
Neuromuscular disease (90%)—cerebrovascular accident, polymyositis and dermatomyositis, scleroderma, myasthenia gravis, tetanus, Parkinson's disease, botulism, lead poisoning, thyroid disease	Obstructive disease (85%)—foreign body, carcinoma, webs, strictures, thyroid enlargement, diverticulum, congenital or acquired large vessel abnormalities
Localized disease—pharyngitis, epiglottis ulcers, candidal infection, peritonsillar and retropharyngeal abscesses, carcinoma of tongue, pharynx, larynx, Zenker diverticulum, cricopharyngeal bar, cervical osteophytes	Motor disorder—achalasia, peristaltic dysfunction (nutcracker esophagus), diffuse esophageal spasm, scleroderma
Inadequate lubrication—xerostomia	Inflammatory disease

TABLE 71-1 Dysphagia

Clinical Features

As noted above, historical information is key to the diagnosis of dysphagia. Table 71-1 summarizes some of the clinical features of transfer versus transport dysphagia. Though often occurring as an independent symptom, dysphagia can be associated with odynophagia, which is painful swallowing (suggesting an inflammatory process), or with chest pain that is esophageal in nature and suggests gastroesophageal reflux disease (GERD) or a motility disorder. Additional pertinent historical features to elicit in a patient complaining of dysphagia include the following: Has this been an acute, subacute, or chronic course? Is the dysphagia present for solids, liquids, or both? Is it intermittent or progressive? Is there a sensation of the food being stuck in the esophagus, and where? Is there any past history of esophageal disease? Transport dysphagia that is present for solids only generally suggests a mechanical/obstructive process. Motility disorders typically cause transport dysphagia for solids and liquids.

A poorly chewed meat bolus that impacts in the esophagus is a well-recognized complication of esophageal disease. A preceding history of dysphagia may or may not be obtained. This can be the presenting complaint of a patient with a variety of esophageal pathologies. The bolus may be well localized by the patient; in general, patients able to identify a level of dysphagia below the neck are usually anatomically accurate, whereas those complaining of dysphagia in the neck may be reporting sensations referred from elsewhere in the esophagus.[7] Esophageal filling proximal to the impacted bolus may make the patient unable to swallow secretions and may present an airway/aspiration risk.

Physical examination of patients with dysphagia should focus on the head and neck and the neurologic exam. Signs of previous cerebrovascular accident, muscle disease, or Parkinson's disease can be present. Cachexia and cervical or supraclavicular nodes can be observed in patients with cancer of the esophagus. Watching the patient as he or she takes a small sip of water can also provide very valuable information. Unfortunately, the physical examination is often normal in patients with dysphagia, despite the high yield nature of this complaint.

Diagnosis

The diagnosis of the underlying pathology of dysphagia is most often made outside of the emergency department (ED). The workup is dependent on whether transfer or transport dysphagia is thought to be present, as noted above. Initial evaluation of dysphagia in the ED can include anteroposterior (AP) and lateral neck radiographs, which can be helpful in transfer dysphagia and cases where the transport dysfunction seems proximal. Chest radiography should be obtained in most patients thought to have transport dysphagia. Direct laryngoscopy can be used to identify structural lesions.

Ultimately, oropharyngeal dysphagia is best worked up with videoesophagography, a specialized form of a barium swallow study in which videotaped images are reviewed at low-speed playback to allow detailed analysis. Traditional barium swallow is usually the first test for patients with transport dysphagia. Manometry and esophagoscopy are also employed, depending on the clinical picture. If a foreign body is suspected, the diagnostic workup takes yet another path (see Chap. 72, "Swallowed Foreign Bodies").

Selected Structural/Obstructive Causes

Neoplasms are a common cause of transfer and transport dysphagia. The esophagus or surrounding structures may be the primary site. Esophageal cancer is diagnosed in about 10,000 people a year in the United States. About the same number die from the disease each year as well. Ninety-five percent of esophageal neoplasms are squamous cell; the remaining 5 percent are adenocarcinomas. Men are affected three times as often as women. Risk factors for squamous cell disease includes alcohol, smoking, achalasia, and previous caustic ingestion with lye. Barrett's esophagus predisposes to adenocarcinoma, which has shown an increase in incidence in recent years.[8] There is usually a fairly rapid progression of dysphagia from solids to liquids (6 months). In addition to dysphagia, patients with neoplasm may present with bleeding. Early diagnosis impacts outcome, and for this reason the emergency physician should assume a neoplastic cause in patients over age 40 who present with new-onset dysphagia. These patients need an expedient workup to rule out malignancy. Definitive diagnosis is made by endoscopy with biopsy. Survival is dismal: the median is less than 1 year.

Esophageal stricture occurs as a result of scarring from GERD or other chronic inflammation. Generally they occur in the distal esophagus, proximal to the gastroesophageal (GE) junction. Strictures may interfere with LES function. Symptoms may build over years and are often noted solely with solids. Stricture can serve as a barrier to reflux, so heartburn may decrease as dysphagia increases. Workup involves ruling out malignancy and treatment is dilatation.[9]

Schatzki's ring is the most common cause of intermittent dysphagia with solids. This fibrous, diaphragm-like stricture near the GE junction is present in up to 15 percent of the population, the majority of whom are asymptomatic. The etiology of these rings is debated: they may form over time in response to GERD.[10] Steakhouse syndrome, food impaction in the esophagus due to poorly chewed meat, is a frequent presentation for patients with this obstructive phenomenon. Treatment of Schatzki's ring is dilatation.

Esophageal webs are thin structures of mucosa and submucosa found most often in the mid- or proximal esophagus. They can be congenital or acquired. Esophageal webs are a component of Plummer-Vinson syndrome (along with iron-deficiency anemia), and can be seen in patients with pemphigoid and epidermolysis bullosa. Treatment, again, is dilatation.

Diverticula may be found throughout the esophagus. Pharyngoesophageal, or Zenker's, diverticulum is a progressive outpouching of pharyngeal mucosa, just above the UES, caused by increased pressures during the hypopharyngeal phase of swallowing.[7] Presentation is usually after age 50, as this is an acquired disease. Patients complain of typical transfer dysfunction; additionally, they may have halitosis and the feeling of a neck mass. Diverticula can also be seen in the body of the esophagus, usually in association with a motility disorder.

Selected Motor Lesions Causing Dysphagia

Neuromuscular disorders typically result in misdirection of the bolus, with repeated swallowing attempts. Liquids, especially at the extremes of temperature, are generally more difficult to handle than solids. Symptoms are often intermittent in nature. Cerebrovascular accident (CVA) is the most common cause in this category. Oropharyngeal muscle weakness is often the mechanism, though there can be poor function of the UES as well. Polymyositis and dermatomyositis are the second

most common causes of transfer dysphagia in this category.

Achalasia is a dysmotility disorder of unknown cause and the most common motility disorder producing dysphagia. Impaired swallowing-induced relaxation of the LES is noted, along with the absence of esophageal peristalsis. Most patients present between 20 and 40 years of age. Achalasia may be associated with esophageal spasm and chest pain and with odynophagia. Associated symptoms can include regurgitation and weight loss. Dilatation of the esophagus can be massive enough to impinge on the trachea and cause airway symptoms.[11] Therapy involves decreasing the LES pressure by oral medications, the endoscopic injection of botulinum toxin into the muscle of the sphincter, dilatations, or surgical myotomy.

"*Nutcracker esophagus*" is a motility disorder in which there are high-amplitude, long-duration peristaltic contractions in the distal esophagus. Manometric criteria require readings of >180 mmHg. The cause of nutcracker esophagus is unknown and the prevalence of this disease is debated in the literature. [12] Patients with this disorder frequently have associated psychiatric disorders and about one-third have GERD.

CHEST PAIN OF ESOPHAGEAL ORIGIN

Most esophageal causes of chest pain are not immediate threats to life; however, differentiating esophageal pain from ischemic chest pain can be impossible in the ED. Patients with esophageal pain can report spontaneous onset of pain or pain at night, regurgitation, odynophagia, dysphagia or meal-induced heartburn; however, these symptoms are also found in patients with coronary artery disease (CAD), and there is no historical feature that is sensitive or specific enough to routinely make a differentiation between the two.

To minimize missing active ischemic heart disease, clinicians often appropriately set into motion a patient evaluation that proceeds beyond what a traditional ED visit can accomplish, including a provocative test to rule out CAD. The high rate of admission for chest pain of noncardiac etiology is well publicized: ultimately, esophageal disease is frequently determined to be the responsible pathology. The incidence of esophageal disease as the cause of chest pain in patients with normal coronary arteries has been reported as ranging from 20 to 60 percent. [7] The use of ED observation units can help to sort through this process by providing time for a protocol-driven, rapid rule-out of acute myocardial infarction, followed by risk stratification for underlying CAD through the use of some form of stress or radionuclide testing. (See Chap. 45 for further discussion.) At a minimum, an electrocardiogram (ECG) and chest radiographs should be obtained in all patients with ambiguous presentations.

If chest pain is determined to be noncardiac in nature, treatment aimed at esophageal disease is often initiated empirically, without further diagnostic workup. There are no good data on which to base a therapeutic plan for these patients. [13] Outpatient workup options in addition to 6 to 8 weeks of empiric treatment for GERD include an acid infusion test, esophagoscopy, and/or manometry to help clarify pain of esophageal origin.

Gastroesophageal Reflux Disease (GERD)

Reflux of gastric contents into the esophagus causes a wide array of symptoms and long-term effects. It affects up to 25 percent of the adult population, possibly with even higher rates in elderly populations. [14] Classically, a weak LES has been the mechanism held responsible for reflux, and this is seen in some patients. However, it is now accepted that transient relaxation of the LES complex (with normal tone in between periods of relaxation) is a primary mechanism causing reflux. Patients with moderate to severe reflux also often have concomitant hiatal hernia. [2,15] Prolonged gastric emptying, agents that decrease LES, pressure, and impaired esophageal motility predispose to reflux. Table 71-2 highlights some common contributors.

Decreased Pressure of Lower Esophageal Sphincter	Decreased Esophageal Motility	Prolonged Gastric Emptying
High-fat food	Achalasia	Medicines (anticholinergics)
Nicotine	Scleroderma	Outlet obstruction
Ethanol	Presbyesophagus	Diabetic gastroparesis
Caffeine	Diabetes mellitus	High-fat food
Medicines (nitrates, calcium channel blockers, anticholinergics, progesterone, estrogens)		
Pregnancy		

TABLE 71-2   Causes of Gastroesophageal Reflux Disease

As noted, differentiating esophageal symptoms from acute ischemic coronary symptoms is often not possible in the ED. Heartburn is the classic symptom of GERD, and chest discomfort may be the sole manifestation of the disease. The burning nature of the discomfort is probably due to localized lower esophageal mucosal inflammation. Many GERD patients will report other associated gastrointestinal symptoms, such as odynophagia, dysphagia, acid regurgitation, and hypersalivation. The association of pain with meals can be helpful in identifying pain that is due to GERD. Postural changes in pain can also be useful: increasing intraabdominal pressure or negating the esophagus's gravity advantage can exacerbate reflux symptoms dramatically. Antacid-induced relief of symptoms is often noted in reflux disease, though the pain can return after the transient antacid effect wears off, and a certain number of patients with ischemic disease also report improvement. Unfortunately, like cardiac pain, GERD pain may be squeezing, pressure-like, and include a history of onset with exertion and offset with rest. Both types of pain may be accompanied by diaphoresis, pallor, and nausea and vomiting. Radiation of esophageal pain may be felt in either arm, the neck, the shoulders, or the back. Given the serious outcome of unrecognized ischemic disease compared with the relatively benign nature of esophageal pain, a cautious posture on the part of the clinician seems warranted.

Over time complications of GERD can develop that produce dysphagia, such as strictures, as discussed above, or inflammatory esophagitis, discussed below. A severe consequence of GERD, Barrett's esophagus, is present in up to 10 percent of patients with GERD. [16] This condition is identified by biopsy: simple columnar epithelium replaces the normal stratified squamous epithelium in the distal esophagus. Metaplasia and ulceration can be present. This is considered a premalignant condition, with a well-reported association between the development of metaplasia and the onset of adenocarcinoma. [17]

Less obvious presentations of GERD are also well recognized. Pulmonary symptoms, especially asthma exacerbations, and multiple ear/nose/throat symptoms are well described. GERD is present in many asthmatics, and in some can contribute to exacerbation by aspiration of minute amounts of gastric contents, with subsequent inflammation and bronchospasm, and by esophageal activation of reflex vagal tone, with consequent bronchospasm. Unfortunately, a reliable means for identifying asthmatic patients with GERD who will show an improvement in pulmonary symptoms with anti-reflux therapy has not been demonstrated in the literature. [17,18] GERD has been implicated in the etiology of dental erosion, vocal cord ulcers and granulomas, laryngitis with hoarseness, chronic sinusitis, and chronic cough. [19,20]

Comprehensive treatment of reflux disease involves decreasing acid production in the stomach, enhancing upper tract motility, and eliminating risk factors for the disease. As noted above, mild disease is often treated empirically. H_2 blockers or proton-pump inhibitors are mainstays of therapy. Dosage is titrated for each patient. A prokinetic drug may also greatly decrease symptoms. Simple discharge instructions should be given to all patients thought to be experiencing reflux-related symptoms: Avoid agents that exacerbate GERD (ethanol, caffeine, nicotine, chocolate, fatty foods), sleep with the head of the bed elevated (30°), and avoid eating within 3 h of going to bed at night. Management of Barrett's esophagus includes intensive treatment of the underlying GERD with proton-pump inhibition. Often, laser or photodynamic ablation therapy and surgical treatment are employed as well. Close monitoring for dysplastic changes is essential.

Esophagitis

Esophagitis can cause prolonged periods of chest pain and almost always causes odynophagia as well. Diagnosis of advanced esophagitis is by endoscopy. Low-grade disease can be seen by histopathologic examination.

INFLAMMATORY ESOPHAGITIS   GERD may induce an inflammatory response in the lower esophageal mucosa. Over time, this can progress to esophageal ulcerations, scarring, and stricture formation. The presence of esophagitis due to reflux warrants aggressive pharmacologic therapy with acid-suppressive medications. If this treatment regimen is not sufficient, surgical options are considered. [17] Barrett's esophagus, mentioned above, can develop as well.

Ingested medications can also be a source for inflammatory esophagitis, usually from prolonged contact of the medication with the esophageal mucosa. Ulceration can be associated with this process. Multiple medications have been implicated: nonsteroidal anti-inflammatory drugs (NSAIDs), potassium chloride, and antibiotics, especially doxycycline, cause a large proportion of medication-related esophageal inflammation. [21] Risk factors for pill-induced esophageal injury include swallowing position, fluid intake, capsule size, and age, with swallowing position being the most important. Withdrawal of the offending agent is generally curative.

INFECTIOUS   Patients with immunosuppression [acquired immunodeficiency syndrome (AIDS), iatrogenic causes, cancer] may develop an infectious esophagitis. AIDS especially has made esophageal infection more routine in the ED. The diagnosis of esophageal infection in an otherwise seemingly healthy host should prompt a search for underlying immunocompromise. Candidal species are the most common pathogens, often associated with dysphagia as a primary symptom. Herpes simplex, cytomegalovirus, and aphthous ulceration are also seen and may be more frequently associated with odynophagia. Other agents are rare and include other fungal infections, mycobacteria, and other viral pathogens such as varicella zoster and Epstein-Barr virus. Endoscopy with biopsy and cultures is used to establish this diagnosis. [22]

Esophageal Motility Disorders

Esophageal dysmotility is the excessive, uncoordinated contraction of esophageal smooth muscle. Debate exists over the correlation between symptoms (pain) and observed motor events. [12] Dysmotility disorders can be divided into distinct entities based on manometric criteria. Achalasia and nutcracker esophagus were discussed above. The other motility disorders commonly recognized include diffuse esophageal spasm, hypertensive LES, and nonspecific motor disorder.

Clinically, chest pain is the presenting symptom in the majority of patients with these disorders. The onset is usually in the fifth decade. The pain often occurs at rest and is dull or colicky in nature. Stress or ingestion of liquids at the extremes of temperature may serve as a trigger. An acute episode of pain may be followed by hours of dull, achy, residual discomfort. Thirty to sixty percent of these patients will also experience dysphagia, which is usually intermittent. Pain from spasm may respond to nitroglycerin. Calcium channel blockers and anticholinergic agents can also be employed.

ESOPHAGEAL PERFORATION

Perforation of the esophagus can occur secondary to a number of disparate processes [23] as noted in Table 71-3. Iatrogenic injury is the most frequent cause of esophageal injury, accounting for up to 75 percent of all perforations. Endoscopy, a prime offender, has a lesser rate of perforation when performed on an esophagus free of disease than does endoscopy of a diseased esophagus. Dilation of strictures increases the risk of perforation greatly. Other intraluminal procedures, such as variceal therapy or Sengstaken-Blakemore tubes and palliative laser treatment for cancer, are also associated with perforation. A well-recognized clinical scenario of postemetic perforation, Boerhaave syndrome, is responsible for roughly 10 to 15 percent of esophageal perforations and is discussed below.

Causes of Perforation	Comments
Iatrogenic	Intraluminal procedures Endoscopy Dilatation Variceal therapy Gastric intubation Intraoperative injury
Boerhaave's syndrome	"Spontaneous," usually associated with transient increase in intraesophageal pressure
Trauma	Penetrating Blunt (rare) Caustic ingestion
Foreign body	Includes pill-related injury
Infection	Rare
Tumor	May be intrinsic or extrinsic cancer
Aortic pathology	Aneurysm Aberrant right subclavian artery
Miscellaneous	Barrett's esophagus Zollinger-Ellison syndrome

TABLE 71-3   Causes of Esophageal Perforation

Perforation causes a dramatic presentation if esophageal contents leak into the mediastinum. A fulminant, necrotizing mediastinitis with polymicrobic infection that rapidly leads to shock and death can ensue. Perforation into the pleural or peritoneal spaces can occur as well, and contamination of these large potential spaces also tends to result in rapidly progressive infection and shock. If the perforation is small and leakage is contained by contiguous structures, the course may be significantly more indolent. Most spontaneous perforations occur through the left posterolateral wall of the distal esophagus. [24] Proximal perforation, seen mostly with instrumentation, tends to be less severe than distal and can be contained locally as a periesophageal abscess with minimal systemic toxicity.

Pain is classically described as acute, severe, unrelenting and diffuse; reported in the chest, neck and abdomen; and with radiation to the back and shoulders. Back pain may be the predominant symptom. Pain is often exacerbated by swallowing. Dysphagia, dyspnea, hematemesis, and cyanosis can be present as well. Less acute and atypical presentations are also described. Esophageal perforation is often ascribed to acute myocardial infarction (MI), pulmonary embolus, peptic ulcer disease, aortic catastrophe, or acute abdomen, resulting in critical delays in diagnosis, the most important factor in determining morbidity and mortality outcome.

Physical examination varies with the severity of the rupture and the elapsed time between the rupture and presentation. Abdominal rigidity with hypotension and fever often occur early. Tachycardia and tachypnea are common. Cervical subcutaneous emphysema is common in cervical esophageal perforations. Mediastinal emphysema takes time to develop. It is less commonly detected by examination or radiography in lower esophageal perforation, and its absence does not rule out perforation. [25] Hammon's crunch, caused by air in the mediastinum being moved by the beating heart, can sometimes be auscultated. Pleural effusion develops in half of patients with intrathoracic perforations and is uncommon in those with cervical perforations. Pleural fluid can be due to either direct contamination of the pleural space or a sympathetic serous effusion from mediastinitis.

Making the correct diagnosis in a timely manner in an ill patients with esophageal perforation requires suspicion on the clinician's part. Chest radiography and contrast esophagography with water-soluble contrast most often make the diagnosis. Endoscopy, computed tomography (CT) of the chest, and thoracentesis can be useful adjuncts if esophagography (10 to 25 percent false-negative rate) is unrevealing in the face of high clinical suspicion. Endoscopy especially is often done after negative esophagography in penetrating trauma with suspicion of esophageal perforation.

Perforation of the esophagus is associated with a high mortality rate regardless of the underlying cause. The elapsed time between perforation and the initiation of therapy, the location of the perforation, and the etiology all affect outcome. Rapid, aggressive management is key to minimizing the morbidity and mortality associated with esophageal perforation. In the ED, resuscitation of shock, broad spectrum parenteral antibiotics, and emergent surgical consultation should be obtained as soon as the diagnosis is seriously entertained. Patients with systemic symptoms and signs after perforation need operative management. Criteria are developing for the nonoperative management of perforation in select patients. [23]

Instrumentation, especially endoscopic dilatation, has a relatively high rate of perforation; therefore, it is patients with strictures who sustain these injuries, usually perforating distally around the level of the obstruction. A patient with a relatively healthy esophagus undergoing instrumentation will more commonly perforate proximally. Perforation from other instrumentation, including nasogastric tube placement, has been reported. [26]

Boerhaave's syndrome refers to full-thickness perforation of the esophagus following a sudden rise in intraesophageal pressure. The mechanism is sudden, forceful emesis in about three-fourths of the cases; coughing, straining, seizures, and childbirth have been reported as causing perforations as well. Alcohol is frequently an antecedent to this syndrome, which is seen more commonly in males. The perforation is usually in the distal esophagus on the left side.

Trauma to the esophagus accounts for roughly 10 percent of all esophageal perforations. Rupture from blunt injury is rare. Penetrating wounds to the esophagus from neck trauma occur but are often masked by more rapidly fatal injuries to the surrounding critical structures, such as the airway and major vessels. A combination of esophagography and esophagoscopy is used to assess patients for potential esophageal injury.

Foreign-body ingestion may result in perforation of the esophagus as well. The perforation is almost always at one of the sites of anatomic narrowing, where foreign bodies become wedged. The injury can be due to pressure necrosis from the object (coin), penetration from the object (pin, bones), or chemical irritation from the object (battery, pill).

ESOPHAGEAL BLEEDING

The general approach to upper gastrointestinal bleeding (UGIB) from an esophageal source does not differ from the approach for bleeding from other sources and is addressed in more depth in Chap. 70, "Gastrointestinal Bleeding." Resuscitation proceeds concurrently with the diagnostic effort of history, physical examination, and laboratory evaluation. Gastric lavage through a nasogastric tube or larger-bore gastric tube is generally accepted, and early airway management should be considered. Prompt mobilization of resources—including blood products, gastroenterology consult for endoscopy, and an appropriate inpatient level of care—is important.

About 60 percent of variceal bleeding will resolve with supportive care alone. [27] The rate of spontaneous cessation is higher for nonvariceal sources of UGIB. Patients who continue to bleed need specific intervention. Early endoscopy is generally accepted in patients with UGIB for its diagnostic and therapeutic applications. Pharmacologic treatment with an intravenous vasopressin/nitroglycerin combination, somatostatin, or octreotide can be used as well. Balloon tamponade is generally considered a last-resort therapy when pharmacologic management has failed and endoscopy is either not feasible secondary to massive bleeding or is ineffective. Surgical treatment also remains an option.

Varices develop in patients with chronic liver disease in response to portal hypertension. Around 60 percent of patients with chronic liver disease will develop varices. Of patients who develop varices, 25 to 30 percent experience hemorrhage. [26] Patients who develop varices from alcohol abuse have a higher risk of bleeding, especially if there is ongoing alcohol consumption. About two-thirds of patients who have an index bleed experience recurrent hemorrhage, 50 percent occurring within 6 weeks of the initial episode.

With variceal bleeding, endoscopic therapy is often successful in controlling the hemorrhage. Sclerotherapy and ligation are the main alternatives, though in Europe the use of injected Histoacryl (a tissue adhesive) to obstruct the variceal lumen has gained popularity. Shunting procedures performed transvenously or by surgical approach should also be considered. [29] Mortality is significant in esophageal variceal bleeding, quoted at 40 percent. [28] Concurrent hepatic failure is a risk factor for poor outcome.

Mallory-Weiss syndrome is arterial bleeding from longitudinal mucosal lacerations of the distal esophagus/proximal stomach. The majority of these lacerations are located at the GE junction, with only 10 percent found in the lower esophagus proper. Mallory-Weiss tears are responsible for between 5 to 15 percent of upper GI hemorrhage. They can occur at any age but are most common in the fourth through sixth decades. The pathophysiology of Mallory-Weiss syndrome is thought to be a transient, large pressure gradient between thorax and stomach, experienced maximally at GE junction.

Acute onset of upper GI bleeding is the usual presentation, though some patients can present with melana or hematochezia. Rarely the presentation will be one of isolated abdominal pain or syncope. Less than half of patients with Mallory-Weiss tears will report a history of vomiting prior to hematemesis. The spectrum of severity of bleeding is broad, but overall a low relative incidence of surgical intervention or adverse outcome is seen. Initial treatment is supportive as the vast majority of Mallory-Weiss tears stop bleeding spontaneously. Ongoing hemorrhage can require treatment with electrocoagulation, sclerotherapy, and laser photocoagulation. Angiographic embolization or surgical intervention remain options as well.

Esophageal cancer often results in heme-positive stools but is an uncommon cause of significant upper or lower GI bleeding.

72 SWALLOWED FOREIGN BODIES

Wade R. Gaasch
Robert A. Barish

Swallowed foreign bodies, a common presentation in emergency departments, can be innocuous or life-threatening. In the United States, approximately 1500 people die yearly as a result of ingesting foreign bodies. Often thought to be confined to the pediatric population, foreign body ingestion occurs in all age groups. The pediatric age group accounts for approximately 80 percent of all cases, followed by edentulous adults, prisoners, and psychiatric patients. The presence of dentures eliminates the tactile sensitivity of the palatal surface vital to the identification of small items. A correlation exists between age groups and specific types of ingested material. Children most often ingest coins, toys, crayons, and ballpoint pen caps; adults tend to have problems with meat and bones. [1] In addition, psychiatric patients and prison inmates may ingest such unlikely objects as spoons and razor blades.

PATHOPHYSIOLOGY

Although most objects pass spontaneously, 10 to 20 percent require some intervention, and only 1 percent demand surgical treatment. [2] Ingested foreign bodies may be found anywhere throughout the digestive tract, but there are several physiologic "narrow spaces" where the majority of articles tend to lodge. The pediatric esophagus has five areas of constriction where coins and other objects may become trapped: cricopharyngeal narrowing (C6), the most common site; thoracid inlet (T1); aortic arch (T4); tracheal bifurcation (T6); and hiatal narrowing (T10–11). Most pediatric obstructions occur in the proximal esophagus; the vast majority of adult impactions arise from esophageal disease in the distal esophagus. Because 97 percent of adults presenting with meat impaction harbor pathologic esophageal conditions, barium swallow must be performed to confirm foreign body clearance and evaluate possible underlying disease.

Once an object has traversed the pylorus, it usually continues to the rectum and is passed in the stool. If, however, the object has irregular or sharp edges, it may become lodged anywhere in the gastrointestinal tract. Objects that lodge in the esophagus (not necessarily limited to sharp or irregular contour) can result in airway obstruction, stricture, or perforation with resulting mediastinitis, cardiac tamponade, paraesophageal abscess, or aortotracheoesophageal fistula. Perforation may be the result of direct mechanical erosion, as with bones, or chemical corrosion, as with button batteries.

CLINICAL PRESENTATION

Objects lodged in the esophagus generally produce anxiety and discomfort. Adult patients often complain of retrosternal pain. Patients are likely to retch or vomit and experience dysphagia, resulting in choking, coughing, or aspiration if they attempt to wash down the object. Eventually, patients may be unable to swallow their own secretions. In the adult, the history often provides all the pertinent information necessary for diagnosis and treatment. However, this is often not true in the pediatric population. In the 16-and-under age group, symptoms include refusal to eat, vomiting (with or without hematemesis), gagging, choking, stridor ("pseudoasthma"), neck or throat pain, inability to swallow, increased salivation, and foreign body sensation in the chest.

Physical examination must include careful evaluation of the nasopharynx, oropharynx, neck, and subcutaneous tissues for air resulting from perforation of a hollow viscus. Laryngoscopy, either direct or indirect, should be done, especially when the patient complains of a sticking sensation or has ingested a bone. Although physical signs are not always present, findings consistent with foreign body ingestion in the 16-and-under age group consist of red throat, dysphagia, palatal abrasion, temperature elevation, anxiety and distress, and peritoneal signs.

EMERGENCY DEPARTMENT MANAGEMENT

General Care

Because the great majority of ingested foreign bodies traverse the entire gastrointestinal tract without any problems, treatment can be expectant once the object has passed through the pylorus. [3] If, however, a foreign body obstructs the esophagus, prevention of aspiration is paramount. This can be accomplished by inserting a tube above the obstructing body to remove unswallowed fluids above the impaction. Conditions warranting consultation with an endoscopist and possible hospital admission are listed in Table 72-1.

Sharp or elongated objects

Multiple foreign bodies

Button batteries

Evidence of perforation

TABLE 72-1   Presentations of Esophageal Foreign Bodies Warranting Endoscopy Consultation and Possible Hospital Admission

The offending object can be located in several ways. A radiopaque object will be demonstrated on standard x-ray films of the neck or abdomen. The procedure of choice for finding and then extracting a foreign body in the esophagus is endoscopy. [4] This procedure has a high success rate and thus avoids progression to surgery. [5] It is also time-efficient. [6] Although many other diagnostic methods are available, they are not as reliable and thorough as endoscopy, so the time spent in arranging for and conducting such tests may not be time well spent for a frightened, uncomfortable patient.

If endoscopic equipment and expertise are not available, an esophagogram can be performed. Consultation with an endoscopist is strongly recommended before initiation of any contrast study, because direct visualization of the foreign body after contrast administration may not be possible because of interference from swallowed contrast medium.

The type of contrast agent must be chosen based on the anticipated clinical findings and course. [7] If perforation is suspected, a water-soluble contrast agent (Gastrograffin) should be used. However, since water-soluble agents are pulmonary irritants, barium should be used if aspiration is possible. The least amount of barium possible should be instilled, because barium will block the endoscopic field. If both perforation and aspiration are possible, a nonionic contrast agent is

indicated.

Progress of the object through the gastrointestinal tract must be monitored with repeat abdominal x-ray films, usually 2 to 4 h apart. The use of metal detectors, if available, has been advocated as a means of localizing and tracking the progression of metal objects, thereby avoiding repeated radiation exposure. Abdominal examinations should be done frequently to detect early signs of developing peritonitis should perforation occur. Virtually all symptomatic patients will require observation and esophagoscopy. If a nonfood object becomes lodged in the esophagus or is unable to pass through the pylorus, it must be removed as soon as possible, using esophagogastroscopy. Fatal lead encephalopathy has been reported in a child who ingested a lead curtain weight, which supposedly had been in the stomach for an extended time.[8]

Food Impaction

Meat impaction may be treated expectantly, providing the patient can manage his or her own secretions. Time and sedation often will allow the meat to pass into the stomach, but the bolus should not be allowed to remain impacted longer than 12 h. Endoscopy is the preferred method for removal. Alternatives have been suggested if endoscopy is not available.

The use of proteolytic enzymes, such as an aqueous solution of papain (e.g., Adolph's meat tenderizer), to dissolve a meat bolus is *not* recommended, however, because of the number of reported complications and because of increasing availability of and expertise in endoscopy. Several reports in the literature have described esophageal perforation secondary to the enzymatic action of the solution. Mucosal ischemia resulting from distention of the esophageal wall renders the esophagus more susceptible to enzymatic degradation. Hemorrhagic pulmonary edema also has been reported following aspiration of Adolph's meat tenderizer.

Intravenous administration of glucagon to relax esophageal smooth muscle also has been suggested as a method of treating food impaction. A test dose should be given to ensure that hypersensitivity does not exist; then the recommended dose is 1 mg. If the food bolus is not passed in 20 min, an additional 2 mg is given intravenously. An esophagogram must be performed following treatment to ensure passage. This strategy was questioned by Tibbling and associates, [9] who found no statistical difference in disimpaction rates between patients given spasmolytic drugs and those given placebo. For patients with esophageal obstruction caused by food, more efficient approaches to treatment are endoscopy and esophagoscopy.

Bell[10] reports the successful use of nifedipine, which reduces lower esophageal sphincter pressure and the amplitude of the sphincter contractions without changing the amplitude of contractions in the body of the esophagus. By this mechanism, a bolus of food lodged in the vicinity of the gastroesophageal junction may pass. The recommended dose is 10 mg administered sublingually. Sublingual nitroglycerin has also been used successfully, but could cause hypotension.

Coin Ingestion

Because as many as 35 percent of children with a coin lodged in their esophagus will be asymptomatic, some authors recommend that radiographs be performed on *all* children suspected of swallowing coins to determine the presence and location of the object. However, Caravati and colleagues [11] noted no difference in 5-day morbidity rates between children who underwent radiographic evaluation and those who did not after coin ingestion. Coins in the esophagus lie in the frontal plane with the flat side visible on an anteroposterior radiograph; coins in the trachea lie in the sagittal plane.

The use of a Foley catheter, initially reported in the late 1960s, has been promoted as a safe and effective technique for removal when the coin has been impacted for less than 24 h. Before attempting extraction, the airway must be secured with endotracheal intubation. The catheter is passed down the esophagus beyond the object and the balloon inflated. As the catheter is slowly withdrawn, the object is withdrawn along with it. Retrieval of a coin by this technique is less effective after 24 h. Most clinicians prefer using the Foley catheter under fluoroscopy. Foley catheter retrieval of foreign bodies may be complicated by aspiration, and personnel and equipment for airway control must be immediately available. If endoscopic expertise is readily available, Foley catheterization retrieval should be a secondary option.

Button Battery Ingestion

A button battery lodged in the esophagus is a true emergency because of the extremely rapid action of the alkaline substance on the mucosa. Burns to the esophagus have been reported to occur in as little as 4 h, with perforation as soon as 6 h after ingestion. Button batteries in the esophagus require emergency removal if significant morbidity is to be averted. Outcome does not appear to be affected by battery discharge state but is affected by chemical composition. [12] Lithium cells are associated disproportionately with adverse outcome. Mercuric oxide cells tend to fragment more frequently than other cells; however, the threat of heavy metal poisoning has not been supported by the literature or clinical experience. This fact notwithstanding, blood and urine mercury levels should be measured whenever a mercury-containing cell is observed to have split while in the gastrointestinal tract.

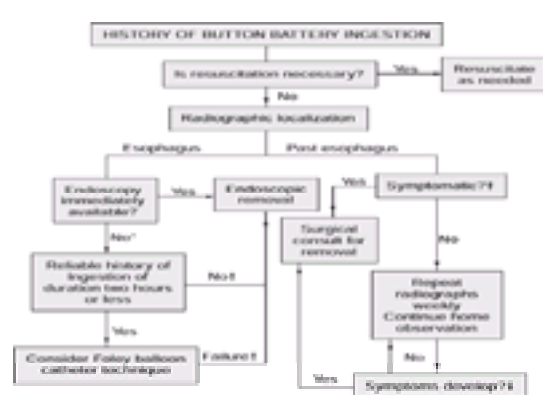
Button ingestion can be managed along two main pathways (Fig. 72-1). If the button battery is lodged in the esophagus, its location should be documented by radiograph; then emergent endoscopic removal is mandatory. Given the widespread expertise with endoscopy, we cannot recommend alternative techniques, many of which are associated with significant complications. Ipecac has no place in the management of button battery ingestion. [12] Button batteries that have passed the esophagus need not be retrieved in the asymptomatic patient unless the cell is not passing through the pylorus after 48 h of observation. This is rarely the case unless the battery is of large diameter and the patient is under 6 years of age. In this case, endoscopic retrieval is again the preferred option. Most batteries pass completely through the body within 48 to 72 h, although passage has been reported to take as long as 14 days. All patients with signs and symptoms of gastrointestinal tract injury require immediate surgical consultation. Assistance with cell identification may be obtained by calling the National Button Battery Ingestion Hotline (National Capital Poison Center, Washington D.C.) at 202-625-3333.


FIG. 72-1. Algorithm for management of button battery ingestion. (Adapted from Kuhns DW, Dire DJ: Button battery ingestions. *Ann Emerg Med* 18:293, 1989.)
*Button batteries in the esophagus must be removed. Endoscopy should be used if available. The balloon catheter technique can be used if the ingestion is less than 2 h old, but should not be used after this because it may increase the amount of damage to the weakened esophagus.
†When the Foley technique fails or is contraindicated due to a greater than 2 h elapsed time period, the button battery should be removed endoscopically. This may require transfer of the patient.
‡Acute abdomen, tarry or bloody stools, fever, persistent vomiting.

Ingestion of Sharp Objects

Management of ingested sharp and pointed foreign bodies is controversial. Objects longer than 5 cm and wider than 2 cm rarely will pass the stomach. Objects of that size and those with extremely pointed edges, such as open safety pins or razor blades, must be removed before they pass from the stomach because 15 to 35 percent will cause intestinal perforation, usually in the ileocecal valve.

Paul and Jaffe[13] recommend the following management for children who have swallowed sharp objects. All patients should have an initial radiograph and physical

examination. If the patient is symptomatic or has ingested a sewing needle, surgical consultation for possible endoscopy and laparotomy is indicated. Children who have swallowed a sharp object (other than sewing needles) yet are asymptomatic can be managed on an expectant basis. Progression of the sharp object should be documented with serial radiographs. If progression past the stomach is not seen, a water-soluble contrast film may document gastrointestinal perforation. At the first sign of perforation, the object should be removed even if the patient remains asymptomatic. If the object does not progress through the gastrointestinal tract, surgical retrieval is indicated.

Cocaine Ingestion

Cocaine ingestion is an increasingly widespread problem. Carriers will ingest multiple small packets of cocaine in attempts to conceal the drug. A favored packet is the condom, which may hold up to 5 g cocaine. Rupture of even one such packet may be fatal. Webb recommends surgery as the safest method of recovery to avoid the likelihood of packet rupture during endoscopic retrieval. If the packet appears to be passing intact through the intestinal tract, the clinician may choose to observe the patient and wait for the packet to be delivered spontaneously through the rectum.

73 PEPTIC ULCER DISEASE AND GASTRITIS

Matthew C. Gratton

Peptic ulcer disease is a chronic illness manifested by recurrent ulcerations in the stomach and proximal duodenum. Acid and pepsin are thought to be crucial to ulcer development, but it is now recognized that the great majority of peptic ulcers are directly related to infection with *Helicobacter pylori* or nonsteroidal anti-inflammatory drug (NSAID) use.[1,2] Gastritis is acute or chronic inflammation of the gastric mucosa and has various etiologies. Dyspepsia is continuous or recurrent upper abdominal pain or discomfort with or without associated symptoms (nausea, bloating, regurgitation, etc.).[3,4] Dyspepsia may be caused by a number of diseases or may be functional.

EPIDEMIOLOGY

Approximately 10 percent of the US population over 17 years of age have peptic ulcer disease at some time. One-third of them report an active ulcer within the last year.[5,6] Peptic ulcer disease has a high rate of morbidity, with 8 million physicians' visits and 275,000 hospitalizations per year and a high cost to society of $5.65 billion per year in lost wages and medical care.[5] The prevalence of *H. pylori* infection in white Americans below age 35 is about 10 percent, rising to almost 80 percent by age 75. Forty-five percent of black Americans below age 25 are infected.[8] The prevalence of dyspepsia is 25 to 30 percent in the United States.[4,7]

PATHOPHYSIOLOGY

Hydrochloric acid and pepsin destroy gastric and duodenal mucosa. Mucous and bicarbonate ion secretions protect mucosa. Prostaglandins protect mucosa by enhancing mucous and bicarbonate production and by enhancing mucosal blood flow, thereby supporting metabolism. The balance between these protective and destructive forces determines whether peptic ulcer disease will occur. *Helicobacter pylori* infection or NSAIDs are thought to be the causal agents of peptic ulcer disease in almost all cases.[1,2] *Helicobacter pylori* infection is present in 95 percent of duodenal ulcers and 80 percent of gastric ulcers.[9] Although traditional treatment of peptic ulcers by various modalities heals most ulcers, eradication of *H. pylori* reduces recurrence rates from 80 to 15 percent for duodenal and from 50 to 10 percent for gastric ulcers.[9] *Helicobacter pylori* is a spiral, urease-producing, flagellated bacterium that is found living between the mucous gel and the mucosa primarily in the gastric antrum.[6,8] The production of urease, cytotoxins, proteases, and other compounds is thought to disturb the mucous gel and cause tissue injury.[2,8] In the presence of acid and pepsin, ulceration may occur. Chronic active (usually asymptomatic) gastritis is an almost universal finding with *H. pylori* infection, but only 10 to 20 percent of infected people develop peptic ulcer disease.[8,10] It is unclear why most infected persons do not develop symptomatic peptic ulcer disease, but it most likely reflects an interaction of factors, including both host and pathogen (different virulence of strains of bacteria).[10]

Helicobacter pylori has been linked to mucosa-associated lymphoid tissue (MALT) lymphoma, and regression has been documented with eradication of infection. In addition, *H. pylori* infection is considered a definite risk factor for adenocarcinoma of the stomach. However, since the prevalence of gastric cancer in the United States is very low and the *H. pylori* infection rate very high, other factors undoubtedly are involved.[8,9]

NSAIDs inhibit prostaglandin synthesis, thereby decreasing mucous and bicarbonate production and mucosal blood flow, allowing ulcer formation.[2] Gastrin-secreting tumors produce ulceration due to high levels of acid and pepsin production, but acid alone rarely causes ulceration.[10,11] However, inhibition of acid secretion may allow ulcers to heal and is the basis for traditional ulcer treatments.

Hereditary factors cause a predisposition to peptic ulcer disease. There is an association between chronic renal failure, renal transplantation, cirrhosis, and chronic obstructive pulmonary disease and peptic ulceration, but the precise mechanism is unclear. Cigarette smoking is a predisposing factor for peptic ulcer disease, perhaps due to an inhibition of bicarbonate ion production or to increased gastric emptying (but not to increased acid production). Emotional stress may predispose to peptic ulcer disease, but diet and alcohol use do not.

Acute gastritis may be related to ischemia from severe illness (shock, trauma, severe burns, organ failure, etc.) or the direct toxic effects of agents (NSAIDs, alcohol, bile acids, etc.). *Helicobacter pylori* infection causes both acute and chronic gastritis (both usually asymptomatic). Chronic gastritis may also be caused by autoimmune factors that destroy gastric parietal cells, resulting in the loss of acid production and the loss of intrinsic factor production, which in turn cause malabsorption of vitamin B_{12} and therefore pernicious anemia.

CLINICAL FEATURES

Burning epigastric pain is the most classic symptom of peptic ulcer disease. The pain may also be described as sharp, dull, an ache, or an "empty" or "hungry" feeling. Pain may be relieved by milk, food, or antacids, presumably due to buffering and/or dilution of acid. Pain recurs as the gastric contents empty, and the recurrent pain may classically awaken the patient at night. Pain tends to occur daily for weeks, resolve, and then reoccur in weeks to months. Although no symptoms allow complete discrimination, in a study by Talley et al, peptic ulceration was more likely than nonulcer dyspepsia or cholelithiasis in the presence of night pain; pain relieved by food, milk, or antacids; and a shorter duration of pain.[7] Postprandial pain, food intolerance, nausea, retrosternal pain, and belching are not related to peptic ulcer disease."[12] Atypical presentations are common in those over age 65, including no pain, epigastric pain not relieved by eating, nausea, vomiting, anorexia, weight loss, and bleeding.[13]

A change in the character of the patient's typical pain may herald a complication. Abrupt onset of severe or generalized pain may indicate perforation with spillage of gastric or duodenal contents and resulting peritonitis. Rapid onset of mid-back pain may be due to posterior penetration into the pancreas, with the development of pancreatitis. Nausea and vomiting may indicate gastric outlet obstruction from scarring or edema. Vomiting bright red blood or coffee-ground emesis, or passing tarry or melanotic stool or hematochezia indicates ulcer bleeding.

On physical examination, the only positive finding in patients with uncomplicated peptic ulcer disease may be epigastric tenderness. This finding is neither sensitive nor specific for the diagnosis.[7] Other physical findings may be indicative of complications: a rigid abdomen consistent with peritonitis in perforation; abdominal distention or a succussion splash due to obstruction; occult or gross blood per rectum or nasogastric tube with ulcer bleeding.

Epigastric pain, nausea, and vomiting may be present with acute gastritis, but the most common presentation is gastrointestinal bleeding, ranging from occult blood loss in the stool to massive upper gastrointestinal hemorrhage. Physical findings may be normal, may reflect only the gastrointestinal bleeding, or may reflect a severe underlying associated illness (as listed above).

DIAGNOSIS

A definitive diagnosis of peptic ulcer disease cannot be made on clinical grounds alone.[12] Uncomplicated peptic ulcer disease can be strongly suspected in the presence of a "classic" history including epigastric burning pain; relief of pain with milk, food, or antacids; and night pain accompanied by "benign" physical

examination findings, including normal vital signs and with or without mild epigastric tenderness. The differential diagnosis of epigastric pain is extensive and in addition to peptic ulcer disease includes gastritis, gastroesophageal reflux disease (GERD), cholelithiasis, pancreatitis, hepatitis, abdominal aortic aneurysm (AAA), gastroparesis, and "functional" dyspepsia. A careful history may elicit features that point away from peptic ulcer disease: burning pain radiating into the chest, water brash, and belching may suggest GERD; more severe pain radiating to the right upper quadrant and around the right or left side suggests cholelithiasis; radiation through to the back indicates pancreatitis or AAA; chronic pain, anorexia, or weight loss may indicate gastric cancer. Myocardial ischemic pain may also present as epigastric pain and should be strongly considered in the appropriate clinical setting.

Physical examination findings may also suggest other diagnoses: right upper quadrant tenderness points to cholelithiasis or hepatitis, epigastric mass to pancreatitis (pseudocyst), pulsatile mass to AAA, jaundice to hepatitis, and peritoneal findings to an acute abdomen.

In a patient presenting with epigastric pain, a number of ancillary tests may be helpful to exclude peptic ulcer disease complications and to narrow the differential diagnosis. A normal complete blood count will rule out anemia from chronic gastrointestinal bleeding due to peptic ulcer disease, gastritis, or cancer (but does not rule out acute blood loss). Elevated liver function test results may indicate hepatitis, and elevated lipase levels may indicate pancreatitis. An acute abdominal series may show free air associated with perforation. A "limited" emergency department ultrasound examination may show gallstones or an AAA. An electrocardiogram and cardiac enzyme determination are indicated if there is a suspicion of myocardial ischemic pain.

The definitive diagnosis of peptic ulcer disease is made by visualization of the ulcer via upper gastrointestinal barium-contrast radiography or via upper gastrointestinal endoscopy. Endoscopy has a higher yield rate for ulcer and other mucosal pathologic conditions, which may affect clinical care.[1] However, endoscopy also has a higher cost and complication rate.[1]

Since most peptic ulcers are caused by *H. pylori* infection and since eradication of *H. pylori* dramatically decreases ulcer recurrence rate, it is important to note how to diagnose infection. *Helicobacter pylori* can be diagnosed by endoscopic tests, including the *Campylobacter*-like organism (CLO) test; histologic study or culture; and noninvasive tests, including serologic tests and breath tests.[1,10,14] The CLO test detects the presence of urease in a biopsy specimen (presumptive evidence of *H. pylori* infection) with about a 90 percent sensitivity and 100 percent specificity and a cost of about $10. Histologic study using special stains has a sensitivity and specificity above 90 percent and costs about $150. Culture is difficult and has a sensitivity no better than histologic studies (although it has 100 percent specificity if results are positive). The aforementioned costs do not include the cost of endoscopy. Serologic studies detect IgG antibodies to *H. pylori* with very high sensitivity and specificity at a cost of about $50 to $75. It is not useful as a test of cure, since antibodies remain for several years after eradication. The breath test also relies on the presence of urease produced by *H. pylori*. Urea, labeled with carbon 13 or 14, is ingested and in the presence of bacterial urease is broken down into labeled carbon dioxide and ammonia. The labeled carbon dioxide is detected in the breath 30 min later. Sensitivity and specificity are greater than 90 percent, and the cost is $200 to $300. This test is ideal for confirming cure of infection.

TREATMENT

After peptic ulcer disease is diagnosed, the goal of treatment is to heal the ulcer while relieving pain and preventing complications and recurrence. Traditional ulcer therapy heals, relieves pain, and prevents complications but does not prevent recurrence. Treatment of *H. pylori* infection, when present, dramatically decreases the recurrence rate.[9] If NSAID-associated ulcers are present, the offending agent must be stopped to reduce the recurrence rate.

Traditional therapy includes histamine (H_2) receptor antagonists (H_2RAs), proton pump inhibitors (PPIs), sucralfate, and antacids[1,15] (Table 73-1). H_2RAs decrease acid production by blocking the actions of histamine on the parietal cell H_2 receptor. All four drugs heal ulcers approximately equally and are available in over-the-counter preparations.[1,15] Side effects are uncommon, but cimetidine has more significant drug interactions than do the other three due to inhibition of cytochrome P-450 activity.[15] PPIs decrease acid production by blocking hydrogen ion secretion by the parietal cell. PPIs generally heal ulcers faster than do H_2RAs and also have some in vitro inhibitory effect against *H. pylori*.[1,15] Side effects are also rare, but omeprazole has some activity against cytochrome P-450, and both PPIs inhibit absorption of drugs that rely on gastric acidity.[15] Sucralfate appears to protect the ulcer from acid exposure and heals about as well as do H_2RAs.[1,15] Sucralfate has few side effects but does inhibit absorption of a number of medications.[15] Antacids heal ulcers by buffering gastric acid and are as effective as H_2RAs.[1] Due to the simplicity of H_2RAs, PPI, and sucralfate dosing requirements, antacids now are used mainly on an as-needed basis for ulcer pain until healing occurs.

Drug	Dosage (PO)
H_2 RECEPTOR ANTAGONISTS	
Cimetidine	400 mg bid
Famotidine	20 mg bid
Nizatidine	150 mg bid
Ranitidine	150 mg bid
PROTON-PUMP INHIBITORS	
Lansoprazole	15 mg qd
Omeprazole	20 mg qd
OTHER DRUGS	
Sucralfate	1 g qid
Misoprostol*	200 μg qid
ANTACIDS	
Magnesium hydroxide-aluminum hydroxide-simethicone	
Maalox Extra Strength Antacid (Ciba)	15 mL qid
Mylanta Double Strength (J & J Merck)	2 tablets qid

*FDA-approved only for prevention of NSAID-associated gastric ulcers.
Source: Drugs for treatment of peptic ulcers,[15] with permission.

TABLE 73-1 Traditional Drugs for Peptic Ulcers

Although NSAIDs should be stopped in patients with peptic ulcer disease whenever possible, misoprostol may prevent ulcer formation in those on concurrent NSAID therapy. Misoprostol is a prostaglandin analogue that may act by increasing mucous and bicarbonate production and by increasing mucosal blood flow.

If *H. pylori* infection is diagnosed in the presence of peptic ulcer disease, eradication is clearly indicated.[18,15] Multiple regimens have been proposed and studied mainly using combinations of bismuth subsalicylate, amoxicillin, tetracycline, metronidazole, clarithromycin, an H_2RA (mainly ranitidine), and a PPI (mainly omeprazole). Usual treatment lasts 2 weeks, costs from $30 to $360 and is effective in from 60 to greater than 90 percent of cases.[1,8,10,15]

Patients generally do not present to the emergency department with a definitive diagnosis of peptic ulcer disease but, rather, with a symptom, such as epigastric pain. If appropriate history, physical examination, and laboratory evaluation result in a physician's impression of "possible peptic ulcer disease" or "dyspepsia," the physician is left with three main options: empiric treatment with conventional antiulcer medication, immediate referral for definite diagnosis (endoscopic or radiologic study), or noninvasive testing for *H. pylori* followed by antibiotic therapy for patients with positive test results.[1,10]

Traditional emergency department treatment would entail initiating a trial of antacids and/or H_2RAs and early referral to a primary care provider to direct evaluation and subsequent treatment. This still is a reasonable option. Immediate referral for definite diagnosis is mandated if certain "alarm" features are present: advanced age, weight loss, long history, anemia, persistent anorexia, early satiety, persistent vomiting, or gastrointestinal bleeding.[1,10,16] Cost-effectiveness analysis supports treatment of *H. pylori*–positive dyspeptic patients with antimicrobial and antisecretory therapy followed by endoscopic study only in those with persistent symptoms.[3,17,18] It would also be reasonable for the emergency department physician to begin symptomatic therapy, order serologic testing for *H. Pylori,* and refer for early follow-up with a primary care provider for initiation of antibacterial therapy if the test results are positive.

COMPLICATIONS

Hemorrhage

In the United States, about 150,000 patients per year are admitted to the hospital with gastrointestinal bleeding due to peptic ulcer disease.[19] Factors predicting death

include large initial bleed, continued or recurrent bleeding, older age, and comorbid illness. [19] The mortality rate is 2 to 3 percent for the 80 to 85 percent of patients who do not rebleed, compared to 20 percent or greater for those who do bleed while hospitalized. [19] Shock, low initial hematocrit, red blood in the emesis or stool, and failure of blood to clear with lavage all predict further bleeding. [19]

Treatment for ulcer bleeding should focus on restoring hemodynamic stability by intravenous administration of isotonic saline solution and packed red blood cells. Appropriate blood work should be performed, including a complete blood count and type and crossmatching for several units of packed red cells. Two large-bore intravenous lines should be started and the patient placed on oxygen and a cardiac monitor. A nasogastric tube should be inserted and lavaged with water until clear. This does not slow bleeding but allows monitoring of ongoing bleeding and clears the stomach for endoscopy. An H$_2$RA or PPI can be started, but there is no proof that either reduce rebleeding rates.

Most patients should undergo upper gastrointestinal endoscopy for diagnostic, prognostic, and treatment purposes. An actively bleeding vessel seen on endoscopy heralds a 35 percent chance of emergency surgery and an 11 percent mortality rate, with decreasing morbidity and mortality rates with findings of a nonbleeding visible vessel; an adherent clot; a flat, pigmented spot; and a low of 0.5 percent emergency surgery and a 2 percent mortality rate if a clear base is found. [19] Treatment through endoscopy includes injection therapy with epinephrine, alcohol, or combinations; heat probe or bipolar electrical coagulation; or laser therapy. All of these treatments stop bleeding, prevent recurrences, and decrease transfusion rates and length of hospital stay. The technique chosen depends on the equipment available and the experience of the endoscopist.[19,20]

The rebleeding rate after endoscopic therapy is about 20 percent and can be treated by repeat endoscopy or emergency surgery. Surgery is also indicated if bleeding cannot be controlled by initial endoscopy. Angiography with arterial vasopressin or embolization can be considered if endoscopy has failed and surgery is thought to be very high risk.[19]

Hospitalization in an intensive care setting is indicated for all patients with significant upper gastrointestinal bleeding due to peptic ulcers. If clinical and endoscopic features suggest a low risk of rebleeding, a ward bed may be acceptable.

Perforation

Perforation is heralded by the abrupt onset of severe epigastric pain as gastric or duodural contents spill into the peritoneal cavity, followed by the development of chemical and then bacterial peritonitis. Patients may not have a prior history of peptic ulcer disease and may in fact have no antecedent history of ulcer-like symptoms. Elderly patients may not have dramatic pain or impressive peritoneal findings.

When the diagnosis is suspected, appropriate laboratory tests, including a complete blood count, type and crossmatch, and a lipase level determination, should be performed; two large-bore intravenous lines started; oxygen and a monitor placed; a nasogastric tube inserted and placed on suction; and an acute abdominal series obtained. Free air is not always present. Some authorities suggest instillation of air into the stomach through the nasogastric tube in order to detect perforation. This procedure may open a sealed perforation, causing more spillage, and if free air is still not visualized, it does not rule out a perforation; thus, it is not recommended. Broad-spectrum antibiotics should be given and a surgical consult promptly obtained. In some cases, nonsurgical therapy has been successful, but operative intervention is the standard in the United States.

Obstruction

Obstruction occurs because of scarring of the gastric outlet due to chronic peptic ulcer disease, edema due to an active ulcer, or some combination of both. Resulting symptoms include abdominal fullness, nausea, and vomiting, and signs may include abdominal distention and a succussion splash. Dehydration and electrolyte imbalances may occur. Treatment includes rehydration with intravenous fluids, correction of electrolyte abnormalities, and relief of distention with nasogastric suction. Hospitalization is almost always indicated. The outlet may open as edema subsides, but surgical correction is often necessary.

DISPOSITION

Patients with complications always require consultation, and most require admission to an appropriate inpatient unit based on the diagnosis and hemodynamic stability. Most patients with epigastric pain or dyspepsia do not leave the emergency department with a definitive diagnosis, but if critical diagnoses (e.g., AAA or myocardial ischemia) are still in the differential, consultation for admission and appropriate workup is indicated. When uncomplicated peptic ulcer disease, gastritis, or dyspepsia is strongly suspected, the great majority of patients can be discharged with antacids and an H$_2$RA, with or without a seralogic test for *H. pylori,* and close follow-up with their primary care provider. If "alarm" features (indicating possible cancer or bleeding) are present, consultation for early endoscopy is indicated.

Discharge instructions should include an explanation of the diagnosis and home treatment, specific follow-up instructions, and warning symptoms that should prompt immediate reevaluation. The explanation of the diagnosis should specify that peptic ulcer disease is a presumptive diagnosis and that more definitive diagnostic testing may be necessary. Home treatment should include a reminder to take medications as directed; a warning against use of alcohol, tobacco products, and aspirin or other NSAIDs; and a recommendation to avoid foods that appear to upset the individual's "stomach." Specific follow-up should include a name and phone number of the appropriate provider whenever possible as well as a time frame for reevaluation, generally 24 to 48 h if not improving or 1 to 2 weeks if improving. Warning symptoms that merit immediate reevaluation include those that may be attributed to ulcer complications or confounding illness: worsening pain, increased vomiting, hematemesis or melena, weakness or syncope, fever, chest pain, radiation of pain to the neck or back, and shortness of breath.

74 APPENDICITIS

Denis J. FitzGerald
Arthur M. Pancioli

EPIDEMIOLOGY

Appendicitis has an overall incidence of approximately 1 case per 1000 population per year, with 6 percent of the population experiencing appendicitis at some point in their lifetime. The overall impact is significant, since acute appendicitis results in an estimated 1 million hospital days annually in the United States. [1] Unfortunately, acute appendicitis can be extremely difficult to diagnose, and misdiagnosis remains an important cause of successful malpractice claims against emergency physicians.[2]

PATHOPHYSIOLOGY

Acute appendicitis probably begins with an obstruction of the lumen. The obstruction can result from food matter, adhesions, or lymphoid hyperplasia. Despite the obstruction, mucosal secretion continues, leading to an increase in intraluminal pressure. This pressure will eventually exceed capillary perfusion pressure and will obstruct venous and lymphatic drainage. With such vascular compromise, the epithelial mucosa begins to break down, allowing bacterial invasion by bowel flora. The subsequent inflammatory response and edema further exacerbate the increased intraluminal pressure. Eventually, this increased pressure leads to arterial stasis and tissue infarction. The end result is perforation and spillage of the infected appendiceal contents into the peritoneum.

In order to understand the clinical presentation and the clinical progression of acute appendicitis, it is important to consider the innervation and anatomic variability of the appendix. Presumably, the initial lumenal distention triggers the visceral afferent pain fibers from the appendix, which enter the spinal cord at the tenth thoracic vertebra. As is characteristic of visceral afferent innervation, this pain is generally vague and poorly localized. Based on the anatomic level of these afferent fibers at the tenth thoracic level, the pain is generally perceived by the patient at the periumbilical or epigastric region. Eventually, as the inflammatory process continues, the appendiceal serosa and adjacent structures become inflamed. This inflammation triggers the somatic pain fibers, which innervate the peritoneal structures, typically localizing the pain in the right lower quadrant. This explains the migration of pain from the periumbilical area to the right lower quadrant, classically associated with acute appendicitis.

The clinician must be aware, however, that there are many exceptions to this classic presentation of the pain of acute appendicitis. These exceptions are often due to the variability of the anatomic location of the appendix. In a study of 71,000 human appendix specimens removed over a 40-year period, 26 percent were retrocecal, and 4 percent were located in the right upper quadrant.[3] With the retrocecal appendix, the pain of acute appendicitis may localize to the flank rather than the right lower quadrant. Similarly, in pregnant patients, the gravid uterus may displace the appendix, leading to a presentation of right upper quadrant or flank pain. In male patients, a retroileal appendicitis may irritate the ureter, causing pain in the testicle. A pelvic appendix may irritate the bladder or rectum and cause suprapubic pain, pain with urination, or the feeling of a need to defecate. These anatomically based variations in presentation help to explain the difficulty in making the diagnosis of acute appendicitis.

CLINICAL PRESENTATION

History

The primary symptom in acute appendicitis is abdominal pain. In approximately one-half to two-thirds of patients with appendicitis, the pain evolves in a classic pattern. Beginning in the epigastrium or periumbilical region early in the illness, the pain is initially vague and difficult to localize. Patients may describe their discomfort as indigestion or as a feeling of the need to defecate or pass flatus. As the illness progresses, the pain becomes more localized, typically in the right lower quadrant. As described above, however, the location of the patient's pain varies with the anatomic location of the appendix. One meta-analysis, in which approximately half of the studies focused on patients suspected of having acute appendicitis and half were series of patients examined for abdominal pain, provides characteristics of some common clinical findings in acute appendicitis. [4] In this analysis, right lower quadrant pain was 81 percent sensitive and 53 percent specific for the diagnosis of acute appendicitis. Similarly, migration of the pain from initial periumbilical pain to the right lower quadrant was 64 percent sensitive and 82 percent specific for the diagnosis of acute appendicitis. [4]

In addition to abdominal pain, the classic triad of symptoms in appendicitis includes anorexia, nausea, and vomiting. In acute appendicitis, these symptoms typically appear after the onset of vague abdominal pain. Anorexia is the most common of these symptoms, with 68 percent sensitivity and 36 percent specificity. [4] Vomiting is more variable in acute appendicitis, occurring in about half of patients with acute appendicitis. [4] The significance of the temporal relationship between abdominal pain and onset of vomiting as a predictor of acute appendicitis has not yet been established. Table 74-1 provides a summary of the sensitivity and specificity of many symptoms associated with appendicitis.

TABLE 74-1   Summary of Clinical Examination Operating Characteristics for Appendicitis*

Physical Examination

Like the history, the findings upon physical examination of a patient with acute appendicitis depend on the duration of the illness prior to the examination. Early in the course of acute appendicitis, the patient may not have localized tenderness. As the illness progresses, the patient typically develops tenderness, especially to deep palpation, over McBurney's point. This is a point just below the middle of a line connecting the umbilicus and the anterosuperior iliac spine. Pain in the right lower quadrant with palpation of the left lower quadrant (Rosving sign) may also be elicited. As with the subjective pain, the localization of tenderness varies with the anatomic position of the appendix. If the patient has a pelvic appendix, the patient's tenderness may be most pronounced on rectal examination. With a retrocecal appendix, tenderness to palpation may be attenuated by the overlying cecum or may be most pronounced in the right flank. Additional components of the physical examination that may help in the diagnosis of pain resulting from acute appendicitis include rebound tenderness, voluntary guarding, local muscular rigidity over the inflamed area (involuntary guarding), and tenderness on rectal examination. The sensitivity and specificity of these findings are seen in Table 74-1.

Special maneuvers that can aid in the diagnosis of acute appendicitis include the psoas sign and the obturator sign. The examiner checks for a psoas sign by placing the patient in the left lateral decubitus position and extending the right leg at the hip. If an inflamed appendix is overlying the psoas muscle, this maneuver will cause an increase in the patient's pain, thereby eliciting a positive psoas sign. The obturator sign is evaluated by passively flexing the right hip and knee and internally rotating the hip. This action will stretch the obturator muscle. An inflamed appendix may irritate the obturator muscle, and this maneuver will increase pain, indicating a positive obturator sign.

Fever is another relatively late physical finding in acute appendicitis. At the onset of pain, the patient's temperature will probably be normal. If the temperature is taken frequently during the progression of the illness, it will usually rise 1 to 2°C. Temperatures above 39°C (102.2°F) are uncommon in the first 24 h of the illness but not uncommon after rupture of an appendix.

Classic Presentation

The classic clinical presentation of acute appendicitis consists of vague, poorly localized, periumbilical pain followed by anorexia, nausea, and possibly vomiting. Over a period of 4 to 48 h the pain will migrate to the right lower quadrant. [4] Low-grade fever is also a later finding in acute appendicitis. The clinician must be aware, however, that many diagnostic errors occur because the physician fails to consider the variability in the presentation associated with acute appendicitis.

DIAGNOSIS

The diagnosis of acute appendicitis is made primarily with the clinical history and physical examination. Patients with a high clinical probability of acute appendicitis should be surgically explored without the delay of any ancillary testing. Additional studies are largely confirmatory or are used to rule out other pathologic conditions when the diagnosis is less clear. These additional studies include a complete blood count (CBC), urinalysis (UA), pregnancy test for females, and various imaging studies. Clinical observation is another common diagnostic modality.

Complete Blood Count

The CBC has long been used to aid in the diagnosis of acute appendicitis, although its utility is contested. [5,6 and 7] The sensitivity of an elevated white blood count (WBC) above 10,000/μL in acute appendicitis is 70 to 90 percent, but the specificity is very low. [7] More important, the positive and negative predictive values of an elevated WBC in acute appendicitis are 92 and 50 percent, respectively. [8] In general, the WBC has limited value in the diagnosis of acute appendicitis. Clearly, overreliance on an elevated WBC will lead the clinician astray and potentially delay necessary surgery. The diagnostic value of C-reactive protein and erythrocyte sedimentation rate have been studied in acute appendicitis with mixed results. [9,10 and 11]

Urinalysis and Urine Pregnancy Tests

UA is frequently performed in the workup of possible acute appendicitis. Abnormal UA results, excluding proteinuria, are found in 19 to 40 percent of patients with acute appendicitis. [12,13] Abnormalities include pyuria, hematuria, and bacteriuria, possibly related to the extension of appendiceal inflammation to the ureter. The presence of greater than 20 WBC/hpf (without epithelial cells) in the urine should elevate consideration of urinary tract pathology in the differential diagnosis. [12]

A pregnancy test is an essential component of the workup of abdominal pain in females of childbearing age. It must be clearly stated that pregnant patients and nonpregnant patients have an equal likelihood of getting appendicitis. [14]

Imaging Studies

Imaging studies performed in the workup of possible acute appendicitis include plain radiographs, ultrasound studies, and computed tomography (CT) scans. The utility and role of these studies is controversial.

Plain radiographs of the abdomen are abnormal in 24 to 95 percent of patients with acute appendicitis. [7] Radiographic indicators of possible acute appendicitis include appendiceal fecolith, appendiceal gas, localized paralytic ileus, blurred right psoas muscle, and free air. Since many of these signs are seen in multiple other processes, abdominal radiographs have limited diagnostic value in acute appendicitis.

Graded compression ultrasonography has been widely utilized in the diagnosis of acute appendicitis. This study is safe, noninvasive, and reported to have a sensitivity of approximately 80 to 89 percent. [15] The use of this technique is based on the fact that normal bowel loops and a normal appendix can be compressed with moderate pressure while an inflamed appendix cannot be compressed. The diagnostic criteria for acute appendicitis include the visualization of a noncompressible appendix that has a diameter of 6 mm or greater, demonstration of an appendicolith, or demonstration of a periappendiceal abscess. This technique has limitations with a retrocecal appendix, in that the overlying bowel may limit visualization and compression testing. In addition, an early perforation may be missed, since the diameter of the appendix may be normal after perforation. [16] In addition, color Doppler ultrasound studies may be helpful when the appendix is well visualized but equivocal in size. With this technique, hyperemia in the wall of the appendix has been found to be a sensitive indicator of inflammation. [17]

CT is another adjunctive study used in the diagnosis of acute appendicitis. In one study which directly compared CT to ultrasound in 100 patients, the CT had greater sensitivity (96 versus 76 percent), greater accuracy (94 versus 83 percent), and a greater negative predictive value (95 versus 76 percent). In this study, there was no significant difference when CT was compared to ultrasound with regard to specificity or positive predicitive value. [18] CT findings suggesting acute appendicitis include pericecal inflammation, abscess, periappendiceal phlegmon, or fluid collections. Given its wide availability and usefulness in establishing alternative diagnoses, CT is probably the best choice as initial imaging study, although its radiation exposure limits its application in pregnant patients and children.

Clinical Observation

For patients presenting atypically with suspicion for appendicitis, clinical observation in the emergency department with serial abdominal examinations has proven to be a valuable diagnostic adjunct in clarifying evolving cases of appendicitis. [19,20] Emergency physicians and surgical consultants can both use this option to select the best course of care; emergency physicians can avert inappropriate discharge of a patient and subsequent return with a worsening course, while surgeons can avoid performing unnecessary appendectomies.

SPECIFIC ISSUES THAT AFFECT DIAGNOSIS, EVALUATION, AND TREATMENT

Special Populations

Certain groups are at high risk for appendicitis. Collectively, these patients present atypically and more often have delayed diagnoses as a result, with a concomitant

increase in complications, such as appendiceal perforation. Emergency physicians must adopt an aggressive approach to evaluating these patients to reduce morbidity and mortality rates associated with unrecognized appendicitis.

Very young patients present insidiously and have a higher perforation rate. The rate of misdiagnosis is as high as 57 percent in children under age 6 years, with perforation rates approaching 90 percent in some studies. [21,22] Diagnosis in the pediatric population can be confounded by difficulty with communication and atypical symptoms, including concurrent respiratory symptoms. It is important to stress that peritonitis in children can present with such varied signs as lethargy, inactivity, and hypothermia. Appendicitis is a common condition requiring emergency operation in children, and early surgical consultation is recommended in suspicious cases.

The very old may have subtle signs and symptoms even late in the course of appendicitis. Members of this population tend to present late to physicians, often after a period of self-medication. Misdiagnosis rates can surpass 50 percent, with a high incidence of perforation, ranging from 40 to 70 percent. [23,24 and 25] Mortality rates for patients over 70 with acute appendicitis approach 30 percent. [26] In addition to late presentation with an advanced course, anatomic changes in the appendix involving the vascular bed and reduced mural thickness are thought to contribute to the fulminant course of appendicitis seen in the elderly. [27] One study found that the most significant predictors of acute appendicitis in the aged were tenderness, rigidity, pain at diagnosis, fever, and previous abdominal surgery. [28] Since extensive laboratory studies may obscure the diagnosis in patients with other concurrent medical problems, a high index of clinical suspicion is needed in the management of these patients. [29]

Pregnant patients can be difficult to diagnose with appendicitis because of variation in presentation resulting from appendix displacement by the gravid uterus as well as the fact that physiologically typical symptoms of appendicitis, such as nausea and vomiting, can be mistakenly attributed to pregnancy. Nonetheless, appendicitis remains the most common extrauterine surgical emergency in pregnancy, and fetal mortality rates can be four times higher if the appendicitis is complicated by perforation and peritonitis. [30] Consequently, the diagnosis of appendicitis must be entertained in any gravid patient presenting with abdominal pain and gastrointestinal symptoms. As an adjunct, ultrasound can be used to aid in diagnosis, particularly in differentiating obstetric causes from appendicitis.

Patients with AIDS are particularly susceptible to complications from appendicitis. Although symptoms are no different for appendicitis in this population, [31] diagnosis can be delayed because of patients' high tolerance for discomfort, the baseline frequency of gastrointestinal symptoms unrelated to appendicitis, and the occurrence of nonsurgical opportunistic pathologic conditions with similar presentations. One study noted a higher incidence of perforation in this population, possibly related to the delay in presentation or to the immunocompromised state. [31] One clear difference in management relates to the WBC, which is generally not elevated even in acute appendicitis. CT remains a good choice for differentiating surgical from nonsurgical pathologic conditions in unclear cases, but the overall management still focuses on basic assessment with aggressive surgical intervention.

Specific Medicolegal Issues

Appendicitis is a leading cause of litigation against emergency physicians. Appendicitis carries a high medicolegal risk because it is difficult to diagnose and there are no definitive diagnostic studies. Several features common to these malpractice cases have been identified. [32] Misdiagnosis of appendicitis more often occurred in patients who presented atypically and who did not receive comprehensive assessments, including rectal examinations. These patients were often given intramuscular narcotics for analgesia, given a diagnosis of gastroenteritis (without manifesting many of the typical symptoms), and discharged without appropriate follow-up care. Based on these considerations, the prudent emergency physician should maintain a high index of suspicion for appendicitis, perform complete examinations, avoid narcotics for unclear diagnoses, use the term *nonspecific abdominal pain* as a diagnosis rather than inappropriate labels for unclear causes, and arrange close follow-up for patients without a clear diagnosis. It is also imperative that all such observations, interventions, and thought processes be clearly documented in the record both to facilitate further care of the patient and to protect against potential litigation.

Transfer Issues

Given the current focus on insurance reimbursement, some authors have noted with concern a trend to transfer uninsured patients with appendicitis to county hospitals for subsequent appendectomy. [35] In a disease process where delayed care has implications for increased morbidity, such a transfer has ramifications for patients' health. Although the Consolidated Omnibus Reconciliation Act (COBRA) restricts transfer of unstable patients, decisions regarding patients' care are increasingly made on the basis of financial concerns. Although no study has yet documented a negative outcome for patients transferred under these conditions, uninsured patients with appendicitis generally have been found to be at increased risk for complications, [34] and the future impact of this practice is not clear.

TREATMENT

Antibiotics

Broad-spectrum antibiotics play an important role in the management of acute appendicitis. Although antibiotics have been found effective alone in treating acute appendicitis, [35] appendectomy remains the standard of care. As a rule, antibiotics should not be given to a patient with undiagnosed abdominal pain, to prevent inadvertent suppression of an evolving clinical presentation. In patients with uncomplicated appendicitis, antibiotics have been found to decrease the incidence of postoperative wound infections. In patients with perforation, early antibiotics have been shown to decrease postoperative abscess formation. [36,37] Antibiotics are most effective when given prior to surgery and should cover anaerobic flora, enterococci, and gram-negative intestinal flora. A common triple-coverage antibiotic combination is metronidazole, ampicillin, and gentamicin. Single coverage with cefoxitin or cefotetan is also an option. [36,38]

Surgery

Appendectomy is the standard of care for acute appendicitis. To prevent complications arising from undiagnosed appendicitis, surgeons accept a 15 to 20 percent negative appendectomy rate. There is some debate regarding an open technique versus a laparoscopic approach in current surgical thought. The postoperative course, morbidity rates, and decreased cost favor the open approach in most cases, with laparoscopic surgery reserved for selected populations. [35] In the emergency department, patients who are being taken to appendectomy should at a minimum be given nothing by mouth, have a peripheral saline IV placed, and be given preoperative antibiotics. Analgesia need not be withheld once the decision for surgery is made. Postoperative care for uncomplicated appendicitis is minimal, with most patients going home 3 days after surgery. In cases of ruptured appendicitis, postoperative care can be complex, requiring multiple interventions to resolve sepsis, paralytic ileus, and abscess formation.

DISPOSITION

The approach to a patient with potential appendicitis varies with the nature of the initial presentation, and it is a paradox in time management. Given the spectrum of appendicitis presentations, the overall goal is to eliminate delay to definitive care in clear cases of appendicitis but to allow time for other potential subtle presentations to evolve into more diagnostic certainty. In general, patients with abdominal pain can be stratified into four groups with respect to their potential for appendicitis. The first group is composed of patients who demonstrate the classic presentation for acute appendicitis. The management of these patients is straightforward, involving prompt surgical consultation and subsequent appendectomy. The emergency department course is focused on preoperative preparation, as outlined previously.

The second group includes those patients with signs and symptoms that are suspicious but not diagnostic for appendicitis. These patients are the most difficult to manage. This group of patients would most likely benefit from imaging studies, either CT or ultrasound, to elucidate the diagnosis. Observation for a 4- to 6-h period with serial examinations may clarify the evolution of the underlying pathologic condition. Surgical consultation is clearly indicated in cases where the examination becomes progressively more characteristic of appendicitis or if a surgical finding is identified on an imaging study.

The third group involves those patients with presentations minimally evoking appendicitis as a diagnostic possibility or for whom appendicitis is not a consideration in the cause of their abdominal complaint. These patients represent the highest medicolegal risk for the emergency practitioner. These patients should be observed in the emergency department for a period, with serial examinations. If the course remains benign and no other contraindications to discharge exist, they should be sent home with no diagnostic label (e.g., nonspecific abdominal pain). Clear follow-up instructions are critical to ensuring optimal outcomes for patients.

For patients with abdominal pain cleared for discharge, follow-up instructions are paramount. Patients should be told that no clear cause for their symptoms was found

but that over time their symptoms will either abate or coalesce into a recognizable pattern. Follow-up instructions should include a description of worrisome symptoms that suggest progressive disease and warrant return to the emergency department. Patients should be reevaluated in 12 to 24 h by their primary physician or by the emergency department to ensure resolution of symptoms. Patients should be cautioned to avoid strong analgesics that might mask evolving pathologic processes; instead, they should be instructed to return if their pain increases. In this fashion, the emergency physician establishes a clear continuity of care for the patient with guidelines that minimize the likelihood of an adverse outcome.

The last group is composed of all high-risk special populations presenting with abdominal pain. This group includes elderly, pediatric, pregnant, and immunocompromised patients. As emphasized earlier, these patients require a high index of clinical suspicion and a low threshold for surgical consultation to avoid morbidity and mortality from undetected appendicitis.

75 INTESTINAL OBSTRUCTION

Salvator J. Vicario
Timothy G. Price

Intestinal obstruction is an important consideration in patients who present with abdominal complaints to the emergency department. It can be defined as an inability of the intestinal tract to allow for regular passage of food and bowel contents. In turn, this can be secondary to mechanical obstruction or adynamic ileus. Adynamic ileus (paralytic ileus) is the more common entity, but is usually self-limiting and does not require surgical intervention. Mechanical obstruction can be caused by either intrinsic or extrinsic factors and generally requires definitive intervention in a relatively short period of time to determine the cause and minimize subsequent morbidity and mortality.

ETIOLOGY

Small bowel obstruction (SBO) accounts for 20 percent of all acute surgical admissions and results in approximately 9000 deaths per year in the United States. Less commonly, the intestine is obstructed at the large bowel.

Both large and small intestines may be obstructed by various pathologic processes (Table 75-1). Extrinsic, intrinsic, or intraluminal processes precipitate mechanical obstruction. Differentiating SBO from large bowel obstruction (LBO) is important because the incidence, clinical presentation, and modes of therapy vary depending on the anatomic site of the obstruction. The small intestine is characterized by transverse linear densities that extend completely across the bowel lumen (plicae circulares). The colon is situated peripherally in the abdomen, is larger in diameter, and contains short, blunt, and thick projections (haustrae) that arise from the bowel wall and extend only partially into the lumen. Haustrae are less numerous and situated farther apart than plicae circulares.

Duodenum	Small Bowel	Colon
Stenosis	Adhesions	Carcinoma
Foreign body (Bezoars)	Hernia	Fecal impaction
Stricture	Intussusception	Ulcerative colitis
Superior mesenteric artery syndrome	Lymphoma	Volvulus
	Stricture	Diverticulitis (stricture, abscess)
		Intussusception
		Pseudo-obstruction

TABLE 75-1   Common Causes of Intestinal Obstruction

The most common cause of SBO is adhesions following abdominal surgery.[1,2 and 3] Although in most cases several months to years have passed from the time of the previous surgery, SBO may occur within the first few weeks following surgery.[3] The second most common cause of small intestinal obstruction is incarceration of a groin hernia[1,2] (see Chap. 76). This can occur in infants as well as adults and should be suspected anytime there is a complaint of a "knot" or growth in the inguinal region that fails to reduce with manipulation. Other sites that are occasionally responsible for SBO secondary to hernia include the umbilicus, femoral canal, and, rarely, the obturator foramen. Umbilical hernias are more readily apparent and occur in any age group. Obturator or femoral hernias are much less common and may present with femoral or medial thigh pain. Elderly females are particularly susceptible to these defects, and one needs to consider them as a possible cause of SBO in these patients. Finally, a defect in the mesentery itself may cause intestinal obstruction.

Other causes of SBO are much less common and are generally due to intraluminal or intramural processes. Primary small bowel lesions include polyps, lymphoma, or adenocarcinoma. An unusual cause of intraluminal obstruction is gallstone ileus. In this situation, a gallstone has eroded from the gallbladder through the bowel wall and can cause obstruction at the ileocecal valve. Besides the findings of bowel obstruction, one may note air in the biliary tree on abdominal radiographs. Lymphomas may be the leading point of intussusception and present as SBO.

Bezoars are most commonly composed of vegetable matter or pulp from persimmons. Patients who have undergone gastrointestinal pyloroplasty or pyloric resection are most susceptible to intraluminal obstruction by bezoars.

Inflammatory bowel disease may also affect the small bowel at various sites. Likewise, infectious processes including abscesses may obstruct the bowel. Radiation enteritis is also a possible cause of SBO in patients who have undergone radiation therapy.

Colonic obstruction is almost never caused by hernia or surgical adhesions. Neoplasms are by far the most common cause of large bowel obstruction. [4,5] Therefore, anyone who has symptoms of colonic obstruction should be evaluated for a neoplasm. Diverticulitis may create significant secondary obstruction and mesenteric edema. Stricture formation may occur with chronic inflammation and scarring. Fecal impaction is a common problem in elderly, debilitated patients and may present with symptoms of colonic obstruction.

The next most frequent cause of large bowel obstruction after cancer and diverticulitis is sigmoid volvulus. Elderly, bedridden, or psychiatric patients who are taking anticholinergic medication are most often subject to this mechanical problem. A history of constipation may precede the volvulus and presenting symptoms. Radiographic appearance is usually classic (Fig. 75-1). Finally, although much less common, cecal volvulus may also cause large bowel obstruction.
FIG. 75-1. Sigmoid volvulus. Note distension of large bowel and central stripe, giving a "coffee-bean" appearance.

PATHOPHYSIOLOGY

Normal bowel contents contain gas as well as gastric secretions and food. Intraluminal accumulation of gastric, biliary, and pancreatic secretions continues even if there is no oral intake. As obstruction develops, the bowel becomes congested and there is failure of intestinal contents to be absorbed. Vomiting and decreased oral intake follow. The combination of decreased absorption, vomiting, and reduced intake leads to volume depletion with hemoconcentration and electrolyte imbalance, and ultimately can cause renal failure or shock.[5]

Bowel distension often accompanies mechanical obstruction. Distension is due to the accumulation of fluids in the bowel lumen, an increase in intraluminal pressure with enhanced peristaltic contractions, and air swallowing. When intraluminal pressure exceeds capillary and venous pressure in the bowel wall, absorption and lymphatic drainage decrease. At this stage, bacteria may enter the bloodstream, the bowel becomes ischemic, and septicemia and bowel necrosis can develop. Shock rapidly ensues. Mortality approaches 70 percent if bowel obstruction has been allowed to progress this far. With a *closed-loop obstruction* this sequence of events may occur more rapidly. In this instance, there is no proximal escape for bowel contents. Examples of closed-loop obstruction include an incarcerated hernia and complete colon obstruction in the presence of a closed ileocecal valve.

CLINICAL FEATURES

The site and nature of the obstruction and the preexisting condition of the patient will determine the clinical presentation. Almost all patients will have abdominal pain.[4] The pain is generally described as crampy and intermittent. Pain of mechanical SBO is often episodic, usually lasting for a few minutes at a time, and it may be periumbilical or more diffuse. In adynamic ileus, the pain tends to be less intense and more constant. If the obstruction is proximal, vomiting is usually present. The vomitus in proximal obstruction is usually bilious but is feculent in distal ileal obstruction. The pain of large bowel obstruction is usually hypogastric. Large bowel obstructions may be associated with fecal vomiting as well.

Other features that are consistently present with obstruction of small bowel or colon include the inability to have a bowel movement or pass flatus. Care should be taken to avoid the diagnosis of constipation, as this symptom is secondary to partial or complete obstruction. Partial bowel obstruction, however, is often associated with regular passage of stool and flatus.

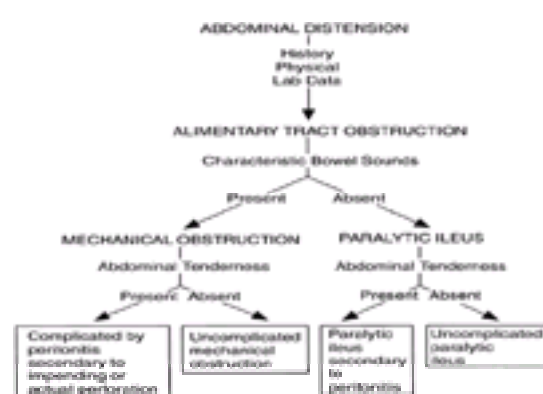
Physical findings vary, depending on the site, duration, and etiology of the pathologic process. Early symptoms are usually associated with some abdominal distension, often impressive with colonic obstruction yet not readily apparent in cases of incarcerated hernia. Abdominal tenderness may be minimal and diffuse or localized and severe.[3,4] Patients who have developed peritonitis will have severe tenderness. The abdomen may be tympanitic to percussion. Mechanical obstruction will produce active high pitched bowel sounds with occasional "rushes." If obstruction has been present for several hours, peristaltic waves and bowel sounds may be diminished. Patients with an adynamic ileus may have some abdominal distension associated with diminished or absent bowel sounds. Careful search for localized or rebound tenderness is essential to rule out the possibility of gangrenous or perforated bowel, which requires immediate surgical intervention (Fig. 75-2).


FIG. 75-2. Logic flow diagram emphasizing the clinical importance of abdominal tenderness in alimentary tract obstruction. (From Schwartz GR: *Principles and Practice of Emergency Medicine,* 3d ed, p 1718. Malvern, PA, Lea & Febiger, 1992, with permission.)

Elderly patients have signs and symptoms that are similar to younger patients with intestinal obstruction. Adhesions and hernias are common causes for SBO in this age group, while carcinomas are the most likely etiology of LBO because of the increased likelihood of cancer as people age.[9] Elderly patients who are debilitated or confused, or who are on multiple medications, may be unable to give a detailed history. Careful examination for characteristic bowel sounds, masses or blood in stool, and radiographic investigation will often distinguish bowel obstruction from ileus. There is also evidence that patients over 60 years old are more likely to succumb secondary to complications of bowel obstruction.[3]

All patients with abdominal pain or distension should be examined for signs of organomegaly or masses that may suggest a cause of the obstruction. A rectal examination may identify fecal impaction, rectal carcinoma, occult blood, or stricture. The absence of stool or air in the vault may aid in the diagnosis of bowel obstruction, but its presence does not eliminate a more proximal obstruction, as patients may not be able to evacuate preexisting rectal contents. A pelvic examination should be performed to identify any gynecologic pathology causing obstruction.

LABORATORY AND RADIOGRAPHIC FINDINGS

All patients with suspected obstruction should have a flat and upright abdominal radiograph and upright chest x-ray or a lateral decubitus view if the patient cannot be upright. An abdominal radiograph can confirm the diagnosis, identify free air or masses, and localize the site to large or small bowel (Fig. 75-3*A*, Fig. 75-3*B*). Laboratory work usually includes a complete blood count and electrolyte measurements. Depending on the duration of symptoms and site of obstruction or whether there is bowel necrosis, one may find a wide range in white blood cell (WBC) counts and hemoglobin, hematocrit, and electrolyte values. Patients will usually have some elevation in WBC. A white count >20,000/μL or left shift should make one suspect bowel gangrene, intra-abdominal abscess, or peritonitis.[5] Extreme WBC elevation (>40,000/μL) suggests mesenteric vascular occlusion. The serum anylase and lipase levels may be mildly elevated. Levels of serum electrolytes are usually normal or mildly reduced,[4] depending on whether the obstruction is of short or long duration or whether there is associated emesis. An increase in Hct, BUN, and creatinine are consistent with volume depletion and dehydration. Other indications of the severity of obstruction or secondary complications include increased urine specific gravity, ketonuria, elevated lactate levels, and metabolic acidosis.
FIG. 75-3. A. Flat plate abdominal film illustrates[5] distended loops of small bowel. **B.** Upright film demonstrates multiple air-fluid levels and "step-ladder" appearance.

Further investigations to determine the site or etiology of obstruction include sigmoidoscopy or barium enema. Upper gastrointestinal studies are rarely indicated. Barium enema can determine the cause and site of large bowel obstruction (Fig. 75-4). Sigmoidoscopy can identify friable mucosa, intraluminal lesions, or the dark-blue gangrenous mucosa associated with dead bowel. If the diagnosis is unclear, repeated examination, preferably by the same examiner, will be necessary. The use of contrast enhanced CT has been advocated to delineate partial from complete bowel obstruction. [7,8]

FIG. 75-4. Barium enema examination demonstrating incomplete filling of the sigmoid secondary to volvulus. Note the "parrot-beak" appearance of the point of the volvulus. (From Schwartz GR: *Principles and Practice of Emergency Medicine,* 3d ed. Malvern, PA, Lea & Febiger, 1992, p 1720, with permission.)

TREATMENT

If a true mechanical obstruction is diagnosed, then surgical intervention is often required. The frequently quoted adage "never let the sun rise or set on a mechanical bowel obstruction" likely refers to the philosophy advocated by surgeons who have noted increased morbidity and mortality when the obstruction has not been treated within 24 h.[6] Prior to surgical intervention, emergency department efforts should be made to decompress the bowel with nasogastric intubation. A nasogastric tube is generally effective in removing excess bowel contents and air. Likewise, because of loss of absorptive capacity, decreased oral intake, and vomiting, most patients will require intravenous fluid replacement. Patients can be monitored prior to surgical intervention by the response of blood pressure and heart rate and measurement of urine output. Surgery should not be delayed unnecessarily by attempting to use long intestinal tubes (Baker, Cantor, or Miller-Abbott) or excessive testing. A volvulus of the sigmoid colon will usually decompress via sigmoidoscopy and insertion of a rectal tube. Should a closed-loop obstruction, bowel necrosis, or cecal volvulus be suspected, then surgical intervention should be performed without delay. [4] All patients with mechanical obstruction require broad-spectrum antibiotic coverage preoperatively, as the risk of infection and septicemia is significant in most conditions. [7,11] If adynamic ileus is the primary problem or the diagnosis is uncertain, conservative measures, including intravenous fluids, nasogastric decompression, and observation, are generally effective in allowing the bowel to resume normal activity and function. Any medication that inhibits bowel mobility should be discontinued. Radiologic examination to confirm nasogastric tube placement or long-tube location is also advised. Some authors advocate contrast radiography to distinguish partial SBO from ileus or for the differentiation of strangulated from simple SBO.[9,10]

PSEUDO-OBSTRUCTION

Intestinal pseudo-obstruction (Ogilvie's syndrome) may also mimic bowel obstruction. Although any segment of bowel may be affected, low colonic obstruction is the most common clinical presentation. Large amounts of gas will be present in the large intestine. Radiographs reveal a dilated colon with well-defined septae and haustral markings and very little fluid, making air-fluid levels uncommon. [11] Patients may be using anticholinergic or tricyclic antidepressants, which depress motility. One must avoid the use of barium studies as the patient may be unable to evacuate the barium. Preference should be given to colonoscopy after digital rectal examination as an early intervention to rule out true obstruction or significant lesions. Colonoscopy will also treat the pseudo-obstruction by decompression. Surgery is not usually helpful and may be harmful. [11,12]

76 HERNIA IN ADULTS AND CHILDREN

Frank W. Lavoie

A *hernia* is technically defined as an *external* or *internal* protrusion of a body part from its natural cavity. Although internal herniations may be found in cerebral, diaphragmatic, hiatal, or other abdominopelvic locations, the usual use of the term is in reference to the abdominal wall and typically to external presentations. Hernias also may be *interparietal*, within the layers of the abdominal wall. Abdominal wall herniations occur both in adults and children and may be present in groin (inguinal or femoral), umbilical, anterior abdominal, pelvic, or lumbar locations.

PATHOPHYSIOLOGY

General Characteristics

Essential to the understanding of hernias are the anatomic characteristics of the abdominal cavity and, in particular, its fascial and aponeurotic layers. Embryologic development produces localized areas of inherent weakness in the abdominal wall. These include areas where extra peritoneal structures penetrate (as in the inguinal, femoral, and obturator canals, the sciatic foramen, and the umbilical region) and areas devoid of strong multilayer structural support (as in the anterior abdominal wall's linea alba and semilunar line). In addition, surgical incision and trauma may produce areas of abdominal wall weakness.

Herniations may include preperitoneal fat, retroperitoneal organs, and a hernial sac composed of peritoneum containing intraperitoneal structures (e.g., omentum or organs). Clinically significant herniation without a peritoneal sac is uncommon. Hernias may be complicated by inclusion of a viscus forming one wall of the hernial sac. This involves a partially retroperitoneal organ and is called a *sliding hernia*. Sliding inguinal hernias most frequently involve the colon.

The entrapment of the content of a hernia is more likely when the hernia opening is narrow. When the content can be returned to its normal cavity by manipulation, the hernia is *reducible*; when it cannot, it is *irreducible* or *incarcerated*. Incarceration may be *acute* or *chronic*. Incarceration of a single wall of a hollow viscus is known as *Richter hernia*. Incarcerated hernias are subject to inflammatory and edematous changes and are at risk for strangulation. *Strangulation* of a hernia refers to vascular compromise of the incarcerated contents. When strangulation is not relieved in a timely fashion, gangrene develops.

Predisposing Factors

Lack of developmental maturity of anatomic structures is known to predispose to the formation of hernias, as in indirect inguinal and umbilical hernias in premature infants. Family history, undescended testis, and genitourinary abnormalities are additional risks for inguinal hernia. Conditions that increase intraabdominal pressure—such as ascites, peritoneal dialysis, ventriculoperitoneal shunt, cystic fibrosis, chronic obstructive pulmonary disease, and pregnancy—are thought to be associated with hernia.

Specific Hernia Types

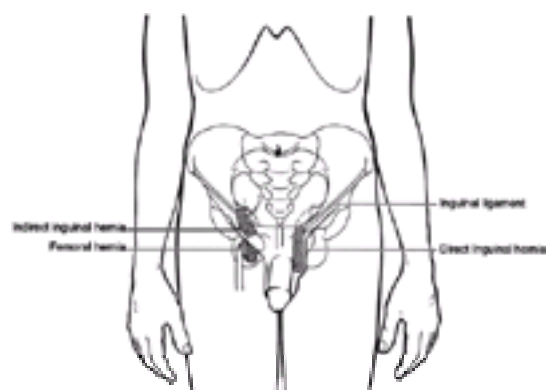
INDIRECT INGUINAL HERNIA   The inguinal canal is the tract in the abdominal wall through which pass the gubernaculum, testis, and spermatic cord in males or the round ligament in females. The canal is defined by an internal ring defect in the transversalis fascia and transversus abdominis aponeurosis, lateral to the inferior epigastric vessels, and a more medial external ring defect in the external oblique aponeurosis (Fig. 76-1 and Fig. 76-2).


FIG. 76-1. Groin hernias.
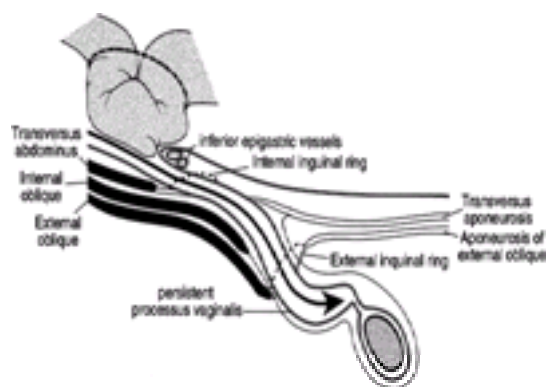

FIG. 76-2. Indirect inguinal hernia.

Normal passage through the inguinal canal is accompanied by peritoneal evagination known as the *processus vaginalis*. Normal obliteration of the processus occurs in infancy. Passage of contents through a persistent patent processus vaginalis along the inguinal canal leads to an indirect inguinal hernia. Congenital failure of obliteration is the etiology for all indirect inguinal hernias. Acquired myoaponeurotic defects may additionally contribute to indirect inguinal hernia in adults.

Passage of the testis is thought to enlarge the canal and increase the likelihood of inguinal hernia in males. It is more common on the right side due to later passage

of the right testis. Indirect inguinal hernias infrequently incarcerate and strangulate, particularly in the first year of life and in females. [1]

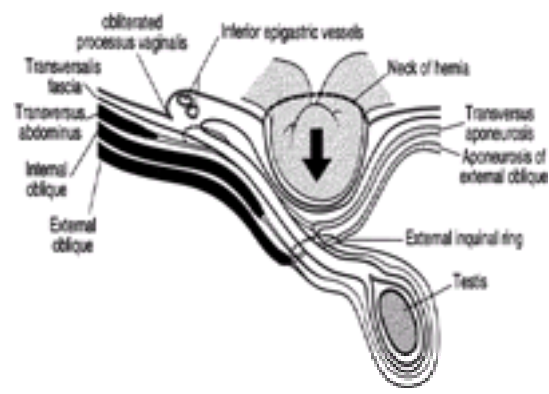
DIRECT INGUINAL HERNIA   These are protrusions through the transversalis fascia and the external ring, medial to the inferior epigastric vessels. (Fig. 76-1 and Fig. 76-3). Direct inguinal hernias are acquired defects that do not involve passage through the inguinal canal and occur predominantly in adults; they rarely incarcerate and strangulate. A hernia with ipsilateral direct and indirect inguinal components may be called a *pantaloon hernia.*


FIG. 76-3. Direct inguinal hernia.

FEMORAL HERNIA   A femoral hernia is a protrusion below the inguinal ligament and adjacent to the femoral vessels in the femoral canal (Fig. 76-1). Femoral hernias are more common in women due to the different anatomic structure of the pelvis. Femoral hernias are far less common than inguinal hernias. They do frequently incarcerate and strangulate. [2]

UMBILICAL HERNIA   In utero contraction of the umbilical cord insertion forms the fibromuscular umbilical ring. Incomplete development or weakness in the ring allows herniation of abdominal contents (Fig. 76-4).
FIG. 76-4. Anterior abdominal wall hernias.

Congenital umbilical hernias affect 10 to 30 percent of white infants and a higher percentage of children of African descent. They are more common in females. Incarceration and strangulation of childhood umbilical hernias are very rare. [1,3]

Umbilical hernias may also develop in adults. This acquired defect is more common in women and is associated with obesity, pregnancy, and ascites. Incarceration and strangulation frequently occur.

EPIGASTRIC HERNIA   An epigastric hernia involves herniation through the linea alba of the rectus sheath, above the umbilicus (Fig. 76-4).

SPIGELIAN HERNIA   Herniation at the site of the semilunar or arcuate line, just lateral to the rectus muscle, through the combined aponeurosis of the transversus abdominis and internal oblique muscles is known as a Spigelian or lateral ventral hernia. This hernia is frequently interparietal, making diagnosis difficult (Fig. 76-4).

PELVIC HERNIA   Pelvic hernias are rare. There are *sciatic hernias*, passing through sciatic foramen; *perineal hernias*, passing between perineal muscles; and *obturator hernias*, passing through the obturator canal with the obturator vessels. Obturator hernias frequently incarcerate. [4]

LUMBAR HERNIA   Herniation rarely may occur through the inferior or superior lumbar triangles.

INCISIONAL HERNIA   Herniation may occur through an incisional area. Infection and obesity contribute to poor wound healing, which increases the likelihood of development of incisional hernia.

TRAUMATIC HERNIA   Traumatic herniation involving a variety of organs and locations may be observed. These usually occur without true hernia sacs. [5]

EPIDEMIOLOGY

The incidence of abdominal hernia is estimated to be from 10 to 20 per 1000 births and is greater among premature infants. [6] In the screening of otherwise healthy young adult military recruits, approximately 3 percent are determined to have groin hernias. [7] Currently, approximately 700,000 herniorrhaphies are performed annually in the United States for inguinal hernias alone. [8]

Virtually all groin hernias are more commonly seen in males than in females, whereas hernias of the anterior abdominal wall are of similar incidence (Table 76-1). Consequently, the distribution of hernia types by sex is markedly different (Fig. 76-5 and Fig. 76-6).

	Males		Females	
	Number	%	Number	%
Indirect	587	53.6	107	32.9
Direct	453	27.4	5	1.5
Combination Direct-indirect-femoral	126	7.6	10	3.1
Incisional	57	3.4	57	17.5
Femoral	47	2.8	36	11.1
Umbilical	38	2.3	54	16.6
Hiatal	36	2.2	48	14.8
Epigastric	11	0.7	8	2.46
Total	1655		325

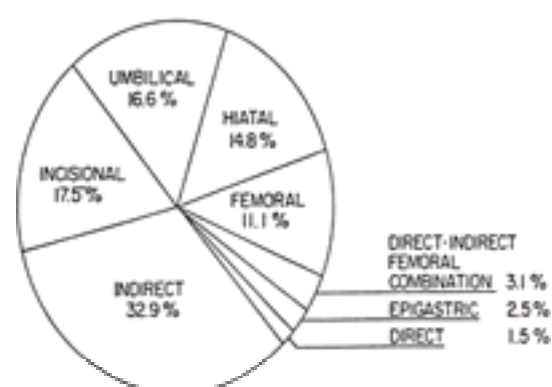
TABLE 76-1   Hernias in Males and Females, Henry Ford Hospital (1965 and 1967)
FIG. 76-5. The relative distribution of common hernias seen in 1655 men in 1965 and 1967. The high proportion of indirect and direct inguinal hernias is striking.(From Ponka JL: *Hernias of the Abdominal Wall.* Philadelphia, Saunders, 1980, p 85. With permission.)


FIG. 76-6. The distribution of common hernias in 325 females in 1965 and 1967. Note the relatively greater frequency of incisional, umbilical, hiatal, and femoral hernias in the female.(From Ponka JL: *Hernias of the Abdominal Wall.* Philadelphia, Saunders, 1980, p 85. With permission.)

Indirect inguinal hernias have a bimodal preponderance, with peaks in the first year of life and after the age of 40 years. [9] Direct inguinal hernias are characteristically seen in adults, with a large male preponderance after 40 years of age. Femoral hernias have roughly equal incidence by sex and also tend to occur predominantly after age 40.

Epigastric hernia is of approximately equal incidence by sex. Most occur between the ages of 30 and 70 years. Congenital umbilical hernias are seen in the newborn population and in early childhood. Acquired umbilical hernias in adults increase gradually in incidence from age 20 and are rarely seen beyond age 70. They are slightly more common in women and constitute a larger percentage of the hernias in the female population.

There is no difference in the incidence of incisional hernia in males versus females. As in the case of many other hernias, the vast majority of patients diagnosed with incisional hernia are over 40 years of age. The incidence and distribution of other uncommon hernias is less clear.

CLINICAL FEATURES

The majority of hernias are asymptomatic and are detected either on routine physical examination or inadvertently by the patient. Patients with incarceration frequently give a history of hernia; the patient can no longer reduce it and therefore seeks medical attention. If incarceration is acute, pain may develop suddenly. With infants, irritability may be the only presenting complaint. Incarceration may be accompanied by nausea and vomiting if partial or complete bowel obstruction has occurred. Incarcerated hernias are a leading cause of bowel obstruction, second to postoperative adhesions.

When strangulation occurs, the patient may be toxic, along with signs and symptoms of bowel obstruction. In the case of Richter hernia, however, strangulation may occur without intestinal obstruction.[10] Unrelieved strangulation may result in perforation, abscess formation, peritonitis, or septic shock.

Pain and hypesthesia along the medical aspect of the thigh to the knee are associated with obturator hernias. These patients additionally have intermittent bouts of small bowel obstruction over years. Obturator hernias are more commonly seen in older women.

Physical examination of the patient with a hernia may reveal an abnormal swelling. In inguinal hernias in males, the swelling may extend into the scrotum. The consistency of the mass varies depending upon the content of the hernial sac. If incarceration is present, the swelling is usually tender due to inflammation of the bowel wall or omentum and surrounding tissues. Tachycardia and mild temperature elevation frequently also are present.

DIAGNOSIS

Patients frequently present to the emergency department with a complaint of groin pain. There may or may not be a history of heavy lifting. In males, palpation of the inguinal canal is easily performed by inversion of scrotal skin and passage of a digit through the external ring. Voluntary increase in intraabdominal pressure during this examination reliably detects most inguinal hernias. With the tip of the digit near the internal ring, a tapping sensation is detected at Valsalva or cough. In females, the external ring is generally narrower and the skin of the labium majora is not easily inverted, making introduction of a digit difficult. Therefore, failure to palpate a hernial sac in women is not foolproof.

Groin hernias have a larger number of differential diagnostic possibilities (Table 76-2). They most commonly are confused with tender lymph nodes and hydroceles. Lymph nodes are generally movable, firm, and multiple. Hydroceles may transilluminate and are not tender. Incarcerated hernias will not transilluminate and are tender. If bowel is contained in the hernia sac, bowel sounds may be heard and peristalsis may be seen. In children, retractile or undescended testes may be mistaken for hernias. Testicular torsion or tumor may be confused with incarcerated hernias.

Direct inguinal hernia	Testicular torsion
Indirect inguinal hernia	Retractile or undescended testis
Femoral hernia	Epididymitis
Lymph nodes	Groin cellulitis
Hydrocele	Femoral thrombophlebitis
Spermatic cord tumor	Femoral artery aneurysm
Testicular tumor	

TABLE 76-2   Differential Considerations in Groin Hernia

When incarceration is acute, the white blood cell count is slightly elevated with a shift to the left. Electrolyte abnormalities and elevation of the blood urea nitrogen level may occur as a reflection of both the patient's state of hydration and the toxic state. In the elderly and immunocompromised, laboratory studies may not be reliable indicators of the patient's state. Occasionally, as part of a diagnostic evaluation for abdominal pain, a hernia is detected on barium enema.

Upright chest films should be obtained to rule out free air under the diaphragm, which may result from perforation or dead bowel. Flat and upright films of the abdomen, including the groin, should be obtained to assess the possible presence of bowel obstruction. Loops of bowel may be seen entering a hernial sac.

Suspicion of spigelian or pelvic hernias often necessitates use of sonography or CT scanning for diagnosis, [11,12] and [13] since detection of herniation is frequently difficult and confusion with other masses is possible.

TREATMENT

If there is a good history that the incarceration is of recent onset, an attempt can be made to reduce the hernia. If there is any question of the duration of the incarceration, no attempt should be made so that no dead bowel is reintroduced into the abdomen. Unfortunately, no specific time line can be delineated.

Before an attempt is made to reduce the hernia, the patient should be placed in the Trendelenburg position and given some mild sedation. A variety of sedating agents can be used, with the benzodiazepines most commonly employed. A warm compress over the area may make the task easier by reducing the swelling and relaxing the abdominal musculature. Only gentle compression of the hernia should be used, and nothing should be forced back. Attempts at reduction should be limited in time and force.

If the incarceration is tender, if it cannot be reduced, or if strangulation is suspected, the patient should not be fed by mouth, and a nasogastric tube should be inserted. Intravenous fluid should be started with the thought of correcting the patient's volume and electrolyte problems.

The treatment of choice for an incarceration which cannot be reduced, or for a strangulation, is surgical. Broad-spectrum antibiotics and vigorous fluid resuscitation may be necessary, but only as a prelude to operation. Mortality is higher in the elderly when emergency surgery is required.

DISPOSITION

Any acutely incarcerated or strangulated hernia, regardless of type or patient age, requires immediate surgical evaluation and repair.

Adult patients with reducible hernias may be discharged and referred for elective surgical repair. They should be advised to avoid conditions that increase intraabdominal pressure, such as lifting activities. Return to the emergency department should be suggested for recurrence that the patient is unable to reduce promptly, emesis, or fever. Following surgical evaluation, patients who are not candidates for operative repair occasionally may be fitted with trusses.

In children, inguinal hernias have a high risk of incarceration, particularly in the first year of life. These hernias should be electively repaired shortly after diagnosis and therefore require timely surgical consultation. Infants with inguinal hernias reduced in the emergency department should generally have repair within a few days.[14]

Umbilical hernias in children very rarely incarcerate. Spontaneous closure of the umbilical ring occurs in 80 percent of these children by age 3 or 4. Discharge and primary care observation is the standard of care for young children with hernias less than 2.0 cm in diameter. Children over age 4 or with larger hernias should be referred for surgical evaluation.

77 ILEITIS, COLITIS, AND DIVERTICULITIS

Howard A. Werman
Hagop S. Mekhjian
Douglas A. Rund

CROHN'S DISEASE

Crohn's disease is a chronic inflammatory disease of the gastrointestinal (GI) tract; the exact cause is still unknown. The disease was first described by Crohn, Ginzberg, and Oppenheimer in 1932. In their initial description, the disease was thought to involve only the distal ileum. We now know that Crohn's disease can involve any part of the GI tract from the mouth to the anus. Segmental involvement of the intestinal tract by a nonspecific granulomatous inflammatory process characterizes the disease. The ileum is involved in the majority of cases. In 20 percent, the disease is confined to the colon, making differentiation from ulcerative colitis, at times, a difficult clinical problem. The terms *regional enteritis, terminal ileitis, granulomatous ileocolitis,* and *Crohn's disease* are used to describe the same disease process.

Etiology and Pathogenesis

Environmental, genetic, infectious, and host factors have all been implicated as a cause of both Crohn's disease and ulcerative colitis. Among the environmental factors, smoking has been associated with an increased recurrence rate of Crohn's disease. *Mycobacterium paratuberculosis* and the measles virus have received recent attention and have also been considered as possible etiologies of Crohn's disease. There are few data to support a primary causative role of psychogenic factors. Immunologic factors have received greatest attention. Several mechanisms of injury have been proposed, including autoimmune destruction of the gut mucosal cells as the result of cross-reactivity with antigens from enteric bacteria as well as nonspecific immunologic injury to the gut mucosa as the result of a chronic inflammatory process for both ulcerative colitis and Crohn's disease. Cytokines, including interleukins and tumor necrosis factor, have been invoked in the perpetuation of the inflammatory response. Whether immune factors play a primary or secondary role in the pathogenesis of these diseases is not known. Extraintestinal manifestations suggest a role for immune complexes or an autoantibody response at various involved sites.

Epidemiology

The peak incidence of Crohn's disease occurs in patients between 15 and 22 years of age, with a secondary peak at age 55 to 60 years. The prevalence varies from 10 to 100 cases per 100,000 population and the incidence from 1 to 7 cases per year per 100,000 population in the United States. The incidence of Crohn's disease has been increasing over the past 20 years.[1] There is a 20 to 30 percent increased risk of Crohn's disease among women as compared with men. The disease has a worldwide distribution but is more frequent in people of European extraction. It is four times more common among Jews than non-Jews and is more common in whites than blacks, Asians, or Native Americans. A family history of inflammatory bowel disease is present in 10 to 15 percent of patients. Ulcerative colitis as well as Crohn's disease may be present in other family members, and siblings of patients with Crohn's disease have a higher incidence of the disease.

Pathology

The most important pathologic feature of Crohn's disease is the involvement of all the layers of the bowel and extension into mesenteric lymph nodes. In addition, the disease is discontinuous, with normal areas of bowel ("skip areas") located between one or more involved areas. On gross inspection, the bowel wall is thickened; subsequent luminal narrowing results in stenosis and obstruction of the intestine. The mesenteric fat often extends over the bowel wall ("creeping" fat). The appearance of the mucosa varies with the extent and severity of the disease. Longitudinal, deep ulcerations are characteristic. These often penetrate the bowel wall, resulting in fissures, fistulas, and abscesses. Late in the disease, a "cobblestone" appearance of the mucosa results from the criss-crossing of these ulcers with intervening normal mucosa.

Microscopically, there is an inflammatory reaction that extends through all layers of the intestine but is most marked in the submucosa. This inflammatory response consists of infiltration by mononuclear cells, lymphocytes, plasma cells, and histiocytes. Fissure ulcers frequently penetrate the muscle layer. Unlike the situation in ulcerative colitis, crypt abscesses are infrequent. Discrete granulomas consisting of epithelioid cells, giant cells, and lymphocytes are seen in 50 to 75 percent of the surgical specimens from Crohn's disease patients. Granulomas are seen uncommonly in mucosal biopsies. Although the finding of granulomas is suggestive, it is not essential for the diagnosis.

Clinical Features

The clinical course of Crohn's disease varies and in the individual patient is unpredictable. Abdominal pain, anorexia, diarrhea, and weight loss are present in 75 to 80 percent of cases. Occasionally, a patient with Crohn's disease may present with acute right-lower-quadrant abdominal pain and fever and, on examination, be found

to have a mass in the right lower quadrant. More commonly, the patient experiences an insidious onset of recurrent abdominal pain, fever, and diarrhea that lasts for several years before the definitive diagnosis is established. Approximately one-third of patients develop perianal fissures or fistulas, abscesses, or rectal prolapse, particularly when there is colonic involvement. Finally, patients may also manifest complications of the disease, such as obstruction with vomiting, crampy abdominal pain, and obstipation, or an intraabdominal abscess with fever, abdominal pain, and a palpable mass. In 10 to 20 percent of patients, the extraintestinal manifestations of arthritis, uveitis, or liver disease may be presenting symptoms. Crohn's disease should also be considered in the differential diagnosis of patients with fever of unknown etiology.

The clinical course and manifestations of the disease appear to be related, partly because of its anatomic distribution; in 30 percent, the disease involves only the small bowel; in 20 percent, only the colon is involved; and in 50 percent, both the small bowel and colon are involved. A small percentage of patients present with disease involving the mouth, esophagus, and stomach. Patients with Crohn's disease of the stomach may demonstrate symptoms similar to those associated with peptic ulcer disease (see Chap. 73, "Peptic Ulcer Disease and Gastritis").

The recurrence rate for all patients with Crohn's disease is 25 to 50 percent within 1 year for patients whose disease has responded to medical management; the recurrence rate is higher for those patients who require surgery. Patients with ileocolitis have the highest recurrence rate following surgery. The incidence of hematochezia and perianal disease is higher when the colon is involved, as in ileocolitis or Crohn's colitis. A slight increase in the incidence of arthritis may be associated with Crohn's colitis. Except for the additional concern of growth retardation, childhood-onset Crohn's disease seems to have a course similar to that of adult-onset disease.

Extraintestinal manifestations are seen in 25 to 30 percent of patients with Crohn's disease (see Table 77-1), and the incidence of these complications does not differ between patients with Crohn's disease and those with ulcerative colitis. Extraintestinal manifestations are divided among arthritic (19 percent), dermatologic (4 percent), hepatobiliary (4 percent), and vascular (1.3 percent) complications. Peripheral arthropathies are commonly seen in both ulcerative colitis and Crohn's disease and tend to manifest during exacerbations of the underlying disease process. Ankylosing spondylitis can be detected in up to 20 percent of patients with inflammatory bowel disease. Symptoms may occur before, during, and after bouts of Crohn's disease or ulcerative colitis.

TABLE 77-1   Extraintestinal Manifestations of Inflammatory Bowel Disease

Dermatologic complications include erythema nodosum and pyoderma gangrenosum. Ocular manifestations include episcleritis and uveitis.

Hepatobiliary disease is common in patients with inflammatory bowel disease and includes pericholangitis, chronic active hepatitis, primary sclerosing cholangitis, and cholangiocarcinoma. Gallstones are detected in up to 33 percent of patients with Crohn's disease. The incidence of acute and chronic pancreatitis is increased in patients with Crohn's disease and ulcerative colitis.

Vascular manifestations include thromboembolic disease, vasculitis, and arteritis. Patients with thromboembolic complications have a mortality rate of approximately 25 percent. Thromboembolic disease is the result of a hypercoagulable state induced in patients with both Crohn's disease and ulcerative colitis and ranks as the third leading cause of death in patients afflicted with these conditions, behind peritonitis and malignancy. Malnutrition and chronic anemia are seen in many patients with long-standing Crohn's disease. Growth retardation can be seen in children. [2]

Hyperoxaluria is a common and potentially treatable occurrence in patients with ileal disease and steatorrhea. This results from increased colonic absorption of dietary oxalate and accounts for the occurrence of nephrolithiasis in 20 to 25 percent of patients with ileal disease. Finally, myelodysplastic disease, osteomyelitis, and osteonecrosis have been reported as rare complications of ulcerative colitis and, in particular, Crohn's disease. [3,4]

Complications

More than three out of four patients with Crohn's disease will require surgery within the first 20 years of the onset of initial symptoms. Abscess and fissure formation is seen in approximately 30 percent. Abscesses can be characterized as intraperitoneal, retroperitoneal, interloop, or intramesenteric. These patients present with abdominal pain and tenderness typical of their underlying disease but may also have fever spikes and a palpable mass. Patients with retroperitoneal abscesses may present with hip or back pain and difficulty ambulating. Liver abscesses have also been reported in patients with Crohn's disease.

Fistulas are the result of extension of intestinal fissures noted in patients with Crohn's disease into adjacent structures. The most common sites are between the ileum and the sigmoid colon, the cecum, another ileal segment, or the skin. Internal fistulas should be suspected when there are changes in the patient's symptom complex, including bowel movement frequency, amount of pain, or weight loss. Enterovesical fistulas are rare complications of Crohn's disease.

Obstruction is the result of both stricture formation due to the inflammatory process and of edema of the bowel wall. The distal small bowel is the most common site of obstruction. Symptoms include crampy abdominal pain, distention, nausea, and bloating.

Perianal complications are seen in one-third of patients with Crohn's disease and include perianal or ischiorectal abscesses, fissures, fistulas, rectovaginal fistulas, and rectal prolapse. These are more commonly seen in patients with colonic involvement.

While gastrointestinal bleeding is common in patients with Crohn's disease, only 1.3 percent of patients develop life-threatening hemorrhage. [5] In patients with Crohn's disease, bleeding is the result of erosion into a vessel in the bowel wall. Toxic megacolon occurs in 6 percent of all cases of Crohn's disease and is associated with massive gastrointestinal bleeding in over half the cases. Fifty percent of all cases of toxic megacolon occur in patients with Crohn's disease. Free perforation, however, rarely occurs.

When bowel symptoms are present, malnutrition, malabsorption, hypocalcemia, and vitamin deficiency can be severe. In addition to the complications of the disease itself are complications associated with the treatment of the disease with sulfasalazine, steroids, immunosuppressive agents, and antibiotics.

The incidence of malignant neoplasm of the GI tract is three times higher in patients with Crohn's disease than for the general population.

Diagnosis

In the majority of patients, the definitive diagnosis of Crohn's disease is established months or years after the onset of symptoms. Occasionally, the initial presenting complaint is not related to the GI tract but is an extraintestinal manifestation such as arthritis or uveitis. A provisional diagnosis of appendicitis or pelvic inflammatory disease may change to Crohn's disease at the time of surgery. A careful and detailed history for previous bowel symptoms that preceded the onset of acute right-lower-quadrant pain and the absence of true guarding or rebound in patients with Crohn's disease may provide clues to the correct diagnosis before surgery.

A definitive diagnosis of Crohn's disease is confirmed by an upper GI series, an air-contrast barium enema, and colonoscopy. Oral barium studies with fluoroscopy are the most sensitive and specific for detecting ileal involvement. The classic radiographic findings in the small intestine include segmental narrowing, destruction of the normal mucosal pattern, and fistulas. Segmental involvement of the colon with rectal sparing is the most characteristic feature.

Colonoscopy is the most sensitive technique for examining patients with Crohn's colitis. This technique is useful in detecting early mucosal lesions, in defining the extent of colonic involvement, and in surveillance for the occurrence of colon cancer. Air-contrast enemas are also useful in defining mucosal detail. Intraabdominal abscesses, mesenteric inflammation, and fistulas are best diagnosed using either computed tomography (CT) or ultrasound.

Differential Diagnosis

Diseases that should be considered in the differential diagnosis of Crohn's disease (Table 77-2) include lymphoma, ileocecal amebiasis, sarcoidosis, deep chronic mycotic infections involving the GI tract, gastrointestinal tuberculosis, Kaposi's sarcoma, *Campylobacter* enteritis and *Yersinia* ileocolitis. Fortunately, most of these are uncommon conditions and can be differentiated by appropriate laboratory tests. *Yersinia* ileocolitis and *Campylobacter* enteritis may cause chronic abdominal pain and diarrhea similar to Crohn's disease but can be diagnosed by appropriate stool cultures. Acute ileitis should not be confused with Crohn's disease. Young patients with acute ileitis usually recover without sequelae and should not undergo surgery. When Crohn's disease is confined to the colon, ischemic bowel disease (particularly in the elderly) and pseudomembranous enterocolitis as well as ulcerative colitis must be included in the differential diagnosis.

TABLE 77-2   Differential Diagnosis of Ileitis, Colitis, and Diverticulitis

Treatment

The aim of therapy includes relief of symptoms, suppression of the inflammatory disease, treatment of complications, and maintenance of nutrition. In a disease that is virtually incurable, the emphasis should be on relief of symptoms and avoidance of complications. The pharmacologic agents available for the management of Crohn's disease include symptomatic agents, anti-inflammatory agents, antibiotics, and immunomodulators.

Initial evaluation in the emergency department (ED) should focus on determining the severity of the attack; identifying significant complications such as obstruction, intraabdominal abscess, life-threatening hemorrhage, or toxic megacolon; and eliminating other possible causes of the patient's complaints. Laboratory evaluation should include a CBC, serum electrolytes, BUN, creatinine, and a type and cross-match where appropriate. Plain radiographs of the abdomen may reveal evidence of obstruction, perforation, or toxic megacolon. Initial treatment (Table 77-3) consists of adequate fluid resuscitation and restoration of electrolyte balance. Nasogastric decompression should be initiated in any patient with evidence of obstruction, peritonitis, or toxic megacolon. Broad-spectrum antibiotics (ampicillin or a cephalosporin, an aminoglycoside, and metronidazole) should be used in patients with fulminant colitis or peritonitis. Patients with severe disease should receive intravenous steroids such as hydrocortisone 300 mg/day or an equivalent dose of methylprednisolone (48 mg/day) or prednisolone (60 mg/day).

TABLE 77-3   Treatment of Fulminant Colitis

Sulfasalazine (Azulfidine), 3 to 4 g/day, has been shown to be effective in treating patients with mild to moderate active Crohn's disease. The mechanism of action is not known but is presumed to be through the topical action of 5-aminosalicylic acid, which is released by the action of colonic bacteria on sulfasalazine. Sulfapyridine is also a by-product of this breakdown. Many of the toxic side effects of sulfasalazine are attributable to sulfapyrizine. These include nausea, vomiting, anorexia, epigastric distress, arthralgias, headache, diarrhea, male infertility, and hypersensivity reactions (pericarditis, pleuritis, pancreatitis, arthritis, and rash). Because of the toxicity profile associated with sulfasalazine, 5-aminosalicylic derivative agents are now available for either oral or topical use. A slow, timed-release mesalamine (Pentasa) 4 g/day or a pH-dependent release mesalamine (Asacol, Claversal, Salofalk) 2 to 4 g/day have the primary advantage of delivery into the colon. Olsalazine (Dipentum) 1 g/day is a derivative of the sodium salt of 5-aminosalicylic acid, which is converted to two 5-aminosalicylic molecules in the colon and has identical anti-inflammatory properties. Balsalazide (Colazide) 1.5 to 6 g/day has the 5-aminosalicylic acid moiety bound to an inert molecule. Sulfasalazine and all the mesalamine formulations are effective in colonic disease. The topical preparations have limited usefulness and only in the management of Crohn's disease limited to the rectum or the distal 40 cm of rectosigmoid.

Glucocorticoids such as prednisone (40 to 60 mg/day) are reserved for the more severely affected patients and are effective primarily in small intestinal disease as well as in ileocolitis. Immunosuppressive drugs such as 6-mercaptopurine (1 to 1.5 mg/kg/day) or azathioprine (2 mg/kg/day) are useful as steroid-sparing agents, in healing fistulas, and in patients in whom there are serious contraindications for surgery. Recent evidence suggests that they are also effective as maintenance agents. Both agents have been associated with leukopenia, fever, hepatitis, and pancreatitis, necessitating the need for close follow-up, particularly during the initial phase of therapy. The response to immunosuppressives should not be expected before 8 to 12 weeks following the initiation of therapy.

Metronidazole (10 to 20 mg/kg/day) has been shown to be effective in controlled clinical trials and is particularly useful in treatment of patients with perianal complications and fistulous disease. Ciprofloxacin (500 to 750 mg bid) has also been used in this setting as well as in active Crohn's ileitis and ileocolitis. Other agents such as cyclosporine, methotrexate, broad-spectrum antibiotics, monoclonal antibodies against tumor necrosis factor, IL-1 receptor antagonist, interferon alpha, and immunoglobulin therapy must all be considered as experimental forms of therapy at this time because of insufficient experience of therapeutic efficacy in controlled clinical trials.

The role of maintenance therapy in ulcerative colitis is well established. Maintenance therapy and the effectiveness of various therapeutic agents in Crohn's disease is somewhat less certain. Glucocorticoids should not be used for maintaining a remission because of lack of sufficient evidence of their efficacy and the potential for

long-term complications. When a patient is responsive to immunosuppressive therapy, it would seem advisable to continue this in a reduced dose for the maintenance of remission. Similarly, a reduced dose of 5-aminosalicyclic acid derivatives is appropriate for the maintenance of remission of colonic disease. The addition of sulfasalazine, azothiaprine, and 6-mercaptopurine to prednisone does not improve the response rate and increases the risk of side effects.

Diarrhea can be controlled by the use of loperamide (Imodium), 4 to 16 mg/day, diphenoxylate (Lomotil), 5 to 20 mg/day, and, in some cases, cholestyramine (Questran), 4 g one to six times daily. The latter is particularly useful as an exchange resin in patients who have limited ileal disease or resection, no bowel obstruction, and mild steatorrhea. The mechanism of action is binding bile acids and eliminating their known cathartic action. The primary aim of dietary therapy is the maintenance of nutrition and the alleviation of diarrhea. Elimination of lactose from the diet is of benefit in patients with lactose intolerance. Reduction in dietary oxalate should be considered in every patient. In addition, supplementation of trace metals, fat-soluble vitamins, and medium-chain triglycerides should be considered in selected patients.

Disposition

Patients who demonstrate signs of fulminant colitis, peritonitis, or complications such of obstruction, significant gastrointestinal hemorrhage, severe dehydration, or fluid/electrolyte imbalance should be hospitalized under the care of a gastroenterologist or surgeon. Hospital admission should be considered in less severe cases that fail outpatient management. Surgical intervention is indicated in those patients with complications of the disease, including intestinal obstruction or hemorrhage, perforation, abscess or fistula formation, toxic megacolon, and perianal disease. In addition, surgery may be indicated in those patients who fail medical therapy. The recurrence rate after surgery approaches 100 percent.

When patients with Crohn's disease are discharged from the ED, alterations in their therapeutic regimen should be discussed with a consulting gastroenterologist. Close follow-up of these patients must be assured prior to discharge.

ULCERATIVE COLITIS

Ulcerative colitis is a chronic inflammatory and ulcerative disease of the colon and rectum characterized most often clinically by bloody diarrhea. The etiology, like that of Crohn's disease, remains unknown, even though extensive investigations into the cause continue.

Epidemiology

Epidemiologic considerations are similar to those of Crohn's disease; the disease is more prevalent in the United States and northern Europe, and peak incidence occurs in the second and the third decades of life. The incidence of ulcerative colitis is about 10 cases per 100,000 and, like the incidence of Crohn's disease, appears to have risen in the last few years.[1] Approximately 250,000 in the United States are afflicted with ulcerative colitis. There is a slight predominance of men among patients with the disease. First-degree relatives of patients with ulcerative colitis have a 15-fold risk of developing ulcerative colitis and a 3.5-fold risk of developing Crohn's disease.

Pathology

Ulcerative colitis involves primarily the mucosa and submucosa. Microscopically, the disease is characterized by mucosal inflammation with the formation of crypt abscesses, epithelial necrosis, and mucosal ulceration. The submucosa, muscular layer, and serosa are often spared. In the usual case, the disease increases in severity more distally, the rectosigmoid being involved in 95 percent of cases. In the early stages of the disease, the mucous membranes appear finely granular and friable. In more severe cases, the mucosa appears as a red, spongy surface dotted with small ulcerations oozing blood and purulent exudate. In very advanced disease, one sees large, oozing ulcerations and pseudopolyps (areas of hyperplastic overgrowth surrounded by inflamed mucosa).

Clinical Features

The clinical features and course of ulcerative colitis vary but are somewhat dependent on the anatomic distribution of the disease in the colon. The disease is classified as mild, moderate, or severe depending on the clinical manifestations.[6] Patients with mild disease have fewer than four bowel movements per day, no systemic symptoms, and few extraintestinal manifestations. Of all patients with ulcerative colitis, 60 percent have mild disease; in 80 percent of cases, the disease is limited to the rectum. Occasionally, constipation and rectal bleeding are the presenting complaints. Progression to pancolitis occurs in 10 to 15 percent of patients with mild disease.

Patients with severe disease constitute 15 percent of those with ulcerative colitis. Severe disease is associated with more than six bowel movements per day, anemia, fever, weight loss, tachycardia, low serum albumin, and more frequent extraintestinal manifestations. Patients with severe disease account for 90 percent of the mortality from ulcerative colitis. Virtually all severely affected patients have pancolitis.

Moderate disease is seen in 25 percent of patients. The clinical manifestations are less severe and patients demonstrate a good response to therapy. These patients usually have colitis extending to the splenic flexure (left-sided colitis) but may develop pancolitis.

Most commonly, ulcerative colitis is characterized by intermittent attacks of acute disease with complete remission between attacks. Such a pattern occurs in the majority of patients. In other patients, the first attack is followed by a prolonged period of inactivity. Infrequently, patients run a chronically active course. The factors associated with an unfavorable prognosis and increased mortality include the severity and extent of disease, a short interval between attacks, and onset of the disease after 60 years of age.

Extraintestinal complications of ulcerative colitis include peripheral arthritis, ankylosing spondylitis, episcleritis, uveitis, pyoderma gangrenosum, and erythema nodosum (see Table 77-1). Clinically apparent liver disease may occur in 5 to 10 percent of patients. The manifestations of liver disease may include any of the following: pericholangitis, chronic active hepatitis, fatty liver or cirrhosis, cholelithiasis, sclerosing cholangitis, and bile duct carcinoma.

Complications

Although blood loss from sustained hemorrhage may be the most common complication of the illness, toxic megacolon is an associated clinical entity that must not be missed.

Toxic megacolon develops in advanced cases of colitis when the disease process begins to extend through all layers of the colon. The result is a loss of muscular tone within the colon, with dilatation and localized peritonitis. If the colon continues to dilate without treatment, signs of toxicity will develop. Plain radiography of the abdomen demonstrates a long, continuous segment of air-filled colon greater than 6 cm in diameter (see Fig. 77-1). Loss of colonic haustra and "thumbprinting," representing bowel wall edema, may also be seen. The distended portion of the atonic colon can perforate, causing peritonitis and septicemia. Mortality from this complication is approximately 50 percent if perforation occurs but less than 10 percent if surgery is undertaken prior to perforation. [7]

FIG. 77-1. Long, continuous colonic loop in toxic megacolon.

A patient with toxic megacolon appears severely ill; the abdomen is distended, tender, and tympanitic. Severe diarrhea (more than 10 bowel movements per day) is often seen. Fever, tachycardia, and signs of hypovolemia are typically part of the clinical picture. Leukocytosis, anemia, electrolyte disturbances, and hypoalbuminemia are the supporting laboratory data.

Some of the more prominent features of toxic megacolon, such as leukocytosis and peritonitis, can be masked in the patient taking corticosteroids. When such therapy is being administered, greater suspicion is required to make the diagnosis. Antidiarrheal agents, hypokalemia, narcotics, cathartics, pregnancy, enemas, and recent colonoscopy have been implicated as precipitating factors in toxic megacolon. Medical therapy with nasogastric suction, intravenous prednisolone 60 mg/day or hydrocortisone 300 mg/day, parenteral antibiotics active against coliforms and anaerobes (ampicillin and clindamycin), and intravenous fluids should be attempted as initial therapy and in preparing the patient for possible surgery. However, prolonged medical treatment of these patients increases mortality; therefore, early surgical consultation must be sought with the aim of performing a colectomy if clinical improvement is not noted in 24 to 48 h with medical treatment.

The fistulas that constitute a hallmark of Crohn's disease occur infrequently in cases of ulcerative colitis. Perirectal fistulas and abscesses are much more common in patients with Crohn's disease but may occur in up to 20 percent of patients with ulcerative colitis. [8] Massive gastrointestinal hemorrhage, obstruction secondary to stricture formation, and acute perforation are other complications of the disease.

There is a 10- to 30-fold increase in the development of carcinoma of the colon in patients with ulcerative colitis. Carcinoma of the colon is the cause of 5 to 15 percent of the deaths attributed to ulcerative colitis. The major risk factors for the development of carcinoma of the colon are extensive involvement and prolonged duration of the disease. The cumulative risk of cancer after 20 and 30 years is 5 to 10 and 12 to 20 percent, respectively. Additional factors that increase the risk of cancer in patients with ulcerative colitis include early onset of the disease and a family history of colon cancer. The availability of fiberoptic colonoscopy allows surveillance of ulcerative colitis patients with periodic colonoscopies and biopsies to detect the high-grade dysplasia thought to predict the development or association of colon cancer. In patients with pancolitis, such surveillance should start 8 to 10 years after the onset of the disease. [9]

Diagnosis

Laboratory findings in patients with ulcerative colitis are nonspecific; they may include leukocytosis, anemia, thrombocytosis, decreased serum albumin, and abnormal liver function studies. Therefore, the diagnosis of ulcerative colitis rests on the following: a history of abdominal cramps and diarrhea, mucoid stools, stool examination negative for ova and parasites, stool cultures negative for enteric pathogens, and confirmation by sigmoidoscopic or colonoscopic examination. The results of the latter examination are abnormal in 95 percent of the patients with ulcerative colitis. The observed pathologic changes vary depending on the severity and duration of the disease. Granularity, friability, ulceration of the mucosa, and, in more advanced cases, pseudopolyposis are quite characteristic.

Sigmoidoscopy may be done in the office or the ED to confirm the clinical suspicion, but the appearance is not specific. Biopsy may help differentiate acute colitis from chronic colitis and diseases caused by specific etiology, such as amebiasis (see "Pathology," above). Barium enema examination may be useful in differentiating it from Crohn's disease and defining the extent of involvement of the colon. Colonoscopy, however, is the most sensitive method for making the diagnosis and defining the extent and severity of the disease. In addition, colonoscopy is extremely useful in the evaluation of the patient for the development of dysplasia or colon cancer. Barium enema examination should be done with caution or postponed in moderately ill patients. Rigid or fiberoptic proctosigmoidoscopy can be used, however, even in the severely ill patient, provided that it is done gently and without the administration of any enemas or laxatives.

Differential Diagnosis

The major diseases that should be considered in the differential diagnosis of ulcerative colitis include infectious colitis, Crohn's colitis, ischemic colitis, irradiation colitis, and pseudomembranous colitis (see Table 77-2). When the disease is limited to the rectum, particular attention should be paid to sexually acquired diseases, which are frequently seen in the male homosexual population ("gay bowel disease"). Some of the more common diseases in this category include rectal syphilis, gonococcal proctitis, lymphogranuloma venereum, and inflammations caused by herpes simplex virus, *Entamoeba histolytica, shigella,* and *Campylobacter.*

Treatment

Patients with severe ulcerative colitis should be treated with intravenous steroids or adrenocorticotropic hormone (ACTH), replacement of fluids, correction of electrolyte abnormalities, and broad-spectrum antibiotics active against coliforms and anaerobes (ampicillin and clindamycin or metronidazole); hyperalimentation may be considered for the individual patient (Table 77-3). Patients who have not previously been treated with steroids respond best to ACTH, 120 U/day, whereas those on steroids should receive hydrocortisone, 300 mg/day or an equivalent dose of methylprednisolone (48 mg/day) or prednisolone (60 mg/day). [10] Recently, cyclosporine (4 mg/kg/day) has been advocated for cases of fulminant colitis that have failed treatment with intravenous corticosteroids. [11] The use of complete bowel rest and routine administration of parenteral nutrition remains controversial in patients with fulminant disease. [12] When toxic megacolon is suspected, nasogastric suction should be initiated, a surgical consultation obtained, and the patient observed by frequent examinations and flat films of the abdomen. When the diagnosis of toxic megacolon is established and the patient fails to show dramatic clinical improvement within 24 to 48 h, emergency surgery should be considered.

The majority of those with mild and moderate disease can be treated as outpatients. Glucocorticoids are effective in inducing a remission in the majority of cases and constitute the mainstay of therapy in an acute attack. Daily doses of 40 to 60 mg of prednisone are usually sufficient and can be adjusted depending on the severity of the disease. In the treatment of patients with active proctitis, proctosigmoiditis, and left-sided colitis (less than 60 cm of active disease), 5-aminosalicylic acid enemas have been used with great success. Topical steroid preparations (beclomethasone, hydrocortisone, tixocortol, and budesonide) have also been successful. This therapy has also been used to maintain remission in these patients. Once clinical remission is achieved, steroids should be slowly tapered and discontinued. There is no evidence that maintenance dosages of steroids reduce the incidence of relapses.

Sulfasalazine has been used in the treatment of acute attacks but is probably inferior to steroids, especially in the more severe cases. Its primary usefulness is in the form of adjunctive therapy and in the maintenance of a remission. Maintenance doses of 1.5 to 2 g/day significantly reduce the recurrence rate of the disease.

In addition to sulfasalazine, the newer 5-aminosalicylic derivatives are quite effective in inducing remission of ulcerative colitis as well as maintaining it. The main advantage of the newer agents is reduced side effects from the sufapyridine moiety of sulfasalazine. The choice of agents available for the treatment of ulcerative colitis is very similar to that in Crohn's disease [mesalamine (Pentasa, Asacol) and olsalazine (Dipentum)]. Topical glucocorticoid enemas or 5-aminosalicylic enemas (Rowasa, 2 to 4 g/60 mL/day for 3 weeks) or suppositories (500 mg bid) are quite effective in distal protosigmoiditis and have lower systemic side-effect profiles. In refractory cases, a combination of glucocorticoids and immunomodulators such as 6-mercaptopurine (1 to 1.5 mg/kg/day) or azathioprine (2 mg/kg/day) should be considered. The beneficial effects of this combination therapy will not be seen before 8 to 12 weeks, somewhat limiting its usefulness in very sick patients. For these reasons, surgical intervention with elective proctocolectomy may be necessary. Newer agents under investigation for the treatment of ulcerative colitis include nicotine and preparations of short-chain fatty acids.

Supportive measures in the treatment of mild to moderately sick patients include the replenishment of iron stores, a nutritious diet with the elimination of lactose, and adequate physical and psychological rest. Hydrophilic bulk agents such as psyllium (Metamucil) can be used in some patients to improve stool consistency. Antidiarrheal agents should be avoided because they may precipitate toxic megacolon and because they are generally ineffective.

Disposition

Patients with fulminant attacks of ulcerative colitis should be hospitalized for aggressive fluid and electrolyte resuscitation and careful observation for the development of complications. Patients with complications such as significant gastrointestinal hemorrhage, toxic megacolon, and bowel perforation should also be admitted with consultation to both a gastroenterologist and a surgeon. [13] In addition to toxic megacolon, the indications for surgery include colonic perforation, massive lower-GI bleeding, suspicion of colon cancer, and disease that is refractory to medical therapy (large doses of steroids required to control the disease). The surgical treatment

options include proctocolectomy with ileostomy, ileostomy with a Koch pouch, proctocolectomy with an ileoanal pouch, or colectomy with ileorectal anastomosis. Age and patient acceptance often influence the choice of surgical procedure, with the increased performance of continent procedures. Unlike the effects of surgery in Crohn's disease, surgical intervention is curative in ulcerative colitis.

Patients with mild to moderate disease can be discharged from the ED. Close follow-up should be arranged with the patient's medical physician or gastroenterologist, and any adjustment in medical therapy discussed. In addition, the patient should be instructed to eat a low-residue diet. Patients should be instructed to return if symptoms do not improve or worsen. Particular attention should focus on the quantity of diarrhea, toleration of oral intake, and associated symptoms such as fever, rectal bleeding, or abdominal pain.

PSEUDOMEMBRANOUS ENTEROCOLITIS

Psuedomembranous enterocolitis is an inflammatory bowel disorder in which membrane-like yellowish plaques of exudate overlie and replace necrotic intestinal mucosa.

Epidemiology

Clostridium difficile is a spore-forming obligate anaerobic bacillus that causes pseudomembranous colitis. *C. difficile* was originally identified as an enteric human pathogen in 1978. The incidence of this disease has been increasing in recent years, coincident with the increased spectrum of antibiotics in use throughout the United States. Three different syndromes have been described: neonatal pseudomembranous enterocolitis, postoperative pseudomembranous enterocolitis, and antibiotic-associated pseudomembranous colitis. Recent antibiotic use, gastrointestinal surgery or manipulation, severe underlying medical illness, and advancing age have all been identified as risk factors for developing pseudomembranous colitis. Transmission of the organism has been implicated from direct human contact as well as contact with inanimate objects (commodes, telephones, rectal thermometers). *C. difficile* is the most common enteric pathogen associated with nosocomial diarrhea.[14]

Pathophysiology

Hospitalized patients are colonized with *C. difficile* in 10 to 25 percent of cases. Broad-spectrum antibiotics—most notably clindamycin, cephalosporins, and ampicillin/amoxicillin—alter the gut flora in such a way that toxin-producing *C. difficile* can flourish within the colon, producing clinical manifestations of pseudomembranous colitis. It should be remembered, however, that almost any antibiotic (including metronidazole and vancomycin) can lead to pseudomembranous colitis. It should also be noted that chemotherapeutic agents[15] and antiviral agents[16] have been implicated as well. Most strains of *C. difficile* produce two toxins, toxin A, an enterotoxin, and toxin B, a cytotoxin, that interact in a complex and not completely understood manner to produce pseudomembranous colitis and its associated symptoms.

Clinical Features

Pseudomembranous colitis results in a spectrum of clinical manifestations that vary from frequent, mucoid, watery stools to a toxic picture that includes profuse diarrhea (20 to 30 stools per day), crampy abdominal pain, fever, leukocytosis, dehydration, and hypovolemia. Examination of the stool may reveal the presence of fecal leukocytes. These are not generally found in more benign forms of antibiotic-induced diarrhea. Complications of the disease include severe electrolyte imbalance, hypotension, and anasarca from decreased serum albumin. Rarely, toxic megacolon or colonic perforation may occur in patients with pseudomembranous colitis. The disease typically begins 7 to 10 days after the institution of antibiotic therapy, although in some cases symptoms may be noted within a few days or up to 8 weeks after the antibiotic is discontinued. *C. difficile* colitis has now been established as a nosocomial infection in hospitals.

Diagnosis

The diagnosis is suggested by a history of diarrhea that develops during administration of antibiotics or within 2 weeks of their discontinuation. The diagnosis may be confirmed by endoscopy, which reveals characteristic yellowish plaques within the intestinal lumen. Lesions may be seen throughout the entire alimentary tract, although they are typically limited to the right colon. For this reason, colonoscopy may be required in some cases to establish the diagnosis, which may be missed by sigmoidoscopy alone. It should be noted, however, endoscopy is not routinely needed to establish a diagnosis of pseudomembranous colitis.

The diagnosis is confirmed by the demonstration of *C. difficile* in the stool and by the detection of toxin in stool filtrates. The organism is best identified by stool culture using a selective growth medium.[17] This technique has a sensitivity approaching 100 percent but lacks specificity. In addition, culture results take between 28 and 72 h, thus limiting their utilization in establishing the diagnosis in patients with suspected pseudomembranous colitis. Instead, *C. difficile* toxin is detected directly using a number of techniques including tissue-culture assay, enzyme-linked immunosorbent assays (ELISA), latex agglutination, dot-immunobinding assays, and polymerase chain reaction (PCR). Tests vary in their sensitivity, specificity, and time to completion. While tissue-culture assays are considered the "gold standard," most laboratories utilize the ELISA technique to detect the clostridial toxins; it has a sensitivity of 63 to 94 percent and a specificity of 75 to 100 percent. [18]

Treatment

The treatment of pseudomembranous colitis includes discontinuing antibiotic therapy and instituting supportive measures such as the administration of fluids and the correction of electrolyte abnormalities. Twenty-five percent of patients will respond to these measures alone. For those patients with mild to moderate disease who do not respond to supportive measures, metronidazole 250 mg four times daily is the therapy of choice. [19] Vancomycin 125 to 250 mg four times daily is an alternative regimen, although this is considerably more expensive than metronidazole. It should be reserved for cases where the patient has not responded to or is intolerant of metronidazole, where the organism is resistant to metronidazole, or where the patient is pregnant.

Severely ill persons must be hospitalized. Oral vancomycin, 125 to 250 mg four times a day for 10 days, is effective in the majority of severely ill patients. [20] The symptoms usually resolve within a few days. Rarely, emergency colectomy may be required for patients with toxic dilatation of the colon or colonic perforation.

Relapses occur in 10 to 20 percent of patients. The use of antidiarrheal agents may prolong or worsen symptoms in patients with pseudomembranous colitis and should be avoided. Steroids and surgical intervention are rarely needed.

Disposition

Patients with severe diarrhea, symptoms that persist despite appropriate outpatient management, or those with a systemic response (fever, leukocytosis, severe abdominal pain) should be hospitalized. Patients with pseudomembranous colitis who are suspected of having a toxic megacolon or perforation should have an immediate surgical consultation. For those patients who are discharged, discontinuation of any antibiotics and good oral intake must be encouraged. The decision to institute therapy using metronidazole or vancomycin should be made in conjunction with the patient's primary physician.

DIVERTICULITIS

Diverticulitis is an acute inflammatory process caused by bacterial proliferation within an existing colonic diverticulum.

Epidemiology

Acquired diverticular disease of the colon has become an increasingly common disorder of industrialized nations. Diverticulosis coli was first described in the early 1700s by Littre but was not identified as a pathologic entity until the mid-nineteenth century by Cruveilhier. Radiologic studies have suggested that one-third of the population will have acquired the disease by age 50 and two-thirds by age 85. [21] Diverticula are rare in individuals under age 20.

Diverticulitis is estimated to occur in 10 to 25 percent of patients with known diverticulosis. The incidence of diverticulitis increases with age. Only 2 to 4 percent of patients with diverticulitis are under the age of 40. Diverticulitis in the younger age group tends to be a more virulent form of the disease, with frequent complications

requiring earlier surgical intervention. [22] Although the frequency of the disease is higher in men, there is an increasing incidence of diverticulitis in women.

Pathophysiology

Colonic diverticula are false diverticula because they do not include all layers of the bowel wall. They consist of mucosa and submucosa with a peritoneal covering that has herniated through a defect in the circular muscle layer of the wall. The sites of herniation are located between the mesenteric and antimesenteric taenia, where intramural blood vessels penetrate the muscularis.

A pathophysiologic mechanism to explain the development of diverticular disease is not apparent. It is still unresolved whether diverticular disease is a disorder of colonic motility, a colonic muscle abnormality, a connective tissue disorder, or a normal concomitant of aging. Low-residue diets have been implicated as a major factor in the pathogenesis of diverticular disease. The most common hypothesis is that acquired diverticula arise because of high intraluminal pressures in areas of relative weakness of the colonic wall. This is based upon observations that the majority of patients have diverticula located within the sigmoid colon. Laplace's law states that the tension on the wall of a hollow cylinder is inversely proportional to the radius of the cylinder multiplied by the pressure within the cylinder. This suggests that the intraluminal pressure in the colon is greatest where the lumen is narrowest. The diameter of the colon is smallest in the sigmoid region, and thus this region of the colon is the most likely location for the development of diverticula.

The complications of diverticular disease that bring the patient to the ED can be divided into two broad categories: (1) inflammation and its associated complications and (2) bleeding (see Chap. 70, "Gastrointestinal Bleeding").

Inflammation, or diverticulitis, is the most common complication of diverticular disease. It results when fecal material becomes inspissated in the neck of an acquired diverticulum, resulting in obstruction of the neck of the diverticulum and subsequent proliferation of colonic bacteria, mucous secretion, and distention of the diverticulum. Clinical diverticulitis always represents microperforation and inflammation of pericolonic tissue. Fortunately, fecal contamination of the peritoneum is usually limited because perforation of a diverticulum occurs into the leaves of the mesentery or because the contamination is walled off by the mobile loops of the sigmoid colon or small bowel and adjacent pelvic structures. Free perforation may occur with generalized peritonitis, but it is uncommon.

Clinical Features

The most common symptom of diverticulitis is pain. This is commonly described as a steady, deep discomfort in the left lower quadrant. Patients will frequently complain of a change in the bowel habits, either in the form of diarrhea or increasing constipation. Tenesmus is another common symptom. The involved diverticulum may irritate the bladder or ureter, causing the patient to have urinary frequency, dysuria, or pyuria. If a fistula develops between the colon and the bladder, the patient may present with recurrent urinary tract infections or pneumaturia. Paralytic ileus with abdominal distention, nausea, and vomiting may develop secondary to intraabdominal irritation and peritonitis. Small bowel obstruction may also occur as adjacent loop of small bowel becomes kinked or narrowed in the inflammatory mass.

Rarely, the clinical presentation may be indistinguishable from acute appendicitis. This may occur when the patient has a redundant sigmoid colon lying on the right side of the abdomen or a right-sided diverticulum that becomes inflamed. The possibility of diverticulitis should always be considered in the patient 50 years of age or older with right lower abdominal pain. Cases of diverticulitis in the cecum or ascending colon have also been reported.

The patient with free perforation will often present with a history of sudden onset of abdominal pain, usually beginning in the lower abdomen and then progressing to generalized abdominal involvement. The patient will appear quite toxic, with signs of diffuse peritonitis. Prior steroid use predisposes the patient to perforation and may mask some of the typical signs and symptoms.

Physical examination frequently demonstrates a low-grade fever, around 38°C (100.4°F). The temperature may, however, be more elevated in patients with generalized peritonitis or in those who have formed an abscess. The abdominal examination reveals localized tenderness, often with voluntary guarding and rebound tenderness. With careful palpation, one may be able to appreciate a fullness or mass over the involved segment of the colon. Rectal examination will often reveal tenderness on the left side. Twenty-five percent of patients may demonstrate occult blood. When free perforation does occur, diffuse abdominal tenderness, rigidity, guarding, and rebound tenderness may be noted. In the female patient, a pelvic examination should always be carried out to eliminate a gynecologic source of symptoms.

Diagnosis

The diagnosis is usually suspected by the clinical history and the findings on physical examination. The presence of peritoneal signs or generalized peritonitis should suggest free perforation or rupture of a peridiverticular abscess. The presence of an abdominal mass associated with occult blood in the stool could indicate colon cancer. Colonic or small bowel obstruction, though uncommon, may necessitate surgical intervention.

Barium contrast studies can easily demonstrate diverticulae but are insensitive in detecting the presence of diverticulitis. In addition, barium introduced under high pressure carries the risk of precipitating a colonic perforation. Abdominal CT is the diagnostic procedure of choice. [23] It can demonstrate inflammation of percolic fat, presence of diverticulae, thickening of the bowel wall, or peridiverticular abscess. [24] Colon cancer is best ruled out by sigmoidoscopy or colonoscopy.

The acute abdominal series may be normal or may demonstrate associated ileus, partial small bowel obstruction, free air indicating bowel perforation, or extraluminal collections of air that might indicate a walled-off abscess. Abdominal ultrasonography is an inexpensive noninvasive method but is operator-dependent and lacks specificity.

Laboratory studies should include routine screening blood tests, urinalysis, and an acute abdominal series. Unfortunately, in many cases laboratory studies are not helpful in the diagnosis. Leukocytosis was seen in only 36 percent of patients with acute diverticulitis. [25] Controversy exists regarding the use of sigmoidoscopy or contrast radiographic studies in the acute inflammatory state. The general opinion in the literature is that these studies should be performed after conservative medical management has been instituted and the acute inflammatory process has subsided.

Differential Diagnosis

In patients over the age of 40 presenting with complaints of abdominal pain, a change in bowel habits, and urinary symptoms, a diagnosis of colonic diverticulitis should be entertained. These symptoms, however, are nonspecific, and a number of pathologic entities may present with similar signs and symptoms (Table 77-2). Some of the most important are discussed below.

Symptoms of irritable bowel syndrome include diffuse crampy or colicky abdominal pain, brought on by meals or emotional upset. The patients may also describe a bloated or distended sensation in the abdomen. The symptoms are usually intermittent and chronic. The passage of flatus or a bowel movement may bring relief. The disease is characterized by alternating bouts of constipation and diarrhea. On physical examination, the patient is afebrile and a cordlike mass may be appreciated in the left lower quadrant corresponding to the sigmoid colon. Signs of localized or generalized peritonitis are not seen. Laboratory studies are normal.

Patients who have colon carcinoma may present with a change in bowel habits, either diarrhea or constipation, and/or abdominal pain that can mimic symptoms of diverticular disease. There may be blood mixed with the patient's stools, and weight loss. Physical examination may reveal a palpable mass, usually nontender. Fever and chills are less common, and laboratory studies may demonstrate anemia without evidence of leukocytosis. An acute abdominal series may demonstrate findings of colonic obstruction. This can be produced by an inflamed diverticula or a carcinoma in an area of the bowel with underlying diverticulosis. Fiberoptic colonoscopy can be useful in differentiating diverticular disease from carcinoma.

Pelvic inflammatory disease may present with abdominal pain, fever, and leukocytosis. The disease is usually found in young women. A careful pelvic examination should be carried out in all female patients with lower abdominal pain. A history of irregular menses and the finding of vaginal discharge should aid in the diagnosis.

Ischemic colitis can present with a broad range of clinical manifestations. Mild transient ischemia may result in mucosal sloughing and painless rectal bleeding. If the disease progresses to gangrene, the patient develops severe abdominal pain and peritonitis. Pain may be out of proportion to physical findings. A plain film of the

abdomen may reveal thumbprinting in the region of the involved colonic segment. In more advanced cases, there may be gas within the bowel wall, or, if perforation has occurred, free air in the abdomen. Cautious endoscopic evaluation and contrast x-ray studies are helpful in distinguishing ischemic colitis from diverticulitis.

Treatment

Initial resuscitation of patients with acute diverticulitis should focus on determining the severity of the illness, eliminating other causes of symptoms, and appropriate fluid and electrolyte resuscitation (Table 77-4). In patients who demonstrate signs of toxicity such as fever, tachycardia, leukocytosis and severe abdominal pain, intravenous antibiotics are administered. These should include an aminoglycoside (gentamicin or tobramycin 1.5 mg/kg) and either clindamycin 300 to 600 mg or metronidazole 500 mg. Ticarcillin-clavulanic acid or imipenem have been used as alternative agents. The patient is placed on bowel rest, but in this case, nothing by mouth is given and intravenous fluids are administered. Nasogastric suction is necessary only if the patient manifests signs of bowel obstruction or an adynamic ileus.

Restore fluid and electrolyte balance

Nothing by mouth

Nasogastric suction for
   Obstruction
   Adynamic ileus

Broad-spectrum antibiotics
   Aminoglycoside (gentamicin or tobramycin)
   Metronidazole or clindamycin

Ticarcillin-clavulanic acid or imipenem (alternative therapy)

Observe for complications
   Obstruction
   Perforation
   Intraabdominal abscess

TABLE 77-4   Treatment of Acute Diverticulitis

Outpatient treatment consists of bowel rest and broad-spectrum oral antibiotic therapy. Patients are instructed to limit activity and to maintain a liquid diet for 48 h. If symptoms improve, low-residue foods are added to the diet. Broad-spectrum antibiotics covering both aerobic and anaerobic bacteria are given. Predominant colonic aerobes include *Escherichia coli, Klebsiella* and *Enterobacter,* while *Bacteriodes fragilis, Peptostreptococcus,* and *Clostridium* are the predominant colonic anaerobes. Common oral antibiotic agents effective against aerobic organisms include ampicillin (500 mg q 6 h), trimethoprim-sulfamethoxasole (2 tablets q 12 h), ciprofloxacin (500 mg q 12 h), or a cephalosporin, such as cefalexin (500 mg q 6 h). One of these agents is taken in combination with metronidazole (Flagyl 500 mg q 8 h), or clindamycin (Cleocin 300 mg q 6 h), which are utilized to treat the anaerobic organisms. Patients are instructed to contact their physician if increasing abdominal pain, fever, or malaise occur. Once the patient has improved, elective evaluation with contrast barium is performed.

Disposition

Patients who have localized pain without signs and symptoms of local peritonitis and without evidence of systemic infection may be treated on an outpatient basis. Careful follow-up should be arranged with the patient's primary physician. The patient should be begun on a clear liquid diet and advance to low-residue foods as symptoms improve. Patients should be instructed to return if fever develops, if they are unable to tolerate oral intake, or if there is worsening abdominal pain.

If a patient has systemic signs and symptoms of infection, has failed outpatient management, or demonstrates signs of localized peritonitis, hospitalization is necessary. Surgical consultation should be obtained at the time of hospitalization. Urgent surgical consultation is indicated if free perforation is found.

78 ANORECTAL DISORDERS

James K. Bouzoukis

Anorectal disorders are varied and multiple and may also be complex, manifesting signs and symptoms of underlying serious local or systemic disorders that could be life-threatening.

ANATOMY

The anorectum is an anatomic structure in which the entodermal intestine unites with and opens into an orifice of ectodermal origin: the anal canal. The junction of these two embryonic structures (the anorectal line) is the dentate line, which marks the anatomic beginning of the anal canal (1 to 2 cm long) and is in continuity with the perianal skin at its distal anal verge. The mucosa of the anal canal consists of stratified squamous epithelium but contains no hair follicles or sweat glands. At the anal verge (perianal region), the anoderm thickens and includes in its structure hair follicles and other cutaneous appendages. Proximal to the dentate line, the rectal ampulla narrows to conform to the opening of the anal canal; in doing so its mucosa takes on a pleated appearance, forming 8 to 14 convoluted longitudinal folds: the columns of Morgagni. Each adjacent column is connected at the dentate line by a flap of mucosa that forms a small anal crypt, normally 1 to 3 mm in longitudinal depth. Infection and inflammation of these crypts and glands become the source of anal sepsis, as characterized by the development of cryptitis, fissures, abscesses, and fistulas.

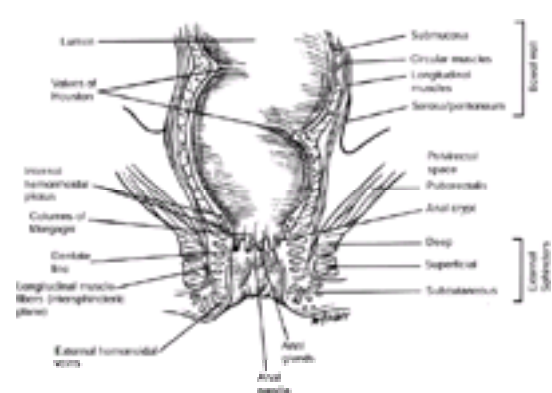
The anal wall, from its mucosal lining to the intersphincteric plane, which separates the internal from the external sphincters, is a continuation of the usual layers of the wall of the colon and rectum. The innermost lining the mucosa, continues to the anal verge, undergoing a transition just proximal to the dentate line from rectal columnar to cuboidal to squamous epithelium. The submucosa, which normally contains the bulk of the bowel's blood vessels (and autonomic nerves), thickens considerably proximal to the dentate line; its dilated veins in this area are referred to as the internal hemorrhoidal plexus. Likewise, the inner circular muscle layer of the rectum thickens considerably as it terminates distally in the anorectum to form the internal sphincter muscles, while the more attenuated longitudinal muscles of the rectum extend caudally, blending with fibers of voluntary skeletal muscles from the levator ani and external sphincter groups to form the intersphincteric plane (Fig. 78-1).


FIG. 78-1. Coronal section of the anorectum.

Additional sphincteric support is provided by an outer layer of voluntary skeletal muscles, the external sphincters, which are divided into three parts: deep, superficial, and subcutaneous. The external sphincters are actually a caudal extension of the puborectalis muscle, which interacts with the levator ani muscle forming the pelvic floor. The puborectalis, the proximal external sphincters, and the internal sphincters form the ring of muscles that one palpates when performing a digital examination of the anorectum.

Lateral to the external sphincters is the ischiorectal space, and superior to the levator ani is the pelvirectal space, where deep, life-threatening infections can occur.

EXAMINATION OF THE PATIENT

No matter how much historical information is obtained, no definitive diagnosis can be made without a careful examination of the anus and rectum, including anoscopy and, if necessary, proctoscopy.

The lateral, or Sims, position, performed with the patient lying on his or her left side with the left leg extended and the right knee and hip flexed, is probably the most

commonly used approach for performing a routine digital rectal examination and is the preferred position for elderly or pregnant patients. From the Sims position, one should elevate the upper right buttock to provide better exposure of the perianal area; if needed, endoscopic examination of the anus and distal rectum can be performed with the patient in this position. In debilitated patients, one may have to perform the examination with the patient in a supine, lithotomy position.

Examining a patient placed in the knee-chest position requires a cooperative patient who is not too ill or in too much distress. This provides for a thorough inspection of the perianal area and is convenient for anoscopy and proctoscopy. Thighs should be at right angles to the table with the feet extended over the end of the table.

A digital examination should always be performed before doing any endoscopic procedure. No bowel preparation is needed to perform an anoscopic examination. After performing a digital examination and determining that the patient will tolerate passage of an anoscope, introduce a well-lubricated, lighted anoscope, remove the obturator, and gently rotate it 360° to view the anorectum circumferentially.

It is usually difficult to perform a proper sigmoidoscopic examination in an emergency department (ED) setting. Ordinarily, the lower bowel must be prepped; a natural bowel movement, spontaneous or induced 1 to 2 h before examination, is usually sufficient preparation. In some acute situations, such as trying to determine the source of lower GI bleeding or obtaining cultures in a case of suppurative proctitis, emergency proctoscopy may be performed. A rigid sigmoidoscope should be utilized, with the patient placed in a Sims position. An inexperienced endoscopist should not attempt to pass the sigmoidoscope beyond the rectosigmoid junction, where the lumen is greatly angulated, because of the risk of perforation.

HEMORRHOIDS

The anorectal area is drained by the internal and external hemorrhoidal venous systems. The internal hemorrhoidal veins, which in essence are submucosal vascular cushions that may contribute to anal continence, are located proximal to the dentate line and drain into the portal system through the superior rectal veins and the inferior mesenteric vein. They also communicate freely with the external hemorrhoidal veins, which are subcutaneous to the anoderm and drain primarily through the pudendal and iliac venous systems. When these hemorrhoidal plexuses become excessively engorged, prolapsed, or thrombosed, they are referred to as hemorrhoids—one of the most common problems afflicting human beings.

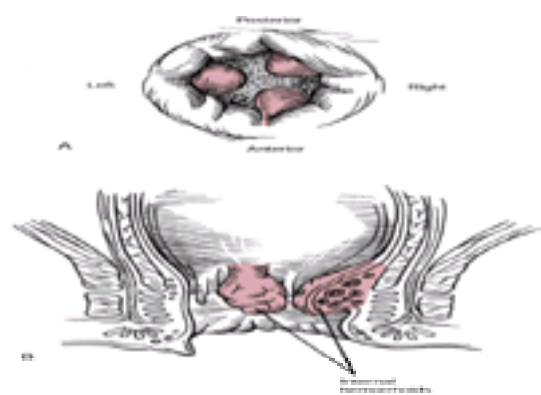
Internal hemorrhoids, which course along the terminal branches of the superior rectal artery, are constant in their location, coursing longitudinally at the right posterolateral, right anterolateral, and left lateral positions (at the 2-, 5- and 9-o'clock positions when the patient is viewed prone) (Fig. 78-2). Internal hemorrhoids are not readily palpable and can best be visualized through an anoscope. External hemorrhoids are dilatation of veins at the anal verge and can be seen at external inspection.


FIG. 78-2. Common sites of hemorrhoids. **A.** Internal hemorrhoids at 2, 5, and 9 o'clock. **B.** Protrusion of anal cushions.

Although the cause of enlarged hemorrhoids is not always known, there is an association with constipation and straining at stool. They are prevalent during pregnancy and may be the result of sustained increased pressure on the venous drainage of the rectum. One of the physiologic shunts of the portal system involves the hemorrhoidal veins. Consequently, increased portal pressure, occurring as a result of chronic liver disease, may produce marked dilatation and varix formation of the hemorrhoids. The bleeding that can result is extremely difficult to control.

Tumors of the rectum and sigmoid colon, often associated with constipation, tenesmus, and incomplete evacuation, may cause hemorrhoids and must be ruled out in all cases of rectal bleeding in patients over the age of 40.

Clinical Features

Uncomplicated internal hemorrhoids are painless, and the chief complaint is painless, bright-red rectal bleeding with defecation. Bleeding is usually limited, with the blood being found on the surface of the stool, on the toilet tissue, or dripping into the toilet bowl. Although the most common cause of rectal bleeding is hemorrhoids, other, more serious causes should be sought in all patients who present with bleeding as the chief complaint. Clinical signs cannot reliably differentiate colonic lesions from hemorrhoids.[1] Chronic, slow blood loss may go unnoticed but can result in a significant anemia. Pain, when present, is most severe at the time of defecation and subsides with time. Pain is usually associated with thrombosed external hemorrhoids.

As they increase in size, hemorrhoids may prolapse, requiring periodic reduction by the patient (Table 78-1). When prolapse occurs, the patient may develop a mucous discharge and pruritus ani.

Degree	Symptoms
First	Bleeding; local, compressible swelling
Second	Protrude with defecation, reduce spontaneously, ± bleeding
Third	Protrude with defecation, must be reduced manually, ± bleeding
Fourth	Incarcerated

TABLE 78-1   Classification of Internal Hemorrhoids

If the prolapse cannot be reduced, strangulation can result. Other complications include severe bleeding and thrombosis. Both strangulation and thrombosis are extremely painful and are accompanied by significant edema that must be treated before surgical intervention. Ulceration of the overlying mucosa may also occur.

Treatment

Most treatment is local and nonsurgical unless a complication is present. Hot sitz baths for at least 15 min three times a day and after each bowel movement are the most effective way to relieve pain. Following the bath, the anus must be dried gently but thoroughly to avoid maceration of the perianal skin. Topical analgesics and

steroid-containing ointments may provide relief. The patient should not sit for a prolonged period on the commode. Bulk laxatives, such as psyllium seed compounds, or stool softeners should be used after the acute phase is treated. Laxatives causing liquid stool must be avoided; this can result in cryptitis and anal sepsis. The addition of bran or other forms of roughage to the patient's diet should help to prevent future problems.

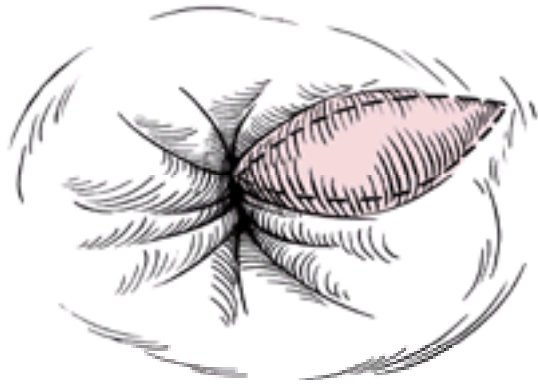
As a rule, internal hemorrhoids bleed and, if not prolapsed, are not palpable. External hemorrhoids thrombose. Selection of therapy for thrombosed external hemorrhoids depends on the severity of symptoms: if the thrombosis has been present less than 48 h, the swelling is not tense, and the pain is tolerable, the patient may be treated with sitz baths and bulk laxatives. Suppositories, which are placed proximal to the anorectal ring, are of no help. If, on the other hand, thrombosis is acute and recent in origin, significant relief can be provided by excising the clots. With the patient in prone position, the area of the overlying skin to be incised is infiltrated with a local anesthetic using a 30-gauge needle. While applying gentle traction to the skin adjacent to the thrombosed hemorrhoid, an elliptical incision is made in the overlying skin, exposing the thrombosed vein, which is locally excised with the elliptical flap of skin (Fig. 78-3). Because of the multiloculated clots that are invariably present, the technique of unroofing a thrombosed hemorrhoid with an elliptical incision gives far better results than the simple incision and evacuation of a clot. Bleeding is controlled by tucking the corner of a small piece of gauze into the wound and leaving it in place for a few hours. A small pressure dressing may be applied external to the gauze and removed when the patient takes the first sitz bath 6 to 12 h after the drainage procedure. Narcotics may be prescribed, but only judiciously, since they cause constipation and may produce more problems.


FIG. 78-3. Elliptical excision of thrombosed external hemorrhoid.

Surgical referral and intervention for hemorrhoids is indicated for continued bleeding; incarceration and/or strangulation; severe, unrelenting pruritus; and intractable pain. Surgical treatment can consist of sclerosing injections, the use of rubber-band ligation, [2] or excision. Up to 5 percent of patients undergoing rubber-band ligation may develop acute thrombosis of external hemorrhoids, and immunocompromised patients so treated may develop pelvic sepsis.

CRYPTITIS

Anal crypts are the superficial mucosal pockets that lie between the columns of Morgagni. They are formed by the puckering action of the sphincter muscles and normally flatten out during the passage of a stool. Sphincter spasm and superficial trauma caused by repeated bouts of diarrhea, or trauma produced by evacuation of large, hard stools associated with constipation cause breakdown in the mucosal lining of the crypts. This permits infecting organisms to enter pockets and inflammation to extend into the lymphoid tissue of both the crypts and anal glands. Cryptitis could well be the common denominator for the development of such anal infections as fissure in ano, perirectal abscesses, and fistula in ano.

Associated with cryptitis is the development of hypertrophied anal papillae, which lie between adjacent crypts. When hypertrophy occurs, the papillae may be palpated as small, hard nodules along the wall of the anal canal. Rarely, papillae may hypertrophy and present as a prolapsing polypoid tumor. The crypts most commonly involved are in the posterior half of the anal ring and, in most cases, in the posterior midline, the same location where anal fissures occur.

Clinical Features

Initially, the locally inflamed crypts produce no symptoms, but as the trauma from recurrent diarrhea or passage of large, hard stools continues, the inflammation of the crypts extends to the adjacent papillae, producing an edematous swelling of the sensitive anoderm that lines this part of the canal. At this stage, the patient will experience pain with bowel movements, and if there is an associated papillitis or fissure in ano, there will also be a small amount of bleeding. Anal pain, spasm, and itching with or without bleeding are the cardinal signs and symptoms of cryptitis.

Treatment

Treatment of anal cryptitis, which should be conservative, is based on establishing a definitive diagnosis and ruling out the possibility of more serious anorectal problems. The diagnosis can be suspected clinically from the history and the palpation of the tender, swollen crypt and its associated hypertrophied papillae. Definitive diagnosis of cryptitis is made by anoscopic examination. Gentle insertion of a hooked probe into the crypts brought into view through the anoscope will reveal the involved crypt(s) to be deeper than normal and definitely more tender.

The goal of treatment is to control the trauma of abnormal bowel movements and thus enable the inflammation to subside. Bulk laxatives and additional roughage to the diet to produce formed, soft stools; combined with hot sitz baths they enhance healing by keeping the anus clean and the crypts empty.

Surgical intervention is indicated when the infection has progressed and there is a deep, redundant crypt that will not drain adequately on its own. In these cases, the roof (mucosal surface), as outlined by the passage of a hooked probe, should be infiltrated with local anesthetic and excised. Thus, what had been a deep pocket is converted into an open wound that should heal with proper control of bowel movements and frequent sitz baths.

FISSURE IN ANO (ANAL FISSURE)

This disorder is the result of a linear tear of the anal canal beginning at or just below the dentate line and extending distally along the anal canal. The epithelium in this area consists of anoderm, which has a rich supply of somatic sensory nerve fibers. Consequently, anal fissures are the most common cause of painful rectal bleeding.

Anal fissures are often associated with swelling of the surrounding tissues, producing hypertrophic papillae proximally and the characteristic sentinel pile distally. The latter is frequently misdiagnosed as an external hemorrhoid when in actuality it is the result of edema and fibrosis secondary to the ulcerating fissure. In more than 90 percent of cases, anal fissures occur in the midline posteriorly. In 10 percent of women but in only 1 percent of men, it may be in the midline anteriorly. This almost constant location of anal fissures may be because of the posterior angulation of the rectum on the anus where the posterior midline of the anorectal canal becomes the "lesser curvature" for the passage of stool. A fissure not located in the midline should arouse suspicion that another, potentially life-threatening cause may be involved. Such diagnostic possibilities include Crohn's disease, chronic ulcerative colitis, squamous cell carcinoma of the anus, adenocarcinoma of the rectum invading the anal canal, localized anal cancers such as Bowen's disease and extramammary Paget's disease, leukemia, lymphoma, syphilitc fissures, and tuberculous ulcer. Such patients must be referred for a diagnostic biopsy of the ulcer edge, culture of the anal canal, and a systemic evaluation.

Most often, the traditional midline anal fissure is caused by the trauma produced by the passage of a particularly hard and large fecal mass, but it is also seen after acute episodes of diarrhea. Fissures persist because of the severe, chronic internal sphincter spasm that occurs along with the secondary infection of its base.

Clinical Features

Pain of the sharp, cutting variety is the most common symptom. Typically, the pain is most severe during and immediately after a bowel movement. The pain may

persist for a few hours after each bowel movement, but invariably it subsides between movements, which is a distinguishing feature of fissures from other forms of painful anorectal disease. The bleeding is bright and small in quantity, usually being noticed only on the toilet paper. In infants, the presence of small amounts of bright blood on the stool or toilet paper is usually the presenting complaint for an anal fissure. Sphincter spasm and pain may be severe enough to make the patient retain stool and avoid defecation.

Diagnosis of anal fissure is usually suggested by the history; however, the anal area must be examined in all cases. With proper exposure, the sentinel pile, if present, and frequently the distal end of the fissure itself, may be seen. The mere retraction of the buttocks and the anal skin may cause considerable discomfort; sphincter spasm may be so severe that the patient will not permit digital examination. Application of a topical anesthetic may provide some relief. If the fissure can be visualized and is present in the posterior midline, rectal examination can be deferred until the patient is having less spasm and pain.

Treatment

Treatment is aimed at providing symptomatic relief, relieving the anal sphincter spasm, and preventing stricture formation. Hot sitz baths for at least 15 min three to four times a day and after each bowel movement will relax the sphincter and provide symptomatic relief. The addition of bran to the diet will serve to prevent stricture formation by providing a bulky stool. Local analgesic ointments provide symptomatic relief. The use of hydrocortisone-containing ointments does provide relief and helps with healing. In a study that compared the effectiveness of these three modalities, most rapid healing of fissures occured with sitz baths and a diet rich in bran, though healing was aided by both an analgesic ointment or a hydrocortisone-containing ointment. Meticulous anal hygiene is imperative; following defecation, the anus must be cleaned thoroughly. Healing is by the development of granulation tissue and the reepithelialization of the ulcerated area. If healing does not occur in a reasonable amount of time, operative treatment consisting of partial sphincterotomy and excision of the fissure may be required.

ANORECTAL ABSCESSES

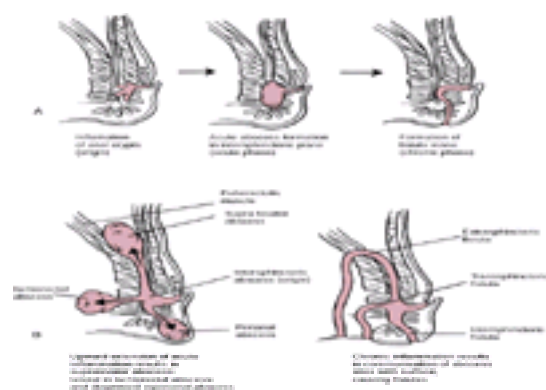
Abscesses are common in the perianal and perirectal regions, as are fistulas, which are common sequelae. Almost all begin with involvement of an anal crypt and its gland. From there, the infection can progress to involve any of the potential spaces that are normally filled with fatty areolar tissue and have little inherent resistance to the progression of infection. These spaces, which can become infected alone or in combination with each other, are as follows: the perianal space, the intersphincteric space, the ischiorectal space, the deep postanal space (connecting the ischiorectal space on each side posteriorly), and the supralevator or pelvirectal space (Fig. 78-4 and Fig. 78-5).


FIG. 78-4. Illustration of mechanism for anorectal abscess and fistula formation.
FIG. 78-5. Anatomical classification of common anorectal abscesses.

The perianal abscess is the most common anorectal abscess and occurs when pus spreads caudally between the internal and external sphincters. It presents close to the anal verge, post midline, as a superficial tender mass, which may or may not be fluctuant. In contradistinction, ischiorectal abscesses tend to be larger, indurated, and to present more laterally, on the medial aspect of the buttocks. Deeper perirectal abscesses may not manifest cutaneous signs, but rectal pain and tenderness are invariably present. The isolated perianal abscess not associated with deeper, perirectal abscess(es) is the only type of anorectal abscess that can be adequately treated under local anesthesia in an ED setting.

Ischiorectal and other deep abscesses pose a different problem. The ischiorectal fossa forms a large potential space on either side of the rectum, communicating behind it through the deep postanal space, and, in males, has extensions anteriorly above the perineal membrane to the prostate. Infections in this area are insidious and extensive and can point in an area some distance from the anal verge. These abscesses can be large, and yet only a diffuse, nonfluctuant, tender "mass" is palpable either through the rectal wall or the overlying skin. If only induration is present, endorectal ultrasonography [3] and/or needle localization under anesthesia may be needed to confirm the diagnosis.

Most abscesses in the anorectal area are the result of obstruction of an anal gland that opens in the base of an anal crypt and normally drains into the anal canal. When obstruction occurs, the gland orifice is blocked, resulting in infection and abscess formation. An element of cryptitis can frequently be identified by anoscopic examination. A variety of diseases are associated with the development of fistulous abscesses, including Crohn's disease, carcinoma of adjacent organs, Hodgkin disease, tuberculosis, and gonococcal proctitis.

Clinical Features

Initially, the patient notices a dull, aching, or throbbing pain that becomes worse immediately before defecation, is lessened after defecation, but persists between bowel movements. The pain is increased by the increased pressure in the rectum that occurs just before defecation.

As the abscess spreads, increases in size, and comes nearer the surface, the associated pain becomes more intense. Pain will be aggravated by straining, coughing, or sneezing. As the abscess progresses, pain and tenderness interfere with walking or sitting.

The patient appears markedly uncomfortable and may be febrile. A tender mass may be present, or there may be a tender, erythematous area with or without fluctuance. On rectal examination, a tender mass or induration is detected. Leukocytosis may be present.

Although clinical evaluation of abscesses is usually sufficient, if pain is out of proportion to physical findings or if the extent of the abscess is uncertain,

ultrasonography can be helpful. [3]

Treatment

Treatment is surgical and should be performed as soon as the diagnosis is made, before the abscesses become fluctuant. Drainage should be both early and extensive. All perirectal abscesses should be drained in the operating room. A recent publication revealed that 32 percent of patients who had undergone a simple incision and drainage under local anesthesia were required to have a second operation because of inadequate drainage and recurrence of disease.

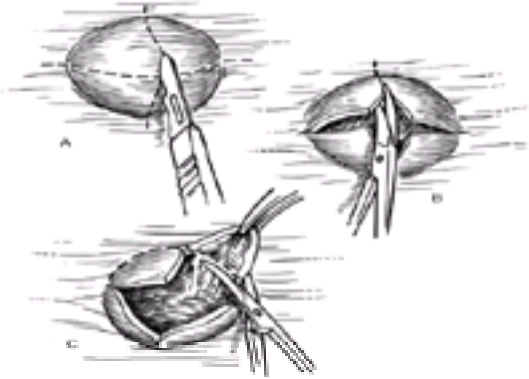
Isolated, simple, fluctuant perianal abscesses that are not associated with the presence of any deeper abscesses may be drained using local anesthetics in an ED setting. The local anesthetic should be administered with the finest-gauge needle available (30-gauge) and should be complemented with the administration of systemic analgesia or conscious sedation. To ensure adequate drainage, a cruciate incision should be made over the fluctuant part of the abscess, and the "dog ears" resulting from the cruciate incision should be excised so as to prevent premature closure of the cutaneous wall of the abscess (Fig. 78-6). No packing is required, but the wound should be covered with a bulk dressing; sitz baths should be started the next day. If a simple, linear drainage incision is made, the abscess is more likely to recur because of premature closure of skin edges. Whenever this technique is used the abscess cavity must be packed initially with strips of gauze for at least 24 h. These patients will require closer follow-up care.


FIG. 78-6. Technique of drainage of perianal abscess.

As a rule, antibiotics are not necessary after an abscess has been adequately drained. On the other hand, patients whose immune system may be compromised by diabetes mellitus, AIDS, malignancies, and chemotherapy and/or those patients who have extensive cellulitis should be given broad-spectrum antibiotics.

FISTULA IN ANO

An anal fistula is an abnormal tract that connects the anal canal with the skin and is lined with epithelium and granulation tissue. A fistula in ano most commonly results from a perianal or ischiorectal abscess (Fig. 78-4). It may, however, be associated with ulcerative colitis, Crohn's disease, or tuberculosis. Although anterior-opening fistulas tend to follow a simple, direct course to the anal canal (Goodsall rule), posterior-opening fistulas may follow a devious, curving path, including some that are horseshoe-shaped.

Clinical Features

As long as the tract remains open, there is a persistent, blood-stained, malodorous discharge. More commonly, the tract becomes blocked periodically, producing bouts of inflammation and even local, recurrent abscess formation that is relieved by spontaneous rupture. An abscess may be the only sign of fistula in ano.

Treatment

The only definitive treatment is surgical excision. Improperly excised fistulas may result in permanent fecal incontinence.

VENEREAL PROCTITIS

Sexually transmitted diseases (STDs) of the anorectum are not uncommon among patients who practice anal sex. The infecting organisms, for the most part, are the same ones that are transmitted with vaginal coitus; infection is transmitted and perpetuated almost entirely by men who fail to use condoms (Table 78-2). Exceptions to this occur with women whose lymphogranuloma venereum (LGV) variety of chlamydia infection extends directly to the rectum from the vagina and on occasions when there is a contamination of the anus with gonococcal-laden discharge emanating from the urethra or cervix.

Bacteria
  Neisseria gonorrheae
  Chlamydia trachomatis
  Treponema pallidum

Virus
  Herpes simplex type 2
  Human immunodeficiency virus
  Papillomavirus

TABLE 78-2   Anorectal Sexually Transmitted Diseases

As a rule, if the patient has an anorectal infection caused by one of the STDs, the assumption must be made that another STD may be present; appropriate blood tests must be obtained, and patients should be anoscoped or proctoscoped in order to obtain specimens for Gram stain as well as for viral and bacterial cultures.

Clinical Features

Most venereal diseases involving the anorectal area manifest themselves initially with itching, seepage, and mild pain or irritation. Some infections may persist with mild to minimal symptoms, rendering the patient a carrier of the disease. Most venereal infections, however, will produce significant symptoms of pain, bleeding, and discharge in addition to a bothersome pruritus.

CONDYLOMATA ACUMINATA   Condylomata acuminata, commonly known as anal warts, are caused by a papillomavirus and are probably sexually transmitted in more than 90 percent of cases. They begin as discreet, soft, fleshy growths on the skin of the perianal area as well as on the squamous epithelium of the anal canal. Occasionally, the mucosa of the lower rectum becomes involved. Patients usually first notice the presence of a growth in the perianal areas as well as associated pruritus and varying degrees of anal pain. With time, bleeding and anal discharge become part of the symptom complex. Evaluation of a patient with condyloma acuminata must include ruling out the presence of other STDs. These patients should be referred to an appropriate specialist for definitive treatment. Because cases

of squamous cell carcinoma arising in association with condyloma acuminata have been reported, multiple biopsies must be taken.

GONORRHEA   Symptoms of gonococcal proctitis vary, ranging from none to severe rectal pain with profuse yellow discharge. Patients in the acute phase generally have mild and burning and/or pruritus with some purulent seepage. Proctoscopic examination during this phase of the disease reveals marked hyperemia and edema of the rectal mucosa and diffuse inflammation with purulent discharge from the anal crypts. Unlike nonvenereal cryptitis, infection is not confined to the posterior crypt. Diagnosis is made by Gram's stain and cultures.

CHLAMYDIAL INFECTIONS   *Chlamydia trachomatis* is an obligate human intracellular parasite that causes, among other conditions, both urogenital and anorectal infections. The lymphogranulomatous (LGV) variety occurs mainly in tropical and subtropical climates. Infection can involve the rectum by perirectal lymphatic invasion from vaginal seeding or from direct anorectal mucosal infections. The non-LGV chlamydial organisms may infect the rectal mucosa, although they do not cause the extensive rectal scarring and stricturing that its lymph gland–invading cousin from the tropics does. A patient with chlamydial proctitis may be asymptomatic or may present with nonspecific symptoms, including anal pruritus, pain, and purulent discharge. Bleeding may also be present.

The more severe form of proctitis occurring with this infection is usually due to the LGV type of chlamydia. In addition to rectal scarring, which is a late sequel, infection of the perirectal tissue results in perirectal abscesses and chronic fistulas.

Chlamydia may be identified by culture. The LGV forms may be distinguished from the non-LGV variety by the Frei intradermal test or the LGV complement fixation test. Treatment for LGV chlamydial infections should be maintained for at least 21 days.

SYPHILLIS   Chancres, the characteristic lesion of primary syphilis, usually manifest themselves at the anal verge or in the anal canal. Rarely will a chancre involve the rectal mucosa, although proctitis due to syphilis can occur in the absence of a chancre. Anal chancres may be very painful. If they are not identified and treated, they will resolve and the patient will proceed to develop secondary and tertiary syphilis. Condylomata lata, which are flatter and firmer than condylomata acuminata, appear in the perianal region as a manifestation of the secondary stage of syphilis.

HERPES   Anorectal herpes is almost always caused by the type II herpes simplex virus (HSV-2). Symptoms are itching and soreness in the perianal area progressing to severe anorectal pain. Initially, the virus manifests itself as small, discreet groups of vesicles superimposed on an erythematous base. These vesicles enlarge, coalesce, and rupture, forming exquisitely tender aphthous ulcers that appear on the perianal skin, the anoderm, and even the rectal mucosa. The pain and tenesmus from these lesions may be so intense that the patient is reluctant to have a bowel movement, resulting in constipation and possibly fecal impaction.

AIDS-RELATED INFECTIONS   Ironically, infection of the rectum by the human immunodeficiency virus (HIV) per se does not cause any local reaction or symptoms, but its effect on the patient inoculated with this virus can be devastating. Patients who have been rendered immunodeficient by the HIV virus are subject to a variety of opportunistic infections that affect the intestinal, anorectal, and other body systems. Chronic perianal infections with herpes simplex type I as well as type II are commonly seen in AIDS patients. Table 78-3 lists other, more common enteric organisms that infect AIDS patients. Severe rectal pain, diarrhea, and hematochezia are common presenting symptoms.

Herpes simplex type 1
Mycobactrium avium-intracellulare
Cytomegalovirus
Salmonella enterocolitis
Shigella
Campylobacter
Entamoeba
Giardia

TABLE 78-3   Anorectal AIDS-Related Infections

Treatment

Success in the management of patients with acute venereal proctitis depends on suspecting the diagnosis, obtaining specimens to confirm the diagnosis, and initiating therapy as expeditiously as possible. Patients presenting with symptoms of anorectal pain, rectal discharge, and/or tenesmus should be considered to have proctitis until proven otherwise. Anoscopy or proctoscopy, and a Gram stain should be performed to document the presence of acute proctitis. In addition to the appropriate culture specimens, blood should be drawn to check for syphilis.

Antibiotic therapy should not be delayed, pending the results of cultures. Empirical therapy aimed at eradicating gonorrhea, non-LGV chlamydia, and incubating syphilis should be initiated for any patient presenting with symptoms and physical signs suggestive of acute proctitis. This therapy should be administered to all patients with acute proctitis even if there are concomitant lesions suggestive of herpetic or papilloma virus infections. Uncomplicated cases of venereal proctitis respond to the same antiobiotic regimens used for venereal urethritis or cervicitis. (see Chap. 137). As is the case for STDs in general, these patients must be referred for appropriate follow-up to ensure completion of therapy and eradication of disease.

RECTAL PROLAPSE

Rectal prolapse, known as procidentia, is the circumferential protrusion of part or all layers of the rectum through the anal canal. There are three classes of rectal prolapse: (1) prolapse involving the rectal mucosa only, (2) prolapse involving all layers of the rectum, and (3) intussusception of the upper rectum into and through the lower rectum so that the apex of the intussusception protrudes through the anus.

In the first group, seen primarily in children under the age of 2, the prolapse occurs because of the loose attachment of the mucosa to the submucosal layers, and there is an associated weakness of the anal sphincter. In the second and third groups, prolapse occurs because of the laxity of the pelvic fascia and muscles in addition to a generalized weakening of the anal sphincters. In all cases, the rectum does not conform with, but lies anterior to the sacral concavity, thus obliterating the angulation that normally occurs between rectum and anus. The prolapsing mucosa of a partial prolapse rarely protrudes more than 4 cm beyond the anal verge; the mucosal folds emanate in a radial fashion from the central lumen of the prolapsed mucosa. Mucosal prolapse is frequently associated with third- and fourth-degree hemorrhoids (see Table 78-1).

Complete rectal prolapse (procidentia) occurs at the extremes of life, most commonly in elderly women. Multiparity is not a contributing factor to rectal prolapse; there appears to be a higher incidence of prolapse in women who have had a hysterectomy.

Clinical Features

Most patients are able to detect the presence of a mass, especially following defecation or strenuous activity. In more advanced cases, this may be present when they stand or walk. Irritation to the rectal mucosa caused by recurrent prolapse results in a mucous discharge with some associated bleeding. Some patients may present because of blood-stained mucus on their undergarments, others because of fecal incontinence caused by associated anal sphincter weakness. In pediatric patients, parents often mistakenly believe that the prolapsed mucosa is hemorrhoids.

Treatment

In young children, after appropriate analgesia and sedation, prolapse can be reduced manually by replacing the protruding mucosa proximal to the anorectal ring of sphincter muscles. Every effort should be made to prevent the child from becoming constipated, and the child should be referred for further evaluation.

Surgical intervention is generally indicated in all other age groups unless the prolapse is minimal. A variety of effective surgical procedures is available and may be used depending on the degree of prolapse and the general health of the patient. All adults should be referred to have a proctosigmoidoscopic examination to rule out tumor. In addition, one should check for the possibility of an anterior rectal wall ulcer that may occur in patients with recurrent prolapse.

If vascular compromise appears to have occurred, reduction may be necessary on an emergency basis. Because of the risk of having reduced ischemic bowel that could perforate, these patients must be hospitalized.

ANORECTAL TUMORS

Carcinoma of the anal area represents less than 5 percent of all large bowel malignancy. At the level of the dentate line and extending approximately 1 cm proximal is a transitional zone of epithelium connecting the squamous cell epithelium of the anoderm with the columnar epithelium of the rectum. This transition zone includes columnar, cuboidal, transitional, and squamous epithelial cells that represent the source for a variety of malignancies that arise in the anal canal (Table 78-4). For the purpose of grading malignancies, the United Nations World Health Organization has divided the anal canal into two regions: (1) malignancies of the portion proximal to the dentate line and including the transitional zone are referred to as anal canal neoplasms and (2) tumors arising in the anoderm distal to the dentate line are referred to as anal margin neoplasms.

Anal canal neoplasms (proximal to dentate line)
  Adenocarcinoma of the rectum
  Adenocarcinoma of anal glands and ducts
  Mucoepidermoid carcinoma
  Transitional cloacogenic (basaloid) carcinoma
  Squamous cell carcinoma of the anal canal
  Malignant melanoma
  Kaposi's sarcoma
  Villous adenoma of the rectum

Anal margin neoplasms (distal to dentate line)
  Bowen's disease
  Squamous cell carcinoma of anal margin
  Extramammary Paget's disease
  Basal cell carcinoma
  Giant solitary trichoepithelioma

TABLE 78-4 Neoplasms of the Anal Region

Anal margin neoplasms have a low-grade malignant potential and are slow to metastasize. Anal canal neoplasms, on the other hand, are far more virulent, metastasize early, and have a poor prognosis. Squamous cell carcinoma of the anal canal has a much poorer prognosis than its anal margin counterpart. Anal canal malignancies metastasize not only to mesenteric lymph nodes and the portal circulation but also to the regional inguinal nodes and via the systemic circulation.

Included among the anal canal neoplasms is Kaposi's sarcoma, the most common AIDS-related malignancy. The anal canal is the third most common site for malignant melanoma (after the skin and the eye), which, when it occurs there, may not be pigmented and is frequently overlooked.

Clinical Features

Early anal canal malignancies usually cause nonspecific symptoms such as pruritus, pain, and bleeding admixed with stool. The sensation and presence of a lump in the anal canal may be erroneously diagnosed as a hemorrhoid. As the neoplasm progresses, the patient experiences anorexia, weight loss, constipation, narrowing of the caliber of the stool, and eventually tenesmus with or without bowel movement. Complete obstruction may also occur.

Anal canal tumors may produce partial rectal prolapse; hemorrhoidal dilatation and prolapse may also occur. More advanced malignancies may present as perirectal abscesses or fistulas.

Villous adenomas, which arise from the rectal columnar epithelium, frequently produce diarrhea and a profuse rectal discharge, with secondary excoriation of skin and pruritus. Patients may suffer a significant loss of electrolytes, resulting in a clinically significant hypokalemia and/or hyponatremia.

Treatment

The anal margin neoplasms may present as persistent ulcers or as chronic dermatologic conditions such as eczema or mycotic infections. Any ulcer that fails to heal within 30 days or any discrete skin lesion that fails to improve with appropriate therapy must be biopsied to rule out the presence of malignancy.

Virtually all anorectal tumors can be detected by careful visual examination of the perianal area, digital palpation of the distal rectum and anal canal, and procto- or sigmoidoscopic examination. In one review of anal malignancies, 80 percent were in the canal and 20 percent at the anal margin. Failure to look, feel, and think would be the only reason not to suspect the presence of these curable but life-threatening lesions.

RECTAL FOREIGN BODIES

The medical literature is replete with the variety of foreign bodies that have been reported to have been inserted into the rectum. Most foreign bodies are in the rectal ampulla and therefore palpable through digital examination and detectable on proctoscopic examination. Any patient presenting with an intrarectal foreign body must have x-rays of the abdomen taken to demonstrate not only the position, shapes, and number of foreign bodies but also the possible presence of free air. Perforation of the rectum or colon is the most frequent and most serious complication. Perforation may be either extraperitoneal or intraperitoneal; both can result in life-threatening sepsis.

Treatment

Although some foreign bodies can be removed in the ED, many require surgical intervention, particularly if they are made of glass or have sharp edges. If the foreign body is removed in the emergency department and is of a size or shape that could cause perforation, a follow-up proctoscopic examination and x-ray studies must be performed. In questionable cases, observations for at least 12 h should be done to ensure that perforation has not occurred. Rectal and anal lacerations may be present and require repair.

Sphincter relaxation is mandatory for removal of large foreign bodies. If the patient's sphincters are taut or otherwise not sufficiently relaxed, local infiltrative anesthesia must be administered to achieve proper relaxation. After the patient has been sedated and placed in the lithotomy position, local anesthetic is injected through a fine, 30-gauge needle to raise an intradermal wheal at the 6- and 12-o'clock positions. The index finger of the physician's nondominant hand is then inserted into the anal canal to act as a guide for a $1\frac{1}{2}$-in., larger-gauge needle through which anesthetic is injected circumferentially along the internal sphincter muscles as they course along the anal canal. Five milliliters of anesthetic should suffice for each quadrant of infiltration. Large bulbar objects create a vacuumlike effect in the rectal ampulla, making it difficult to retrieve the object by simple traction. The vacuum can be overcome by passing a catheter beyond the object and injecting air. A modification of this technique is to insert Foley catheters around the foreign body and, after the vacuum is relieved by injecting air, inflate the balloons of the Foley catheters and use the catheters as traction devices to deliver the foreign body or manipulate it into a more accessible position.

If there is a risk of perforation or if excess manipulation (potential for bacteremia) will be needed to remove the foreign body, the patient should be prepared for emergency surgery, which includes obtaining appropriate laboratory studies, initiating intravenous therapy with crystalloid solution, and administering a loading dose of broad-spectrum (second-generation cephalosporin) antibiotics.

PRURITUS ANI

Pruritus ani is a symptom complex that occurs secondary to a variety of anal and systemic problems. It is not in itself a specific disease process. It effects men far more often than women, and it occurs most commonly during the fifth and sixth decades of life.

There is an entity of primary or idiopathic pruritus ani, the etiology of which is unknown. To make such a diagnosis, one has to rule out the many specific, known causes of secondary pruritus ani. Even so, idiopathic pruritus ani may occur in association with or be precipitated by secondary pruritus ani. Table 78-5 lists the major categories of the various likely causes of secondary pruritus ani.

Anorectal disease

Dietary factors

Local infection

Local irritants

Dermatologic conditions

Systemic illness

Psychogenic factors

TABLE 78-5   Pruritus Ani

In Table 78-5 "anorectal disease" includes the various categories that have been discussed in this chapter. The pruritus that accompanies such conditions as fissures, fistulas, hemorrhoids, and prolapses occurs as a result of the perianal skin's being exposed to and macerated by constant mucous and purulent discharge. It is probably the increased perianal moisture caused by these conditions that results in itching. The itching triggers a vicious cycle of scratching, excoriation, and more itching.

Numerous dietary factors have been implicated and are associated with secondary pruritus ani, although proof of cause is lacking for most of them. Those dietary factors most commonly listed include excessive consumption of caffeine-containing liquids, such as coffee, tea, or colas, and beer, although one recent study failed to demonstrate any correlation between pruritus ani and alcohol consumption. Milk, chocolate, tomatoes, and citrus fruits are other food products that allegedly contribute to pruritus ani. Likewise, certain drugs, such as colchicine and mineral oil, have been associated with pruritus ani. Ingestion of these products can result in increased liquidity and seepage of fecal material, which in itself is a probable cause of pruritus ani.

Infectious agents that have to be considered as causes of pruritus ani include bacteria, viruses, fungi, spirochetes, and parasites. More common bacterial infections, such as staphylococci and streptococci, in addition to all sexually transmitted organisms, will cause pruritus, if not actual pain. Pinworms (*enterobius/vermicularis*) are the most common cause of anal pruritus in children. *Candida/albicans* is commonly found on the perianal skin but is not usually associated with pruritus; the *Trichophyton* species, on the other hand, are always associated with pruritus.

Local irritants, if not the initial cause, commonly contribute to the incidence of pruritus. Fecal contamination, resulting from poor anal hygiene, is by far the most common irritant to the perianal skin. Lysozyme from intestinal mucous secretions, acting together with bacterial exotoxins to raise the stool and skin pH, will cause pruritus. Ironically, patients who compulsively clean their anus, particularly if they use perfumed toilet tissue, soaps, or detergents or hygiene sprays, cause pruritic reactions. Also, wearing of synthetic, tight-fitting underwear retains moisture that normally occurs in the perianal area, another leading cause of pruritus.

Dermatologic conditions contributing to this symptom complex include atopic dermatitis, lichen planus, psoriasis, and seborrheic dermatitis. Any of the anal margin neoplasms, particularly Bowen's disease and extramammary Paget's disease, may initially manifest itself as pruritus.

Finally, certain systemic conditions, such as diabetes mellitus, lymphoma, and certain vitamin deficiencies (vitamins A and D and niacin), because of their secondary effect on the perianal skin, will cause pruritus.

Clinical Features

Appearance of the perianal skin will depend on the severity and chronicity of the underlying conditions that are causing the pruritus. The skin will appear normal with early, mild cases. With acute, more severe exacerbations, the perianal skin will appear reddened, edematous, and moist; frequently, there are excoriations caused by scratching. In chronic cases, the perianal skin takes on a thickened, almost leathery, depigmented appearance. The normal radiating folds of skin thicken into rugae and may include superficial fissures factitiously induced.

Treatment

Pruritus, like any other symptoms, suggests the presence of an underlying cause that should be diagnosed and treated appropriately. Thus, excision of malignancies or surgical correction of fistulas, prolapses, or hemorrhoids would be the definitive treatment for patients with those conditions.

In most cases, specific anorectal lesions are not apparent, and the patient must be referred to a proctologist or dermatologist for probable long-term management.

In the meantime, the patient should be advised to make certain dietary changes, if appropriate, and should be instructed about proper anal hygiene. Scratching of the area must be avoided; if necessary, the patient should be advised to wear gloves at bedtime, when most of the scratching is likely to occur. Patients with maceration of perianal skin should use moist cotton rather than toilet paper. Soaps should be avoided, and the patient should take sitz baths for at least 15 min two to three times a day. The skin should then be thoroughly dried by gently blotting with a soft cloth. Zinc oxide ointment can provide a protective covering for the perianal skin and may enhance the healing. Fungicidal creams should be prescribed for patients with secondary fungal infections. One percent hydrocortisone cream is effective for the allergic component of the inflammation. Finally, as an adjunct to providing symptomatic relief, consider prescribing hydroxyzine hydrochloride (Atarax) as an effective bedtime sedative.

PILONIDAL SINUS

Pilonidal sinus has nothing to do with the anorectum, anatomically or embryologically. Pilonidal sinuses or cysts occur in the midline in the upper part of the natal cleft overlying the lower sacrum and coccyx. Because of their proximity to the anus, infected pilonidal cysts (abscesses) are sometimes mistakenly diagnosed as perirectal abscesses. An abscessed pilonidal sinus is always located in the midline (although there may be secondary fistulous openings on either side of the midline) and does not communicate with the anorectum. On the other hand, long, horseshoe-type fistulas emanating from a perirectal abscess may drain close to the location of a pilonidal sinus but not in the midline.

Although once thought to be congenital in nature, pilonidal sinus is now considered an acquired problem. The sinus is formed by the penetration of the skin by ingrowing hair, which causes a foreign body granuloma reaction. The sinus is perpetuated by the presence of the hair and repeated bouts of infection. Although

pilonidal sinuses or infected pilonidal cysts occur most commonly before the fourth decade of life, a small portion of patients may develop this problem in their fourth decade. Pilonidal sinus and abscess formation should be considered a chronic and recurring disease.

Carcinoma is a rare complication of chronic, recurring pilonidal sinus disease. It is more frequent in men and is usually a well-differentiated dermal-type squamous cell carcinoma.

Clinical Features

Depending on whether the disease presents as a cyst or a sinus, the patient generally complains of swelling, pain, or a persistent discharge. When abscess formation occurs, the patient complains of a tender mass. Although there may be more than one sinus with several tiny openings in the midline of the intergluateal cleft, the most common finding is that of a single opening from which hair is protruding. Patients usually present to the ED when an abscess has formed that can no longer drain.

Treatment

Surgery is the treatment of choice. Ideally, a patient should undergo elective excision of the entire pilonidal sinus system and primary closure of skin when there is no infection present in any of the sinuses. Minimal excision, and packing using a local anesthetic in the ED results in reoccurrence. Patients presenting with acute inflammation should have their abscess drained in the ED. Their wounds should be allowed to heal, and then, at least 6 weeks later, if there is no evidence of active infection, they should be referred for definitive surgical excision.

The technique for incising and draining a pilonidal abscess is as follows: Place the patient prone on the proctoscopic table with the buttocks retracted laterally. The patient should receive conscious sedation. Tuck an ABD pad between the lower gluteal cleft to prevent the prep solution from pooling at the anus or genitals. After having prepped the skin, infiltrate the area to be incised with an intradermal injection of anesthetic solution, using a fine-gauge needle. A suction apparatus should be available to aspirate the unusually foul-smelling pus that has accumulated within the abscess. Following drainage, gently break down any loculations that may be present and loosely pack the wound with iodoform gauze. A bulky dressing should then be applied and secured with tape. The patient should be given a prescription for a strong oral analgesic and advised to begin hot sitz baths the following day. Before the sitz bath, the patient should remove the outer dressing but should not attempt to remove the packing until after having soaked in hot water for a few minutes. Ideally, one should allow the warm water current to flush the packing out of the wound. The patient should be seen in 48 to 72 h for evaluation and further advice concerning wound management.

Unless the patient is immunocompromised or there is cellulitis, there is no need to obtain cultures or prescribe antibiotics for an abscess that has been adequately drained.

79 VOMITING, DIARRHEA, AND CONSTIPATION

Annie Tewel Sadosty
Brian J. Browne

Vomiting, diarrhea, and constipation are among the most common complaints of patients presenting to emergency departments. Gastrointestinal dysfunction is the final common pathway for a variety of diseases. Therefore, many patients complaining of vomiting, diarrhea, or constipation have a cause for their symptoms remote from the gastrointestinal system. Emergency physicians must consider not only the gastrointestinal emergencies manifested as vomiting, diarrhea, or constipation but also the nongastrointestinal emergencies manifested as gastrointestinal dysfunction.

An important and often difficult step in the evaluation of patients with vomiting, diarrhea, or constipation is having the patient define the illness. The layperson's definitions of *vomiting, diarrhea,* and *constipation* often differ tremendously from the medical definitions. For example, patients often say "vomiting" when they really mean "coughing up sputum." Some patients complain of "constipation" and mean that they are straining to defecate. Defining the complaint allows the physician to treat patients correctly and in turn increases patients' satisfaction. A complete history of the current illness is the first step toward the correct diagnosis.

After defining the illness, the emergency physician's next step is to determine whether the illness represents an emergency. At the end of the emergency department evaluation, the cause of the patient's symptoms may not be clear. Nevertheless, the physician must decide, based on limited information, whether a patient may be discharged safely and what the initial treatment plan will be.

VOMITING

Pathophysiology

Vomiting is a complex, highly coordinated activity involving the gastrointestinal tract, the central nervous system (CNS), and the vestibular system. In 1952, Wang and Borison identified a medullary vomiting center.[1] The proximity of the medullary vomiting center to other CNS nuclei allows for the coordinated activity of vomiting.[1] Three stages of vomiting have been described: nausea, retching, and emesis.[2] With nausea come hypersalivation and tachycardia. Retching occurs when the pylorus contracts and the fundus relaxes, thereby moving food to the gastric cardia. Finally, emesis occurs when the powerful abdominal muscles contract simultaneously and thus eject food or gastric secretions from the stomach.

Clinical Features

HISTORY   There are hundreds of causes of vomiting (Table 79-1). Fortunately, the patient's history often leads the physician to the correct diagnosis. Asking the right questions will help to uncover the etiology.

TABLE 79-1   Vomiting and Diarrhea: The GASTROENTERITIS Mnemonic

First, define the vomitus. Is it bloody, bilious or nonbilious, feculent or posttussive? Hematemesis is seen with gastritis, peptic ulcer disease, gastric and esophageal tumors, and Mallory-Weiss tears. Nonbilious emesis occurs with gastric outlet obstruction, as in patients with pyloric strictures secondary to ulcer disease or infants with pyloric stenosis.

Second, determine what symptoms accompany the vomiting. Is the patient febrile? Fever could point toward an infectious or inflammatory source, or it could represent a toxicologic cause, such as salicylate intoxication. Is there associated abdominal pain, back pain, headache, or chest pain that may point to a specific cause? Pancreatitis, cholecystitis, peptic ulcer disease, appendicitis, and pelvic inflammatory disease typically cause abdominal pain. Back pain usually accompanies aortic dissections, rupturing aortic aneurysms, pyelonephritis, and renal colic. Vomiting is one of the signs of increased intracranial or intraocular pressure and may be a foreboding sign in patients complaining of headache. Finally, the complaint of vomiting associated with chest or epigastric pain might suggest a diagnosis of myocardial ischemia. In female patients, obstetric and gynecologic causes of vomiting should always be considered. In a pregnant woman, epigastric pain and vomiting accompanying hypertension may indicate preeclampsia.

Learning more about the patient is as important as defining the illness. What complicating medical conditions does the patient have? Is the patient diabetic? If so, could the vomiting be a manifestation of diabetic ketoacidosis? In a patient with a history of peripheral vascular disease, vomiting may be a sign of mesenteric ischemia. Patients with a history of multiple abdominal surgeries are at risk for intestinal obstruction due to adhesions. Knowledge of the medications to which the patient has access is also critical, since intentional and unintentional poisonings often present first with emesis. Physicians should be suspicious of drug-induced toxicity in patients taking medicines known to have gastrointestinal toxicity (e.g., lithium, digoxin, or theophylline). The social history provides clues, too. Vomiting in a person who enjoys mushroom hunting may well represent *Amanita* poisoning.

PHYSICAL EXAMINATION   Clinical clues may also assist in making the diagnosis. In addition to evaluating the ABCs, much of the physician's initial attention should be directed toward the assessment of hydration status. Severely volume-depleted patients require immediate intervention, lest circulatory collapse be imminent. The abdominal, genitourinary, and pelvic examinations are often revealing. Physicians should search carefully for tenderness, peritoneal signs, hernias, masses, and evidence of obstruction or torsion. The findings of a careful physical examination may point toward unsuspected causes of vomiting, such as bulimia (scars on the dorsum of hands), pneumonia (consolidative findings on lung examination), or Addison's disease (hyperpigmentation). The rectal examination is important. An anal fistula may be the only clue to Crohn's disease in an otherwise healthy teenager with vomiting, or may demonstrate fecal impaction.

Acquire data selectively and smartly. Order diagnostic tests according to the differential diagnosis. In the vomiting, premenopausal woman, consider pregnancy high on the differential diagnosis, and rule it in or out with a pregnancy test. Other laboratory tests that may be of assistance are determination of blood urea nitrogen, creatinine, and amylase levels; liver function tests; determination of blood alcohol and drug levels; and urinalysis. Addisonian crisis can present with vomiting, and the laboratory results may show hyperkalemia and hyponatremia. An electrocardiogram can help if the physician is considering the diagnosis of myocardial ischemia. Chest and abdominal radiography can assist in the determination of the presence or absence of pneumoperitoneum, pneumonia, or intestinal obstruction.

Treatment

Initial management of the acutely ill, vomiting patient is the same, regardless of cause. The ABCs always take precedence. For patients with circulatory collapse secondary to severe dehydration, aggressive volume repletion must begin immediately upon arrival. Two large-bore intravenous catheters should be placed, and crystalloid should be administered aggressively in order to restore circulation quickly.

For patients with less acute conditions, treatment hinges on making the correct diagnosis. A vomiting patient with diabetic ketoacidosis will not respond to symptomatic therapy with antiemetics: vomiting continues until the underlying illness is treated. It is important, therefore, to recognize the illnesses that are not self-limited and to treat them appropriately. However, not all patients with the chief complaint of vomiting are discharged from the emergency department with a clear diagnosis. These patients should be treated symptomatically, and follow-up should be ensured. For patients with mild-to-moderate dehydration who are actively vomiting, we recommend intravenous rehydration and antiemetic therapy in the form of prochlorperazine [Compazine 10 mg IV or IM q8h or 25 mg rectally q12h] or promethazine (Phenergan 25 mg IM, IV, or rectally q6h). Physicians may prescribe the suppository form of these for the patient to use should vomiting continue at home.

Disposition

Patients with life-threatening causes of vomiting should be admitted to the hospital, as should severely dehydrated patients with presumably self-limited causes of emesis. The patient in whom the diagnosis is unclear, but who the physician feels confident does not have a life-threatening cause of emesis, may be discharged safely, provided the patient tolerates fluids in the emergency department and that follow-up the next day, if vomiting continues, is ensured. A dehydrated patient who cannot tolerate oral intake should not be discharged.

DIARRHEA

Epidemiology

At the turn of the twentieth century, diarrhea was one of the leading causes of death in the United States. In the 1990s, however, diarrhea accounted for less than 0.5 percent of all deaths in the United States.[3] Most diarrheal deaths occur in the elderly and the young.[3,4] Worldwide, however, diarrhea remains one of the leading causes of death. In fact, in 1990, diarrhea was listed as the fourth leading cause of death globally and was responsible for a total of 2.9 million deaths.[5] Despite the low US mortality rate, diarrhea causes significant morbidity. It is the second most common reason for work absenteeism and is estimated to cost $608 million in lost productivity per year.[6,7]

Pathophysiology

There are four basic mechanisms of diarrhea: increased intestinal secretion, decreased intestinal absorption, increased osmotic load, and abnormal intestinal motility. Knowledge of normal intestinal function assists in understanding these various mechanisms. Normally, the jejunum receives between 6 and 8 L/day of fluid in the form of oral intake and gastric, pancreatic, and biliary secretions. Dietary intake actually constitutes a small portion of the jejunal load (1.5 L). A healthy small intestine absorbs nearly 75 percent of the fluid to which it is exposed. The 2 L of fluid not absorbed by the small intestine then enter the colon, where fluid is absorbed at an even higher rate. The absorptive power of the colon approaches 90 percent efficiency and far exceeds that of the small intestine. In fact, the colon can make up for a decrease in small-intestinal absorption. Under normal conditions, very little fluid (<100 mL) is lost in the stool each day.[8]

In diarrheal states, normal intestinal physiology is disrupted. At a cellular level, intestinal absorption occurs through the villi, while secretion occurs through the crypts. Often, in diarrheal states, enterotoxins, inflammation, or ischemia damage the intestinal villi preferentially. As a result, diarrhea occurs because of diminished intestinal villi absorption *and* unopposed crypt secretion (the crypts are more resilient after injury).[9] Diarrhea also accompanies the delivery of an osmotic load to the intestine. For example, administration of a laxative results in the collection of an osmotically active, nondigestible agent within the intestinal lumen. Osmosis occurs, drawing fluid into the intestinal lumen, and results in diarrhea. Finally, increased intestinal motility causes diarrhea, as in patients with irritable bowel syndrome, neuropathies, or a shortened intestine secondary to surgery.

Clinical Features

HISTORY   The definition of diarrhea varies within the medical literature, so it is not surprising that patients' definitions vary too. Many patients come to the emergency department complaining of "diarrhea" when what they really have is soft stools or two stools per day compared with their usual one. Strictly speaking, diarrhea is present when the daily stool weight exceeds 200 g.[10] Practically speaking, however, diarrhea is present when the patient is making more stools of lesser consistency, more frequently.

Once a true diarrheal illness is confirmed, the physician's focus should change toward attempting to ascertain the cause of the diarrhea. As already mentioned, there are many causes of diarrhea (Table 79-1). Fortunately, the history usually leads the physician to the etiology. The first step is to determine whether the diarrhea is acute (<3 weeks) or chronic (>3 weeks). The acute diarrheas are of greatest concern to the emergency physician, for they are more apt to be a manifestation of an immediately life-threatening illness (infection, ischemia, intoxication, or inflammation).[10] The next step is to define the diarrhea. Is it bloody or melanotic? Is it associated with the ingestion of certain foods, such as milk or sorbitol? What symptoms accompany the diarrhea? Is there fever or abdominal pain, which may suggest diverticulitis or infectious gastroenteritis? Seizures accompanying diarrhea often point toward shigellosis but could also indicate theophylline toxicity. Does the patient have heat intolerance and anxiety, suggesting thyrotoxicosis, or paresthesias and reverse temperature sensation, suggesting ciguatera?

Finally, define the host. A patient's medical and surgical history often assists in narrowing the differential diagnosis. For example, diarrhea resulting from malabsorption secondary to pancreatic exocrine insufficiency need not be considered in an otherwise healthy host. Conversely, the differential diagnosis for diarrhea is broadened for a patient with acquired immunodeficiency syndrome (AIDS). Medications commonly have diarrhea as a side effect or sequel. Is the patient taking medication that may have contributed to the diarrhea (e.g., antibiotics, lithium, chemotherapy, colchicine, and laxatives)? Has the patient traveled outside the United States or to the countryside recently? Rural hiking places the patient at risk for *Giardia*, particularly if water purification procedures were not strictly followed, and travel to Third World countries increases the chances of parasitic infection. Sexual and occupational histories are also important. A patient's sexual preference or occupation may be the physician's only clue to a diagnosis of gay bowel disease or organophosphate poisoning.

PHYSICAL EXAMINATION   As with a vomiting patient, the examination begins with the ABCs. Thus, assessment of hydration status occurs shortly after the physician arrives at the bedside. Like the history, a careful physical examination can help narrow the differential diagnosis. Only by doing a thyroid examination can the physician discover a thyroid mass that may be contributing to diarrhea. Abdominal and rectal examinations are critical. Especially in the elderly, fecal impaction may result in diarrhea as liquid stool passes around the impaction. Special attention should be given to the presence or absence of surgical scars, tenderness, masses, or peritoneal signs. Checking the stool for the presence or absence of blood is also important, since bloody diarrhea can be caused by inflammation, infection, or

ischemia. An elderly patient with bloody diarrhea and abdominal pain out of proportion to the physical examination may have mesenteric ischemia—a true emergency.

DIAGNOSTIC STOOL EVALUATION   Tests specific to the emergency department evaluation of a patient with diarrhea include Wright's stain for fecal leukocytes; stool culture for bacteria, ova, and parasites; and stool analysis for *Clostridium difficile* toxin. Diagnostic testing, while rarely helpful to the emergency physician, occasionally is helpful to the primary care physician. Who should be tested? Stool cultures for bacteria should be obtained in children, toxic patients, patients with a protracted diarrheal illness lasting longer than 3 days, and immunocompromised patients in whom infectious diarrhea is suspected. A request for an ova and parasite evaluation can be made for patients at risk for parasitic disease. In adddition, patients at risk for *C. difficile* colitis should have a stool sample sent for *C. difficile* toxin assay.

Wright's Stain   When applied to a stool sample, Wright's stain allows detection of fecal leukocytes. A positive Wright's stain has a sensitivity of 82 percent and a specificity of 83 percent for the presence of bacterial pathogen. [11] Historically, Wright's stain for fecal leukocytes has been used to differentiate invasive and noninvasive infectious diarrheas. In the past, this was an important distinction because physicians were reluctant to prescribe antibiotics for patients with infectious diarrhea because of the fear of prolonging the *Salmonella* carrier state. They therefore reserved antimicrobial treatment for the toxic patients who they felt *truly* had invasive diarrhea. Recently, this dictum has been questioned, and many physicians now treat patients with diarrheal illness with antibiotics regardless of whether or not the diarrhea is invasive or bacterial in origin. [15] Therefore, ascertaining the presence or absence of fecal leukocytes is superfluous if it does not change management.

Bacterial Stool Culture   Bacterial stool culture is an expensive and labor-intensive diagnostic test that plays a minor role in the emergency department evaluation of a patient with diarrhea. Most laboratories culture for only three common bacterial pathogens: *Salmonella*, *Shigella*, and *Campylobacter*. Because of a low sensitivity for detecting pathogens, each positive routine stool culture costs the laboratory approximately $950 to $1200, depending on the number of samples tested and the number of tests run on each sample.[9] To limit cost and increase yield, diagnostic testing should be limited to patients with high pretest probabilities of bacterial disease: severely dehydrated or toxic patients, children, immunocompromised patients, and patients with diarrhea lasting longer than 3 days. [9] In addition, if other enteric pathogens are suspected, the laboratory should be notified so that appropriate testing may be performed.

Ova and Parasitic Evaluation   Patients in whom a parasitic cause of diarrhea is suspected should have stool sent for evaluation for ova and parasites. These tests lack sensitivity, since many parasites are fastidious. Recently, direct immunoflouresence staining has been shown to improve the sensitivity for detecting *Giardia* and *Cryptosporidium*.[12]

***Clostridium Difficile* Toxin Assay**   Diarrhea in a patient with an antecedent history of antibiotic use may be caused by pseudomembranous colitis from *C. difficile* infection. This is diagnosed with the *C. difficile* toxin assay. Unfortunately, this assay has a 10 percent false-negative rate and is rarely available to the emergency physician, since the turnaround time on the test approaches 24 h. [13]

Other Diagnostic Tests   If diarrhea is not felt to be infectious in origin, data acquisition should be dictated by the differential diagnosis. Rarely are serum chemistry results or complete blood count results diagnostic or necessary. Electrolyte measurements are warranted in severely dehydrated patients, regardless of the cause of dehydration. They can also be helpful in patients experiencing an addisonian crisis. Serum drug levels can assist the physician in making the diagnosis of theophylline, lithium, or heavy metal intoxication. In patients with a history of abdominal surgery, abdominal films may help rule out partial obstruction as a cause of diarrhea. Finally, a chest radiograph may help diagnose an occult pneumonia (i.e., *Legionella*) in a patient with diarrhea and a cough. For patients in whom mesenteric ischemia is suspected, mesenteric angiography is the test of choice.

Treatment

Initial treatment of any patient begins with the ABCs. Patients with diarrhea are no different. Diarrhea of any type can cause circulatory collapse. Rehydration of severely dehydrated patients should begin immediately after large-bore intravenous access is achieved. Thereafter, treatment is dictated by the differential diagnosis. The emergency medicine approach to a patient with diarrhea, therefore, hinges on treating or excluding the life-threatening causes of diarrhea. Because infectious diarrhea is the most common cause of acute diarrhea, after the differential diagnosis is considered, physicians most commonly are left considering that diagnosis.

NONINFECTIOUS DIARRHEA   Almost all true diarrheal emergencies (e.g., gastrointestinal bleed, adrenal insufficiency, thyroid storm, toxicologic exposures, acute radiation syndrome, and mesenteric ischemia, all discussed elsewhere in this textbook) are of noninfectious origin. The emergency physician must be ever mindful of them because patients with those conditions require intensive treatment and hospitalization. The less emergent, noninfectious causes of diarrhea are listed in Table 79-1. They, too, are covered elsewhere in this textbook.

INFECTIOUS DIARRHEA   Viruses cause the vast majority of infectious diarrheas, followed by bacterial and parasitic organisms. Treatment of infectious diarrhea involves antibiotic therapy, antimotility agents, restoration of fluid balance, and avoidance of agents that worsen diarrhea. For the past 30 years, two pervasive myths involving the use of antibiotics and antimotility agents in the treatment of infectious diarrhea have dictated the management of large numbers of patients with diarrhea. These myths are discussed in detail below, and a discussion of the modern medical approach to infectious diarrhea follows.

Antibiotics   MYTH   For years, physicians avoided antibiotic use in the treatment of infectious diarrhea because of a fear of prolonging the *Salmonella* carrier state. This fear arose from an article published in 1969 in which the duration of *Salmonella* excretion following a salmonellosis epidemic was studied. [14] The study compared the length of excretion in patients who received antibiotics (ampicillin or chloramphenicol) with that of patients who were not treated and found that *Salmonella* excretion was longer in the cohort that received antibiotics. The authors concluded that, because of a prolonged carrier state, antibiotics should not be given to patients suspected of having a diarrheal illness due to *Salmonella*.

MODERN MEDICINE   For adults with domestically acquired diarrhea in whom the origin is felt to be infectious, antibiotics [ciprofloxacin 500 mg by mouth (PO) bid for 5 days] shorten the duration of illness by approximately 24 h. Regardless of the causative agent, all patients—even those who had a negative Wright's stain, negative stool culture, and a low diarrheal illness score, suggesting less clinically significant disease and/or a viral cause—improved on ciprofloxacin. [15] Even though most infectious diarrheas are self-limited, because of the inconveniencing and occasionally life-threatening nature of the disease, we recommend ciprofloxacin treatment for all patients believed to have an infectious diarrhea who do not have a contraindication to antimicrobial treatment (e.g., pediatric age group, allergy, pregnancy, or drug interaction). Single-dose and 3-day ciprofloxacin regimens have been proposed but deserve further investigation. Trimethoprim-sulfamethoxazole (Bactrim DS on tablet PO bid for 5 days) also shortens the duration of infectious diarrhea in adults but was proven to be inferior to a 5-day course of ciprofloxacin in the above-mentioned study.

Antimotility Agents   MYTH   Since the early 1960s, the use of antimotility agents in the treatment of diarrhea has been denounced by most of the medical community. This dictum emerged out of a 1963 study published by Formal and colleagues. [16] In this study, guinea pigs were starved and poisoned to make them susceptible to *Shigella* infection (an organism to which guinea pigs are not usually susceptible). They were then innoculated with *Shigella,* and a subset of the study was then given opium. The authors discovered an association between opium administration and fatal *Shigella* infection. From these data, the authors concluded that a major defense mechanism of the guinea pig is its peristaltic activity and that antimotility agents (opium) might increase susceptibility to enteric infection.

A study in 1973 on human volunteers perpetuated the myth. In this study, DuPont and Hornick examined, among other things, the effect of diphenoxylate and atropine (Lomotil) on shigellosis. [17] The authors found that Lomotil seemed to diminish the number of unformed stools but in so doing may have increased patients' susceptibility to invasive infection, since fever was prolonged only in the patients receiving Lomotil. However, the sample size in this study was 25, and there were four treatment arms, making the number of patients in each treatment arm approximately six. The authors admitted that the study was inconclusive due to its small sample size and suggested that further investigation occur before conclusions could be made regarding the use of Lomotil in infectious diarrhea. Nevertheless, the two studies led to a nearly universal avoidance of the use of antimotility agents in patients with infectious diarrhea.

MODERN MEDICINE   In 1990, Ericsson, DuPont, Mathewson, and colleagues[18] published a paper that addressed the use of loperamide (Imodium) in the treatment of traveler's diarrhea. In a study of 227 adults with acute diarrhea, combination treatment with Bactrim and loperamide was proven to be both safe and effective in treating traveler's diarrhea. In 1993, a randomized, placebo-controlled, double-blind study was performed in Thailand comparing the use of ciprofloxacin and loperamide with ciprofloxacin and placebo in the treatment of adults with bacillary dysentery. [19] The study showed that loperamide combined with ciprofloxacin decreased the number of diarrheal stools and shortened the duration of illness in adult patients with dysentery due to *Shigella* or enteroinvasive *Escherichia coli*. No complications were seen in the group treated with loperamide. Although the study size was small (*n* = 88), it was much larger than DuPont's 1973 study,[17] and it was

the first of its kind to suggest the safety of antimotility agents in the treatment of adult invasive diarrheas. We therefore recommend the prescription of loperamide 4 mg PO initially, then 2 mg PO after each diarrheal stool to a maximum of 16 mg/d, since it has clearly been proven to shorten duration of symptoms when combined with an antibiotic regimen. Diphenoxylate and atropine (Lomotil) is a more potent antidiarrheal whose modern-day safety is less well studied. For patients with severely inconveniencing diarrhea refractory to loperamide, diphenoxylate and atropine (Lomotil two tablets PO qid) may be helpful. It should be used with caution, however, in patients with a history of constipation or cardiac disease.

Rehydration   For patients presenting to the emergency department with significant dehydration, intravenous fluid therapy is indicated. For a mildly dehydrated patient who is not vomiting, oral rehydration therapy is recommended. Glucose-containing, caffeine-free beverages are the fluids of choice. For patients who can afford to buy it, Gatorade is a good rehydration choice. Otherwise, the World Health Organization recipe for oral rehydration solution can be followed easily and inexpensively (Table 79-2). Mildly dehydrated patients should aim to drink 30 to 50 mL/kg over the next 4 h. For moderate dehydration, patients should drink 100 mL/kg over the next 4 h.[10]

1 L sterile water (boiled or bottled)
1 cup orange juice
4 tsp sugar
1 tsp baking powder
½ tsp salt

Source: From Park and Giannella,[8] with permission.

TABLE 79-2   World Health Organization Recipe for Oral Rehydration Therapy

Dietary Restrictions   Patients should be counseled to avoid caffeine, sorbitol-containing chewing gum, lactose, and raw fruits until after the diarrhea subsides.

Disposition

Patients with the noninfectious emergencies outlined above warrant hospitalization. Most other patients can be discharged home safely. When deciding whether to admit a patient with diarrhea, conservatism should be the rule with the young and the elderly. They do have higher morbidity and mortality rates and should be evaluated with a careful eye. Regardless of age, any toxic patient should be admitted, as should any patient who cannot convincingly comply with oral rehydration guidelines. Upon discharge, patients with infectious diarrhea should be counseled on limiting the spread of disease through the use of judicious hand washing. Work excuses should be given liberally to patients employed in the food, day care, and health care industries.

CONSTIPATION

Epidemiology

Constipation is the most common digestive complaint in the United States and accounts for more than 2.5 million physician visits per year. [20,21] There is an age-related increase in the incidence of constipation, with 30 to 40 percent of adults over age 65 citing constipation as a problem. [21,22]

Pathophysiology

The cause of constipation is usually multifactorial. Dietary intake affects bowel motility. Diminishing intake of fiber associated with decreased fluid intake can result in constipation. In addition, exercise, medical conditions, and medications affect gut motility. Sedentary patients often become constipated. Medical conditions such as hypothyroidism, hyperparathyroidism, lead poisoning, and chronic neurologic disorders are well-known causes. Some anal pathologic conditions cause painful defecation and in turn can result in constipation due to consequent fear, particularly in children. Patients confined to a hospital bed after an orthopedic injury, for example, may become constipated due to their inability to use a bedpan successfully. Certain medications, such as calcium-channel blockers, iron, narcotic analgesics, and antipsychotics, are also common causes of constipation. Indeed, constipation is a complicated condition with multiple causes (Table 79-3).

ACUTE OR SUBACUTE
Gastrointestinal: obstructing cancer, volvulus, stricture, hernia, adhesion, pelvic or abdominal masses
Medicinal: addition of new medicine (e.g., antipsychotic, anticholinergic, narcotic analgesic, antacids)
Environmental: change in defecation regimen (e.g., forced to use bedpan)
Exercise and diet: decrease in level of exercise, fiber intake, fluid intake
CHRONIC
Gastrointestinal: slowly growing tumor, colonic dysmotility, anal pathology
Medicinal: chronic laxative abuse, antipsychotics, anticholinergics, narcotic analgesics
Neurologic: neuropathy, Parkinson's disease, paraplegia, cerebral palsy
Endocrine: diabetes, hypothyroidism, hyperparathyroidism
Rheumatologic: scleroderma
Toxicologic: lead poisoning

TABLE 79-3   Differential Diagnosis of Constipation

Clinical Features

HISTORY   As with diarrhea, part of the challenge of treating patients with the complaint of constipation is determining whether they actually are constipated. The easiest, most practical definition of *constipation* is the following: the presence of hard stools that are difficult to pass. Some patients become bowel fixated and feel they are constipated if they do not have a daily bowel movement. They are not.

Once a physician determines that a patient truly is constipated, the physician must attempt to determine the cause. The differential diagnosis is broad (Table 79-3). Determining the onset of the constipation helps narrow the differential diagnosis. Acute constipation represents intestinal obstruction until proven otherwise. Tumors, strictures, and volvuli can all present as acute constipation. Physicians often mistake subacute for chronic constipation. The important distinction here is to determine exactly when bowel habits changed. Generally, acute and subacute conditions have the same differential diagnosis. Chronic constipation, that is, a lifelong or persistent habit, is usually less ominous and, if uncomplicated, can often be managed on an outpatient basis. The presence or absence of associated symptoms may help guide decision making. Vomiting rarely accompanies benign constipation. Inability to pass flatus also raises concern about obstruction. A history of gradually diminishing stool caliber may suggest colon cancer, especially if accompanied by weight loss. The physician should ask the patient about recent changes in dietary fiber or fluid intake. What other medical problems does the patient have? Is there a history of hypothyroidism or diabetes? An antecedent history of diverticulitis may point toward inflammatory stricture. A history of nephrolithiasis could suggest hyperparathyroidism as a cause for constipation. A quick review of the patient's medication list may also point to the culprit.

PHYSICAL EXAMINATION   The physical examination should concentrate on ruling out organic causes of constipation. First and foremost, intestinal obstruction must

be ruled out. The patient should be examined carefully for the presence or absence of hernias and abdominal or pelvic masses. Rectal and pelvic examinations are necessary. In addition to detecting the presence or absence of an obstructing rectal mass, rectal examination also enables the physician to ascertain whether there is fecal impaction. Anal fissures are also detected during the rectal examination. In addition, rectal examination allows the physician to determine whether the stools are bloody. Guaiac-positive stools can be seen in both functional constipation and constipation resulting from colon cancer. With constipation resulting in fecal impaction, rectal mucosa often ulcerates, forming stercoral ulcers on the rectal walls, which yield guaiac-positive stools. With constipation caused by tumor, stools are also often guaiac positive. Constipation and new ascites in postmenopausal women should prompt evaluation for ovarian or uterine carcinoma. Signs of hypothyroidism may also be evident during the physical examination.

The evaluation of a constipated patient depends on the clinician's level of concern for organic causes of constipation. Patients with a long-standing history of constipation often require little, if any, data acquisition, provided the history and physical examination do not point toward an organic process. An upright chest film and abdominal flat and erect films should be obtained in patients who are at risk for intestinal obstruction: patients with prior abdominal surgery, associated vomiting, significant abdominal distention, abdominal pain, and an acute or subacute history of constipation. In addition to assessing the presence or absence of intestinal obstruction, abdominal films allow the physician to assess stool burden. In patients in whom an organic cause for constipation is suspected, a complete blood count should be obtained to screen for anemia. In addition, thyroid function tests may be helpful with patients in whom the physician suspects hypothyroidism. Electrolyte abnormalities, specifically hypokalemia and hypercalcemia, can be associated with constipation and are worth checking with patients suspected of having an organic cause.

Treatment

FUNCTIONAL CONSTIPATION   The treatment of functional (chronic) constipation involves a multidisciplinary approach. Many patients come to the emergency department looking for medication. Medications often employed in the treatment of constipation are listed in Table 79-4. However, the most important part of treatment is dietary and behavior modification. The most important prescription a patient with constipation receives is for a strict dietary and exercise regimen, for without adequate fluid (1.5 L/day), fiber (10 g/day), and exercise, medicinal methods usually fail. [21] In addition, patients should be urged to take advantage of the gastrocolic reflex by attempting to defecate daily after a certain meal.

TABLE 79-4   Medicinal Adjuncts Used in the Treatment of Constipation

In its extreme form, functional constipation can result in a variety of potentially life-threatening complications. Fecal impaction and intestinal pseudo-obstruction are two sequelae of which the emergency physician should be acutely aware.

Fecal Impaction   Patients with fecal impaction must be disimpacted manually prior to leaving the emergency department. Manual disimpaction is not a glamorous procedure, and, as a result, many physicians avoid doing it. This is unfortunate, since enemas—the alternative therapy—rarely work for fecal impaction. It must be remembered that manual disimpaction can be a painful procedure for which patients at times require sedation. After disimpaction, a host of medicines may be used to assist the patient in achieving normal fecal flow (Table 79-4). The agents listed in the table start with the least potent and end with the most potent.

Intestinal Pseudo-Obstruction   Intestinal pseudo-obstruction is a condition seen in patients with a long-standing history of colonic dysmotility. Patients present in a manner that mimics intestinal obstruction: abdominal distention, crampy abdominal pain, and obstipation. Abdominal x-ray films may reveal a severely dilated colon. Treatment is varied and is best determined in consultation with a surgeon. Sometimes the symptoms resolve with conservative management. Other times, however, patients require operative or colonoscopic decompression of the very dilated intestine.

ORGANIC CONSTIPATION   The treatment of organic constipation is dictated by the cause of the constipation. In the emergency department, the precise cause of the constipation is not always known. Emergency physicians often suspect organic causes, such as hypothyroidism and hyperparathyroidism, but seldom actually confirm these diagnoses in the emergency department. Patients in whom an organic cause of constipation is suspected and who are without evidence of obstruction may start a bowel-cleansing regimen in accordance with Table 79-4. Fecal impaction occurs with organic constipation (i.e., hypothyroidism or hyperparathyroidism) also and must be managed aggressively, as outlined above.

Constipation caused by intestinal obstruction is an emergency. Definitive treatment is dictated by the cause of the obstruction. For example, sigmoid volvulus can often be reduced by means of rigid sigmoidoscopy. Large-bowel obstruction resulting from colon cancer requires operative management. Regardless of the cause, intestinal obstruction warrants surgical consultation to assist with management decisions.

Disposition

Patients with functional constipation with or without fecal impaction can be managed safely as outpatients provided patients with fecal impaction are disimpacted manually prior to discharge. Patients with organic constipation of a nonobstructive cause can also be managed safely as outpatients. The primary care provider should be contacted to ensure follow-up and to communicate concern for an organic process. If thyroid function tests were performed, the primary care doctor should be informed so that they may be followed up.

Referral to a gastroenterologist is warranted for patients with constipation of recent onset; chronic constipation associated with weight loss, anemia, or change in stool caliber; refractory constipation; and constipation requiring chronic laxative use. [21]

Finally, patients with organic constipation of obstructive origin require hospitalization and surgical evaluation. The type of bed to which the patient is admitted is dictated by the patient's clinical picture.

80 JAUNDICE

Richard O. Shields, Jr.

Jaundice is a physical finding that emergency physicians see both as a presenting complaint and as an abnormal finding during the evaluation of other complaints and symptoms. Except in neonates, jaundice itself causes no adverse effects; it serves as a clinical marker of a defect in the metabolism and excretion of bilirubin. The emergency physician must identify those jaundiced patients who require inpatient treatment of the underlying problem and initiate the laboratory or imaging studies on those who will be worked up as outpatients and arrange for their follow-up care.

PATHOPHYSIOLOGY

Jaundice (also called icterus) is the yellowish discoloration of the sclera, skin, and mucous membranes caused by the deposition of bile pigments associated with elevated levels of bilirubin in the blood (hyperbilirubinemia). Jaundice can usually be clinically detected when serum bilirubin levels reach 2.0 to 2.5 mg/dL or above, about twice the upper level of normal. It is usually first noticed in the sclera because scleral tissue contains a large amount of elastin, which has a high affinity for bilirubin. Jaundice is easier to detect in people with light complexions and in the presence of significant anemia. The brownish discoloration of the sclerae in many people with darker complexions may be confused with scleral icterus and makes it more difficult to detect. A greenish tint to the skin indicates long-standing jaundice during which some of the bilirubin deposited in the skin has been metabolized to biliverdin. A yellow-orange discoloration of the skin can be caused by the presence of high levels of carotene in the blood (resulting from the dietary intake of large amounts of beta-carotene) or by longstanding hemochromatosis. Neither of these will discolor the sclera, however.

Bilirubin, a breakdown product of hemoglobin from injured or senescent red blood cells and other heme-containing proteins, is produced in the reticuloendothelial system and then released into the plasma, where it is bound to albumin. Hepatocytes take up the bilirubin, conjugate it (mostly as the mono- and diglucuronide) and excrete it through the bile channels into the small intestine. In the gut, bacterial enzymes release some of the bilirubin and reduce it to urobilinogen and the other pigments that give fecal material its typical color. Some urobilinogen is reabsorbed into the portal circulation, where most is taken up by the liver and reexcreted into the bile. A small amount reaches the kidneys and is excreted unchanged into the urine. Hyperbilirubinemia and jaundice, therefore, can be produced by an overproduction of bilirubin in the reticuloendothelial system, a failure of hepatocyte uptake of bilirubin, a failure of the hepatocyte to conjugate or excrete bilirubin, or an obstruction of biliary excretion into the intestine (Table 80-1).[1]

TABLE 80-1   Causes of Jaundice

Depending on whether the defect occurs before or after the conjugation phase in the hepatocyte, two types of hyperbilirubinemia can be produced: unconjugated and conjugated. If increased production of bilirubin exceeds the ability of the liver to process it or if there is a defect in bilirubin uptake or conjugation, then levels of the unconjugated form will rise, producing unconjugated hyperbilirubinemia. Causes include hemolysis from hemoglobinopathies, hemolytic anemias, or transfusion reactions, and in-born errors of bilirubin metabolism.

If the liver can produce but not normally excrete conjugated bilirubin because of a metabolic defect or intra- or extrahepatic obstruction, conjugated hyperbilirubinemia and cholestasis results. Intrahepatic cholestasis is caused by decreased excretion of conjugated bilirubin, hepatocellular damage, or damage to the biliary endothelium. Obstruction of biliary outflow by a congenital defect, inflammation, a mass lesion, or gallstones produces extrahepatic cholestasis.

Jaundice can also be classified as hemolytic (or prehepatic), hepatocellular (or hepatic), and obstructive (or posthepatic), depending on the location of the pathologic mechanism.[1] More than one type can be present in a given patient.

CLINICAL FEATURES

A careful history and physical examination coupled with judicious use of the clinical laboratory enables the emergency physician to determine whether jaundice is produced by a hemolytic process, hepatocellular disease, or a potentially surgically correctable obstructive process. Often, more extensive diagnostic procedures are needed before the precise etiology of jaundice can be determined.

The sudden appearance of jaundice in a previously healthy young person, especially if preceded by a brief prodrome of fever, malaise, and myalgias, is likely to be caused by a viral hepatitis. Inquire about body fluid exposure over the previous few months, including transfusion of blood products, intimate contact with someone with hepatitis or jaundice, promiscuous sexual activity, intravenous drug use, accidental needle-stick injuries or mucosal contact with body fluids, travel to countries where hepatitis is prevalent, raw shellfish ingestion, and recent tattoos or body piercing. Many times, however, no history of exposure can be elicited. Right upper quadrant pain and tenderness and hepatomegaly may be present, but pruritis is usually absent. Examine for needle tracks, since patients may not volunteer a history of drug use.

Jaundice that develops gradually and is accompanied by weakness, peripheral muscle wasting, ascites, spider angiomata, pruritus, and symptoms of portal hypertension is frequently caused by alcoholic liver disease and cirrhosis. A history of sustained, significant alcohol intake should be elicited from the patient or from family and friends. A history of any previous episodes of jaundice, pancreatitis, or hematemesis should be obtained. Fever, vomiting, and right upper quadrant tenderness accompany episodes of alcoholic hepatitis. The presence of asterixis, fetor hepaticus, or encephalopathy indicates advanced disease.

Toxic hepatitis should be suspected if a history of ingestion or exposure to a known hepatotoxin is obtained. Signs of hepatocellular damage may be present with toxicity from agents such as acetaminophen, halothane, methyldopa, isoniazid, or phenytoin. Cholestatic changes predominate in toxicity from anabolic steroids, oral contraceptives, and chlorpromazine. Mushroom poisoning, carbon tetrachloride, and phosphorus can produce massive hepatic necrosis.

A family history of jaundice or a history of recurrent mild jaundice that resolves spontaneously is most consistent with a familial cause, such as Gilbert's syndrome. Most patients with sickle cell disease develop chronic jaundice, but in the presence of abdominal pain, vomiting, and fever, acute cholecystitis or biliary obstruction

must be strongly suspected. The patient should also be asked about other hemoglobinopathies or prior episodes of hemolysis.

Jaundice that develops acutely with abdominal pain, vomiting, fever, and right upper quadrant tenderness is strongly suggestive of acute biliary obstruction from choledocholithiasis. A history of fatty food intolerance and typical biliary colic is supportive. Cholecystitis alone does not produce jaundice. Painless jaundice in an older patient, especially if accompanied by an epigastric mass and weight loss, strongly suggests biliary obstruction from a malignancy. A history of known gastrointestinal malignancy accompanied by a hard, nodular liver indicates metastatic disease as the cause of jaundice. A history of prior biliary tract surgery, pancreatitis, cholangitis, or inflammatory bowel disease should be elicited, since they may be associated with the development of biliary obstruction.

Hepatomegaly with pedal edema, jugular venous distention, and a gallop rhythm makes congestive cardiac failure the likely cause of jaundice.

Laboratory Evaluation

The initial laboratory evaluation of the jaundiced patient should include determinations of the serum bilirubin level (both total and the direct-reacting fraction), the serum liver aminotransferase levels, and the serum alkaline phosphatase level; urinalysis for bilirubin and urobilinogen; a complete blood count; and any other pertinent tests suggested by the physical examination and history (e.g., determinations of serum amylase or lipase levels, and prothrombin time). The serum bilirubin level is measured by the van den Bergh reaction using two techniques to measure both total bilirubin and conjugated bilirubin (the direct fraction). The indirect fraction can then be calculated by subtracting the direct fraction from the total.

If the patient has unconjugated hyperbilirubinemia, the bilirubin is usually only mildly elevated and consists predominately (more than 85 percent) of the indirect fraction. Since unconjugated bilirubin is tightly bound to albumin, it does not appear in the urine. Liver aminotransferase levels will be normal, and the blood count and smear may show evidence of anemia or hemolysis. A Coombs test and hemoglobin electrophoresis may be helpful if no history of hemolytic anemia or hemoglobinopathy is known. Gilbert's syndrome is the most common cause of mild unconjugated hyperbilirubinemia. This is an inherited deficiency in bilirubin conjugation that produces no symptoms other than variable elevations of bilirubin and no adverse effects. Factors that can cause bilirubin to rise include fever, heavy physical exertion, fasting, surgery, and heavy alcohol consumption.

A direct-reacting fraction of at least 30 percent (and usually much higher) is present with conjugated hyperbilirubinemia. Conjugated bilirubin is water soluble and appears in the urine at very low serum concentrations. Urobilinogen will be absent from the urine if significant cholestasis is present. If liver enzyme levels are normal, the jaundice is caused by sepsis or recent systemic infection, in-born errors of bilirubin metabolism (such as Rotor syndrome or Dubin-Johnson syndrome), or pregnancy rather than by primary hepatic disease. If liver enzyme levels are abnormal, which is much more common, the pattern of abnormality suggests the cause. Predominance of aminotransferase elevation is more suggestive of hepatocellular disease, such as viral or toxic hepatitis or cirrhosis, while marked elevations of alkaline phosphatase (two to three times normal) and g-glutamyl transpeptidase suggest intra- or extrahepatic obstruction, such as malignancy or gallstones.

Further laboratory testing and imaging studies should be undertaken next, directed by which type of jaundice is present. If the initial laboratory studies suggest hepatocellular disease and the clinical examination suggests viral hepatitis, then serologic studies for viral hepatitis should be done. If the clinical picture points to alcoholic liver disease or other toxins, then prothrombin time, platelet count, and serum albumin levels should be determined to help estimate the degree of liver injury. If results of the serologic studies are negative, there is no improvement with withdrawal of the suspected toxic agent, or there is no other obvious etiology, liver biopsy should be considered.[2]

If the clinical examination and initial laboratory findings suggest intrahepatic cholestasis or extrahepatic biliary obstruction, ultrasound studies should be performed to look for gallstones, dilated extrahepatic biliary ducts, or masses in the liver, pancreas, or portal area. Computed tomography can also be used but is usually more costly, involves radiation exposure, and is less sensitive than is ultrasound at detecting stones in the gallbladder.

DISPOSITION

Jaundice alone is not an indication for admission. A hemodynamically stable patient with new-onset jaundice without evidence of liver failure or acute biliary obstruction can be discharged from the emergency department if the appropriate laboratory studies have been ordered and follow-up has been arranged. Surgical consultation should be obtained if extrahepatic biliary obstruction is suspected. For other admission indicators, refer to the appropriate chapters in this text (Chap. 81 and Chap. 82).

81 CHOLECYSTITIS AND BILIARY COLIC

Tom P. Aufderheide
William J. Brady
Judith E. Tintinalli

Biliary tract emergencies result primarily from obstruction by biliary calculi in the gallbladder and bile ducts. The four major biliary tract emergencies related to gallstones include biliary colic, cholecystitis, gallstone pancreatitis, and ascending cholangitis. While gallstones are common, most are asymptomatic. The incidence of new-onset biliary pain among patients with previously asymptomatic gallstones is about 2 percent per year for the first 5 years and 15 percent at 10 years. [1] Although the classic patient with symptomatic biliary tract disease is an obese female aged 20 to 40 years, the disease occurs in all age groups and must be especially considered in diabetics and the elderly. [2] In both men and women, age over 60, right upper quadrant (RUQ) pain has the highest positive predictive value (11 to 16 percent) for gallstones. [3]

A number of risk factors are associated with cholecystitis and calculi, including increased age, female sex, parity, obesity, diabetes, profound weight loss, prolonged fasting, cystic fibrosis, intestinal malabsorption syndromes, various medications (particularly oral contraceptive agents and clofibrate), and a familial tendency. Clinical characteristics associated with an increased risk of the development of pigment stones are Asian descent, chronic biliary tract infection, parasitic infection (e.g., *Ascaris lumbricoides*), chronic liver disease (particularly related to alcohol), and chronic intravascular hemolysis (sickle cell anemia and hereditary spherocytosis). Hepatitis A, B, C, and E; HIV; and the herpesviruses are associated with viral cholangitis and hepatitis. [4]

PATHOPHYSIOLOGY

Bile is manufactured in and secreted from hepatocytes and transported to the gallbladder for storage via the canaliculi, ductiles, and bile ducts. The bile ducts become progressively larger and eventually coalesce to form the right and left hepatic ducts, which unite to form the common hepatic duct. The common hepatic duct joins with the cystic duct from the gallbladder to form the common bile duct, which empties into the duodenum through the ampulla of Vater. The pancreatic duct often merges with the common bile duct immediately prior to entering the duodenum. The wall of the gallbladder is innervated with sympathetic and parasympathetic nerves from the celiac plexus. [5]

Bile is composed primarily of water (80 percent), bile acids (10 percent), lecithin and other phospholipids (4 to 5 percent), cholesterol (1 percent), conjugated bilirubin, electrolytes, mucus, and various proteins. The major stimulus for release of bile is the gastrointestinal hormone cholecystokinin, which is secreted from the small intestinal mucosal cells when fats and amino acids enter the duodenum. Cholecystokinin causes forceful contraction of the gallbladder, relaxation of the sphincter of Oddi, increased hepatic bile production, and ultimately release of bile into the duodenum for digestion of a meal. Approximately 95 percent of bile is conserved via enterohepatic circulation.

Gallstones, crystalline structures formed from both normal and abnormal bile components, are divided into three major types: cholesterol (70 percent), pigment (20 percent), and mixed (10 percent). Cholesterol stones, the most commonly encountered gallstones, contain more than 70 percent cholesterol monohydrate. The formation of such stones is complex, involving cholesterol supersaturation of the bile; the formation of monohydrate crystals, with aggregation into successively larger structures; and delayed gallbladder emptying, with bile stasis. Pigment stones are subdivided into black and brown varieties. Black stones are noted in patients with advanced liver disease and hemolytic disorders, while brown stones are found commonly in patients of Asian descent, usually resulting from bacterial or parasitic infection. Both subtypes of pigment stones result from abnormal solubilization of unconjugated bilirubin coupled with the precipitation of calcium salts. The calcium content of cholesterol stones is much lower than that of pigment stones, making cholesterol stones most frequently radiolucent and pigment stones radiopaque. Anatomically, cholesterol gallstones are found in the gallbladder, cystic duct, intrahepatic ducts, and common bile duct. Brown pigment stones have a distribution similar to that of cholesterol gallstones, while black stones occur exclusively in the gallbladder.

The pathogenesis of symptomatic cholelithiasis involves stone migration from the gallbladder into the biliary tract and eventual obstruction. The stone, once lodged in either the cystic or common bile duct, produces increased intraluminal pressure and distention of the hollow viscus, resulting in pain, nausea, and vomiting. Forceful, repetitive contractions of the entire biliary system may relieve the obstruction. If obstruction persists, particularly in either the cystic duct or the infundibulum of the gallbladder, acute cholecystitis may develop. The inflammatory response in acute cholecystitis results from a combination of three factors: mechanical, chemical, and infectious. The mechanical factor produces the rise in intraluminal pressure and distention of the viscus, which culminates in visceral ischemia. Chemical inflammation occurs with the release of various mediators (lysolecithin, phospholipase A, and prostaglandins), resulting in direct mucosal injury. The contribution to the inflammatory response by bacterial agents is variable, occurring in 50 to 80 percent of patients with acute cholecystitis. Bacterial pathogens include enterobacteriaceae (70 percent, particularly *Escherichia coli* and *Klebsiella* species), enterococci (15 percent), bacteroides (10 percent), *Clostridium* species (10 percent), group D *Streptococcus*, and *Staphylococcus* species. The inflammatory process may progress to gangrene of the gallbladder wall with or without perforation.

Gallstone pancreatitis is similarly multifactorial, since it is experimentally produced by injecting bile, bacteria, and trypsin under pressure. [6]

CLINICAL FEATURES

Patients with acute biliary colic display a wide range of symptoms. Location, radiation, and duration of pain are all poor discriminators of gallbladder disease. There is overlap of signs and symptoms with peptic ulcer disease, gastritis, esophageal reflux, and nonspecific dyspepsia. In addition, it has been difficult to determine which symptoms are attributable to biliary tract disease. [7,8] RUQ pain is a common symptom in patients with and without gallstones. [3,9] Up to 25 percent of postcholecystectomy patients may experience RUQ pain of unknown cause.

Biliary tract disease is an important consideration in the evaluation of dyspepsia. [10] Biliary dyskinesia or increased resting pressure of the sphincter of Oddi, or incoordination between gallbladder contraction and relaxation of the sphincter of Oddi, has been proposed as a cause of biliary tract induced dyspepsia. [10]

One study has reported that epigastric pain was the predominant symptom of biliary tract disease in over 60 percent of patients studied, [9] thus accounting for the difficulty in using clinical signs and symptoms to make or exclude the diagnosis. The same study found that radiation of pain to the left upper back appears to be more commonly associated with biliary tract disease than with other upper gastrointestinal disorders, with a likelihood ratio of 4.0 for gallbladder pathology. [9]

The duration and character of the pain are also nonspecific, but the pain of biliary colic is reported to persist for 2- to 6 h. Pain quality is generally persistent, not colicky, and pain episodes are infrequent, occurring at intervals greater than a week. [9] Gallstone pain is not related to meals in at least one-third of patients, [9,11] and clinical studies have not been able to identify an association with fatty food intolerance that is different from its association with a number of other upper gastrointestinal disorders. [3,9,11] Investigators have noted a circadian rhythm to biliary colic, [11] with a peak of symptoms occurring around midnight to 1 A.M., and a time distribution from 9 P.M. to 4 A.M. Attacks tend to reoccur at the same time. This circadian rhythm has obvious diagnostic implications for patients who present with upper abdominal pain during the midnight shift.

Acute cholecystitis usually begins with pain similar to that of biliary colic but that persists beyond the typical 6 h. Associated nausea, vomiting, and anorexia are noted; a history of fever and/or chills is not uncommon. Patients may have either a history of similar attacks or documented gallstones. As the inflammatory process progresses, the patient's pain changes in character and location from visceral (dull and poorly localized mid-upper abdominal) to parietal (sharp and localized RUQ). The examination reveals a patient in moderate-to-severe distress with signs of systemic toxicity, including tachycardia and fever. The abdomen is tender in the RUQ, at times with evidence of localized peritoneal irritation, distention, and hypoactive bowel sounds. Generalized peritonitis with rigidity is rare and, if found, suggests

perforation. The Murphy sign—worsened pain or inspiratory arrest resulting from deep, subcostal palpation on inspiration—has been estimated to be 97 percent sensitive for acute cholecystitis.[3] Volume depletion is frequently found. Jaundice, usually not present, may be found in patients with prolonged biliary obstruction with late onset of inflammation or in cases of chronic intravascular hemolysis.

Acalculous cholecystitis, which occurs in 5 to 10 percent of patients with acute cholecystitis, tends to have a more rapid, malignant course. Patients frequently are elderly and have a history of diabetes mellitus. Other risk factors include multiple trauma, extensive burn injury, prolonged labor, major surgery, gallbladder torsion, systemic vasculitic states, and bacterial or parasitic infections of the biliary tract. Patients with acalculous cholecystitis are indistinguishable from those with calculous cholecystitis with two major exceptions: acalculous cholecystitis frequently occurs as a complication of another process (e.g., multiple trauma or extensive burns), and patients frequently are gravely ill on initial presentation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of biliary colic includes other conditions associated with upper abdominal pain, including gastritis, gastroesophagal reflux, pancreatitis, hepatitis, and peptic ulcer disease. Atypical myocardial infarction should be considered in older patients. Acute renal colic can be associated with upper abdominal and upper back pain. Both conditions can also be associated with flank tenderness, nausea, and vomiting. Renal colic does not have a circadian rhythm, and the pain is colicky, not continuous, as in biliary colic. Nonetheless, it can be difficult to distinguish biliary from renal colic, and definitive imaging studies may be needed to make the correct diagnosis. Acute pyelonephritis, like cholecystitis, can be associated with flank and upper quadrant pain, but pyuria confirms the former diagnosis. Appendicitis can sometimes be associated with RUQ pain, especially in pregnancy or in patients with a retrocecal or redundant appendix. In women of childbearing age, the differential diagnosis is expanded to include a wide variety of gynecologic disorders, including pelvic inflammatory disease, perihepatitis (Fitzhugh-Curtis syndrome), and ectopic pregnancy. Pregnancy testing, gynecologic history, and pelvic examination should focus on the correct diagnosis. Finally, pneumonia or pleural effusion can be associated with RUQ pain. Diagnosis is confirmed by chest x-ray. However, pancreatitis can also be associated with pleural effusions, usually on the right.

DIAGNOSTIC STUDIES

Results of laboratory studies in patients with biliary colic are frequently normal. The hemogram may reveal chronic anemia with or without evidence of hemolysis in patients with pigment stones. The white blood cell count, serum bilirubin level, alkaline phosphatase level, and aminotransferase levels are often normal. The serum lipase level should be obtained to rule out pancreatitis. The urine must be examined to exclude other causes of abdominal pain. In females, serum or urine pregnancy testing should be performed to rule out obstetric causes of abdominal pain. A negative pregnancy test result also enables one to proceed safely with radiologic studies, if indicated.

The presence of leukocytosis or abnormal liver function study results or lipase levels are often used as indicators for the diagnosis of acute cholecystitis. However, no single test or combination of laboratory tests has a sufficiently high sensitivity to detect acute cholecystitis.[12] A retrospective review of emergency department patients with acute cholecystitis found that 32 percent lacked a white blood cell count greater than 11,000 cells/mL.[13] Typical signs, symptoms, and laboratory findings may not be present in patients over age 60. The sensitivity of Murphy's sign is only 48 percent in the elderly.[14] In a cohort of geriatric emergency department patients with abdominal pain who were determined at surgery to have acute cholecystitis, 56 percent were afebrile, 41 percent had no leukocytosis, and 13 percent were both afebrile and had normal values on routine laboratory tests.[15]

Additional studies in patients with biliary colic may be performed to support the diagnosis and rule out other causes of upper abdominal pain with nausea. Plain film radiographs of the abdomen demonstrate gallstones in only 10 to 20 percent of cases. The majority of stones are cholesterol and therefore radiolucent. Pigment and mixed stones containing at least 4 percent calcium by weight are radiopaque. Abdominal films are more useful in excluding other causes of pain. A chest radiograph should be obtained to identify right lower lobe pneumonia or pleural effusions. A 12-lead electrocardiogram should be obtained in all older patients to exclude myocardial ischemia or infarction.

Ultrasonography is now the initial diagnostic modality of choice. It may show the presence of stones as small as 2 mm, gallbladder distention, wall thickening, and pericholecystic fluid, and during the procedure a sonographic Murphy sign may be elicited. Ultrasonography has a sensitivity of 94 percent and a specificity of 78 percent for the diagnosis of acute cholecystitis.[16]

Computed tomography (CT) scanning can be most useful in the diagnosis of acute cholecystitis when other intraabdominal disorders are considerations in the differential diagnosis. Wall thickening, pericholecystic fluid, and subserosal edema can be identified. However, the sensitivity of CT scanning is insufficient (as low as 50 percent) for it to replace ultrasonography as the diagnostic procedure of choice.[17]

Radioisotope cholescintigraphy using technetium-iminoacetic acid analogues (HIDA), has a sensitivity and specificity of 97 percent and 90 percent, respectively.[16] The study is performed by injecting radioisotopes intravenously. The material is absorbed by the hepatocytes and secreted into the biliary tract. A normal patient will have a clearly outlined gallbladder and cystic duct within 1 h. Failure to demonstrate the gallbladder within this time frame is consistent with cystic duct obstruction. The HIDA scan can only be used in patients with a serum bilirubin level of less than 5 mg/dL. With serum bilirubin above this level, an alternative radioisotope study, the DISIDA scan, is preferred.

COMPLICATIONS

Fluid and electrolyte deficits due to protracted vomiting and anorexia, and upper gastrointestinal hemorrhage from emesis-related Mallory-Weiss tears can coexist with biliary tract emergencies. Complications associated with cholelithiasis include gallstone pancreatitis, ascending cholangitis, and cholecystitis. Patients with cholecystitis may further develop a number of serious complications, including gallbladder empyema and emphysematous (gangrenous) cholecystitis.

Approximately 70 percent of cases of acute pancreatitis are due to either gallstones or alcohol. Depending on the population studied, gallstones are involved in 30 to 70 percent of patients with acute pancreatitis. Of all patients with gallstones, 15 to 20 percent will develop pancreatitis as a result of biliary calculi. Patients with pancreatitis due to gallstones will present similarly to patients with pancreatic inflammation caused by ethanol, with epigastric or diffuse abdominal pain radiating to the back, associated with nausea and vomiting. Patients may manifest symptoms of both acute cholecystitis and acute pancreatitis. Management includes intravenous fluids, nasogastric decompression, analgesics, and parenteral antibiotics with subsequent surgery. In patients who present in extremis or in those who demonstrate clinical deterioration, urgent biliary decompression (surgical or endoscopic) is mandatory.

Ascending cholangitis is a life-threatening emergency with a mortality rate approaching 100 percent in untreated or improperly treated patients. The process results from complete biliary obstruction in the presence of bacteria (gram-negative organisms as well as enterococcal and various anaerobic species). As the obstruction persists, intraluminal pressure increases, resulting in reflux of bacteria into the lymphatic vessels and hepatic veins, with eventual entrance into the systemic circulation. The obstruction most often is due to choledocholithiasis (gallstone obstruction of the common bile duct) and less often to biliary tract strictures, surgical anastomotic strictures, various postprocedural complications, and extrinsic compression from malignancy. Patients present with jaundice, fever, RUQ pain, mental confusion, and shock. The classic Charcot triad of fever, jaundice, and RUQ pain is noted in only 25 percent of patients. Management includes initial volume resuscitation with vasopressor support in cases unresponsive to crystalloid infusion alone, broad-spectrum parenteral antibiotics, and rapid decompression (surgical or endoscopic) of the biliary tree.

Gallbladder empyema, a life-threatening complication of cholecystitis, results from complete obstruction of the cystic duct with bacterial infection of the stagnant bile and abscess formation within the gallbladder wall. Risk factors include age, diabetes mellitus, trauma, burns, vasculitis, and bacterial or parasitic infections of the biliary tract. The presentation is similar to cholangitis, with fever, RUQ pain, altered mentation, and hypotension. Patients frequently develop gram-negative sepsis and require immediate broad-spectrum antibiotic coverage, fluid resuscitation, and urgent surgical consultation for cholecystectomy. The outcome is poor without prompt definitive care.

Gangrene of the gallbladder wall may be focal or diffuse. Focal gangrene results from segmental ischemia of the gallbladder wall caused by severe distention, acute inflammation, empyema, torsion with arterial compromise, or coexisting vasculitis. Patients with diabetes mellitus are at risk for this complication. Perforation of the wall may occur in a contained fashion (into the omentum) or free (into the peritoneal cavity).

Gangrene of the entire gallbladder, also known as emphysematous cholecystitis, is an uncommon complication, occurring in approximately 1 percent of patients with cholecystitis. Emphysematous cholecystitis is acalculous in 30 percent of patients. The gallbladder wall becomes ischemic, with eventual bacterial infection and gangrene. Patients present in extremis with fever, RUQ pain, and septic shock. Plain-film radiographs may demonstrate air in the gallbladder itself, the gallbladder wall, or the biliary tree because of the frequent presence of gas-forming organisms. An abdominal CT scan is the suggested imaging study. The bacteriology of either focal or diffuse gallbladder gangrene includes gram-negative, gram-positive, and anaerobic organisms. Polymicrobial infection is common. Management is similar to that of gallbladder empyema. Mortality rates for gangrenous cholecystitis are very high because of associated sepsis and attendant comorbidity in the typical elderly diabetic patient.

TREATMENT

Patients with accurately diagnosed uncomplicated symptomatic cholelithiasis do not necessarily require immediate surgical intervention. Patients presenting with biliary colic and emesis are best treated with antispasmodic agents (glycopyrrolate), opiate analgesics (meperidine), and antiemetics (promethazine). Meperidine is the analgesic of choice because it produces significantly less spasm of the sphincter of Oddi than do other narcotic agents, such as morphine. Gastric decompression with nasogastric suction may be warranted for protracted vomiting. Volume deficits and electrolyte imbalance can be corrected with isotonic intravenous fluids. With an accurate diagnosis, resolution of symptoms, correction of intravascular volume deficits, and a demonstrated ability to maintain hydration orally, the patient may be discharged from the emergency department. Prior to discharge, the case should be discussed with a surgical consultant or the patient's primary care physician to arrange for timely outpatient follow-up. Patients may be given oral narcotic-acetaminophen pain medication for the common residual abdominal aching. If the symptoms do not resolve within a 4- to 6-h period in the emergency department, the diagnosis of biliary colic must be questioned. Such prolonged pain may represent early, acute cholecystitis.

Ketorolac tromethamine, an injectable nonsteroidal anti-inflammatory drug, has been shown effective in relieving the pain of gallbladder distention. This distention causes the release of prostaglandins, which are associated with the production of pain. Ketorolac inhibits the production of prostaglandins, which may explain why it is effective in this situation. It is not as effective in relieving pain in the presence of infection. When ketorolac does not relieve pain in the clinical setting of symptomatic cholelithiasis, the clinician should reconsider the diagnosis.

Patients with uncomplicated symptomatic cholelithiasis have several options for definitive treatment, including open or laparoscopic cholecystectomy, medical dissolution therapy, and gallstone lithotripsy. Open cholecystectomy with intraoperative cholangiogram provides definitive cure for patients with biliary colic. The laparoscopic technique is rapidly replacing the traditional open cholecystectomy as the procedure of choice. Patients with frequent or severe attacks of biliary colic, a history of associated complications of gallstones, large biliary calculi (>2 cm in diameter), a congenitally abnormal hepatobiliary system, diabetes mellitus, or a desire for rapid cure are best managed with open or laparoscopic cholecystectomy or endoscopic retrograde cholangiopancreatography with possible endoscopic sphincterotomy (ES). Approximately 5 percent of patients have complications from cholecystectomy. The majority of these adverse outcomes are wound infections. Abscess, hemorrhage, bile leakage, and fistula formation are infrequent.[18] Approximately 8 percent of patients develop complications from ES. Pancreatitis and hemorrhage are the most common complications within 30 days of the procedure. Complications, occurring months to years later, such as recurrent stones and cholangitis, are seen in about 10 percent of patients.[19] Medical dissolution therapy with oral bile acid treatment is an option for those with small radiolucent stones (about 10 percent of patients).

Treatment of calculous and acalculous acute cholecystitis is surgical. Basic supportive medical therapy occurs in the emergency department prior to hospital admission and/or surgery. As with biliary colic, patients with acute cholecystitis require volume resuscitation with intravenous isotonic fluid, pain control with opiate analgesics, and bowel rest with nasogastric suction and antiemetic agents. Antibiotic treatment is recommended despite the questionable role of acute infection in all cases of early acute cholecystitis. In patients presenting without sepsis, single-agent therapy with a third-generation cephalosporin is adequate. Patients with obvious infection should receive broadened coverage with ampicillin, gentamicin, and clindamycin, or the equivalent. A minority of patients (usually those with either acalculous or emphysematous cholecystitis or a complication of cholecystitis) present in septic shock and require aggressive resuscitation. All patients with acute cholecystitis must be admitted to the hospital for continued intravenous fluid therapy and antibiotics. Approximately 75 percent of patients treated medically have a complete remission of symptoms within 2 to 7 days of hospitalization; the remainder of patients experience either a progression of the inflammatory process or a complication of acute cholecystitis within this time frame. Most often, surgery is performed 24 to 72 h after admission, once symptoms have resolved. Surgical options include open or laparoscopic cholecystectomy. Patients with a toxic presentation or clinical deterioration require immediate surgery.

82 HEPATIC DISORDERS AND HEPATIC FAILURE

Rawden W. Evans

This chapter will briefly highlight important issues regarding the epidemiology, pathophysiology, and clinical features of acute and chronic liver disease. A rational approach to the interpretation of liver function serologies will be outlined. Specific presentations of hepatobiliary disease will be reviewed, including jaundice, cirrhosis, and complications of end-stage liver disease (ESLD), gallbladder and biliary tract disease, and vascular liver disease. Content will be limited primarily to immediate diagnostic and therapeutic concerns, avoiding discussion of the science of hepatopathology so as to focus on issues most pertinent to the practice of emergency medicine.

ACUTE AND CHRONIC LIVER DISEASE

Epidemiology

The prevalence of chronic liver disease, cirrhosis, and ESLD is steadily increasing. Chronic liver disease is currently the tenth leading cause of death among adults in the United States and accounts for 25,000 deaths yearly, or 1 percent of all deaths. The majority of ESLD (approximately 50 percent) is related to alcohol abuse. However, in recent decades, an increasing number of cases can be attributed to chronic viral hepatitis. [1,2 and 3]

Currently, hepatitis C virus (HCV) infection is the most common of all bloodborne infections in the United States, with approximately 28,000 to 180,000 new cases yearly. An estimated 3.9 million (1.8 percent) Americans have been infected. Chronic HCV infection occurs in 85 percent of patients, and chronic liver disease follows in as many as 70 percent of patients. It is further estimated that 40 percent of chronic liver disease is now related to HCV infection and results in 8000 to 10,000 deaths yearly. For perspective, HIV-related deaths number approximately 14,000 yearly. The majority of HCV-infected individuals are in the age group 30 to 49 years, and infection is often subclinical, with symptoms of chronic liver disease and cirrhosis delayed 1 to 2 decades. Therefore, it is anticipated that the number of cases of chronic liver disease related to HCV will increase sharply in the next 10 to 20 years. [4,5]

Effective vaccination against hepatitis B virus (HBV) has lead to a decline in the prevalence of related disease in the general population. Still, there are an estimated 140,000 to 320,000 cases of HBV infection yearly, with 140 to 320 deaths due to acute infections. Chronic HBV infection occurs in 6 to 10 percent of patients, with 5000 to 6000 related deaths yearly. There are currently 1 to 1.25 million Americans with chronic HBV infection. [6]

The hepatitis D virus (HDV) is uncommon and described as a defective agent because infection depends on concomitant or preexisting chronic infection by HBV. In individuals with chronic HBV infection, superinfection with HDV often results in a rapidly progressive or fulminant form of liver disease carrying a high short-term mortality rate. This variety of infection is most commonly associated with intravenous drug use. [2,3]

Hepatitis A virus (HAV) is commonly encountered by Americans, with 33 percent of the population having acquired immunity secondary to exposure. There are approximately 125,000 to 200,000 cases of HAV infection reported yearly, with an estimated 100 related deaths. Fulminant liver failure is a rare complication of HAV infection, and chronic infection does not occur. [2,7]

Acute illness with liver function test abnormalities also occurs with infection by other hepatotropic viruses such as cytomegalovirus (CMV), herpes simplex virus, Coxsackie virus, and Epstein-Barr virus (EBV), although these agents are unlikely to cause clinically evident hepatitis and jaundice in otherwise healthy individuals.

Alcoholic liver disease and viral hepatitis comprise the vast majority of cases of acute and chronic liver disease. Other causes include a variety of toxins, idiosyncratic drug reactions, and autoimmune and metabolic hepatobiliary diseases (Table 82-1 and Table 82-2). The epidemiology and clinical features of these disorders are not discussed but are referenced. [1,7,8 and 9]

Condition	Cause	Examples
Acute hepatitis	Viral	Hepatitis A, B, C, D EBV CMV
	Toxins	Alcohol Carbon tetrachloride Mushroom poisoning (*Amanania phalloides*)
	Drugs	Acetaminophen Isoniazid Halothane anesthesia Chlorpromazine Erythromycin
Chronic hepatitis (>6 months)	Viral	Hepatitis B, C, D
	Drugs	Methyldopa Amiodarone Isoniazid
	Idiopathic	Autoimmune features (lupoid hepatitis) No autoimmune features
	Metabolic liver disease	Wilson disease α_1-Antitrypsin deficiency

Cryptogenic		

TABLE 82-2   Causes of Chronic Liver Disease and Cirrhosis

Pathophysiology

Hepatobiliary diseases are classified according to the main pathologic processes involved and include hepatocellular, cholestatic, immunologic, and infiltrative disorders. Considerable overlap occurs among these different processes, with a common result being progressive hepatic dysfunction along with attendant complications. The liver is the largest organ and serves as the command and control center for all major metabolic functions. The liver is central to glucose homeostasis, plasma protein and coagulation factor synthesis, lipid and lipoprotein synthesis, bile acid synthesis and secretion, vitamin storage (B$_{12}$, A, D, E, and K), and the biotransformation, detoxification, and excretion of an array of both endogenous and exogenous substances.

Common to essentially all causes of chronic liver disease is ongoing hepatocellular injury and death with the progressive disruption of the functional microanatomy of the liver. Deposition of collagen in tracts of scar tissue accompanies this process and characterizes cirrhosis. Eventually, the metabolic function of the liver becomes both compromised and isolated, resulting in nutritional deficiencies, bleeding diatheses, and the accumulation of toxic metabolic wastes. The cirrhotic liver becomes increasingly resistant to blood flow from the splanchnic circulation, contributing to development of portal hypertension and portosystemic shunting of splanchnic blood through collateral veins into the general circulation. Portal hypertension results in splenomegaly and the development of gastroesophageal varices. These varices are thin-walled submucosal vessels prone to ulceration and hemorrhage. Splenomegaly contributes to anemia and thrombocytopenia. Ascites develops secondary to portal hypertension and abnormalities in renal sodium and water excretion caused by diminished glomerular filtration rate (GFR) and elevations in both aldosterone and antidiuretic hormone. Ascites is often massive, worsens chronic fatigue, and compromises respiratory function. Furthermore, ascites sets the stage for recurrent episodes of spontaneous bacterial peritonitis. Add to this the particularly debilitating occurrence of encephalopathy related to the accumulation of a variety of neurotoxic substances in the circulation. Each of these complications will be further addressed below. [1,10]

Clinical Features

Clinical presentation of acute liver disease is variable. Symptoms of hepatocellular necrosis accompanying viral hepatitis include anorexia, nausea, vomiting, and low-grade fever. Cholestatic disease is accompanied by jaundice of varying degree, pruritus, clay-colored stools, and dark urine. Biliary colic implies acute obstructive cholestasis of extrahepatic or mechanical etiology, as in common duct gallstones or rapidly growing tumors. Cholestasis resulting from intrahepatic processes and infiltrative disease presents more insidiously with the slow development of jaundice and few other constitutional complaints.

Chronic liver disease often presents with complications of advancing cirrhosis and portal hypertension that include abdominal pain, ascites, gastrointestinal bleeding, fever, and altered mental status. However, progressive generalized fatigue is not uncommonly the only symptom of chronic liver disease in the absence of supervening complications.

Features of history are sometimes useful: sexual behaviors, travel, volume and duration of alcohol use, illicit drug use, consumption of nutritional supplements (vitamin A), history of blood transfusions, needle-stick blood exposures, herbal remedies, mushroom ingestion, or raw oyster consumption. Family history may be revealing. Gilbert's syndrome is a relatively common and benign familial condition revealed by periodic modest elevations in unconjugated bilirubin, particularly in response to the stress of an acute illness. Family history of jaundice (elevated conjugated bilirubin) may indicate the presence of Dubin-Johnson or Rotor syndrome. The differential diagnosis of familial severe premature liver disease includes Wilson's disease, hemochromatosis, or α_1-antitrypsin deficiency. These uncommon disorders are mentioned because the emergency physician routinely sees and hence screens a large number of patients and is therefore more likely to encounter such diseases.

Physical findings of acute hepatitis are often limited to moderate enlargement of the liver and tenderness. Chronic liver disease is accompanied by a host of physical findings, including sallow complexion, appendicular wasting, palmar erythema, distinctive cutaneous spider nevi, parotid gland enlargement, and testicular atrophy and gynecomastia in males. The liver may be uniformly enlarged and firm or, in advanced cirrhosis, shrunken and grossly nodular. Splenomegaly and ascites accompany portal hypertension.

Liver Function Tests

Liver function tests might better be termed simply *liver tests,* since routine test panels do not assess function as much as serving as general markers of hepatobiliary disease. Liver tests are obtained frequently in emergency medicine practice, and abnormalities of an incidental nature are common. Abnormal liver tests results are found in as many as one-third of those screened, with the incidence of clinically significant liver disease in this fraction only about 1 percent. Questions often arise regarding what to make of the isolated abnormality and, further, how to interpret a pattern of abnormalities to aid in making a specific diagnosis. Each test will be discussed briefly, with an emphasis placed on results that provide specific diagnostic utility. [12,13]

Bilirubin Bilirubin is a breakdown product of hemoglobin and the other heme-containing proteins myogobin and the cytochromes. Unconjugated bilirubin is a poorly soluble anion that travels in the circulation bound tightly to albumin. Unconjugated bilirubin is efficiently taken up by the liver, where it undergoes conjugation and secretion into the bile. The majority of bilirubin is excreted in stool, and a fraction is reabsorbed through the enterohepatic circulation. Test panels usually report total bilirubin and the "indirect" fraction representing unconjugated bilirubin. The conjugated fraction is derived simply as the difference between total and indirect. (Note: *Direct* and *indirect* fractions refer to reagent reactivity in the bilirubin assay and have no pathophysiologic meaning.) Total serum bilirubin is normally less than 1.1 mg/dL, and the indirect fraction (unconjugated) is 70 percent. Any disease state increasing bilirubin production or interfering with hepatic bilirubin metabolism and secretion can result in elevations in total bilirubin and variable elevations in the conjugated and unconjugated fractions. The differential diagnosis of these conditions is discussed below.

Transaminases Serum transaminases aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are markers of both hepatocellular disease and hepatobiliary dysfunction. Serum AST derives primarily from the liver but is also released by the heart, smooth muscle, kidney, and brain and is thus relatively nonspecific. A number of medications cause increased AST, including acetaminophen; nonsteroidal anti-inflammatory drugs (NSAIDs); ACE inhibitors; nicotinic acid; the antibiotics isoniazid, sulfonamides, and erythromycin; and the antifungals griseofulvin and fluconazole. ALT is a more specific marker of hepatocellular disease. Mild elevations of the transaminases in the hundreds of units per liter indicate ongoing inflammatory hepatocellular damage as in viral hepatitis and subclinical exposure to hepatotoxic drugs and chemicals. Values in the thousands suggest acute hepatocellular necrosis and signify extensive liver injury as characterizes more fulminant disease or ischemia (so-called shock liver). The value in measuring both enzymes is in consideration of AST:ALT ratios. Ratios greater than 2 are common in alcoholic hepatitis because AST production is stimulated by alcohol. In acute and chronic viral hepatitis, the ratio is generally less than 1. In the absence of ongoing alcohol use, mild elevations of AST and ALT with a ratio greater than 1 suggests the presence of underlying cirrhosis.

Alkaline Phosphatase Elevated alkaline phosphatase (AP) is associated with biliary obstruction and cholestasis. However, mild to moderate elevations accompany virtually all hepatobiliary disease. As a rule of thumb, AP elevations greater than four times normal indicate cholestasis as opposed to primary hepatocellular processes such as hepatitis. Elevations also may be a nonspecific finding because AP is derived from bone, placenta, intestine, kidneys, and leukocytes. Specificity can be increased by comeasurement of the enzyme gamma-glutamyl transpeptidase (GGTP), which when elevated supports the diagnosis of a cholestasis. However, like AST, GGTP production is stimulated by alcohol consumption and is also elevated by drugs inducing hepatic microsomal enzyme activity such as phenobarbital and warfarin. GGTP elevations are also seen in acute and chronic pancreatitis, acute myocardial infarction, uremia, chronic obstructive pulmonary disease, rheumatoid arthritis, and diabetes mellitus. Isolated significant elevations of AP in the absence of marked hyperbilirubinemia (AP:bilirubin of 1000:1) is characteristic of infiltrative and granulomatous liver disease such as lymphoma, fungal infections, sarcoidosis, and tuberculosis. The uncommon conditions primary biliary cirrhosis and primary sclerosing cholangitis also produce AP elevations disproportional to bilirubin levels. AP levels in healthy children are often two- to threefold higher than the upper limit of normal for adults. Likewise, doubling of AP levels is common and normal in pregnancy. Incidental findings of three- to fivefold elevations in transaminase levels and doubling of AP in otherwise healthy diabetics and the obese suggest the presence of nonalcoholic steatohepatitis (NASH). Other conditions associated with NASH include jejunoileal bypass, total parenteral nutrition, hyper- and hypothyroidism, and the antiarrhythmic drug amiodarone. [14]

Lactate Dehydrogenase Lactate dehydrogenase (LDH) is often included in liver test panels, although its lack of specificity is limiting. Moderate elevations are seen in all hepatocellular disorders and cirrhosis, but less so in purely cholestatic conditions. LDH may become significantly elevated as a result of hemolysis and accompany a related increase in unconjugated bilirubin. The isoenzyme LDH-5 is specific to the liver and sometimes useful, though not widely available.

Ammonia Metabolism of nitrogen-containing compounds results in the generation of ammonia, which is further metabolized to urea via the Krebs cycle in the liver. Elevated serum ammonia may occur in acute and chronic liver disease as a manifestation of hepatic metabolic failure. Very high ammonia levels are seen in fulminant

liver failure, contributing to overall toxicity and signifying poor prognosis. In cirrhosis with worsening portal hypertension and isolation of remaining functional hepatic tissue, ammonia formed by colonic bacteria is carried into the general circulation. This process is worsened by large intestinal protein loads as occurs with gastrointestinal bleeding. However, elevated serum ammonia levels do not reliably correlate with acute worsening of hepatic function in the cirrhotic and serve more as a marker of generalized decline than as a useful diagnostic tool or therapeutic end point.

Prothrombin Time   Prolongation of prothromin time (PT) in liver disease reflects the decreased synthesis of the vitamin K–dependent coagulation factors II, VII, IX, and X and as such serves as a real measure of liver function. Prolonged PT is seen typically as a complication of advancing cirrhosis, although it also may be seen in acute hepatitis and exacerbations of chronic, but otherwise compensated, liver disease. When present in acute viral hepatitis, prolonged PT often indicates more severe disease reflecting widespread hepatocellular necrosis. There is a degree of correlation between the extent of PT prolongation and clinical outcome in fulminant liver disease. Abnormalities in PT are also seen in conditions affecting lipid assimilation by the gut because vitamin K is fat soluble. Cholestatic syndromes interfere with fat absorption and thereby promote vitamin K deficiency. Distinguishing vitamin K deficiency from liver synthetic dysfunction can be accomplished by administering parenteral vitamin K (phytonadione 10 mg IM), which should result in a 30 percent reduction in PT within 24 h.

Albumin   Like PT, albumin level is a reflection of liver synthetic function. It may be decreased in advancing cirrhosis or severe cases of acute hepatitis, serving as a marker of poor short-term prognosis. Albumin level is not as useful in evaluating fulminant liver disease because its serum half-life is approximately 3 weeks, whereas PT becomes prolonged in a matter of days. Serum albumin is also a reflection of overall nutritional status, and a low value may be nonspecific in a chronically ill individual.

Viral Hepatitis Serology   Serum testing for viral hepatitis is often offered as screening panels by hospital laboratories. In hepatitis A, the IgM anti-HAV is detectable at the onset of clinical illness. Hepatitis B serology is somewhat more complicated. Hepatitis B surface antigen (HBsAg) is measurable before clinical illness and elevations in tranaminases are seen, and remains elevated for 1 to 2 months. Antibodies to the hepatitis B core antigen (anti-HBc) appear 2 weeks after HBsAg, and their presence is useful in defining the so-called window period before antibody to the surface antigen (anti-HBsAg) appears. Thus anti-HBc may be the only reliably positive test in the window period and also provides a rough estimate of the time of exposure for epidemiologic purposes. Antibody testing for hepatitis C has become standardized in recent years and is now part of all viral hepatitis screening panels. The alphabetized nomenclature is expanding as more infectious agents responsible for acute and chronic liver disease are recognized. However, hepatitis A, B, and C remain the principal varieties of concern to practitioners in North America.[2],[3]

Nonhepatic Causes of Abnormal Liver Tests   Hypoalbuminemia accompanies protein wasting enteropathies, malnutrition, and nephrotic syndrome. Alkaline phosphatase elevations occur with a variety of bone diseases, pregnancy, and malignancies. AST elevations accompany acute myocardial infarction and rhabdomyolysis. Bilirubin elevations occur in severe hemolysis, sepsis, and syndromes involving abnormal erythropoesis. PT elevations occur in vitamin K deficiency, chronic antibiotic use, warfarin therapy, and long-standing steatorrhea.

SPECIFIC CLINICAL SYNDROMES

Jaundice

Defined, *jaundice* is simply the yellow pigmentation imparted to the skin, sclera, and mucous membranes by bilirubin when elevated in a host of diseases. Jaundice develops when there is an overproduction of bilirubin and/or a defect in hepatic bilirubin uptake, conjugative metabolism, or biliary excretion. Clinical jaundice reflects hyperbilirubinemia. The clinical syndromes of jaundice are broadly divided into those characterized by predominate elevations in unconjugated or conjugated bilirubin. Unconjugated hyperbilirubinemias are less common and reflect overproduction, decreased hepatic uptake, and decreased conjugation. Conjugated hyperbilirubinemias result from a variety of processes that cause cholestasis, broadly divided as intrahepatic and extrahepatic.   Table 82-3 outlines the distinguishing clinical features of these general classifications, and Table 82-4 provides a differential diagnosis useful once a categorical diagnosis is made.

TABLE 82-3   Classification of Jaundice and Clinical Findings

TABLE 82-4   Differential Diagnosis of Hyperbilirubinemias

Generalizations may benefit the emergency practitioner. A degree of unconjugated hyperbilirubinemia accompanies all hepatocellular diseases, but primary elevations in unconjugated bilirubin are rare and mostly limited to the infant pediatric population, as in neonatal jaundice and Crigler-Najjar syndrome. In the absence of severe underlying or concomitant liver disease, hemolysis does not result in jaundice. Jaundice presenting in the acutely ill and febrile patient will reflect either viral hepatitis or bacterial cholangitis; a distinction may be made by noting that cholangitis is usually accompanied by much greater elevations in alkaline phosphatase. The subacute presentation of jaundice in the patient without a history of chronic liver disease is most likely the result of infiltrative disease or slowly obstructing extrahepatic tumor, as in the head of the pancreas.[15],[16]

A patient with fulminant liver failure (acute hepatic necrosis) presents as acutely ill with jaundice and often complications related to impaired hepatic function, including encephalopathy, coagulopathy, and water, electrolyte, and acid-base metabolic disorders (Table 82-5). Progression of disease to complete liver failure often occurs in 8 weeks or less. The appropriate emergency response to such patients involves recognizing the severity of the illness, instituting appropriate resuscitation, assembling an appropriate database including liver serologies and toxicology screens, and arranging for appropriate inpatient care as indicated by the acuity of the presentation. Appropriate guidelines for inpatient management should be based on age, underlying medical conditions, hemodynamic stability on presentation, and response to initial resuscitation measures. General hospital admission is indicated for management of refractory nausea, vomiting, and dehydration; intensive care unit admission is reserved for patients with encephalopathy, hemorrhage, or hemodynamic instability, especially when a question of sepsis is entertained; and transfer

of the patient with fulminant liver failure to a tertiary facility with transplant capabilities would be appropriate. [17,18]

TABLE 82-5   Fulminant Liver Failure

Cirrhosis and Complications of End-Stage Liver Disease

Hepatic cirrhosis results from fibrous scarring mixed with hepatocellular regeneration in response to sustained inflammatory, toxic, metabolic, and congestive insults. Over time, the functional anatomy of the liver is replaced by scar tissue isolating nodules formed by foci of regenerating hepatocytes. Normal function of the liver is dependent not only on preservation of hepatocyte number but also on the elaborate microscopic architecture of the functional hepatic units. In addition to progressive loss of synthetic and metabolic function, scarring and degeneration of the liver contribute to increased resistance to blood flow from the splanchnic circulation, contributing to portal-systemic shunting and portal hypertension. Shunting isolates the remaining functional tissue of the liver, further contributing to the metabolic derangements that characterize progressive and end-stage liver disease. Emergent complications of cirrhosis and end-stage liver disease include gastroesophageal variceal hemorrhage, refractory ascites and spontaneous bacterial peritonitis, hepatorenal syndrome, and hepatic encephalopathy. [1,19]

Gastroesophageal Varices and Hemorrhage   Cirrhosis results in a progressive increase in resistance to portal blood flow through the liver and shunting of blood through venous collaterals into the systemic circulation. Increased blood flow and pressure in these collateral veins contribute to the formation of submucosal varices in the gastric fundus and esophagus. These superficial and thin-walled varices are prone to ulceration and hemorrhage. Gastroesophageal variceal hemorrhage is a common and dangerous complication of hepatic cirrhosis and portal hypertension. The prevalence among cirrhotics is approximately 25 to 70 percent. Acute hemorrhage carries a 30 to 60 percent mortality rate.

Hemorrhage is heralded by hematemesis, hematochezia, and/or melena, plus varying degrees of hemodynamic instability. Complicating factors include preexisting anemia, thrombocytopenia, and coagulopathy. The differential diagnosis of acute gastrointestinal hemorrhage in the cirrhotic is less important than identification of a condition that requires aggressive managment and appropriate consultation. Basic priorities in management include airway protection and appropriate intravenous access for the infusion of fluids and blood products. Significant coagulopathy should be assumed, and placement of central venous catheters should be performed with extreme caution. Gastric lavage is indicated when active bleeding is suspected to evacuate the stomach and help alleviate repeated vomiting, which can exacerbate hemorrhage. Gastric lavage provides some indication of the location of hemorrhage and a gross assessment of ongoing blood loss. The presence of known gastroesophageal varices is not a contraindication to the careful placement of a nasogastric or orogastric tube. Consultation for emergent endoscopy should be arranged as soon as possible. Endoscopy provides a definitive diagnosis and often a direct means for hemorrhage control by sclerotherapy. Unavailability of such consultation should prompt consideration of early transfer. [20]

In addition to the replacement of blood loss with fluids and blood products, the pharmacologic agents vasopressin and somatostatin have been shown to be useful short-term measures to stem variceal hemorrhage (see Table 82-6). Both agents produce a reduction in portal venous blood pressure, although by importantly different mechanisms. Vasopressin causes splanchnic arteriolar constriction, reducing portal venous inflow and pressure. Somatostatin decreases splanchnic blood flow by causing a direct and selective relaxation of mesenteric vascular smooth muscle. Vasopressin action is nonspecific and has potential for undesireable cardiac and hemodynamic side effects, particularly in older individuals. Coronary vasospasm can cause cardiac ischemia, infarction, and arrhythmias. There is also potential for stroke and mesenteric and limb ischemia. To attenuate these complications, some authorities recommend the coadministration of nitroglycerin by continuous intravenous infusion starting at 40 µg/min and titrating upward for a systolic blood pressure of more than 100 mmHg. Terlipressin is a synthetic derivative of vasopressin that is slowly converted to vasopressin in vivo. Terlipressin has a much longer half-life than vassopressin and has been shown to be superior in a comparison study. This drug is not widely available, but the studied treatment protocol used 1 to 2 mg IV every 4 to 6 h and was compatible with the coadministration of intravenous nitroglycerin. [20,21 and 22]

TABLE 82-6   Pharmacologic Adjuncts to Management of Acute Gastroesophageal Variceal Hemorrhage

Somatostatin has been demonstrated to be effective in reducing variceal bleeding without significant adverse side effects. The short half-life of somatostatin (1–2 min) has limited its usefulness. Octreotide (Sandostatin), an analogue of somatostatin, has been demonstrated to be as effective as injection sclerotherapy in the management of acute variceal hemorrhage and is considered by many to be a useful primary therapy and adjunct to sclerotherapy. Octreotide may be particularly beneficial in the management of hemodynamically unstable patients undergoing resuscitation but unable to tolerate emergent endoscopy. Octreotide has minimal hemodynamic side effects, giving it a distinct advantage over vasopressin [20,22 and 23] (Table 82-6).

Balloon tamponade with inflated gastroesophageal obturators such as the Sengstaken-Blakemore tube is used infrequently because of the high rate of complications and the increasing effectiveness and availability of endoscopic sclerotherapy. Principal complications of these devices include bronchopulmonary aspiration and esophageal rupture. b Blockers and portosystemic shunt surgery or transjugular intrahepatic portosystemic shunts (TIPS) are effective prophylactic measures in some patients with gastroesophageal varices but have no proven role in the management of acute gastroesophageal hemorrhage.

Ascites and Spontaneous Bacterial Peritonitis   Ascites and anasarca occur in hepatic cirrhosis as a result of portal hypertension, impaired renal sodium and water excretion, and hypoalbuminemia. When extreme, ascites may cause immobility, abdominal pain, and respiratory compromise. Umbilical hernia is common in this setting, and hernia ulceration with rupture, although rare, is a life-threatening complication. [24] Primary or spontaneous bacterial peritonitis (SBP) is the most frequently encountered complication of cirrhotic ascites, with a yearly risk of approximately 29 percent. The presentation of SBP usually includes fever, abdominal pain, and diffuse abdominal tenderness, but it may be relatively silent and present only with subacute functional decline or worsening in baseline encephalopathy [26,27] (Table

).

Setting	Cirrhosis with ascites
Presentation	Fever, abdominal pain and tenderness ± worsening encephalopathy
Diagnosis	Ascitic fluid WBC > 1000/mm³ PMN > 250/mm³
Treatment	Cefotaxime 2 g IV, or Standard dosages of TC/CL,* PIP/TZ,* or AMP/SB* Alternate: ceftriaxone 2 g IV, or ofloxacin 400 mg PO bid†
Disposition	Hospitalize, unless clinically well, compliant, with access to timely follow-up†

*TC/CL = ticarcillin-clavulanate (Timentin), PIP/TZ = piperacillin-tazobactam (Zosyn), AMP/SB = ampicillin-sulbactam (Unasyn).
†Oral therapy with ofloxacin reserved for clinically well and compliant patients with ready access to timely follow-up.

TABLE 82-7   Diagnosis and Treatment of Spontaneous Bacterial Peritonitis

SBP is diagnosed by sampling the ascitic fluid by paracentesis. Ideally, ascitic fluid is localized and marked for paracentesis by ultrasound to ensure fluid recovery and avoid encountering intestine during the procedure. In the absence of ultrasound, ascitic fluid can be localized with relative safety by percussion of dullness in the lateral aspects of the lower quadrants with the patient semirecumbant. Alternately, the patient is positioned supine, resting partially on the side where the paracentesis is to be performed. In choosing the site for puncture, avoid areas proximate to remote surgery. The site is prepared and draped in a sterile fashion, and lidocaine is infiltrated locally for anesthesia. An 18- or 20-gauge angiocatheter on a 20-cc syringe is adequate for fluid sampling. Postprocedural leaking of ascitic fluid can be lessened by advancing the catheter in a Z fashion through the skin, subcutaneous fat, and abdominal wall or by placing traction on the overlying skin prior to puncture so that on removing the catheter there is a lateral distance between the skin puncture and the peritoneum. Ascitic fluid is a transudate with protein content generally less than 3 g/dL. Culture results are frequently negative; however, yield can be improved by drawing 10 cc of fluid and processing it as a blood culture. Cell count with white blood cell (WBC) differential is ordered. A total WBC count in excess of 1000/mm³ and/or neutrophil count (PMNs) greater than 250/mm³ is considered diagnostic for SBP. The Enterobacteriaceae account for 63 percent of infections, *Streptococcus pneumoniae* 15 percent, enteroccoci 6 to 10 percent, and anaerobes less than 1 percent. Appropriate antibiotic regimens are outlined in Table 82-7.[35]

Occasionally patients present with refractory and incapacitating ascites as a primary complaint. Associated symptoms include extreme fatigue, increased respiratory effort, and orthopnea. These individuals often have failed maximal diuretic therapy and have undergone high-volume paracentesis in the past. Before performing this procedure, it is useful to consult with the patient's primary care provider or hepatologist to review a protocol. As much as 6 to 8 L of ascitic fluid can be drained over a 60- to 90-min interval with the concomitant peripheral infusion of albumin (6–8 g/L of ascites collected). Many practitioners believe the albumin infusion is unnecessary when peripheral edema is present because mobilization of edema fluid attenuates intravascular volume loss. Complications of the procedure are not infrequent and include hemorrhage, infection, acute renal failure, and hemodynamic compromise. Such patients may be ideal candidates for an observation unit or short-stay admission.[28]

Hepatorenal Syndrome   Hepatorenal syndrome is characterized by acute renal failure in the cirrhotic patient in the presence of histologically normal kidneys. The exact pathophysiology is elusive but is tied in with the metabolic derangments of end-stage liver failure, decreased effective circulating blood volume, and elevated aldosterone and antidiuretic hormone secretion. GFR drops, as does urine sodium secretion, and azotemia worsens with blood urea nitrogen–creatinine ratios usually greater than 20. This characteristic and refractory form of renal failure complicates cirrhosis with ascites and can be precipitated by any acute illness resulting in dehydration and/or sepsis or as a complication of overzealous diuresis or high-volume paracentesis. The ill cirrhotic patient with evidence of acute or worsening renal insufficiency should be hospitalized for appropriate consultation and carefully monitored intravenous fluid administration and diuretic therapy adjustment.   [29]

Hepatic Encephalopathy   Hepatic encephalopathy is a complex syndrome that often accompanies acute or fulminant liver failure and frequently complicates the course and management of cirrhotics. In acute or fulminant liver failure, encephalopathy occurs in response to the metabolic insults of the disease and also cerebral edema. In chronic liver disease, fluctuating encephalopathy occurs in response to the accumulation of a variety of nitrogenous metabolic wastes normally cleared by the liver and also the prolonged effects of incompletely metabolized substances ingested such as prescription drugs and other more overt hepatotoxins such as acetaminophen, NSAIDs, and alcohol.[30]

To appreciate the presence or worsening of baseline encephalopathy, one must determine the patient's underlying functional status. Questions related to changes in personality, worsening dementia, alterations in level of consciousness, and neuromuscular function should be pursued. The staging of hepatic encephalopathy is outlined in Table 82-8. Asterixis characterizes stage II and is a manifestation of neuromuscular weakness made evident when the patient tries to maintain a certain posture. Typically, the hands begin to "flap" when the patient is asked to hold the hands up and extended at the wrist ("stop traffic"). Alternately, the tongue moves back and forth like a snake when the patient is asked to keep his or her tongue extended. Serum ammonia level is often measured in this setting and is frequently significantly elevated. However, this is a nonspecific finding, and ammonia levels are notoriously inaccurate. Thus ammonia may serve as a marker but not as an index of encephalopathy. The list of potential causes of encephalopathy in the cirrhotic patient is long and includes gastrointestinal bleeding, increased dietary protein intake, constipation, infection/sepsis, drugs (frequently benzodiazepines, opiates, or commonly prescribed "muscle relaxers"), acute worsening of hepatic function, or electrolyte and acid-base disturbances. Falls are not uncommon in this population and, along with coagulopathy, place them at increased risk of head injury and intracranial bleeding. Therefore, computed tomographic (CT) imaging of the head is appropriate in the evaluation. The majority of cirrhotics presenting with acute or worsening encephalopathy are best served by hospitalization. There is the occasional patient presenting with a baseline of variable encephalopathy who appears otherwise well (stage I or II) and has an unrevealing workup for serious causes of mental deterioration who may be managed successfully as an outpatient. The cathartic lactulose is prescribed at a dose of 30 cc three times daily until one or two soft stools are produced daily. Lactulose traps ammonia within the lumen of the gut by decreasing intestinal pH and stimulates bacterial uptake of ammonia into fixed bacterial proteins. The antibiotic neomycin is an alternative therapy that decreases intestinal bacterial number, thus reducing toxic substances generated by bacterial protein degradation. Neomycin can be prescribed as 1 g four times daily; infrequent side effects include oto- and nephrotoxicity.

Stages	Features
I	General apathy
II	Lethargy, drowsiness, variable orientation, asterixis
III	Stupor with hyperreflexia, extensor plantar reflexes
IV	Coma

TABLE 82-8   Staging of Hepatic Encephalopathy

Gallbladder and Biliary Tract Disease

Gallstones are the most common cause of biliary tract disease in the United States. Gallstones occur in 20 to 35 percent of the population by age 75 years but in the majority are asymptomatic. Acute colicky pain localizing to the right upper quadrant accompanied by nausea and vomiting, sometimes with a finding of a palpable and tender gallbladder, characterizes gallstone obstruction of the cholecystic duct. The acutely ill patient frequently will give a history of past episodes of postprandial

pain, although less severe or prolonged. Typically, pain is of rapid onset and slow resolution with a pattern of radiation to the right lower scapula or right shoulder. Fever and toxicity suggest infection and cholecystitis. Gallstone obstruction of the common bile duct produces pain, frequently mild jaundice, and serologies suggesting biliary obstruction, hepatocellular injury, and pancreatitis. Fever and toxicity suggest infection and cholangitis. The diagnosis usually can be made by clinical presentation, serologies, and ultrasonography. There is an approximate 5 percent incidence of "acalculus cholecystitis" that is usually a late complication of concurrent severe illness or injury, prolonged fasting, or surgery or is related to hyperalimentation. Gallbladder disease is common in the elderly, who often present late in the course of their illness with a higher rate of infectious complications, perforation, and subsequent mortality. Symptoms in the elderly are often nonspecific and nonlocalizing, requiring greater vigilance on the part of the emergency practitioner. When infection is an apparent complication, initial antibiotic therapy should cover Enterobacteriaceae, enterococci, *Bacteroides,* and *Clostridium* species. See Table 82-9 for specific antibiotic recommendations.[31,35]

Regimens	Antibiotics
Primary	Ticarcillin or piperacillin 4.0 g IV plus Metronidazole 1.0 g IV
	or
	Ampicillin 2.0 g IV plus Gentamicin 2 mg/kg IV plus Metronidazole 1.0 g IV
	or
	Single agents: Imipenem Meropenem TC/CL* PIP/TZ* AMP/SB*
Alternative	Third-generation cephalosporin plus metronidazole or clindamycin
	or
	Aztreonam plus clindamycin

*TC/CL = ticarcillin-clavulanate (Timentin), PIP/TZ = piperacillin-tazobactam (Zosyn), AMP/SB = ampicillin-sulbactam (Unasyn).

TABLE 82-9 Antibiotic Treatment of Cholecystitis and Cholangitis

Vascular Disease of the Liver

Vascular diseases of the liver are relatively uncommon when compared with the aforementioned conditions, and their diagnoses are unlikely to be made during an evaluation in the emergency department. However, these conditions warrant brief inclusion because their consideration in the evaluation of the acutely ill patient is key to timely diagnosis, treatment, and ultimately improved outcome. These conditions include portal vein thrombosis, hepatic vein thrombosis (Budd-Chiari syndrome), and nonthrombotic venoocclusive disease.

Portal vein thrombosis can result as a late complication of abdominal trauma, sepsis, pancreatitis, and hypercoagulable states and in neonates with umbilical vein infection. Portal hypertension and related complications develop in a subacute manner. Splenomegaly may occur in the absence of hepatomegaly, and liver histology is normal. The diagnosis is made by angiography, and therapy is surgical. [32]

Hepatic vein thrombosis, or Budd-Chiari syndrome, has both acute and chronic presentations that include abdominal pain, hepatomegaly, ascites, and usually mild alterations in liver serologies. Causes and associations include a history of abdominal trauma, oral contraceptive use, polycythemia vera, paroxysmal nocturnal hemoglobinuria, hypercoagulable states, and congenital webs of the vena cava. Diagnosis can be made by Doppler ultrasound of the hepatic veins, and therapy includes anticoagulation. [33]

Nonthrombotic occlusion of hepatic venules creating a small-vessel variant of Budd-Chiari syndrome is associated with the ingestion of certain medicinal teas containing pyrrolozidine alkaloids. These alkaloids are found in *Senecio* and *Crotalia* genera of plants.[34] Venoocclusive hepatic disease also occurs rarely as a complication of chemotherapy and bone marrow transplantation.

83 ACUTE AND CHRONIC PANCREATITIS

Robert J. Vissers
Riyad B. Abu-Laban

ACUTE PANCREATITIS

Pancreatitis is a common cause of abdominal pain, and the lack of a pathognomonic clinical presentation and the absence of a diagnostic gold standard make this disease a diagnostic challenge. Its clinical presentation can vary from mild abdominal pain to refractory shock, and many of its signs and symptoms are shared by other intraabdominal conditions.

Epidemiology

Acute pancreatitis is secondary to cholelithiasis or alcohol abuse in up to 90 percent of cases in the United States, but the etiology varies in different countries. [1] The overall prevalence is estimated to be 0.5 percent, but this also depends on the setting and patient population. Patients with biliary pancreatitis are more commonly female, over 50 years of age, and represent the most common form of pancreatitis in a community hospital setting. Alcoholic pancreatitis presents more frequently to urban emergency departments and is seen most commonly in men between the ages of 35 and 45. [2]

The list of other factors associated with the development of acute pancreatitis is extensive, including drugs, infection, inflammation, trauma, and metabolic disturbances (Table 83-1). Drugs account for up to half of the remaining cases after alcohol and biliary diseases have been excluded (Table 83-2).

TABLE 83-1   Etiologic or Contributing Factors in Acute Pancreatitis

TABLE 83-2   Drugs Associated with the Occurrence of Acute Pancreatitis

Pathophysiology

Although there are many distinct etiologies for acute pancreatitis, the specific mechanism that leads to the disease state remains unclear. The central pathophysiologic cause is believed to be the intracellular activation of digestive enzymes and subsequent autodigestion of the pancreas. [1,3] A number of factors (e.g., endotoxins, toxins, ischemia, infections, and anoxia) are believed to trigger the activation of proenzymes. Activated proteolytic enzymes, such as trypsin, then digest cellular membranes within the pancreas and cause edema, interstitial hemorrhage, vascular damage, coagulation, and cellular necrosis. [1] This noninfectious destruction of the pancreatic parenchyma rapidly causes a local inflammatory reaction that further contributes to the vascular dilatation, permeability, and edema.

The autodigestion theory replaces a previously held belief that the cause was primarily due to an anatomic "common channel" between the common bile duct and the pancreatic duct, in actuality a rare occurrence. Alternatively, it was proposed that obstruction at the ampulla of Vater was the primary initiating event in acute pancreatitis, but this does not produce pancreatitis in the experimental setting. Only by injecting bile, bacteria, and trypsin under pressure can pancreatitis be experimentally induced. [2]

Adult pancreatitis is distinguished from most other intraabdominal diseases by its propensity to cause remote systemic effects. It is believed that this represents an extension of the localized process into a generalized systemic inflammatory response. [4] This may lead to shock, adult respiratory distress syndrome (ARDS) and, eventually, multisystem organ failure. Recently, pancreatitis research has focused on the identification of systemic inflammatory mediators. A number of compounds has been implicated, including bradykinin, compliment, platelet-activating factor, nitrous oxide and, most recently, inflammatory cytokines. [4] Inflammatory mediators

presently hold the most promise for the identification of better prognostic markers and potential therapies for acute pancreatitis. [5]

Clinical Features

The major symptom of acute pancreatitis is mid-epigastric or left upper quadrant pain. It is most commonly described as a constant, boring pain that often radiates to the back as well as the flanks, chest, or lower abdomen. Although usually described as severe, the intensity can be extremely variable and does not correlate with the severity of the disease.[1] The pain is exacerbated in the supine position and can be relieved when sitting with the trunk and knees flexed. Colicky discomfort is atypical and suggests another etiology. Nausea and vomiting are common, and abdominal bloating from gastric and intestinal hypomotility is a frequent complaint.

Physical examination usually reveals a patient in moderate distress. Low-grade fevers and tachycardia are frequently present, and hypotension is not unusual. [1] About 10 percent of patients have respiratory symptoms secondary to atelectasis, pleural effusion (usually left sided) and, rarely, ARDS. Abdominal examination is notable for epigastric tenderness. Peritonitis is a late finding, presumably due to the retroperitoneal location of the organ. Bowel sounds may be diminished from an associated ileus. Cullen sign, a bluish discoloration around the umbilicus, and Grey Turner sign, a bluish discoloration of the flanks are characteristic but rare signs of hemorrhagic pancreatitis.

Patients with pancreatitis may present in hypovolemic shock and multisystem organ failure. Hypotension can result from fluid third-spacing, hemorrhage, increased vascular permeability, vasodilatation, cardiac depression, and vomiting. [2]

Diagnosis

The absence of a pathognomonic clinical syndrome often precludes a diagnosis based solely on presentation. Unfortunately, the only diagnostic gold standard is pathologic examination of the pancreas. Laboratory and radiographic investigations can be helpful in the diagnosis of acute pancreatitis, but both suffer from limited diagnostic accuracy.

LABORATORY TESTS   Serum amylase and lipase are the most widely used laboratory tests used in the evaluation of acute pancreatitis (Table 83-3). Both enzyme markers, released during pancreatic inflammation, lack the sensitivity and specificity to be the sole indicators of disease and must be interpreted in the context of the clinical setting.[6,7]

Test Characteristic	Amylase	Lipase
Sensitivity	80%–90%	90%
Specificity	75%	90%
Suggested best cutoff	3× upper limit of normal	2× upper limit of normal
Prognostic value	Poor	Poor
Rate of rise	Rapid	Rapid
Return to baseline	3–4 days	7–14 days
Other	No additional benefit to ordering both amylase and lipase.	

TABLE 83-3 Laboratory Utilization in Suspected Acute Pancreatitis

Amylase   This digestive enzyme, used to cleave starch into smaller carbohydrates, is primarily found in the pancreas and salivary glands. Low levels of amylase can also be found in numerous other tissues, including the fallopian tubes, ovaries, testes, adipose tissue, small bowel, lung, thyroid, skeletal muscle, and certain neoplasms. As a result, serum amylase can be elevated in many conditions, making this test relatively nonspecific.

Amylase levels are expressed in either Somogyi units (SU) or international units, with the normal ranges generally reported as 60 to 160 SU/100 mL or 110 to 300 IU/L, respectively.[8] Amylase has a half-life of about 2 h and, although the elimination is incompletely understood, it is at least partially cleared by the kidneys, leading to elevated levels in renal failure.

Not only are there many extrapancreatic causes of an elevated amylase, but serum amylase levels may be normal in proven cases of acute pancreatitis. [9] The lack of a diagnostic gold standard has made estimates of the sensitivity of this test difficult, but most studies suggest a sensitivity of 80 to 90 percent if blood is sampled within 36 h of symptom onset.[10] Amylase rises quickly but, because of its short half-life, returns to normal in 3 to 4 days (even in the presence of ongoing inflammation), making it less sensitive after the first 36 h.

The main difficulty in using serum amylase for the diagnosis of acute pancreatitis is its poor specificity. Depending on the cutoff used, the specificity of amylase ranges from 40 percent when the normal range is used to greater than 90 percent at a cutoff of five times the upper limit of normal. The best accuracy appears to occur at a cutoff of three times the upper limit of normal, which improves the specificity to 75 percent without greatly compromising the sensitivity. [7,8]

Lipase   This enzyme, which catalyzes the breakdown of triglycerides into free fatty acids, is predominantly found in the pancreas, but lipase activity is present in the gastric and intestinal mucosa and in the liver. An elevated serum lipase level has been noted in a number of nonpancreatic diseases, most of which are intestinal or hepatobiliary disorders.[7,11] Heparin may cause a release of endothelial membrane-bound lipase into the serum, resulting in a measurable increase in lipase activity within minutes of heparin administration. Lipase is cleared by the kidneys and can be elevated to three times the upper limit of normal in renal failure. The half-life is approximately 7 h, and serum lipase will remain elevated for several days after amylase has returned to baseline. Lipase activity is expressed in units per liter, and the normal range varies greatly, depending on the assay that is used.

Many of the reservations regarding the utility of lipase in pancreatitis were based on the use of older, less specific assays of lipase activity. The recent addition of colipase to these assays has improved the specificity to greater than 90 percent (specificity ranges from 80 to 99 percent, depending on the cutoff used). In addition, the sensitivity of lipase is at least as good as amylase (greater than 90 percent). The most appropriate cutoff in the emergency department appears to be two times the upper limit of normal.[7,8]

Lipase is clearly a more accurate test than amylase in the diagnosis of acute pancreatitis. Although lipase suffers from imperfect sensitivity, a recent study of over 5000 patients in whom both amylase and lipase tests were ordered found that the addition of amylase was not warranted. [12] It is also not cost-effective to order amylase or lipase indiscriminately in all cases of undifferentiated abdominal pain. [6]

Other enzymatic markers have been investigated, including isoenzymes of amylase, but variables such as time, cost, and test accuracy have prevented their use in clinical practice. Lipase-amylase ratios and amylase-creatinine clearance ratios add little to the diagnosis of acute pancreatitis beyond lipase alone. [2,3]

RADIOLOGY   Plain radiographs of the chest and abdomen are most useful in excluding other diseases that may be confused with pancreatitis. Calcification of the gland is suggestive of chronic pancreatitis. A sentinel loop secondary to small bowel ileus, or a colon-cutoff sign suggesting local colonic ileus, may be present but neither is diagnostic. Chest radiographs may reveal an elevated hemidiaphragm or a pleural or pericardial effusion.

Ultrasonography is most helpful in the identification of gallstones or dilatation of the biliary tree, which has both diagnostic and therapeutic implications in pancreatic disease. Although pancreatic edema and associated pseudocysts may be visualized on ultrasound, it is generally an insensitive test for the diagnosis of acute pancreatitis, particularly in nonbiliary etiologies. Overlying bowel gas or adipose tissue and the retroperitoneal location of the pancreas frequently impair adequate

imaging.[2]

Computed tomography (CT) cannot be used to rule out pancreatitis, as it is insensitive in early or mild disease. Because of better anatomic definition, CT scanning may facilitate grading the severity of the disease and enable better prognostication. [13]

Endoscopic retrograde cholangiopancreatography (ERCP) is rarely employed in the emergency department evaluation but can be very useful for patients in whom the etiology of the pancreatitis remains unclear after initial assessment. Magnetic resonance imaging is being investigated in this role.

Prognostic Markers

For most patients, acute pancreatitis is a self-limited disease, but 5 to 10 percent suffer from significant associated morbidity and mortality. [2,14] It can be difficult to identify patients at risk, although signs of a systemic response suggest a more complicated course. Ranson has identified multiple diagnostic criteria used to predict patient outcome (Table 83-4).[15] The number of factors present is then used to predict mortality. Patients with fewer than three criteria have a 1 percent mortality, those with three to four criteria have a 16 percent mortality, those with five to six criteria have a 40 percent mortality, and those with more than six criteria have 100 percent mortality. Although the presence of several risk factors in the emergency department portends a worse prognosis, the Ranson criteria require an assessment of clinical values within the first 48 h of hospitalization and therefore have limited utility in the initial evaluation. Other scoring systems have been used to predict severity in pancreatitis, such as the acute physiology and chronic health evaluation (APACHE II) score, but complexity and poor sensitivity on initial presentation limit their role in the emergency department.[1] In general, the presence of extraabdominal complications or comorbid conditions indicates an increased mortality risk. Hypotension, tachycardia of more than 130 bpm, a P_{O_2} of less than 60 mmHg, oliguria, increasing blood urea nitrogen or creatinine, and hypocalcemia are key indicators of a potentially complicated course.[1,3,15]

On Admission	48 Hours later
Age over 55	Change in HCT (falling) decreased more than 10 percent
Blood sugar > 200 mg/dL	Rise in BUN over 5 mg/dL
WCB > 16,000/μL	↓ CA²⁺ below 8 mg/dL
SGOT > 250 Sigma-Fankel units/L	↓ Arterial P_{O_2} below 60 mmHg, Rapid fluid sequestration over 6 L
LDH > 350 IU/L	Base deficit over 4 meq/L

TABLE 83-4   Ranson Criteria for Predicting Mortality Risk from Acute Pancreatitis

There is no specific serum marker predictive of outcome in acute pancreatitis, although cytokines show great promise. [4] The absolute level of serum amylase or lipase does not correlate with severity.[3,7]

A CT scan, particularly if contrast enhanced, may provide valuable estimates of the severity and prognosis in cases of moderate to severe acute pancreatitis. [13] A CT severity index score has been described. It is suggested that CT scan be performed on patients with three or more Ranson's criteria, significantly ill patients, and patients with clinical deterioration. [16]

Complications include phlegmons, abscesses, or pseudocysts,[16] usually in the first 2 to 3 weeks after the onset of pancreatitis. Systemic complications include pulmonary, cardiovascular, renal, hematologic, central nervous system, and metabolic abnormalities (Table 83-5).[14]

Pulmonary
  Pleural effusions, usually left sided
  Atelectasis
  Hypoxemia
  Adult respiratory distress syndrome (>50% mortality)
Cardiovascular
  Myocardial depression
  Hemorrhage, hypovolemia, and myocardial depressant factor
Metabolic
  Hypocalcemia
  Hyperglycemia
  Hyperlipidemia
  Coagulopathy, disseminated intravascular coagulopathy
Other
  Hemorrhage
  Colonic perforation
  Renal failure
  Erythema-nodosum dermatitis
  Arthritis
  Pseudocyst
  Abscess

TABLE 83-5   Complications of Acute Pancreatitis

Treatment

Of patients with acute pancreatitis, 90 percent recover without complications and require supportive measures only. [1] The general principle is to "rest the pancreas." Although the use of a nasogastric tube is widely advocated, no studies have demonstrated that its presence alters the course of the illness. It is traditionally recommended to withhold all oral intake, but clear liquids do not appear to be harmful in mild to moderate disease.

The mainstay of treatment for acute pancreatitis is fluid resuscitation. A balanced electrolyte solution, such as normal saline, should be administered for rehydration. Amounts should be given to ensure renal perfusion and good urine output of about 100 mL/h. In unstable patients, hemodynamic monitoring may be required, and pressors are indicated for persistent hypotension despite adequate fluid resuscitation.

Other aspects of supportive care include parenteral narcotics and antiemetics.

In biliary pancreatitis, urgent decompression is indicated if there is persistent biliary obstruction, ideally by endoscopic sphincterotomy of the ampulla of Vater. [1,2] If the obstruction is transient, most patients can be managed with supportive care, and elective cholecystectomy may be performed once inflammation subsides.

Empiric antibiotics are not indicated in mild to moderate pancreatitis but should be given if secondary infection is suspected. Although many other drugs have been used as a potential therapeutic agent in acute pancreatitis, such as H $_2$ blockers, steroids, nonsteroidal anti-inflammatory drugs, and glucagon, none has demonstrated benefit in controlled, prospective trials. [2]

Peritoneal lavage may provide short-term clinical improvement but does not appear to alter clinical outcome. Acute fluid collections are rarely symptomatic and frequently resolve spontaneously.[16] Laparotomy is indicated for hemorrhage control and abscess drainage. Abscesses and pseudocysts may also be drained radiologically or endoscopically, if indicated.

Disposition

Patients with mild pancreatitis, no evidence of systemic complications, and a low likelihood of biliary tract disease may be managed as outpatients if they are able to tolerate oral fluids and their pain is well controlled. A clear-liquid diet is recommended, oral analgesics should be prescribed, and follow-up in 24 to 48 h is needed. All other patients with acute pancreatitis should be admitted to the hospital. Patients with significant systemic complications, shock, or extensive pancreatic necrosis will need an intensive care setting. Evidence of a pancreatic abscess requires surgical consultation.

CHRONIC PANCREATITIS

Chronic pancreatitis is a chronic inflammatory condition that causes irreversible damage to pancreatic structure and function.

Epidemiology

Table 83-6 lists the causes of chronic pancreatitis. Of these, alcohol abuse is the most important, accounting for 70 to 80 percent of cases. [17] Most of the remaining cases are idiopathic. The mean ages of onset and death in chronic pancreatitis are 42 and 52 years, respectively. [18] Because the disease can be undiagnosed, the true prevalence is unknown, with estimates ranging from 0.04 to 5 percent. [19] As with alcohol abuse, chronic pancreatitis is most common in men. Gallstones are not a cause of chronic pancreatitis, despite their role in the acute form of the disease. [20,21] It is believed that acute pancreatitis does not progress to chronic disease unless complications such as pseudocysts or ductal strictures are present. [19]

Alcohol abuse
Malnutrition ("tropical pancreatitis")
Hyperparathyroidism
Pancreas divisum
Ampullary stenosis
Cystic fibrosis
Hereditary
Trauma
Idiopathic

TABLE 83-6   Causes of Chronic Pancreatitis

Pathophysiology

The pathophysiology of chronic pancreatitis remains poorly understood. [19] In contrast to acute pancreatitis, the pancreas is pathologically abnormal in chronic pancreatitis, both before and after exacerbation. In alcohol-induced disease, it is thought that either alcohol is directly toxic to acinar cells or induces pathologic changes in secretory function. [20] The risk of alcohol-induced chronic pancreatitis is clearly related to the amount and duration of alcohol consumption. [17] Once established, the disease may progress despite abstinence, although the mortality rate is reduced. [18,20] Chronic pancreatitis, regardless of the etiology, results in interstitial inflammation with duct obstruction and dilatation leading to parenchymal loss and fibrosis. This causes pain and eventual impairment of both exocrine and endocrine pancreatic functions, with endocrine impairment occurring later in the disease process. [19] Clinically significant malabsorption does not occur until more than 90 percent of glandular function is lost. [17] The etiology of pain is likely multifactorial and may include parenchymal inflammation, pressure on acinar tissue or small ducts, perineural inflammation, and duodenal or common bile duct stenosis. [20] It is controversial whether pain "burns out" as chronic pancreatitis progresses. [19]

Clinical Features

The hallmark of chronic pancreatitis is abdominal pain, but in about 10 percent of cases the disease may be painless. [21] As in acute pancreatitis, pain is usually mid-epigastric and may radiate to the back, although abdominal tenderness is often less prominent. [2] Nausea and vomiting may be present. In the early stages of chronic pancreatitis, discrete attacks of pain (formerly called "relapsing pancreatitis") occur, lasting days to weeks. [17] Pain is frequently worse after alcohol ingestion or a fatty meal. As the disease progresses, pain-free periods become less frequent and often disappear completely. [2] In distinction to acute pancreatitis, patients with chronic pancreatitis appear chronically ill and may have signs and symptoms of pancreatic insufficiency, including weight loss, steatorrhea, clubbing, and polyuria. Stigmata of chronic liver disease may be present if the etiology is alcohol abuse.

Diagnosis

Differentiating acute and chronic pancreatitis may be difficult during an exacerbation, since the primary distinction is based on disease reversibility. [2] Laboratory investigations are nonspecific in chronic pancreatitis. Amylase and lipase levels may be elevated but have no prognostic significance and are usually normal, particularly when fibrosis is advanced. Glucose tolerance is often impaired, occasionally with an elevated fasting blood sugar level. In 5 to 10 percent of patients with chronic pancreatitis, compression of the intrahepatic portion of the bile duct leads to elevations of bilirubin and alkaline phosphatase levels. [19] Pancreatic calcification on abdominal radiographs is considered pathognomonic for chronic pancreatitis and is present in some 30 percent of patients, particularly those with alcohol-induced disease. [17,22] Lists of diagnostic criteria for chronic pancreatitis have been developed since no single gold standard exists. [23] Either CT or ultrasound may be indicated to identify local complications of chronic pancreatitis, such as abscess or pseudocyst. The differentiation between chronic pancreatitis and pancreatic cancer can be challenging and is an essential component of imaging interpretation.

Treatment

The management of chronic pancreatitis in the emergency department involves ruling out other diagnoses or complications and includes supportive care. Intravenous narcotic analgesics and antiemetics are usually required. Fluid and electrolyte abnormalities should be corrected. The long-term goals of treatment are pain control, relief of mechanical obstruction or complications, correction of malabsorption, and alteration of the disease course. Pancreatic extracts are frequently administered to improve absorption and reduce pain. Cessation of alcohol ingestion is essential because the 5-year mortality rate of chronic pancreatitis in patients who continue to abuse alcohol is 50 percent. [17] If pain is increasing or intractable, imaging should be performed to assess for complications such as pseudocyst or mechanical obstruction. Surgery, either open or endoscopic, can be helpful in such cases. Other complications include mechanical obstruction of the duodenum or common bile duct, fistulae, ascites or pleural effusions, splenic vein thrombosis, and pseudoaneurysm. Celiac plexus nerve block is frequently performed for long-term pain control.

Disposition

Many patients with chronic pancreatitis can be safely discharged from the emergency department once complications have been ruled out or addressed. Appropriate follow-up is particularly important if pain management is poor or significant weight loss or symptom changes have occurred. Hospital admission may be required during severe pain exacerbation.

84 COMPLICATIONS OF GENERAL SURGICAL PROCEDURES

Edmond A. Hooker

Outpatient surgical procedures are commonplace, and, with increasing pressure for cost containment, admitted patients are being discharged earlier in their postoperative course. As a result, more patients are presenting to the emergency department with postoperative fever, respiratory complications, genitourinary complaints, wound infections, vascular problems, and complications of drug therapy (Table 84-1). This chapter reviews the complications common to all surgical procedures as well as procedure-specific complications.

TABLE 84-1   Complications of General Surgical Procedures

The operating surgeon should be called when one of his or her patients appears in the emergency department with a surgical complication. This is not just courtesy but provides continuity of care important for the patient's well-being.

FEVER

Fever is a common presenting complaint (Table 84-2). A mnemonic for the common causes of postoperative fever is the "five W's": wind (atelectasis or pneumonia), water (urinary tract infection), wound, walking (deep vein thrombosis), and wonder drugs (drug fever or pseudomembranous colitis.[1] Fever during the initial 24 h is usually caused by atelectasis; however, necrotizing streptococcal and clostridial infections also occur in surgical wounds early in the postoperative course. Respiratory complications, such as pneumonia and atelectasis, and intravenous catheter-related problems, such as thrombophlebitis, are the predominant causes of fever in the 24- to 72-h time period.

Atelectasis	Pseudomembranous colitis
Pneumonia	Hepatitis
Urinary tract infections	Peritonitis
Skin and soft tissue injury	Pulmonary embolism
Thrombophlebitis (septic and sterile)	Transfusion reaction
Deep vein thrombosis	Thyrotoxicosis
Intraabdominal abscesses	Pheochromocytoma
Unrelated bacterial infection	Adrenal insufficiency

TABLE 84-2   Causes of Postoperative Fevers in General Surgical Patients

Urinary tract infections become evident 3 to 5 days postoperatively. Seven to ten days postoperatively, clinical manifestations of wound infections develop. Deep venous thrombosis can result in fever any time but usually not until the fifth postoperative day. Antibiotic-induced pseudomembrane colitis occurs up to 6 weeks postoperatively. An approach for evaluating and managing fever in postoperative patients is presented in   Table 84-3.

TABLE 84-3 Evaluation and Management of Postoperative Fever

RESPIRATORY COMPLICATIONS

Respiratory complications occur in many surgical patients and range from atelectasis and pneumonia to pneumothorax or pulmonary embolism.

Atelectasis

Atelectasis, the collapse of pulmonary alveoli, is very common. Contributing factors include inadequate clearance of secretions following general anesthesia, decreased intraalveolar pressure, and postoperative pain, which results in hypoventilation. While atelectasis can occur following any procedure, it frequently occurs following upper abdominal and thoracic surgery. The presentation varies from an isolated fever to tachypnea, dyspnea, and tachycardia.

Evaluation includes a chest radiograph, pulse oximetry, and a complete blood count (CBC). Chest radiographs may be normal or show platelike linear densities, triangular-shaped densities, or lobar consolidation. Mild hypoxemia from ventilation-perfusion mismatch is common, but hypercarbia is uncommon. Patients with mid atelectasis and no evidence of hypoxemia may be managed as outpatients with pain control and increased deep breathing. Admission is indicated for aggressive pulmonary toilet and supplement oxygenation in debilitated patients, patients with underlying lung disease, patients with hypoxemia, or those in whom the diagnosis is in question.

Pneumonia

Pneumonia usually presents between 24 and 96 h postoperatively. Predisposing factors include prolonged ventilatory support and atelectasis. Presenting symptoms can include dyspnea, chest pain, productive cough, fever, and tachypnea. Postoperative pneumonia is likely to be polymicrobial. After cultures of sputum and blood are obtained, parenteral antimicrobial therapy with an aminoglycoside and an antipseudomonal penicillin should be administered. Admission to the hospital is generally indicated.

Pneumothorax

Pneumothorax can occur as a complication of thoracic wall surgery, breast biopsy, laparoscopic abdominal surgery, abdominal paracentesis, nasogastric and feeding tube insertion, thoracic surgery, central venous catheter insertion, endoscopic procedures, shoulder arthroscopy, and tracheostomy. The pathophysiology varies with these different procedures, but clinical features are similar. Patients complain of chest pain, shoulder pain, and/or dyspnea. Physical findings can include tachypnea, hyperresonance to percussion, and decreased breath sounds on the affected side. Diagnosis is confirmed by chest x-ray with expiratory views.

Pulmonary Embolus

Pulmonary embolism may present any time during the postoperative period. A lower-extremity or pelvic thrombus dislodges and migrates to the pulmonary vasculature. The presenting signs and symptoms vary, depending on the size of embolus and the underlying cardiopulmonary status of the patient. Patients have varying degrees of dyspnea, chest pain, cough, and anxiety. Hemoptysis is usually seen only late in a patient's course and with massive pulmonary embolism. The patient may have essentially normal vital signs or be tachypneic and tachycardic.

Diagnosis of pulmonary embolism is difficult because of the poor sensitivity of noninvasive tests. While hypoxemia and a widened alveolar-arterial (A-a) oxygen gradient are frequently found with larger emboli, patients may have normal oxygen content and a normal A-a gradient. Diagnosis requires venous Doppler ultrasonography, ventilation-perfusion scan, pulmonary computed tomography (CT) scan, or pulmonary angiography. Patients with low clinical suspicion, normal vital signs, good oxygenation, and a low probability scan can be discharged, provided other causes of their symptoms have been addressed.

GENITOURINARY COMPLICATIONS

The most common postoperative genitourinary complication is urinary tract infection. However, patients may present with acute urinary retention and acute renal failure (ARF).

Urinary Tract Infection

Urinary tract infections can occur after any surgical procedure. However, there is an increased incidence in patients who have had instrumentation of the genitourinary tract or bladder catheterization. The cause is direct contamination of the urinary bladder, most commonly with *Escherichia coli.* Other organisms isolated include *Staphylococcus aureus, Staphylococcus epidermidis, Proteus mirabilis, Klebsiella, Pseudomonas,* and enterococci. Oral antibiotics are appropriate for most infections; however, elderly or debilitated patients and patients with evidence of sepsis require admission for parenteral antibiotics.

Urinary Retention

Acute urinary retention occurs in about 4 percent of all surgical patients.[2] It is postulated that urinary retention occurs as the result of catecholamine stimulation of a-adrenergic receptors in the bladder neck and urethral smooth muscle. Increased incidence of urinary retention is likely to occur in elderly males, with excessive fluid administration during surgery, and with the use of spinal or epidural anesthesia.

Patients with urinary retention present with lower abdominal discomfort, urinary urgency, and inability to void. The diagnosis is confirmed by placement of a Foley catheter. The bladder can be safely drained quickly without clamping, since there appears to be no foundation for the fears of hematuria, postobstructive diuresis, and hypotension.[3] For patients with normal renal function and no anatomic obstruction, continued catheter drainage is not necessary. For patients with retention after genitourinary procedures, the urologist must be consulted before disposition. Prophylactic antibiotics can be given if the genitourinary tract has been instrumented, if retention is prolonged, or if the patient is at risk for infection.

Acute Renal Failure

ARF is classified according to the primary cause: prerenal, intrinsic, and postrenal. Volume depletion is the most common prerenal cause. Intrinsic causes include acute tubular necrosis and drug nephrotoxicity. Obstructive uropathy is the cause of postrenal ARF. Patients with ARF have either oliguria or anuria, and, depending on the degree of ARF, may have signs of uremia and electrolyte abnormalities.

Patients should be examined for signs of hypovolemia and have a urinary catheter placed. Indwelling urinary catheters must be irrigated or replaced. If the patient is hypotensive, a fluid bolus is given to determine whether the cause is prerenal. In patients with urinary outlet obstruction, the urinary catheter is both diagnostic and

therapeutic. If there is doubt about the cause of the renal failure, central venous pressure and pulmonary capillary wedge pressure measurements can be helpful. The presence of postobstructive uropathy above the urinary bladder can be confirmed using abdominal ultrasound. When no prerenal or postrenal cause can be identified, there is likely to be an intrinsic cause of ARF.

WOUND COMPLICATIONS

Wound complications are frequent and include hematomas, seromas, infections, necrotizing fasciitis, and dehiscence. The patient's surgeon should be notified of all wound complications.

Hematomas

Wound hematomas result from unrecognized inadequate hemostasis. Patients have pain, pressure, and swelling within the wound. Patients with wound hematomas may be febrile and have sanguineous or serous wound drainage. Differentiating between hematoma and wound infection can be difficult. A few sutures are removed to allow the hematoma to drain, and cultures are obtained. If there is no evidence of infection and hemostasis can be maintained, the patient can be discharged. In patients with a hematoma of the neck or who have undergone vascular surgery, extreme caution and consultation are appropriate.

Seromas

A seroma, a collection of serous fluid, is usually the result of inadequate control of lymphatics during dissection but can also occur under split-thickness skin grafts and areas with large dead spaces (e.g., axilla, groin, neck, or pelvis). Patients have painless swelling below the wound or graft, and needle aspiration yields a serous fluid. Aspiration confirms the diagnosis and alleviates the problem, although it may have to be repeated later.

Infection

Systemic factors (e.g., extremes of age, poor nutrition, or diabetes) contribute to wound infections; however, local factors (e.g., necrotic tissue, poor perfusion, foreign bodies, and hematomas) are of greatest significance. In nontraumatic, uninfected operative wounds in which the respiratory, alimentary, and genitourinary tract were not entered, infection rates are low. In these cases, the infecting organism is usually from the skin but can originate from remote infected sources (e.g., urinary tract infection). If there is a remote infected source, the organism is probably the same in both infections. Wounds associated with entering the respiratory, alimentary, or genitourinary tract or secondary to trauma have a higher risk of infection.

Presenting signs and symptoms of wound infections include increasing pain, erythema, swelling, drainage, and tenderness at the incision site. Wounds not inolving the perineum and not associated with entry into the gastrointestinal or biliary tract are most often infected with *S. aureus* or streptococci. Such wounds can be safely managed with drainage, culture of the wound, irrigation, loose packing with gauze, and outpatient antibiotics. Wounds involving the perineum or associated with the gastrointestinal or biliary tract are often infected with multiple organisms, including gram-negative bacteria and anaerobes. Parenteral broad-spectrum antibiotics are administered, and admission is necessary.

Necrotizing Fasciitis

Necrotizing fasciitis is a feared complication. The usual cause is direct contamination of the wound with group A streptococcus or *S. aureus;* however, mixed aerobic and anaerobic infections have been reported. Risk factors include diabetes mellitus, alcoholism, immunosuppression, and peripheral vascular disease, but necrotizing fasciitis also occurs in young, otherwise healthy individuals. Early clinical differentiation from cellulitis can be difficult. CT may show asymmetric fascial thickening, gas tracking along fascial planes, or focal fluid collections; however, the actual sensitivity and specificity of CT in the diagnosis of necrotizing fasciitis has not been defined.[4] Magnetic resonance imaging has been shown to be highly sensitive but not totally specific for necrotizing fasciitis and can be a useful adjunct. [5] The presence of marked systemic toxicity and pain out of proportion to local findings indicates fasciitis. In more advanced cases, there may be deep pain with patchy areas of surface hypesthesia, crepitance, or bullae. Treatment should include antibiotics and immediate surgical debridement. Antibiotic choice is controversial but should probably include a penicillin or cephalosporin, an aminoglycoside, and clindamycin. [6]

Wound Dehiscence

Wound dehiscence can be superficial or can extend into the deeper fascial planes. Dehiscence is caused by either inadequate closure or intrinsic host factors, such as malnutrition, glucocorticoid use, or diabetes. The patient may have serosanguineous fluid leaking from the wound. Dehiscence of abdominal incisions has the potential for evisceration. If evisceration is not present, conservative management using abdominal binders is appropriate. However, if there is any uncertainty, operative exploration is indicated.

VASCULAR COMPLICATIONS

Postoperative vascular complications include thrombophlebitis and deep venous thrombosis. Superficial thrombophlebitis usually occurs in the upper extremities, secondary to prolonged cannulation of the vein or infusion of irritating fluids. Deep venous thrombosis is secondary to stasis, endothelial damage, or hypercoagulopathy.

Superficial Thrombophlebitis

Superficial thrombophlebitis of the lower extremities is most frequently secondary to stasis in varicose veins. It is usually aseptic. The patient complains of redness and warmth of the affected vein. If there is no evidence of surrounding cellulitis or lymphangitis, the patient is treated with local heat and elevation. Suppurative superficial thrombophlebitis is characterized by erythema, palpable tender cord, lymphangitis, and pain. Suppurative thrombophlebitis requires excision of the affected vein.

Deep Venous Thrombosis

When lower-extremity superficial thrombophlebitis is seen, the possibility of concurrent deep venous thrombosis must be considered. Swelling of the extremity is the most specific physical sign, and its presence requires diagnostic evaluation. Doppler ultrasonography is generally the preferred diagnostic test. Patients with normal color-flow study results should be treated with elevation and bed rest. Repeat color-flow Doppler ultrasound studies should be performed in 3 days if symptoms persist but sooner if symptoms worsen.

COMPLICATIONS OF DRUG THERAPY

Many medicines have been reported to cause drug fever (Table 84-4).[7] The mechanisms proposed are hypersensitivity reactions, pyogenic effect, and disturbed thermoregulation. In patients in whom no source for the fever can be found, it is appropriate to consider stopping medications known to cause drug fever.

TABLE 84-4 Medications Associated with Drug Fever

Many antibiotics can cause diarrhea; however, the greatest concern in postoperative patients is pseudomembranous colitis (PMC). PMC is due to the toxin produced by the bacterium *Colstridium difficile.* PMC is related to antibiotic use, which destroys the normal enteric bacterial flora, allowing an overgrowth of the *C. difficile.* Even short courses of antibiotics have been associated with PMC. Patients have watery, and sometimes bloody, diarrhea, elevated temperature, and crampy abdominal pain. Although tissue culture for *C. difficile* is the diagnostic gold standard, the diagnosis is usually made by detecting *C. difficile* cytotoxin in the stool.[1] This immunoassay is slightly less sensitive than is the tissue culture, but it is technically easier to do and provides an answer within 2 to 3 h. If results on the first specimen are negative and the diagnosis is still suspected, a second sample should be sent for immunoassay. When severe illness is present, consider empiric therapy with metronidazole while awaiting diagnostic studies.

COMPLICATIONS OF BREAST SURGERY

Breast biopsy is a common procedure. While complications are infrequent, patients can develop minor wound infections and hematomas. Rarely, pneumothorax has been reported. Wound hematomas frequently require operative control for proper evacuation and hemostasis.

Early complications seen with mastectomies include wound infection, necrosis of skin flaps, and the accumulation of seromas. The most common late complication is lymphedema of the arm. The incidence of postmastectomy lymphedema ranges from a low of 5.5 percent to a high of 80 percent. Most patients can be managed using a combination of fitted compression garments, nighttime elevation, and minor activity restrictions.[8]

COMPLICATIONS OF GASTROINTESTINAL SURGERY

Patients who have undergone any gastrointestinal surgery may have intestinal obstruction, intraabdominal abscess, pancreatitis, cholecystitis, fistulas, and tetanus. Certain procedures, such as anastomoses, gastric surgery, placement of gastrostomy tubes, biliary tract surgery, other laparoscopic surgery, stomas, colonoscopy, and rectal surgery have specific complications.

General Considerations

INTESTINAL OBSTRUCTION   Ileus, a functional obstruction of the bowel, is postulated to be the result of stimulation of the splanchnic nerves, leading to neuronal inhibition of coordinated intrinsic bowel wall motor activity. It is expected after any operation in which the peritoneal cavity is violated. Following gastrointestinal surgery, small bowel tone usually returns to normal within 24 h, and colonic function within 3 to 5 days.[9] While ileus can also occur following nongastrointestinal procedures, it is usually secondary to anesthetic agents, and function returns to normal after 24 h.[9] Prolonged ileus can be caused by peritonitis, intraabdominal abscess, hemoperitoneum, pneumonia, electrolyte imbalance, sepsis, and medications.

Presenting symptoms of ileus include nausea, vomiting, obstipation, constipation, abdominal distention, and abdominal pain. When these symptoms are present in the first few days after surgery, they are most often due to adynamic ileus. The symptoms of adynamic ileus are most often mild and respond to nasogastric suction, bowel rest, and intravenous hydration. However, in cases of prolonged ileus, the physician must always look for an underlying cause. Evaluation of patients with suspected ileus includes abdominal radiographs to identify air-fluid levels, chest x-ray, CBC, electrolytes, and urinalysis for secondary causes of ileus.

Mechanical ileus of the bowel is most often secondary to adhesions. Small bowel obstruction above the ligament of Treitz is associated with frequent bouts of bilious emesis. In cases of more distal obstruction, pain and distention become more severe, the frequency and volume of vomiting decrease, and emesis becomes more feculent. Abdominal radiographs demonstrate multiple air-fluid levels and a paucity of gas in the colon; however, with high obstruction, above the ligament of Treitz, there may be no air-fluid levels. In the emergency department, differentiating between functional ileus and mechanical bowel obstruction can be difficult. Both disorders result in varying degrees of abdominal pain, distention, nausea, vomiting, and constipation. Once the diagnosis of mechanical obstruction is confirmed or suspected, surgical consultation is indicated.

INTRAABDOMINAL ABSCESS   Intraabdominal abscess is caused most frequently by preoperative contamination, spillage of bowel contents during surgery, contamination of a hematoma, or postoperative anastomotic leaks. Patients may have abdominal pain, nausea, vomiting, ileus, abdominal distention, fever, chills, anorexia, and abdominal tenderness. If the diagnosis is suspected, CT or ultrasound studies of the abdomen are required. The patient should receive broad-spectrum antibiotics. Although some abscesses are amenable to percutaneous drainage, many patients require surgical exploration.

PANCREATITIS   Pancreatitis following abdominal surgery is secondary to direct manipulation or retraction of the pancreatic duct. It most commonly occurs following gastric resection, biliary tract surgery, and endoscopic retrograde cholangiopancreatography (ERCP). Clinical presentation varies from mild nausea, vomiting, and abdominal discomfort to intractable vomiting, leukocytosis, and left pleural effusion. Severe hemorrhagic presentation can cause lumbar pain accompanied by blue-gray discoloration of the skin in the flank area (Turner sign) or similar changes around the umbilicus (Cullen sign). While the serum amylase level rises in acute pancreatitis, it is also elevated in patients with severe cholecystitis, renal insufficiency, intestinal obstruction, perforated ulcer, or ischemic bowel. A serum lipase measurement may help to identify those with true pancreatitis, although it may be elevated in a patient with a perforated viscus. Abdominal radiographs may show localized ileus in the region of the pancreas (sentinel loop). CT is useful in defining pancreatic fluid collections or abscesses. Generally, the treatment of postoperative pancreatitis is similar to the treatment of nonoperative pancreatitis: bowel rest, antiemetics, and nasogastric suction.

CHOLECYSTITIS   Patients may present during the postoperative period with biliary colic, acute calculous cholecystitis, or acute acalculous cholecystitis. The etiology of these disorders in the postoperative period is not clear. Ultrasound studies of the gallbladder and pancreas should be performed to aid in the diagnosis.

Acalculous cholecystitis is of particular concern in the postoperative period. While it may occur in any age group, it seems to be more common in elderly males. Signs and symptoms are similar to those for calculous cholecystitis, but ultrasound studies fail to reveal gallstones. Liver function studies and the neutrophil count may be normal. Important findings on ultrasonography include gallbladder enlargement, wall thickening, and pericholecystic fluid collection. Hepatobiliary scintigraphy may be helpful. Early diagnosis is critical because early operative intervention can reduce morbidity and mortality rates.

FISTULAS   Enterocutaneous fistulas can occur almost anywhere in the gastrointestinal tract and are usually the result of technical complications or direct bowel injury. High-output fistulas can result in electrolyte abnormalities and volume depletion. Fistulas involving the proximal gastrointestinal tract are frequently high output and are of the greatest concern. Sepsis is the other major complication. Most patients require admission, although many fistulas ultimately close spontaneously.

TETANUS   While most cases of tetanus in the United States occur after minor trauma, there have been numerous reports of tetanus following general surgical procedures. *Clostridium tetani* is found in the gastrointestinal tract of 1 percent of the population.[10] During gastrointestinal surgery, there is spillage of *C. tetani.* Proliferation of the organism is facilitated by the presence of devitalized tissue, blood clots, and surgical suture. Incubation can take from 1 to 54 days, at which time the toxin leads to clinical tetanus.[11] The classic symptoms of tetanus, trismus and opisthotonos, may not be manifested at initial presentation. Patients may present with nonspecific symptoms of abdominal discomfort, fever, and abdominal wall rigidity. Diagnosis is based on physical examination and a history of inadequate immunization.

Specific Considerations

ANASTOMOSIS   Anastomotic leaks occur most frequently after esophageal and colonic surgery and least frequently after gastric and small intestinal anastomoses. The cause of anastomotic leakage is mainly related to surgical technique.

Intrathoracic esophageal anastomotic leaks usually manifest within 10 days of surgery. The presentation is dramatic, with fever, chest pain, tachypnea, tachycardia, and possibly shock. Chest x-ray may reveal a pneumothorax with pleural effusion. Disruption can be confirmed by contrast esophagography using a water-soluble

contrast agent. Even with immediate reoperation, morbidity and mortality rates are high.

The signs and symptoms of gastric anastomotic leaks include abdominal pain, fever, leukocytosis, gastric outlet obstruction, hyperamylasemia, hyperbilirubinemia, peritonitis, and shock. Plain radiographs may reveal pneumoperitoneum or air-fluid levels. The patient should have immediate volume resuscitation, parenteral broad-spectrum antibiotics, and nasogastric tube drainage. Immediate surgery is required.

Small-intestinal anastomoses infrequently leak because of the excellent blood supply and rapid healing of the area. However, if a leak occurs, the patient usually presents with local abscess formation or peritonitis. Treatment is immediate reoperation.

Colorectal anastomoses are prone to disruption because of the large number of pathogenic bacteria, propensity for colonic distention, and single thin layer of circular muscle to support sutures. The patients usually present 7 to 14 days postoperatively with evidence of intraabdominal or pelvic abscess. CT studies can be helpful in diagnosis. Patients should receive broad-spectrum parenteral antibiotics, nasogastric tube drainage, and adequate fluid resuscitation in preparation for surgery.

GASTRIC SURGERY   Patients who have undergone partial or complete gastrectomy can present with a few distinct syndromes: dumping syndrome, alkaline reflux gastritis, afferent loop syndrome, and postvagotomy diarrhea. While these complications are rare, the symptoms can be disabling.

Dumping syndrome can occur either early or late after a meal. While the precise etiology of dumping symptoms is unclear, it occurs when the pylorus is either bypassed or removed. The hyperosmolar chyme contents of the stomach are dumped into the jejunum, resulting in rapid influx of extracellular fluid and an autonomic response.

Patients experience nausea, epigastric discomfort, palpitations, abdominal colic, diaphoresis, and, in some cases, dizziness and syncope. Patients with early dumping symptoms experience diarrhea, while those with late dumping symptoms, 2 to 4 h postprandial, usually do not. The late dumping syndrome is felt to be due to a reactive hypoglycemia. The mainstay of treatment is dietary modification; eating small, dry meals; and separating solids from liquids. In refractory cases, pyloroplasty can be tried. Most of these patients do not require admission.

Patients with alkaline reflux gastritis present with continual burning epigastric pain that is aggravated by meals and unrelieved by vomiting. The syndrome is caused by reflux of bile into the stomach. Diagnosis is made by endoscopic examination.

Patients with afferent loop syndrome also present with severe epigastric pain 1 to 2 h after eating, which is relieved by vomiting. The vomitus will be bilious, without food. The syndrome occurs in patients who have undergone gastroenterostomy (Billroth II) reconstruction after partial gastrectomy. Diagnosis is made by contrast radiography or endoscopy. Operative reconstruction is required.

Although most patients undergoing truncal vagotomy have increased bowel movements, some will have diarrhea. The precise etiology is not clear. Patients present with diarrhea that is variable in its occurrence and not associated with food intake. It is often unpredictable and explosive, which can lead to weight loss and malnutrition as well as severe social complications. The incidence of the diarrhea decreases with time, and treatment is mostly symptomatic.

GASTROSTOMY TUBES   Most gastrostomy tubes are now placed by either an endoscopist via percutaneous endoscopy or by a radiologist via percutaneous fluoroscopy. If the patient has undergone a laparotomy, the general surgeon may place a gastrostomy tube at the time of surgery. If the tube was placed by the surgeon and has not been replaced, it will have a bumper holding the tube in place. The tube has to be cut and the bumper allowed to pass, or the bumper has to be removed by endoscopic technique. For further discussion, see Chap. 85, "Complications of GI Devices."

BILIARY TRACT SURGERY   More than half of all cholecystectomies are now performed laparoscopically. There are complications seen after both open and laparoscopic cholecystectomy (Table 84-5) and complications related to the laparoscopic technique (Table 84-6).[12,13] Patients are likely to present to the emergency department with nonspecific abdominal symptoms.

Bile leak
Bile duct stricture
Bleeding
Bowel injury
Intraabdominal abscess
Myocardial infarction
Pancreatitis
Pulmonary complications

Biliary cutaneous fistula
Chronic pain
Infertility
Cholelithiasis
Metastases to the trocar site

TABLE 84-6   Complications of Laparoscopy

The evaluation of abdominal pain after cholecystectomy depends on the clinical condition of the patient. If there are signs of peritoneal irritation or fever, an injury to the biliary system is likely. The patient should have a CT scan of the abdomen in addition to a CBC, electrolyte measurements, liver function tests, and a serum lipase test. ERCP will be required to identify the site of the injury; however, a collection of bile can be seen in a CT scan. Depending on the ERCP results, reoperation may be necessary. Small collections of bile may require only observation or percutaneous drainage.

Patients presenting soon after cholecystectomy with pain, pancreatitis, and/or jaundice may have retained common duct stones. If the CT scan does not reveal an intraabdominal collection of fluid, an ERCP should be performed. Endoscopic sphincterotomy is usually an effective means of dealing with retained stones. Patients presenting late after cholecystectomy with fever, pain, and jaundice may have bile duct stricture. Diagnosis requires ERCP. While stents are usually tried at first, surgical repair may be necessary. A more recent concern has been the spillage of gallstones into the peritoneal cavity at the time of surgery. Initially, such stones were thought to be innocuous. However, they have been linked to abdominal pain, pelvic pain, dysmenorrhea, intraabdominal abscess, colocutaneous fistula, and implantation into the ovary with subsequent infertility. [14]

OTHER LAPAROSCOPIC SURGERIES   Laparoscopic techniques are now being used for an increasing number of procedures. In addition to cholecystectomy, they have been used for appendectomy, colon resection, antireflux surgery, herniorrhaphy, fundoplication, and most gynecologic surgical procedures, including hysterectomy. The complications associated with these procedures have not been completely identified; however, they are likely to be similar to those seen with cholecystectomy.

STOMAS   The two most common stomas placed are the ileostomy and the colostomy. Problems with these stomas can be quite debilitating. Most complications are related to technical errors as to where the stomas are placed; however, there can be problems of new disease within the stoma (e.g., Crohn's disease or cancer). Possible complications include ischemia and stomal necrosis, peristomal skin irritation, peristomal hernia, and stomal prolapse.

Ischemia and stomal necrosis are manifested very early in the postoperative course. The cause is inadequate blood supply to the stoma. Normally, the stoma is pink, without any evidence of cyanosis. Any evidence of compromised blood flow requires surgical evaluation.

Peristomal maceration and skin destruction are most likely secondary to a poor seal of the stomal appliance. Consultation with an enterostomal therapist for a properly fitting appliance is indicated.

Prolapse can occur with both ileostomies and colostomies. The cause is usually inadequate fixation of the intraabdominal portion or too large an abdominal wall opening. Patients present with the stoma protrusion, with or without pain. The stoma must be examined to determine viability. The stoma should be pink and painless. Reduction should be attempted if the tissue is viable, followed by consultation with a surgeon. Definitive therapy requires surgical revision.

Parastomal hernias are secondary to too large an abdominal wall opening. As with any hernia, the physician should determine whether the hernia is incarcerated, attempt reduction, and consult a surgeon. Definitive therapy requires local reconstruction of the orifice.

COLONOSCOPY   Potential complications of colonoscopy include hemorrhage, perforation, retroperitoneal abscess, pneumoscrotum, pneumothorax, volvulus, postcolonoscopy distention, bacteremia, and infection.

Hemorrhage is the most common complication and can be secondary to the polypectomy procedures, biopsies, laceration of the mucosa by the instrument, or tearing of the mesentery or spleen. If the bleeding is intraluminal, the patient will present with rectal bleeding. Patients with mesenteric or splenic injury will present with signs of intraabdominal bleeding. Treatment of intraluminal bleeding depends on the magnitude of hemorrhage. Signs of intraabdominal bleeding require emergency laparotomy.

Perforation of the colon with pneumoperitoneum usually is evident immediately but can also take several hours to manifest. Perforation is usually secondary to intrinsic disease of the colon (e.g., diverticulitis) or to vigorous manipulation during the procedure. Most patients will require immediately laparotomy; however, in some patients presenting late (1 to 2 days later) without signs of peritonitis, expectant management may be appropriate.

RECTAL SURGERY   Patients who have undergone hemorrhoidectomy frequently have problems with postoperative urinary retention, the management of which has been previously discussed. Three other problems that can occur are constipation, rectal hemorrhage, and rectal prolapse.

The management of constipation in a patient who has undergone rectal surgery is no different from that of any other patient with constipation. Gentle rectal examination is indicated, and enemas can still be used. Posthemorrhoidectomy rectal hemorrhage can occur immediately postoperatively but may also be delayed (4 ± 2 days).[15] Proposed causes of delayed bleeding include sepsis of the pedicle, disruption of a clot, and sloughing of tissue. [16] The patient may present with minimal bleeding or massive hemorrhage. While ligation of the affected vessel is needed, a temporary tamponade with a Foley catheter may be helpful.

Patients may present with mucosal prolapse or complete rectal prolapse. Mucosal prolapse occurs when the surgeon has not removed all redundant mucosa during hemorrhoidectomy and is much more common than rectal prolapse. Local treatment by a surgeon is usually corrective. Rectal prolapse can occur after any anorectal surgical procedure and probably is related to injury of the puborectalis muscle. The patient will present with the sensation of protrusion and may complain of pain. The treatment is reduction and surgical consultation.

Infection following anorectal surgery is surprisingly uncommon. The patient usually complains of increasing pain and fever. Examination of the area is necessary to detect an abscess or cellulitis. Fournier's gangrene may follow anorectal surgery. If this is suspected, broad-spectrum parenteral antibiotics are given immediately. The patient requires immediate surgical debridement.

85 COMPLICATIONS OF GASTROINTESTINAL DEVICES

Edmond A. Hooker

The gastrointestinal (GI) device that is most commonly used by emergency physicians is the nasogastric (NG) tube. Other GI devices encountered in the emergency department (ED) include large-bore orogastric tubes, small-bore nasointestinal ("feeding") tubes, and transabdominal feeding tubes (gastrostomy, jejunostomy, and gastrojejunostomy tubes). Although complications from the use of these are rare, they must be anticipated and prevented if possible.

NASOGASTRIC TUBES

The NG tube is probably the most common device placed in the GI tract. Tubes range in size from 6 to 18 Fr (1 Fr = 0.333 mm). These devices are relatively easy to place blindly in an alert, cooperative patient. Obtunded patients or those without an active gag reflex may require endotracheal intubation prior to NG insertion. It is important to note that the presence of an endotracheal tube with an inflated balloon does not prevent passage of these tubes into the respiratory tract.

Major complications have been reported with the use of NG tubes (Table 85-1). Improper placement is the principal cause of these complications, and different techniques have been proposed to help identify improper placement of nasogastric tubes (Table 85-2).[1] However, according to published research, none of the techniques have proven effective. The technique that is probably most commonly used, insufflation of air into the NG tube while listening over the stomach, has many reported failures.

Epistaxis

Intracranial placement

Bronchial placement

Pharyngeal perforation

Esophageal obstruction or rupture

Bronchial or alveolar perforation

Pneumothorax

Charcoal instillation into the lungs and pleural cavity

Gastric or duodenal rupture

TABLE 85-1 Complications of Placement of Nasogastric and Nasoenteric Tubes

  pH testing of aspirates (pH ≤ 6 indicates gastric placement)

Indicates tracheobronchial placement
  Coughing or choking
  Inability to speak
  Air bubbles when proximal end of tube is placed in water

TABLE 85-2 Techniques for Identifying Nasogastric and Nasointestinal Feeding Tube Placement

Placement of the NG tube into the respiratory tract can result in pneumonia or pneumothorax. If charcoal is instilled, the outcome can be fatal. While not the standard of care, chest radiographs may aid in the confirmation of NG placement prior to instilling charcoal or other medications. If the tube is identified in the chest cavity, it must be determined whether it entered through the lungs or through the esophagus. All possible charcoal should be removed by suctioning prior to removing the NG tube or, in the case of charcoal thorax, by chest tube drainage.

There are numerous reports of intracranial placement of NG tubes.[2] Most cases have been reported in trauma patients; however, there is at least one report of intracranial placement in a nontrauma patient.[3] As with any catheter insertion, force should never be used, and nasogastric tubes should be inserted through the mouth in trauma patients who may have facial or basilar skull fractures. Any time a NG tube is placed and cannot be easily removed, an x-ray should be obtained to determine the location of the tube.

OROGASTRIC LAVAGE TUBES

Large-bore tubes (28 to 40 Fr) are used for gastric decontamination and charcoal instillation. The use of these tubes has come into relative disfavor in recent years.[4] This was not because of complications but rather because of a lack of proven efficacy. Complications have only been rarely reported with the use of the tubes but have included esophageal tears and inability to remove the tube secondary to esophageal spasm. If an orogastric lavage tube cannot easily be removed, the patient should undergo fluoroscopic examination with contrast in order to determine its exact location and any kinking. If the tube is simply stuck because of esophageal spasm, glucagon can be given to assist in its removal.[5]

NASOINTESTINAL TUBES

The small-bore nasointestinal tubes (more commonly called feeding tubes) are usually placed to support nutrition. Complications of these tubes include all of those described with NG tubes (Table 85-1), but the former are also more easily dislodged and clogged. With numerous reports of placement of these tubes into the respiratory tract and subsequent intrapulmonary instillation of tube feedings, most institutions require radiographic confirmation of tube placement.[6,7] Since patients can easily dislodge these tubes after initial confirmation of placement, some recommend pH testing prior to each usage.[8]

Replacement of a dislodged tube should be performed using the manufacturer's instructions and radiographic confirmation should be obtained (Table 85-3). When one of these tubes is clogged from buildup of sediment, the physician can attempt to unclog the tube by instilling saline or cola drink into the tube and leaving it for 30 min; however, replacement will frequently be necessary.[9]

Step 1: Prepare nares with topical anesthetic and lubricant. Restrain uncooperative patients. Lubricate and insert the stylet into the feeding tube (ensure that the stylet does not protrude beyond tip of tube).

Step 2: Place tube through nares into hypopharynx. If patient starts coughing or choking, tube may be in respiratory tract or coiled up in hypopharynx. The cooperative patient may swallow liquids to assist passage.

Step 3: After successful passage, remove stylet from tube and obtain a chest x-ray that includes the epigastric area. If tube is in proper position, start feedings.

*Warnings: Never reinsert a stylet into a feeding tube while the tube is still in the patient and never use a feeding tube prior to radiographic confirmation of placement.

TABLE 85-3   Method for Inserting a Nasointestinal Feeding Tube*

TRANSABDOMINAL FEEDING TUBES

While the techniques for the initial placement of transabdominal feeding tubes (gastrostomy, jejunostomy, and gastrojejunostomy) are beyond the scope of emergency physicians, complications related to these tubes need to be recognized (Table 85-4). These tubes can be placed by a surgeon via open technique, by a gastroenterologist via endoscopic technique [percutaneous endoscopic gastrostomy (PEG)], or by a radiologist via percutaneous techniques. The radiographic technique has been associated with fewer complications than either open or endoscopically assisted placement. [10,11]

TABLE 85-4   Complication Seen with Transabdominal Feeding Tubes

Frequent minor complications are associated with the use of these tubes, including purulent drainage and leakage around the stomal site, clogging, dislodgement, and vomiting and diarrhea.

Drainage from the stomal site is a common finding and represents a foreign-body reaction due to the catheter. As long as there is no evidence of cellulitis or necrotizing fasciitis, local skin care with hydrogen peroxide and warm water will usually clear up the problem. If there is granuloma formation with localized bleeding from friable skin, local treatment with silver nitrate will usually help.

Leakage of gastric contents can become a problem. This is managed by careful insertion of a larger tube. Care should be used not to force too large a tube into the stoma, as this can cause separation of the stomach wall from the abdominal wall.

Prevention is the best treatment for clogging of gastrostomy (G) and jejunostomy (J) tubes. Frequent flushing with water and careful crushing of pills will usually prevent this problem. Vomiting and diarrhea can be relieved by decreasing the amount of the feedings and/or diluting them.

If the tube cannot be unclogged or if it has fallen out, replacement will be necessary. If the tube was placed by a surgeon or gastroenterologist and has not been replaced, it will probably have a bolster (also called a mushroom) holding the tube in place (Fig. 85-1). This will prevent the tube from being removed. The tube must either have the bolster removed endoscopically or the tube may be cut off and the bolster allowed to pass through the GI tract. [12] The latter technique is generally safe in adults; however, its use in children has been associated with more frequent complications. [13] Endoscopic removal is advisable when there is suspected or potential obstructive disease of the GI tract, such as pyloric stenosis, intestinal pseudoobstruction, and intestinal stricture (e.g., due to radiation, ischemia, or inflammatory bowel disease). If the tube is cut, an abdominal radiograph should be obtained 1 week later to confirm passage of the internal component. Most reported complications from a retained internal bolster have occurred when the bolster did not pass within 1 to 2 weeks. [14]

FIG. 85-1. Percutaneous endoscopic gastrostomy tube with a mushroom bolster in place. (Adapted from Gauderer MWL, Ponsky JL: A simplified technique for constructing a tube feeding gastrostomy. *Surg Gynecol Obstet* 152:83, 1981, with permission.)

When the feeding tube has already been replaced or was originally placed via radiographic technique, it should have a balloon holding it in place. The balloon can usually be deflated and the tube easily removed. If there is a problem with removal, the tube can be cut off halfway down; this will usually allow the balloon to deflate. If the catheter still cannot be removed easily, it can be cut off at the skin and the internal component allowed to pass. It should be replaced as quickly as possible to prevent closure of the tract. While there is no published research stating how long it takes for a tract to mature, tracts that are 7 to 10 days old will probably remain open long enough to allow replacement. The physician must first determine, if possible, which type of tube is being used. If the tube is available, replacement with the same size is usually possible. If the tube is not available, it can be difficult to determine whether the tract is for a jejunostomy or gastrostomy tube. Location on the abdominal wall is not helpful. A tract for a G tube is usually larger. Old records may be useful and should be obtained if possible. After determining the type of tract and size of tube used previously, insertion should be performed by the physician using a water-soluble lubricant. If the size of the tube being replaced cannot be ascertained, it is reasonable to start with a 16-Fr replacement gastrostomy tube or Foley catheter. The lubricated tube should pass easily into the stoma without any additional equipment. If resistance is met, the attempt should be abandoned. A smaller tube can be tried to keep the tract open. After replacing the tube, a 20- to 30-mL bolus of a water-soluble contrast material (e.g., Gastrografin) should be instilled through the tube and a supine abdominal x-ray obtained within 1 to 2 min. [15] The x-ray should demonstrate rugae of the stomach for a G tube and flow into a small bowel for a J tube. If there is any question of improper placement, immediate

consultation should be obtained.

A special caution regarding jejunostomy tubes should be noted. Jejunostomy tracts are smaller, and smaller-size tubes are used (8 to 14 Fr). These tubes are usually not sutured in place and frequently become dislodged. They can be replaced with catheters made specifically for jejunostomies or with Foley catheters. If a Foley catheter is used to replace a lost jejunostomy catheter, the balloon should never be inflated because it can cause a bowel obstruction or damage the jejunum. The tube is lubricated, inserted into the stoma, and advanced 20 cm. These tubes are easily replaced if the tract is mature: however, if resistance is met, referral to a radiologist for fluoroscopic placement using guidewires is recommended. [16]

86 THE LIVER TRANSPLANT PATIENT

Steven Kronick

DEMOGRAPHICS AND SURVIVAL

Worldwide, approximately 7000 liver transplantations are performed yearly. In the United States, more than 4000 liver transplantations are performed at more than 100 centers each year. At present, the number of transplantations performed is limited only by the availability of organ donors. Before the 1980s, 1-year survival after liver transplantation was approximately 30 percent. Improvements in surgical techniques, immunosuppression protocols, and patient selection have increased mean patient survival to 87 percent at 1 year and 77.4 percent at 3 years. [1] Transplantation is the treatment of choice for end-stage liver disease (ESLD) refractory to all other interventions and is considered an effective means to improve quality of life as well as survival. [2] As this population of patients continues to grow, so will the number of patients with liver transplantation who present to the emergency department (ED) with transplant- and non-transplant-related problems. The incidence of transplant-related problems is high (Table 86-1) and evaluation is made difficult by the fact that many of the complications present with similar signs, symptoms, and laboratory abnormalities. Most transplant-related problems will require, at a minimum, direct communication with the transplant center for consultation and follow-up.

Complication	% with Complication
Infection	>60
Rejection	>50
Neurologic	≤47
Vascular clot, stenosis	≤30

TABLE 86-1   Common Complications Following Liver Transplantation

TRANSPLANT PROCEDURE

Indications for liver transplantation are listed in Table 86-2. The harvested liver can tolerate ischemia up to 24 h, but it functions best if ischemia time is less than 8 h. The risk of preservation injury increases after this time. Most patients undergo bilateral subcostal incision with upper midline extension to the xiphoid process. After recipient hepatectomy, the donor liver is placed in the recipient typically in the same (orthotopic) location as the liver it is replacing (Fig. 86-1). Venovenous bypass, used in most centers, may predispose the patient to thrombosis and pulmonary embolism. Normal color and consistency return to the organ in approximately 15 min. Early bile production after vascular reanastomosis is most indicative of graft function. [3] The preferred method for biliary tract reconstruction is an end-to-end choledochocholedochostomy. The use of a percutaneous biliary drain varies by center and when used typically stays in place 3 to 6 months. In children and in those whose anatomy will not allow choledochocholedochostomy, Roux-en-Y hepaticojejunostomy is performed. Newer techniques being used increasingly in pediatric patients include reduced-size liver transplant, split liver transplant, and living-related transplantation. [4]

Primary biliary cirrhosis
Primary sclerosing cholangitis
Fulminant and subfulminant hepatitis
Cirrhosis due to hepatitis B or C virus
Alcoholic cirrhosis
Children: biliary atresia (accounts for >50%)
  selected inborn errors of metabolism
Controversial Indications
Hepatocellular carcinoma
Contraindications
Extrahepatic malignancy
Liver metastases
Extrahepatic organ failure
Noncompliance
Active substance abuse
AIDS

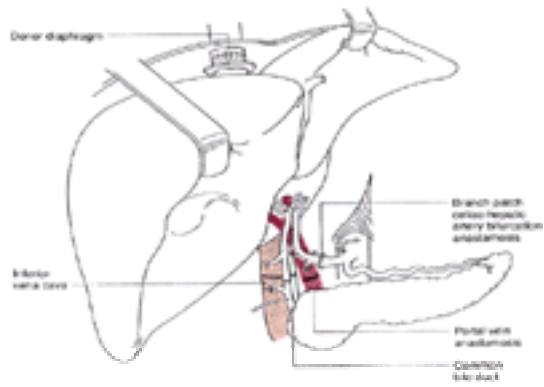
TABLE 86-2   Indications for Liver Transplantation


FIG. 86-1. End-to-end choledochocholedochostomy. If the recipient's system permits, this is the preferred method for reconstruction of the biliary system, the last part of the operative phase in liver transplantation.

POSTOPERATIVE COMPLICATIONS

Immediate postoperative complications are not seen in the ED, since patients typically remain hospitalized for approximately 2 weeks. Postoperative problems seen in the ED are most commonly related to bleeding, biliary, vascular, and wound complications.

Bleeding Complications

The vast majority of postoperative bleeding complications in patients will occur in the first week and will not be seen in the ED. More likely is gastrointestinal bleeding, which should be managed in the usual fashion but may signal graft dysfunction and be accompanied by profound hypoglycemia and progressive coagulopathy. [3] Portal hypertension is reversed by liver transplantation and gastrointestinal (GI) bleeding from varices postoperatively may be indicative of portal vein thrombosis. Another contributing factor that may predispose patients to GI bleeding is high-dose steroids. Cytomegalovirus (CMV), herpes simplex virus (HSV), and candidal infection can also lead to significant bleeding.

Biliary Complications

Biliary problems account for a significant proportion of complications, and incidence may be as high as 29 percent. [5] Leaks, strictures (ductal narrowing), and obstruction (ductal blockage) account for 80 percent of these complications. In general, leaks occur early, with 38 percent in the first 30 days and most (80 percent) within the first 6 months. [6] Early leaks tend to be more severe owing to duct disruption and higher immunosuppression and are notoriously difficult to treat. Leaks after the first month are invariably associated with either elective or inadvertent removal of an indwelling biliary catheter. [7] In children, stricture and obstruction are responsible for 90 percent of complications. [6] For patients with Roux-en-Y, the leak tends to occur at the anastomosis, whereas for the majority of patients who have choledochocholedochostomy, the leak is at the anastomosis early or the T-tube site later. [8] The cause of biliary injury is either immunologic or preservation injury, infection, or ischemia. Biliary leaks present most commonly with peritonitis, fever, abdominal pain, constipation, and abdominal distention, but signs and symptoms may be subtle or masked owing to the use of immunosuppressive agents. Laboratory abnormalities include leukocytosis, hyperbilirubinemia, and increased alkaline phosphatase. If abdominal drains are still in place, you may see bile in the drain, or if a T-tube is present, bile may appear at the tube site. [5] Evaluation should include Doppler ultrasound, as there is an association with hepatic artery thrombosis (HAT). Treatment of the leak includes drainage of abscess, if present, and intravenous antibiotics. Broad-spectrum antibiotic coverage should be directed against gram-positive, gram-negative, and anaerobic organisms. [6] Bacterial infections tend to be polymicrobial and include *Enterobacter, Enterococcus, Bacteroides, Clostridium,* species, and *Pseudomonas.*[3] Biliary leakage is associated with high mortality.

After 12 months, stricture and/or obstruction account for the vast majority of biliary complications. Development of a biliary complication is heralded by three typical presentations. Most common is intermittent episodes of fever and fluctuating liver function tests. The second presentation is gradual asymptomatic worsening of liver function tests. Finally, biliary complication may present as acute bacterial cholangitis with fever, chills, abdominal pain, jaundice, and bacteremia. Stricture or narrowing of the bile duct frequently develops insidiously. [7] The presentation of biliary complication can be difficult to distinguish clinically from rejection, HAT, CMV infection, or a recurrence of a preexisting disease (especially hepatitis).

Liver transplant recipients with suspected biliary complications should be referred to a transplant center. All patients should have a complete blood count (CBC) with platelet count and differential; serum chemistries including electrolytes, blood urea nitrogen (BUN), creatinine, liver function tests, amylase, and lipase levels; cultures of blood, urine, bile, and ascites if present; chest x-ray; and abdominal ultrasound with Doppler flow studies. Ultrasound rules out the presence of fluid collections, screens for the presence of thrombosis of the hepatic artery or portal vein, and identifies any dilation of the biliary tree. The intrahepatic ductal system rarely appears dilated appreciably by ultrasound, even in the presence of complete obstruction. Patients often require cholangiography for complete evaluation. Those patients with choledochocholedochostomy are best evaluated by endoscopic retrograde cholangiopancreatography (ERCP) because it permits both a radiographic diagnosis and the potential for nonoperative intervention. Patients who have Roux-en-Y hepaticojejunostomy or those who cannot have ERCP must undergo percutaneous cholangiography. Early broad-spectrum prophylactic antibiotics should be administered prior to any biliary tract manipulation.

Vascular Complications

Vascular complications are less common than biliary complications but are associated with high morbidity, mortality, and graft failure. HAT is the most common vascular complication and tends to occur within the first 3 weeks after transplantation. The incidence reported is between 5 and 40 percent and tends to be higher in children. For this reason, children are frequently treated prophylactically with antiplatelet agents.

The presentation of HAT may be signaled by elevated prothrombin (PT) and transaminase levels, little or no bile production, liver abscess, unexplained sepsis, or as a biliary tract problem (leak, obstruction, abscess, or breakdown of the anastomosis). HAT may present with massive hepatic necrosis, sepsis, fever, and bacteremia after early thrombosis; bile leak, since the hepatic artery is the sole blood supply; relapsing fever with bacteremia secondary to focal abscesses or biloma; or it can be asymptomatic if collaterals have formed. [5] HAT is ominous, and frequently requires retransplantation. Occasionally, if diagnosed early, immediate thrombectomy and revision of the anastomosis may preclude the need for retransplantation. Pediatric patients are more susceptible to HAT and have a much more varied presentation, with an incidence as high as 26 percent in children and 31 percent in neonates. [9] Duplex ultrasonography (Doppler ultrasound with real-time scanning) has a sensitivity of 92 percent. [10] If ultrasound is not diagnostic and suspicion remains, one should proceed to angiography. [11] Hepatic artery rupture is uncommon and generally associated with intraabdominal sepsis and poor prognosis. [5] Portal vein thrombosis is less common and affects 2 to 3 percent of patients. The diagnosis is suggested by variceal hemorrhage, massive ascites, or other signs of portal hypertension. Initially, effort is directed toward reducing the portosystemic pressure gradient, but retransplantation may be necessary.

Wound Complications

Wound problems are probably underreported and include infection, hematomas, and seromas as the most common complications. Presentation may be subtle. Fever, chills, incisional pain, swelling, erythema, or drainage may not always be present due to immunosuppressive diminution of signs of inflammation. Infection can lead to necrotizing fasciitis. An increased degree of suspicion is necessary. Early broad-spectrum antibiotic coverage should be considered.

REJECTION

Acute allograft rejection is most commonly seen at 7 to 14 days. The incidence of acute rejection varies from 40 to 80 percent during the first posttransplant year. After several months, the incidence of acute rejection decreases steadily, but it may be triggered at any time by tapering of immunosuppressive agents. [12] Though frequently subtle in presentation, a syndrome of acute rejection includes fever, liver tenderness, lymphocytosis, eosinophilia, liver enzyme elevation, and a change in bile color or production. In the perioperative period, the differential diagnosis must include infection, acute biliary obstruction, and vascular insufficiency. The diagnosis can be made with certainty only by excluding other causes of graft dysfunction and biopsy, which usually requires referral back to the transplant center for management and

follow-up. Acute rejection is typically treated by high-dose glucocorticosteroid bolus followed by a rapid taper over 5 to 7 days. This treatment is effective in 65 to 80 percent of transplant recipients.[3] Secondary therapy includes the infusion of antilymphocyte globulin (e.g., OKT3), which is accompanied by a variety of potential side effects. Both these therapies are best managed at an experienced transplant center.

Chronic allograft rejection occurs in approximately 5 to 10 percent of recipients and is a major cause of late graft failure. The primary manifestation of chronic rejection is a persistently cholestatic liver injury pattern with elevated serum alkaline phosphatase and bilirubin, which can be associated with pruritus. Significant loss of hepatic synthetic function is often not evident until late in the course of chronic rejection. The diagnosis is made by biopsy.

INFECTION

General Considerations

The vast majority of liver transplant recipients have at least one episode of infection at some time after their transplantation and many have more than one episode. Infections or their complications are believed to account for most of the deaths. Vigilance for infection must remain high, since immunosuppression-induced blunting of the inflammatory response may mask the classic signs and symptoms of infection. Timing of infection after transplantation can be organized into three segments: less than 1 month, 1 to 6 months, and greater than 6 months. Infection in the first 30 postoperative days is primarily from bacteria and fungi. The patient is typically at the greatest levels of immunosuppression and the anastomoses are at their most vulnerable during the first month. The vast majority of infectious agents seen in less than 1 month are the same nosocomial agents seen in similar surgical patients. Opportunistic organisms are notably absent in the first month. CMV is discussed below.

During the first postoperative month, intraabdominal infections—including cholangitis, peritonitis, as well as liver and other intraabdominal abscesses—predominate. Presentation is marked by fever, abdominal pain and distension, ascites, and occasionally jaundice. Workup should include CBC with differential, liver function tests, urinalysis, chest x-ray, abdominal ultrasound, and blood and fluid cultures. Evaluation may include ultrasound, CT scan, T-tube cholangiography, ERCP, liver biopsy, and cultures of blood, urine, or aspirated fluid. The organisms responsible tend to be enterococci, gram-negative aerobes, anaerobes, *Staphylococcus,* and *Candida* species. Patients may also present with pneumonia or urinary tract infections related to intubation or indwelling bladder catheterization while hospitalized. Cultures may need to be held in order for fungi, viruses, CMV, *Nocardia* species, and *Mycobacterium tuberculosis* to grow. Shell-vial cultures should be obtained if there is any suspicion of CMV disease.

From 1 to 6 months, most infection is from viruses [reactivation, donor transmission, Epstein-Barr virus (EBV)] or opportunistic organisms. After 6 months, the incidence of serious infection declines, with cholangitis predominating. Risk of infection after 6 months approaches that of the general population, although morbidity and mortality may be higher.[15] A high index of suspicion should be maintained whenever immunosuppression is high.[14] Close monitoring is essential, as rapid deterioration can take place while the patient is still in the ED.

Bacterial Infection

Bacterial infection is most common in the first month, with gram-negative enteric organisms accounting for over 50 percent. Although gram-negative organisms predominate (especially *Pseudomonas aeruginosa*), gram-positive and anaerobic organisms are not uncommon. Broad-spectrum antibiotics should be considered early in the patient's course. Bacterial infection is frequently associated with the vascular or biliary anastomosis, especially hepatic artery thrombosis but also portal vein thrombosis. Ischemia may lead to bile leak and abscess or deep soft tissue infection. After the first month, the incidence of bacterial infections decreases and the incidence of opportunistic infection increases, but vigilance for bacterial illnesses should remain high. Community-acquired pneumonia is most likely due to *Streptococcus pneumoniae* and *Haemophilus influenzae.* Meningitis shows a high preponderance of Listeria monocytogenes as well as *S. pneumoniae, Staphylococcus aureus,* and gram-negative rods. Empiric antibiotic coverage should be aimed at this flora.

Fungal Infection

Although uncommon, fungal disease is seen most within the first 2 months; it can be disseminated and is accompanied by high mortality. Fungal disease can present with multiple organ involvement, peritonitis, fungemia, pneumonitis, or asymptomatic colonization. The incidence of fungal disease is continuing to decrease, but mortality remains high. Mortality is up to 78 percent if disease is systemic. *Candida* species are responsible for up to 75 percent of fungal illnesses. The diagnosis is by culture or biopsy, and the fungus may be difficult to isolate. Disseminated infection is present when infection is found in two or more sites and is associated with even higher morality. Fungal infection becomes more likely with retransplantation, Roux-en-Y, preoperative steroid use, accompanying vascular complications, the use of three or more intravenous antibiotics, and when the transplant is performed emergently.[12] Endemic mycoses (coccidioidomycoses, histoplasmosis, blastomycosis) are always possible in the immunocompromised host but are rarely seen in liver transplant patients.[3]

Viral Infection

Viral illnesses tend to present within the first few months. Viral and bacterial illnesses are often seen concurrently. The most common viral agent, and the most common cause of infection after transplantation, is CMV, a herpesvirus. It is reported to occur in between 23 and 85 percent of all liver transplant patients. Despite its high incidence and morbidity, it is rarely fatal unless disseminated and rarely has a significant effect on graft survival. It generally occurs within the first 3 months, with the peak incidence in the third and fourth weeks. Later occurrence is generally related to the need to increase immunosuppression for treatment of a prolonged episode of rejection. CMV can cause primary infection, or the infection can be a reactivation. Infection has three basic effects. First, it can produce a mononucleosis-like syndrome with spiking fever, arthralgias, malaise, neutropenia, atypical lymphocytes, and thrombocytopenia, with mild or moderate elevation in transaminase levels. Jaundice is rare. Second, CMV is frequently associated with opportunistic infection, which may be due to an additional immunosuppressive effect of its own. Finally, there is an increased propensity for allograft rejection.

The patient may present with a pneumonitis that, when present, is characterized by bilateral interstitial infiltrates that may lead to adult respiratory distress syndrome. Diagnosis may require bronchoalveolar lavage, but the appearance of the chest x-ray and the clinical picture may be suggestive enough for diagnosis. CMV pneumonitis may be seen in conjunction with *Pneumocystis carinii* pneumonia (PCP). CMV hepatitis may present similarly to rejection, with fever, malaise, anorexia, abdominal pain, hepatomegaly, and liver dysfunction. Liver biopsy is frequently needed for diagnosis but still may not be able to distinguish CMV disease from rejection. Disseminated disease is frequently associated with an increase in immunosuppression, especially with treatment with OKT3. CMV chorioretinitis may present with decreased visual acuity, photophobia, scotomata, floaters, eye redness, or pain. Its presence signals a poor prognosis and the presence of profound immunosuppression.[15]

There are three patterns of CMV infection. The patient at greatest risk is the seronegative recipient of a seropositive donor. Disease may also be caused by reactivation of latent virus that replicates after the initiation of immunosuppression—typically in the seropositive recipient of a liver from a seronegative donor. Finally, a seropositive recipient may receive a liver from a seropositive donor, which may produce either reactivation or superinfection, although it is clinically impossible and irrelevant to distinguish between them.

Effective treatment depends on rapid diagnosis. Treatment is with intravenous ganciclovir for 2 to 4 weeks. Diagnosis has been traditionally based on histology and culture. Standard fibroblast tube cell culture, however, can require 10 to 14 days for incubation. Serologic markers are too insensitive in the immunosuppressed patient, and electron microscopy is cumbersome. The shell-vial technique can detect the presence of CMV after 16 h of incubation. It is an indirect immunofluorescence testing method that uses a monoclonal antibody directed at an early antigen of the virus. Early detection and high antigenemia correlate positively with the severity of the infection.

Other viruses may cause illnesses in the posttransplant patient. Up to 34 percent of all transplant patients develop HSV, and half of these present within the first 3 weeks. Mucocutaneous or genital disease is generally due to reactivation of latent infection. It is generally not severe, and diagnosis can be made with Tzanck smear or culture. EBV can cause primary infection in children or the more common reactivated infection in adults. The disease can be self-limited and cause a mononucleosis-like syndrome, with fever, tonsillitis, and lymphadenopathy, or it may progress to a polymorphous, multiorgan B-cell infiltrative process with high mortality. Finally, it may produce a localized solid tumor. EBV plays a role in the development of a posttransplantation lymphoproliferative disorder and has a high incidence (20 to 30 percent) in patients maintained on immunosuppression and higher (80 percent) in patients who have received antithymocyte antibody.[13] Adenovirus and enteroviruses may cause systemic illness but are uncommon.

Parasitic Infection

Parasites are not common. PCP may present concomitantly with CMV or by itself. Diagnosis may require bronchoalveolar or transbronchial biopsy. Prophylaxis with trimethoprim/sulfamethoxazole (Bactrim) for the first 3 months has greatly reduced the incidence of PCP. Toxoplasma gondii is also uncommon but may cause a meningoencephalitis or single or multiple mass lesions. Toxoplasma infection causes fever, mental status changes, focal neurologic signs, seizures, or visual changes.

COMPLICATIONS OF IMMUNOSUPPRESSIVE AGENTS

Therapeutic immunosuppression is accompanied by a number of side effects and complications. Common and most life-threatening are the variety of infections that occur with the suppression of cell-mediated immunity. The agents of immunosuppression also have a number of nonspecific toxicities that complicate their use. Combined toxicities can produce or worsen preexisting renal insufficiency, hypertension, and hyperglycemia. Hypertension is perhaps the best example of combined toxicity.

Azathioprine interferes with both B- and T-cell responses to antigenic stimulation. Generalized myelosuppression is a common side effect resulting in leukopenia and, to varying degrees, thrombocytopenia and anemia (megaloblastic) and is generally seen within the first few weeks. Other observed toxicities include hepatitis, cholestasis, hepatic vein thrombosis, pancreatitis, dermatitis, and alopecia. Prolonged use also predisposes to malignancies such as squamous cell carcinoma of the skin and lip, cervical carcinoma, and lymphoproliferative disorder.

Glucocorticoids act primarily by inhibiting T-cell and macrophage function. In addition to immune suppression, long-term use of glucocorticoids suppresses endogenous adrenal function, which may produce Cushing syndrome and cause hypertension, glucose intolerance, osteoporosis, avascular necrosis of the hip, cataracts, pancreatitis, peptic ulcer disease, delayed wound healing, behavioral disorders, and malignancies.

Cyclosporine and FK506 inhibit T-cell proliferation. Nephrotoxicity is a common and usually reversible side effect manifest by elevated serum creatinine levels, hypertension, hyperkalemia, hyperuricemia, and gout. Patients are sensitive to dehydration. [12] Other side effects include headache, hirsutism, gingival hyperplasia, hyperglycemia, hypomagnesemia, hypercholesterolemia, hypertriglyceridemia, hepatotoxicity, and hemolytic uremic syndrome. Unlike those of other immunosuppressive agents, blood levels of cyclosporine and FK506 can be monitored along with serum creatinine to avoid serious toxicity; however, random levels are rarely helpful and dose is adjusted based on trough levels. [3]

Nonsteroidal anti-inflammatory agents should be avoided since they may increase nephrotoxicity. [16]

There are numerous drug interactions to consider with the immunosupressive agents. Some of these are summarized in Table 86-3.

Azathioprine
Allopurinol causes severe leukopenia
Pancuronium may require dose increase
Succinylcholine may require dose reduction
Warfarin (Coumadin) may require dose increase
Avoid drugs that may suppress bone marrow activity: sulfonamides, ganciclovir, cyclophosphamide, methotrexate

CSA(cyclosporine)/FK506(tacrolimus)
Drugs that may increase concentration: erythromycin, metoclopramide diltiazem, nicardipine, verapamil, OCP, ketoconazole, fluconazole, itraconazole, josamycin
Drugs that decrease concentration: octreotide, phenytoin, rifampin, nafcillin, phenytoin, phenobarbital, carbamazepine
Drugs that increase the risk of nephrotoxicity: aminoglycosides, amphotericin B, nonsteroidal anti-inflammatory drugs

Abbreviation: OCP, oral contraceptive pills

TABLE 86-3   Reported Drug Interactions with Immunosuppressive Agents

INCIDENTAL PROBLEMS

Immunization

Immunization is important in the transplant patient because the prevention of even a common illness may be lifesaving. The key to immunization in the immunosuppressed patient is that all live virus vaccines are contraindicated. Vaccines consisting of denatured protein, carbohydrate, or killed virus are safe, so diphtheria/pertussis/tetanus (DPT), inactivated polio. *H. influenzae* Pittman type, and Heptavax are all safe. Live viral or bacterial vaccines are absolutely contraindicated [oral polio, measles, mumps, rubella, yellow fever, BCG, TY21a typhoid, varicella]. [17] All of these may produce clinical disease.

Surgery

If surgery for problems other than those related to the graft is necessary, complications secondary to chronic steroids and immunosuppression should be anticipated. Also, caution must be taken in the presence of a coagulopathy. It is recommended that immunosuppression not be stopped unless there is sepsis, in which case the immunosuppression might need to be reduced. Two series looking at cardiac and general surgery showed no documented decline in graft function and no need for stress dosing of steroids. [18],[19]

Bone Disease

Skeletal complications are responsible for significant morbidity and, because of increased survival times, are becoming more prevalent. Osteopenia and osteonecrosis can occur due to immobility, poor nutritional status, decreased muscle mass, steroid use, and immunosuppressive drugs. The first 3 to 6 months posttransplant are accompanied by accelerated bone loss (mostly trabecular). Fractures are common in the first year postoperatively, particularly at sites of trabecular bone (vertebrae and ribs), although long bone and pelvic fractures are also seen. The incidence of vertebral compression fracture may be as high as 38 percent. Patients may develop avascular necrosis of the femoral head from steroid use. Fractures should be treated in the standard fashion.

Neurologic Complications

It is reported that between 19 and 47 percent of all adult liver transplant patients have a neurologic complication at some time during their posttransplant course. Neurologic complications in children, however, are much less common (8 percent). [14] Common presenting problems include headache, seizure, and mental status changes. The etiology is more likely to be noninfectious than infectious. Common noninfectious etiologies are hemorrhage, immunosuppressive toxicity, and metabolic derangement. Central nervous system (CNS) infection is most common in the first few months, with viral and fungal etiologies predominating. CNS CMV infection is rare and CNS herpesvirus infection is seen with the same frequency as in the general population. Bacterial etiologies include *Listeria, Klebsiella, S. aureus, Nocardia,* and *Escherichia coli. Aspergillus, Candida,* and *Cryptococcus* sp. are the more common fungal agents involved. Cryptococcal disease is most common between 2 and 7 months.[16] Patients presenting with headache, seizures, or mental status changes need to evaluated for the presence of metabolic derangement as well as hemorrhage or infection. They will often require computed tomography (CT) of the head and lumbar puncture to rule out these etiologies. [12] Neuropathic pain may be seen and is poorly responsive to opioids. It may respond to tricyclic antidepressants. [16]

Malignancy

There is an increased risk of new malignancy including squamous cell carcinoma, lymphomas, posttransplant lymphoproliferative disorder (PTLD). There is no increased risk of lung, colon, breast, or prostate cancer.[3] The most common posttransplant malignancy is squamous cell cancer of the skin, but sarcoma, Kaposi's sarcoma, and hepatobiliary cancer occur.[20]

87 GASTROINTESTINAL IMAGING

Michael J. Bono

BASIC IMAGING TECHNIQUES

Plain Film Radiography

Plain films remain the workhorse imaging study for the emergency department evaluating a patient with abdominal pain. Plain films can be obtained quickly, cause no discomfort to the patient, and are relatively inexpensive compared to other gastrointestinal (GI) imaging modalities. The emergency physician can interpret plain films. Unlike the chest, where the organs have great differences in water and air content and therefore in radiodensity, the abdomen contains structures of similar radiodensities. Only the presence of air and fat in the bowel or other structures allows indentification of organ boundaries, and the air is transient. A plain film of the abdomen represents a "snapshot" of a dynamic system and should be examined systematically. A time-honored technique is to first examine the bones (spine, ribs, pelvis, and hips); then the upper quadrants, flanks, and mid-abdomen for organ masses and calcifications; and finally the lower abdomen. The physician should attempt to look at the area of special interest last.

At most centers, an "acute abdominal series" includes a supine film centered at the iliac crest, an upright film centered at the crest, and an upright posteroanterior (PA) chest film. The supine film detects fluid or blood in the peritoneum as well as gas in the bowel, and the upright film displays any air-fluid levels. If the patient is too ill to stand, a left lateral decubitus (left side down) view is acceptable, but a right lateral decubitus is not. On a left lateral decubitus view, free air can be detected between the liver and the peritonuem; this is not possible in a right lateral decubitus view (right side down) because air in the bowel loops will contact the peritoneum. The standard upright PA chest view is best for demonstrating free air in the peritoneal cavity as well as other pathologic conditions of the chest that cause abdominal pain, such as pneumonia, pneumothorax, or atelectasis.

Contrast Radiography

Barium sulfate remains the standard substance for contrast GI imaging. Barium is an insoluble material that is suspended in different carriers by different manufacturers. It has high viscosity and is not absorbed by the GI tract. Gastrograffin is a water-soluble substance, has low viscosity, and, like barium, is not absorbed by the GI tract in most normal adult patients. It is absorbed slightly by the gut in children. Gastrograffin draws substantial amounts of fluid into the bowel lumen, and its low viscosity causes rapid transit through the small bowel into the colon. It therefore has a considerable laxative effect. Gastrograffin is not a recommended oral contrast agent in children, particularly neonates and infants, since the fluid shifts and laxative effect may cause significant fluid and electrolyte disturbances.

Computed Tomography Scanning

Computed tomography (CT) provides imaging of solid organs and, very importantly, a view into the retroperitoneum. Unlike plain radiographs, CT scanning is not dependent on the amount of air and gas in the bowel. Oral contrast material must be given to identify bowel, and intravenous contrast material enhances the density of blood vessels. The introduction of the helical CT scan (spiral CT) has made a significant impact on abdominal imaging due to the speed of the procedure. Routine CT scanning of the abdomen usually requires the patient to lie motionless for 15 to 30 min, while the helical CT scan may be finished in a single breath hold. Helical CT was originally developed to compensate for errors produced by variations in respiratory depth of the patient. [1] The radiation dose to the patient is unchanged. Another advantage of helical CT is improved vascular opacification, which allows excellent imaging of the thoracoabdominal aorta and renal arteries. Data obtained from helical CT can be reformatted in several ways, revealing three-dimensional surface anatomy and obviating the need for arteriography.

Radionuclide Scanning

Radionuclide scanning has been virtually replaced by ultrasonography for emergency department patients with right upper quadrant pain. Technectium-99m–labeled iminodiacetic acid (IDA) is injected intravenously, is taken up by hepatocytes, is secreted into the bile canaliculi, and then flows into the small bowel. Normally there is a small amount of reflux into the cystic duct and gallbladder, but in cholecystitis the cystic duct is frequently occluded. The gallbladder, hepatic duct, and common duct should be visualized within 1 h of IDA administration, but total test time may be several hours.

Ultrasonography

Ultrasound has emerged as a valuable tool for the diagnosis of select conditions in the emergency department. It is noninvasive and inexpensive, and should be readily available to the emergency department physician. Improvements in transducer technology have greatly improved ultrasound imaging. Ultrasound is somewhat operator dependent, and the images are difficult to interpret in obese patients or patients with large amounts of intestinal air or gas. Air is a poor conductor of ultrasound because it scatters, refracts, and reflects the sound waves. Fluid-filled structures transmit sound exceedingly well, and since most of the soft tissues are composed of varing amounts of water, ultrasound is feasible throughout the GI tract and pelvis. A full bladder is an acoustic window into the pelvis, and the liver helps transmit ultrasound in the right upper quandrant.

SPECIFIC GASTROINTESTINAL CONDITIONS

Plain Film Radiography

In the past, tradition dictated the routine use of plain films to screen patients with acute abdominal pain. [2,3] Screening acute abdominal pain patients routinely with plain films is not advisable, since the yield of positive findings that would change clinical management is low, in the range of 10 to 40 percent. [4,5] However, in the proper clinical setting, plain abdominal radiographs are entirely appropriate and are still considered the first test of choice. In patients with a suspected perforated ulcer or free air in the abdomen, plain films demonstrate free air, if present, in a high percentage of patients. [6] Plain films may demonstrate as little as 1 to 2 mL of air. [7] In patients with suspected small bowel obstruction, plain films are the initial method of imaging. Plain films have a sensitivity for revealing high-grade small bowel obstruction of 69 to 82 percent, but, when combined with barium contrast studies, the sensitivity rate may approach 100 percent. [8,9] Low-grade small bowel obstruction is difficult to demonstrate on plain films and has much lower diagnostic rates. [10] Other appropriate conditions for the use of plain film radiographs include moderate or severe abdominal tenderness, suspicion of bowel ischemia, ingestion of radiopaque foreign bodies, and penetrating foreign bodies, such as gunshot wounds.

Abdominal Computed Tomography

CT is the diagnostic tool of choice for many acute abdominal conditions. CT is the first imaging study of choice for patients with suspected diverticulitis, pancreatitis, pancreatic pseudocyst, aortic aneurysm, blunt trauma, and appendicitis. The diagnosis of appendicitis can be made on clinical evaluation, but CT has been proven remarkably sensitive and specific in confirming the diagnosis.[11] Whether patients with suspected appendicitis require oral, intravenous, and/or rectal contrast versus "no-contrast" thin cuts through the ileocecal area is debated in the radiology literature.[12] CT is a useful adjunct to plain films in suspected cases of intestinal ischemia, where specific findings may include pneumotosis intestinalis, portal venous gas, mesenteric vessel occlusion, and enlargement of a thrombosed vein.[13] While patients with suspected small bowel obstruction should be imaged initially with plain radiographs, CT has similar sensitivity in revealing obstruction, both high and low grade. When CT correctly showed a small bowel obstruction, the cause of the obstruction was demonstrated in 95 percent of cases. CT offers a further advantage to the emergency physician evaluating the patient with multiple potential causes for acute abdominal pain. While never advocated as a "screening tool," CT scanning can pinpoint a diagnosis in 95 percent of cases where clinical judgment and other imaging studies fail to narrow a wide range of potential diagnoses.[14]

Ultrasonography

Ultrasound is the initial imaging study of choice for evaluation of patients with right upper quandrant pain. Using the liver as an acoustic window, ultrasound can detect cholelithiasis, cholecystitis, choledocholithiasis, biliary duct dilation, and pancreatic masses, both solid and cystic. Ultrasound is also the modality of choice for evaluating patients with pelvic pain. Transvaginal scanning has supplemented the transabdominal approach because of better visualization with higher-frequency endovaginal probe transducers (see Chap. 109, "Pelvic Imaging"). Ultrasonography of the genitourinary system is discussed in Chapter 97, "Renal Imaging."

Graded-compression ultrasound imaging for acute appendicitis has been studied extensively. Sensitivities for appendicitis range from 68 to 93 percent and specificities between 73 and 100 percent, with accuracy in the 95 percent range.[15] Negative laparotomy result rates were reduced significantly using graded-compression ultrasonography.[16] The ultrasonographer is searching for a tubular structure off the cecum that is compressible without pain and is no more than 6 mm in diameter. An infected, inflamed appendix is tender, larger than 6 mm in diameter, fluid filled, and noncompressible. The appendix is difficult to visualize, and the examination is best left to experienced ultrasonographers. Negative ultrasound results in the face of a strong clinical suspicion should never delay surgical intervention. The false-negative rate for graded-compression ultrasonography is from 6 to 14 percent. Other disease processes that can confuse the clinical picture are cecal diverticulitis, inflammatory bowel disease involving the terminal ileum, and periappendiceal phlegmon. Graded-compression ultrasonography is most helpful in the evaluation of patients with atypical right lower quadrant pain and a suspicion of appendicitis.

Barium Enema

Children with signs and symptoms suggestive of intussusception, such as colicky abdominal pain, vomiting, and passage of stool mixed with blood, require stabilization and a barium enema. Plain films may demonstrate signs of intestinal obstruction, such as distended loops, air-fluid levels, and a paucity of bowel gas in the right lower quadrant, the so-called Dance's sign. A barium enema is indicated, and a hydrostatic reduction of the intussusceptum is successful in 50 to 90 percent of cases.[17] A barium enema may be useful for the diagnosis of bowel obstruction, volvulus, appendicitis, and diverticulitis, usually in consultation with surgical colleagues.

Angiography

CT has replaced angiography for imaging patients with suspected abdominal aortic aneurysm. Angiograpy may be helpful in evaluating patients with lower GI bleeding, particularly when combined with colonoscopy to pinpoint the bleeding lesion.[18]

Radionuclide Scanning

Radionuclide scanning can be a useful adjunct to ultrasonography for patients with right upper quadrant abdominal pain. When the ultrasound results are negative or inconclusive in a patient with suspected cholecystitis or cystic duct obstruction, radionuclide scanning may be diagnostic in the absence of stones. These studies involve several hours for the radioisotope to localize to the affected area and may be utilized best in an emergency department observation unit or inpatient setting.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) currently has no role in imaging the GI tract in the emergency department patient. MRI is outstanding for imaging the central nervous system and musculoskeletal system, but cost, time in the scanner, and poor image quality due to movement of the bowel limit applicability. MRI is being evaluated as a tool for imaging relatively stationary GI structures, such as the appendix and biliary tree, and has shown some promise.[19,20]

88 ACUTE RENAL FAILURE

Richard Sinert

Acute renal failure (ARF) is defined as a deterioration of renal function over hours or days that results in the accumulation of toxic wastes and the loss of internal homeostasis. Glomerular filtration rate (GFR) is commonly used as an index of renal function, and rapid declines in GFR are viewed synonymously with ARF. Although this concept of ARF is universally accepted, exact definitions of ARF vary in the medical literature. Laboratory scientists, who can directly measure GFR, define ARF as a 50 percent decline in GFR. Clinicians must rely on indirect measures of GFR to define ARF, such as a 50 percent decline in creatinine clearance or a 50 percent increase in serum creatinine from baseline. Finally, some physicians define only those patients requiring dialysis treatment as having ARF. ARF is very common and emergency physicians play a critical role in the early recognition of ARF and prevention of further iatrogenic injury.

ARF is not a disease by itself, but a potential complication of many other disorders (Table 88-1). The incidence ARF varies widely, reflecting the study of different patient subsets. In general, a patient's age, volume status, and previous history of renal insufficiency significantly influence the risk of ARF (Table 88-2).

Clinical Setting	Incidence of ARF (%)
Community hospital ward	2–5
Intensive care unit	15–25
Acute pancreatitis	4–6
Trauma	3–9
Rhabdomyolysis	25–30
Severe burns	20–60
Radiocontrast agents	2–30
Aminoglycoside therapy	10–30
Cardiac surgery	5–40

TABLE 88-1   Incidence of Acute Renal Failure (ARF) in Selected Settings

Preexisting Conditions	Potential Nephrotoxins
Hypovolemia	Aminoglycosides
	Amphotericin
	Heme-pigments
	Radiocontrast agents
Angiotensin-converting enzyme inhibitors	Diuretics
	Small and large vessel renal arterial disease
Nonsteroidal anti-inflammatory drugs	Congestive heart failure
	Hypertension
	Renal artery stenosis
Preexisting renal disease (elderly, diabetics, jaundice)	Radiocontrast agents
	Aminoglycosides
	Atheroembolism
	Cardiovascular surgery

TABLE 88-2   Iatrogenic Acute Renal Failure: Common Preexisting Conditions and Potential Nephrotoxins

PATHOPHYSIOLOGY

The driving force for glomerular filtration is the pressure gradient from the glomerulus to Bowman space of the proximal tubule. Glomerular pressure depends on renal blood flow (RBF) and is controlled by the combined resistances of the renal afferent and efferent arterioles.

Regardless of the cause of ARF, reductions in RBF represent a common pathologic pathway for decreasing GFR.[1] This relationship is most clear in prerenal failure, defined by conditions with normal tubular and glomerular function, where GFR is depressed by compromised renal perfusion. Intrinsic renal failure occurs with diseases of the glomerulus, interstitium, or tubule, associated with the release of renal vasoconstrictors.[2] Postobstructive renal failure initially produces an increase in tubular pressure decreasing the filtration driving force. This pressure gradient soon equalizes, and the maintenance of depressed GFR depends on vasoconstrictors.[3]

Depressed RBF and nephrotoxins result in ischemia and renal cell death. This initial injury triggers the production of oxygen free radicals and release of leukotrienes that continue to cause cell injury. Tubular cellular damage results in disruption of tight junctions between cells, allowing backleak of glomerular filtrate, further depressing effective GFR. In addition, dying cells slough off into the tubules, forming obstructing casts further decreasing GFR and leading to oliguria.

During this period of depressed RBF, the kidneys are especially vulnerable to further insults.[4] Exposure to known nephrotoxins such as radiocontrast agents, aminoglycosides, and nonsteroidal anti-inflammatory drugs (NSAIDs) at this time explains the high rate of iatrogenic causes of ARF [5] (Table 88-2).

Recovery from ARF is first dependent on restoration of RBF. In prerenal failure, restoration of circulating blood volume is usually sufficient. Rapid relief of urinary obstruction in postrenal failure results in a prompt decrease of vasoconstrictors. Clearance of tubular toxins and initiation of therapy for glomerular diseases decrease vasoconstriction and restore RBF in patients with intrinsic renal failure.

Once RBF is restored, the remaining functional nephrons will increase their filtration and eventually hypertrophy. Depending on the size of this remnant nephron pool, GFR will proportionally recover. If the number of remaining nephrons is below a critical value, continued hyperfiltration results in progressive glomerular sclerosis eventually leading to nephron loss. A vicious cycle then ensues where continued nephron loss causes more hyperfiltration until complete renal failure occurs. Hyperfiltration of remnant nephrons explains the commonly observed scenario where progressive renal failure is frequently observed after recovery from ARF.[6]

The differential diagnosis of ARF is classified according to the prerenal, intrinsic renal, and postrenal etiologies of ARF.

Prerenal failure is the most common cause of ARF, accounting for 40 to 80 percent of all cases. [7] Prerenal failure is produced by conditions that decrease renal perfusion (Table 88-3). Besides being an independent cause of ARF, prerenal failure is a common precursor to ischemic and nephrotoxic causes of intrinsic renal failure.[8]

TABLE 88-3   Differential Diagnosis of Prerenal Failure

The etiologies of intrinsic renal failure are subdivided anatomically into diseases of the tubules, interstitium, glomeruli, and vessels (Table 88-4). Intrinsic renal failure accounts for approximately 11 to 45 percent of all cases, depending on the population studied. For adults in a community hospital, prerenal failure accounted for 70 percent of ARF cases as compared with only 11 percent from intrinsic renal etiologies. [9] ARF has a different spectrum in the pediatric population: a higher incidence of intrinsic renal causes for ARF (45 percent) secondary to diseases such as glomerulonephritis and hemolytic-uremic syndrome. [10]

TABLE 88-4   Differential Diagnosis of Intrinsic Renal Failure

Acute tubular necrosis (ATN) secondary to renal ischemia accounts for the majority of cases of intrinsic renal failure. Nephrotoxins are the second most common cause of ATN, accounting for approximately 25 percent. When the etiologies of ARF were reviewed in a multivariate analysis, a synergistic effect was noted for the combination of ischemic and nephrotoxic ATN.[11]

Postrenal failure accounts for 2 to 5 percent of all cases of ARF, but has a significantly higher incidence in selected populations (Table 88-5). In large surveys of elderly men for symptoms of urinary obstruction, prevalence between 20 to 35 percent has been estimated. [12] In young males, renal calculi are the most common cause of obstruction. In young females, cervical carcinoma can cause urinary obstruction. In children, postrenal failure is commonly secondary to congenital malformations such as urethral valves in boys and vesicoureteral reflux in girls.

TABLE 88-5   Differential Diagnosis of Obstructive Renal Failure

CLINICAL FEATURES

Morbidity/Mortality from Acute Renal Failure

Reported mortality rates for ARF have remained the same from before to after the advent of dialysis: 40 to 90 percent. [13,14] This statistic reflects a changing epidemiology and etiology of ARF. Before the availability of effective dialysis, many young patients died directly of complications specific to ARF. Now that dialysis effectively treats life-threatening complications of ARF, the patient's age and underlying diseases determine mortality from ARF. ARF has become an index of the severity of patients' other disease processes. With the advent of dialysis, the most common causes of death with ARF are sepsis, cardiac, and pulmonary failure.

This is not to imply that ARF is a benign disease: even in those patients not requiring dialysis, mortality was 31 percent in patients with ARF compared with only 8 percent in matched patients without ARF.[15] Even after adjusting for comorbidity, the odds ratio for dying in patients with ARF was 4.9 compared with patients without ARF.

Mortality rates are generally less for nonoliguric ARF (more than 400 mL/day) compared with oliguric ARF (less than 400 mL/day). This difference is because drug-induced nephrotoxicity and interstitial nephritis usually cause nonoliguric ARF. [16]

Approximately 20 to 60 percent of patients experiencing ARF will require dialysis during their hospital stay. [17] The majority of these patients will recover, with only 25 percent requiring long-term dialysis. [18]

History

A focused history should be obtained using the pathophysiology and differential diagnosis of ARF as a guide.

In prerenal failure, patients commonly present with symptoms related to hypovolemia: thirst, decreasing urine output, dizziness, and orthostatic hypotension. Inquire about a history of excessive vomiting, diarrhea, urination, hemorrhage, or sweating. Third spacing of fluids commonly occurs with burns and with liver and pancreatic diseases. Patients with advanced cardiac failure leading to depressed renal perfusion present with orthopnea, paroxysmal nocturnal dyspnea, and dyspnea on exertion. Insensible fluid losses can result in severe hypovolemia in patients with restricted fluid access and should be suspected in elderly, comatose, or sedated patients.

For intrinsic renal failure, patients can be divided into those with glomerular, interstitial, and tubular etiologies. The nephritic syndrome of hematuria, edema, and hypertension is synonymous with a glomerular etiology of ARF. These patients should be queried about prior throat or skin infections. ATN should be suspected in any patient with a period of hypotension secondary to cardiac arrest, hemorrhage, sepsis, drug overdose, or surgery. A careful search for exposure to nephrotoxins should include a detailed list of all current medications and any recent x-ray examinations (radiocontrast agents). Pigment-induced ARF should be suspected in patients with possible rhabdomyolysis (e.g., muscle tenderness, recent coma, seizures, drug abuse, alcohol, excessive exercise, or limb ischemia) and with hemolysis (e.g., recent blood transfusion). Allergic interstitial nephritis should be suspected with recent drug use associated with fevers, rash, and arthralgias.

Postrenal failure most commonly occurs in elderly men with relatively asymptomatic high-grade prostatic obstruction. Because of their chronicity and slow onset, the classic symptoms of prostatism—urgency, frequency, and hesitancy—are often not communicated to physicians. In females, a history of prior gynecologic surgery or carcinoma can often be helpful in providing clues to the level of obstruction. Flank pain and hematuria indicate the possibility of renal calculi or of papillary necrosis. Recent use of acyclovir, methotrexate, or sulfonamides suggests the possibility of tubular obstruction by crystals of these medications.

Physical Examination

The patient's volume status must be assessed. Hypotension and tachycardia are obvious clues to decreased renal perfusion. Since hypertension is a common premorbid condition for ARF, knowledge of baseline blood pressures may prove helpful in individualizing a definition of hypotension. Further investigations into the possibility of hypovolemia should include tests for orthostatic hypotension or tachycardia, mucosal membrane moisture, and tissue turgor.

Examination of the *skin* may suggest a systemic vasculitis (livedo reticularis, digital ischemia, butterfly rash, and palpable purpura), allergic interstitial nephritis (maculopapular rash), or endocarditis (track marks of intravenous drug use).

Examination of the *eyes* may find evidence of autoimmune vasculitis (keratitis, iritis, uveitis, and dry conjunctiva), liver disease (jaundice), multiple myeloma (band keratopathy from hypercalcemia), diabetes mellitus, hypertension, or atheroemboli (retinopathy).

Examination of the *ears* can indicate Alport's disease or aminoglycoside toxicity (hearing loss) and Wegener's granulomatosis (mucosal or cartilage ulcerations).

The *cardiac* examination may find potential signs of peripheral arterial emboli (atrial fibrillation), endocarditis (murmurs), and heart failure (jugular venous distention, hepatojugular reflux, and S3 cardiac gallop).

The *pulmonary* examination may find evidence of heart failure or of Goodpasture's syndrome or Wegener's disease (rales). The *abdominal* examination may find evidence of aortic aneurysm, nephrolithiasis or papillary necrosis (flank tenderness), or urinary obstruction (pelvic, rectal masses, prostatic hypertrophy, and distended bladder).

Examination of the *extremities* may find clinical evidence of rhabdomyolysis (limb cyanosis, pulselessness, and edema), vasculitis (palpable purpura), or atherosclerotic disease (diminished pulses).

DIAGNOSIS

Ancillary Tests

Microscopic examination of urine is very useful in establishing the differential diagnosis of ARF (Table 88-6). While changes in urine output are poorly correlated with changes in GFR, the categories of anuria, oliguria, and nonoliguria can be useful in the differential diagnosis of ARF (Table 88-7). Approximately 50 to 60 percent of all causes of ARF is nonoliguric.

Urine Sediment	Etiology of ARF
Normal urinary sediment	Prerenal, postrenal failure, hemolytic uremic syndrome/thrombotic thrombocytopenic purpura, preglomerular vasculitis, or atheroembolism
Hemoglobin without red blood cells	Rhabdomyolysis, massive hemolysis
Albumin	Glomerulonephritis, malignant hypertension
Granular casts	Acute tubular necrosis, glomerulonephritis, interstitial nephritis
Red blood cell casts	Glomerulonephritis, malignant hypertension
White blood cell casts	Acute interstitial nephritis, pyelonephritis
Eosinophiluria	Acute allergic interstitial nephritis, atheroembolism
Crystalluria	Renal calculi, acyclovir, sulfonamides, methotrexate, ethylene glycol, radiocontrast agents

TABLE 88-6   Differential Diagnosis of Acute Renal Failure (ARF) According to Urinalysis

Urine Output (24 h)	Differential of ARF
Anuria (<100 mL/day)	Urinary tract obstruction, renal artery obstruction, rapidly progressive glomerulonephritis, bilateral diffuse renal cortical necrosis
Oliguria (<400 mL/day)	Prerenal failure, hepatorenal syndrome
Nonoliguria (>400 mL/day)	Acute interstitial nephritis, acute glomerulonephritis, partial obstructive nephropathy, nephrotoxic and ischemic acute tubular necrosis, radiocontrast-induced ARF, rhabdomyolysis

TABLE 88-7   Differential Diagnosis of Acute Renal Failure (ARF) According to Urine Volume

To help differentiate prerenal failure from ATN, chemical analysis of the urine may provide important clues [19] (Table 88-8). The fractional excretion of sodium (FeNa) is

a test that is commonly used but, unfortunately, fails to distinguish prerenal causes of ARF from other causes of ARF [20] (Table 88-9).

Laboratory Test	Favors Prerenal	Favors ATN
Urine specific gravity	>1.018	<1.012
Urine osmolality (mosm/kg H₂O)	>500	<500
Urine sodium (meq/L)	<20	>40
Plasma blood urea nitrogen/creatinine ratio (mg/dL)	>20	<10–15
Urine/plasma creatinine ratio (mg/dL)	>40	<20
Fractional excretion of Na: FeNa = U$_{Na}$/P$_{Na}$ ÷ U$_{Cr}$/P$_{Cr}$	<1%	>1%

TABLE 88-8   Urine Chemical Indices in Differentiating Prerenal from Acute Tubular Necrosis (ATN)

Urinary tract obstruction
Acute glomerulonephritis
Hepatorenal syndrome
Radiocontrast acute renal failure (ARF)
Myoglobinuric and hemoglobinuric acute renal failure
Renal allograft rejection
Drug-related alterations in renal hemodynamics (captopril and nonsteroidal anti-inflammatory drugs)

TABLE 88-9   Exceptions: Intrinsic Renal Failure with FeNa <1%

Blood urea nitrogen (BUN) concentration is poorly correlated with GFR. Since urea is highly permeable to renal tubules, urea clearance varies with urine flow rate: at urine flow rates of less than 30 mL/h, urea clearance is as low as 30 percent of GFR and, with urine outputs greater than 100 mL/h, urea clearance can increase to 70 to 100 percent of GFR. This relation is used clinically to help differentiate prerenal failure from other etiologies of ARF. In prerenal conditions, low urine flow rates favor BUN reabsorption, out of proportion to creatinine (Cr). This results in a disproportionate rise of BUN to relative creatinine, creating a serum ratio of BUN/Cr that is greater than 20 in prerenal failure.

BUN concentration depends on both nitrogen balance and renal function. BUN concentration can rise significantly with no decrement in GFR by increases in urea production with protein loading, trauma, or gastrointestinal bleeding. Corticosteroids and tetracycline increase BUN by decreasing tissue anabolic rates. Basal BUN concentration can be severely depressed by malnutrition or advanced liver disease. Baseline BUN concentration should be estimated when attempting to correlate changes in BUN with GFR. For example, in a cirrhotic patient with a BUN of 12 mg/dL, a normal range GFR might be assumed, but only with the knowledge of a baseline BUN of 4 mg/dL does the real decrease in GFR become apparent.

Serum creatinine provides the most accurate and consistent estimation of GFR, yet the proper use of creatinine in gauging changes in GFR requires knowledge of its production and clearance.

Creatinine is the breakdown product of the skeletal muscle protein, creatine. Creatinine production is linked to muscle mass, which in turn depends on lean body weight, age, and gender. Muscle mass is a greater percentage of body weight in males and decreases with age.

Variations in muscle mass have important implications in using creatinine to estimate GFR. GFR declines by 1 percent a year after the age of 40 years, but serum creatinine remains unchanged because the decline in GFR is balanced by decreasing muscle mass with age. This implies that older patients have lower GFRs than younger patients with the same serum creatinine. The following formula attempts to compensate for these effects of body weight, age, and gender on the correlation between creatinine and GFR:[21]

$$\text{For males:}$$
$$\text{Creatine clearance (mL/min)} = \frac{[(140 - \text{age(years)}) \times \text{lean body weight (kg)}]}{[\text{serum creatinine (mg/dL)} \times 72]}$$
$$\text{For females: Above formula} \times 0.85$$

Some diseases and medications can interfere with the correlation of serum creatinine with GFR. Acute glomerulonephritis causes increased tubular secretion of creatinine; this falsely depresses the rise in serum creatinine. Trimethoprim, cimetidine, and salicylates all cause decreased creatinine secretion, falsely elevating creatinine with no change in GFR.

A possible error may occur according to the laboratory method used to measure creatinine. The most commonly used method uses alkaline picurate. This method is also called the total chromogen method because it measures all serum chromogens: creatinine plus glucose, fructose, uric acid, acetone, acetoacetate, protein, ascorbic acid, pyruvate, and cephalosporins. At normal serum levels, these noncreatinine chromogens constitute only 5 to 20 percent of the total chromogens. In conditions such as diabetic and isopropyl ketosis, elevations of acetone and acetoacetate falsely elevate serum creatinine. High levels of bilirubin with this method falsely indicate a low creatinine level.

The imidohydrolase method is an enzymatic method for measuring creatinine, which resolves the problem of noncreatinine chromogens and bilirubin with the picurate method. However, the imidohydrolase method has been shown to report falsely high creatinine levels in the presence of high glucose and the antifungal agent flucytosine.

The rate of increase in serum creatinine can be used to estimate GFR. In patients with no renal function (GFR = 0), serum creatinine will increase 1 to 3 mg/dL/day. Lessor increases in serum creatinine indicate remaining renal function (GFR) and larger increases indicate excessive muscle breakdown (e.g., rhabdomyolysis). Under stable conditions, serum creatinine correlates with GFR (Table 88-10).

Creatinine (mg/dL)	GFR (mL/min)
1.0	Normal–baseline
2.0	50% reduction
4.0	70–85% reduction
8.0	90–95% reduction

TABLE 88-10   Estimation of Glomerular Filtration Rate (GFR) by Serum Creatinine

Knowledge of a patient's baseline creatinine becomes very important: small changes from low baseline levels of creatinine are much more clinically important than large changes from high basal creatinine. For emergency physicians, significant decrements in GFR can occur in the normal range of creatinine: a change of creatinine from 0.6 to 1.2 mg/dL represents a 50 percent decrease in GFR although both values are in the normal range for creatinine, yet a change in creatinine from 8 to 12 mg/dL represents only a 25 percent decline in GFR.

To investigate the possibility of myocardial ischemia and hyperkalemia, an electrocardiogram should be performed on all patients presenting with ARF. Serum electrolytes should be measured. A chest radiograph may also help detect infectious causes of ARF and fluid overload.

Renal Biopsy

Renal biopsy should be considered in all causes of intrinsic ARF, especially in the estimated 10 to 25 percent of patients with ARF that cannot be diagnosed clinically.[22] Retrospective studies have shown that the results of the renal biopsy significantly change the diagnosis and management of ARF in 40 percent of cases.[23] The most common complication of renal biopsy is hematuria, which occurs in almost all patients. Serious complications defined as the need for blood transfusion, nephrectomy, puncture of other organs, or perinephric hematoma occur at a rate of 2.1 percent. Overall mortality for renal biopsy is 0.1 percent.

Imaging Studies

Imaging studies in ARF have their greatest utility in diagnosing urinary obstruction. The goal of the imaging study is to identify the site of blockage and to distinguish anatomic etiologies from merely functional forms of collecting system dilation. The patient's condition (e.g., pregnancy and radiation risks, renal failure and radiocontrast risks) must be taken into consideration in choosing the most appropriate study.

Plain radiographs with or without tomograms (the KUB: kidneys, ureter, and bladder) can provide information on the size and contour of the kidneys. A difference in kidney size of greater than 2 cm is suggestive of unilateral obstruction. Plain radiographs can identify renal blockage approximately 85 to 90 percent of the time and locate ureteral calculi approximately 50 percent of the time. Renal tomograms improve the resolution of renal calculi to 2 mm.

Intravenous pyelography (IVP) is considered the gold standard for defining the extent and anatomy of urinary obstruction, but unfortunately several drawbacks limit its utility for all patients. The nephrotoxicity of radiocontrast dye is of particular importance to patients with chronic renal failure and diabetes mellitus.[24] In patients with a low GFR, sufficient dye for adequate visualization may not excreted until 12 to 24 h after injection. Dilation of the urinary tract is not always indicative of obstruction, and the lack of hydronephrosis does not always rule out obstruction. Functional abnormalities of the urinary system, such as vesicoureteral reflux and the chronic massive diuresis (secondary to diabetes insipidus), can have dilated urinary tracts without obstruction. In addition, intermittent or partial obstructions will often not have hydronephrosis.

Invasive pyelography can be used when the risks of IVP are considered too great. Dye can be injected directly into the renal pelvis (antegrade) or cystoscopically into the ureter (retrograde). These techniques provide the same information as an IVP but without being dependent on renal function and without the nephrotoxicity of intravenous dye. Antegrade and retrograde pyelography also have the same drawback as IVP of not being able to distinguish functional from obstructive causes of urinary system dilation. In addition, these invasive techniques have the added risk of infection.

Ultrasonography—which has excellent sensitivity, safety, low cost, and lack of radiation and nephrotoxic dye—has become the procedure of choice to determine the presence of hydronephrosis, particularly in patients with low GFR. Although ultrasonography has a 90 percent sensitivity for detecting hydronephrosis (compared with the IVP), it may have a high false-positive rate of up to 20 percent.[25] Ultrasonography can misidentify a dilated urinary system as being due to obstruction rather than extrarenal pelvis, calyceal diverticula, congenital megacalyces, diuresis, and ileal conduits. In addition, numerous forms of obstructive uropathy may occur without dilation of the urinary collecting system: intrarenal crystals, nephrocalcinosis, staghorn calculi, and retroperitoneal obstruction.

Radionuclide scanning is performed by the intravenous injection of a radionuclide agent, followed by sequential imaging of its urinary excretion by using a gamma scintillation camera. This technique provides a 90 percent sensitivity in diagnosing upper urinary tract obstruction but without the nephrotoxic risk of IVP dye.[26] However, compared with IVP, radionuclide scanning lacks the resolution to define the exact site of anatomic obstruction adequately. Injection of a diuretic agent during the study will help in the differentiation of a functional versus anatomic obstruction in a dilated collecting system. The finding of increased radionuclide excretion after a diuretic points to a functional rather than an obstructive cause of a dilated collecting system. RBF measurement by radionuclide scanning is becoming the technique of choice to assess the potential for renal recovery after relief of obstruction.[27] However, recovery of renal function is possible even after nonvisualization of the kidney on radionuclide scanning.[28]

Computed tomography (CT) is a sensitive technique for diagnosing hydronephrosis and may delineate the anatomy of obstruction when ultrasound and IVP fail to identify an etiology. CT is particularly adept at diagnosing obstruction at the ureteric level compared with ultrasound.[29] A further advantage of CT is that a dilated urinary collecting system is well visualized even without the use of intravenous dye. CT may replace invasive pyelography as the secondary procedure to define the anatomy of obstruction after ultrasound and IVP.

Magnetic resonance (MR) imaging has yet to become fully integrated into the workup of urinary obstruction. Recently reviews have demonstrated MRs potential for the morphologic and functional evaluation of the urinary system. MR urography has demonstrated sensitivity up to 100 percent and specificity of 96 percent for urinary obstruction.[30] The advantages of MR include no radiation exposure, and paramagnetic contrast agents enable renal functional assessment without risks of iodinated contrast materials. MR urography can often differentiate acute from chronic obstruction, by demonstrating perinephric fluid accumulation, which is highly correlated with acute obstruction. Disadvantages of MR include the lack of large-scale accessibility and acceptance. MR can only diagnose obstruction with dilation and cannot differentiate functional dilatation from anatomic obstruction.

Diagnostic Sequence

After obtaining the medical history and performing the physical examination, the following general principles are useful in the diagnosis of ARF (Table 88-11).

TABLE 88-11   Diagnostic Sequence for Acute Renal Failure (ARF)

Although postrenal failure accounts for only a small proportion of ARFs, it should be the first differential of ARF investigated because of its ease of diagnosis and treatment. A properly positioned bladder catheter can be diagnostic as well as therapeutic for obstruction below the level of the bladder. If no urine is obtained, then placement of the catheter should be tested by irrigation. If fluid returns freely, the catheter tip is most probably in the bladder, and obstruction above the bladder should be investigated. If a question remains, ultrasound may also be used to establish catheter placement.

Large postvoid residuals after catheterization suggest obstruction below the bladder, and catheter drainage should be maintained until the obstruction is relieved. To prevent hypotension and hematuria, the traditional recommendation is for intermittent clamping of the catheter during drainage of a distended bladder, but experimental and clinical evidence provides no support for this tradition. [31] Hematuria upon catheter drainage of a distended bladder is related to the degree of bladder wall damage before relief obstruction and not correlated with the rate of emptying. Urine should be completely and rapidly drained from an obstructed bladder, because prolonged urine stasis only predisposes the patient to urinary tract infection, urosepsis, and renal failure.

Once obstruction below the bladder level has been investigated, obstruction in the upper urinary tract should investigated with a renal ultrasound. If the renal ultrasound detects hydronephrosis, a confirmatory study to define the exact location of obstruction is required: either a CT scan or an IVP. If functional obstruction is still a consideration in the presence of a dilated genitourinary tract, a radionuclide scan before and after diuretics should be obtained.

After excluding postrenal etiologies, investigation of prerenal causes for ARF starts with an assessment of circulating volume. Abnormalities in standard vital signs and the orthostatic tilt test are unreliable detectors of acute volume loss; these tests are significant only when the findings are grossly abnormal. [32,33] More sensitive and reliable indicators of acute changes in circulating volume are base deficit, lactate, and central venous oxygen saturation. Invasive hemodynamic monitoring provides the most reliable means of assessing hemodynamic performance. [34]

Urine output is a generally poor method of gauging blood volume. [35] Oliguria requires differentiating prerenal from intrinsic renal etiologies. Low urine output in prerenal syndromes is the result of normal renal concentrating mechanisms reacting appropriately to hypovolemia, resulting in urine with high specific gravity and high osmolality. To maintain circulating volume, functioning kidneys in a hypovolemic state preferentially reabsorb both urea and sodium, resulting in an increased BUN/Cr ratio and a low FeNa level (Table 88-8). Exceptions to this rule include the etiologies of intrinsic renal failure where the renal concentrating mechanism is preserved or is even stimulated (e.g., glomerulonephritis) (Table 88-9).

Low urine output with intrinsic renal failure is the not result of increased sodium and water reabsorption but, rather, of a decline in GFR. In tubular and interstitial diseases, normal concentrating mechanisms are often lost and decreased GFR is a defense to prevent hypovolemia from excessive renal fluid losses. This results in low urine output, but with isotonic urine that is high in sodium. With intrinsic ARF, the reabsorption of urea and sodium is not augmented as it is in prerenal causes. Intrinsic ARF typically has a parallel rise in both BUN and creatinine that preserves the BUN/Cr ratio and an elevated FeNa level greater than 1 percent.

The classic nephritic triad of hypertension, edema, and red blood cell casts is diagnostic of glomerular forms of intrinsic ARF. These patients require a more detailed evaluation and testing for autoimmune diseases such as poststreptococcal glomerulonephritis and SLE. A renal biopsy should usually be done to define the exact nature of their disease and individualize treatment protocols

TREATMENT

Patients with ARF present challenging fluid-management problems. Hypovolemia potentiates and exacerbates all forms of ARF. The reversal of hypovolemia by rapid fluid infusion is often sufficient to treat and/or ameliorate many forms of ARF, [36] yet rapid fluid infusion can result in life-threatening fluid overload in patients with ARF. Accurate determination of these patients' volume status is essential, often requiring invasive hemodynamic monitoring. The most important treatment for ARF in emergency departments is prompt and appropriate fluid resuscitation.

Patients with nonoliguric compared with oliguric ARF have improved mortality and renal function recovery rates. This has prompted many authors to recommend diuretics in treating oliguric ARF. Unfortunately, randomized double-blind controlled trials have failed to show a benefit in administering diuretics to patients with ARF.[37] These studies concluded that diuretics were only useful in the management of volume-overloaded patients. Care should be taken in prescribing high-dose furosemide because of the association with long-term hearing deficits.

Renal vascular vasodilators in ARF have theoretical and experimental support. Low ("renal")-dose dopamine [1 to 5 μg/kg/min] has been widely used to treat ARF. Dopamine in these dosages is a potent vasodilator, which increases RBF in the experimental setting of ARF. Most clinical studies have failed to show that dopamine improves the recovery or mortality rates in patients with ARF. [36] In the majority of ARF studies, dopamine was only associated with an increase in urine output. Current recommendations for dopamine favor its use in ARF patients only with congestive heart failure. Dopamine is proarrhythmic, and controlled studies using dopamine for ARF found an increased mortality associated with its use. [39]

In animal models, calcium channel blockers are protective against ARF if given before the renal insult. [40] In humans, their major benefit has been in preventing ARF in renal transplant patients taking cyclosporine.

If given within 6 h of rhabdomyolysis, infusion of bicarbonate and mannitol has been reported to be protective against myoglobinuric ARF. [41] In addition, mannitol infusion may decrease the rate of ARF if given before radiocontrast agents. [42] There are no controlled studies showing any benefit to mannitol infusion for patients with established ARF. In fact, mannitol given in high doses has been associated as a cause of ARF. [43] There are also significant risks of fluid overload and hyperkalemia in administering large doses of mannitol to ARF patients.

The advent of hemodialysis had a significant impact on the treatment of the life-threatening fluid and electrolyte complications of ARF. However, dialysis may adversely affect remaining renal function. Hemodialysis may decrease RBF or produce hypotension if circulating volume is reduced below normal. Dialysis also causes oliguria that could lead to increased cast formation and further tubular obstruction. Studies comparing intensive dialysis with traditional regimens have failed to show any improvement in outcome of patients with ARF.[44] Hemodialysis should be reserved for complications of ARF unresponsive to medical management. The complications amenable to hemodialysis include acidosis, electrolyte imbalance (e.g., hyperkalemia), fluid overload, uremia (e.g., encephalopathy, pericarditis, and bleeding diathesis), and drug intoxication (e.g., digoxin, aminophylline, aspirin, and lithium).

DISPOSITION

Patients with ARF require admission to the hospital, usually to an intensive care setting where their fluid and medical management can be monitored on an hour-to-hour basis. An appropriate specialist (nephrologist, intensive care specialist, or internist) should be consulted early.

89 EMERGENCIES IN RENAL FAILURE AND DIALYSIS PATIENTS

Richard Sinert

End-stage renal disease (ESRD) is the irreversible loss of renal function, resulting in the accumulation of toxins and the loss of internal homeostasis. Uremia, the clinical syndrome resulting from ESRD, is universally fatal without some form of renal replacement therapy (RRT). At present, RRT consists of two basic modalities: renal transplant and dialysis therapy. This chapter discusses the pathophysiology and clinical features of uremia and the specific techniques and complications related to hemodialysis (HD) and peritoneal dialysis (PD).

EPIDEMIOLOGY

The 1996 annual data report of the United States Renal Data System (USRDS) noted there were 73,091 new cases of ESRD (incidence, 2.7 per 10,000), with 283,932 patients being treated for ESRD (prevalence, 10.4 per 10,000) during that year.[1] The most common age group with ESRD is the 45-to-64 age group, representing 38.7 percent of patients. African Americans make up a disproportionate number of ESRD patients, accounting for 32.3 percent, while making up just 12.2 percent of the US population.

USRDS projects that the incidence of ESRD is growing by 6 to 7 percent per year. An expanding incidence and life span will result in an expected increasing prevalence of ESRD of 8 to 9 percent per year. USRDS projects similar growth rates of ESRD for African Americans and Caucasians but predicts a two times greater growth rate for Native Americans and Asians and Pacific Islanders. The highest growth rate by age occurs in the over-75 age group.

Diabetes mellitus is the most common disease causing ESRD, accounting for 32.5 percent of patients, followed by hypertension (24.5 percent), glomerulonephritis (17.7 percent), and cystic kidney disease (4.7 percent).

The utilization of RRT for ESRD is divided into 62 percent on dialysis therapy and 38 percent with renal transplants.[2] Of the patients on dialysis, 83 percent are on HD and 17 percent on PD. African Americans have significantly lower rates of renal transplantation and PD than do Caucasians and Asians and Pacific Islanders. Pediatric patients ages 0 to 19 have significantly higher rates of renal transplantation and PD than do other age groups.

Overall, ESRD patients have a life expectancy of between 19 and 47 percent of the expected remaining years of life for age-, sex-, and race-matched control subjects without ESRD.[3] One-, two-, and five-year survival rates for ESRD are 78.2, 62.7, and 29.3 percent, respectively. Cardiac causes account for approximately 50 percent of all cases of ESRD death.[4] Infectious causes of death occur in 25 percent of patients in the 20- to 44-year-old age group. Cerebrovascular events make up 6 percent of ESRD deaths, with malignancy accounting for another 1 to 4 percent. Approximately 20 percent of dialysis patients withdraw from therapy before death. Patients over 65 years of age have the highest withdrawal rate, 25 percent. The increasing incidence of withdrawal with age is linked to an increasing severity of comorbid conditions affecting patients' quality of life on RRT.

PATHOPHYSIOLOGY

Piorry, in 1840, was the first to use the term *uremia,* contamination of the blood with urine, to describe the clinical syndrome from ESRD. The concept that uremia is from an excretory failure resulting in toxin accumulation is reinforced by the continued use of the term *azotemia,* the buildup of blood nitrogen.

Excretory Failure

Levels of over 70 chemicals are elevated in uremic plasma, leading to the hypothesis that these toxins, individually or in combination, cause uremic organ dysfunction and produce the symptoms. For over 100 years it has been observed that limiting protein intake markedly improves the symptoms of uremia. Urea, the major breakdown product of proteins, reproduces a few of the neurobehavioral uremic symptoms, but only at very high concentrations. Other potential uremic toxins include cyanate, guanidines, polyamines, and b$_2$-microglobulin. Ammonia is not a toxin candidate, since ammonia levels are not elevated in ESRD patients.

In conclusion, while toxins from ESRD excretory failure are definitely a factor in uremia, they cannot explain all its clinical features. In addition, if uremia was simply a toxidrome, then dialysis should reverse all its untoward effects. Yet, many uremic organ dysfunctions persist after dialysis, and other processes are clearly important.

Biosynthetic Failure

Biosynthetic failure refers to the aspects of uremia from loss of the renal hormones 1,25 (OH)$_3$ vitamin D$_3$ and erythropoietin. The kidneys are primarily responsible for the secretion of erythropoietin and 1-a-hydroxylase, which is necessary to produce the active form of vitamin D$_3$. In ESRD patients, levels of both these hormones are significantly depressed. Since 85 percent of erythropoietin is produced in the kidneys, ESRD patients have depressed levels, contributing to anemia. Vitamin D$_3$ deficiency results in decreased gastrointestinal (GI) calcium absorption, inducing secondary hyperparathyroidism, responsible for the development of renal bone disease.

Regulatory Failure

Regulatory failure results in an oversecretion of hormones, leading to uremia by disruption of normal feedback mechanisms after renal failure. In response to the accumulation of ions and other waste products with ESRD, the maintenance of internal homeostasis is dependent on a variety of extrarenal processes. These homeostatic responses, while adaptive to one toxin, may have untoward effects outside the system they are attempting to regulate. The "trade-off" hypothesis, first proposed by Bricker, was initially postulated to explain how hyperparathyroidism in ESRD was a trade-off for the beneficial effects of high parathyroid hormone (PTH) levels on controlling phosphate levels. The trade-off for the maintenance of normal calcium and phosphate levels is hyperparathyroidism, causing increased bone turnover and leading to renal bone disease. Bricker has extended this trade-off hypothesis to sodium regulation in ESRD. As the glomerular filtration rate (GFR) decreases in ESRD patients, increasing fractional sodium excretion prevents salt retention. Bricker postulated that the trade-off for this natriuretic factor was a generalized inhibition of sodium transport, which he stated explained many aspects of uremic organ dysfunction.

While Bricker's trade-off hypothesis is still controversial, sodium transport abnormalities have been well documented in uremia. Na$^+$, K$^+$-ATPase activity is reduced in the red blood cells, leukocytes, intestinal epithelium, cardiac muscle, and skeletal muscle in uremic patients. Inhibition of Na$^+$, K$^+$-ATPase activity results in partial cellular depolarization and increased calcium entry, which are linked to both the high prevalence of hypertension and heart failure in ESRD. Recently an endogenous

dialyzable digitalis-like inhibitor of Na $^+$, K$^+$-ATPase activity has been isolated in uremic plasma. This defect in Na $^+$, K$^+$-ATPase activity is reversed by dialysis.

CLINICAL FEATURES

Uremia should only be viewed as a clinical syndrome; no single symptom, sign, or laboratory test is reliable in diagnosing all aspects of uremia. Although a correlation exists between the symptoms of uremia and a low GFR (8 to 10 mL/min), available laboratory tests [e.g., determinations of blood urea nitrogen (BUN) and creatinine] are inaccurate detecting trends in low GFR. The decision to start chronic dialysis is a clinical decision based on the symptoms of uremia (Table 89-1).[5]

TABLE 89-1   Clinical Features of Uremia

Neurologic Complications

UREMIC ENCEPHALOPATHY   Progressive neurologic symptoms of uremia are the most common indications for initiating chronic dialysis. Uremic encephalopathy is a constellation of nonspecific central neurologic symptoms associated with renal failure that respond, in large part, to RRT. Uremic encephalopathy should remain a diagnosis of exclusion after other structural, vascular, infectious, toxic, and metabolic causes of neurologic dysfunction have been investigated. Objective findings of uremic encephalopathy include a significant increase in slow delta waves on the electroencephalogram (EEG) and consistently low scores on psychometric testing. These objective findings of neurologic dysfunction have been linked to inhibition of Na $^+$, K$^+$-ATPase activity and increases in brain calcium either from elevated parathyroid hormone levels or abnormal calcium transport in uremic brains. Both symptomatic and objective neurologic findings of uremia improve with dialysis and can be followed to judge the adequacy of RRT.

DIALYSIS DEMENTIA   Dialysis dementia (encephalopathy), similar to uremic encephalopathy, consists of a nonspecific set of neuropsychiatric dysfunctions that, unlike uremic encephalopathy, are progressive and eventually fatal. This disorder usually becomes evident after at least 2 years on dialysis and fails to respond to increases in dialysis frequency or renal transplantation. EEG findings can differentiate uremic encephalopathy from dialysis dementia. High brain aluminum levels from oral ingestion of aluminum or high levels of aluminum in dialysate water have been correlated with the development of dialysis dementia. Dialysis dementia has shown some improvement with desferroxamine binding of aluminum.

PERIPHERAL NEUROPATHY   Peripheral neuropathy occurs in over 50 percent of HD patients and generally responds poorly to dialysis but can be reversed by renal transplantation. Patients can have both asymmetric (mononeuropathies) and symmetric (polyneuropathies) peripheral deficits. Another common deficit is "glove-and-stocking" sensory involvement, presenting with pain or anesthesia affecting the most distal nerves. Electrophysiologic testing of patients with uremia shows depression of motor and sensory nerve conduction. No single pathologic correlate has yet been identified for peripheral uremic neuropathy.

AUTONOMIC DYSFUNCTION   Autonomic dysfunction is very common in ESRD patients and presents a significant risk factor for hypotension during dialysis. Resistance to norepinephrine is one postulated mechanism.

SUBDURAL HEMATOMA   Subdural hematoma occurs in approximately 3.5 percent of HD patients, presumably related to head trauma, anticoagulants, excessive ultrafiltration, and hypertension. Bilateral subdural hematomas can mimic the symptoms and signs of uremic encephalopathy or dialysis dementia, making the correct diagnosis difficult.

Cardiovascular Complications

HYPERTENSION   Hypertension occurs in 80 to 90 percent of patients starting dialysis. Hypertension represents a significant risk factor for coronary artery disease, cerebrovascular accidents, and heart failure. Hemodynamic profiles of hypertensive ESRD patients show that maintenance of hypertension is dependent on increases in total peripheral resistance. The etiology of the increase in total peripheral resistance appears to be multifactorial. Increases in blood volume, the vasopressor effects of native kidneys, the renin-angiotensin system, and the sympathetic nervous system all have been shown to play a role in ESRD hypertension. Management of hypertension in ESRD patients should begin with the control of blood volume. If that is unsuccessful, most patients' hypertension can be controlled with adrenergic-blocking agents, angiotensin-converting enzyme (ACE) inhibitors, or vasodilating agents, such as hydralazine or minoxidil. Bilateral nephrectomy is rarely necessary for blood pressure control.

HEART FAILURE   Congestive heart failure (CHF) occurs for many of the same reasons in ESRD patients as in other patients; hypertension is the most common cause of CHF in ESRD patients, followed by coronary artery disease and valvular defects. Causes of CHF unique to ESRD include arteriovenous (AV) fistula-related high-output failure, uremic cardiomyopathy, and fluid overload. Large AV fistulas can cause high-output CHF, characterized by high cardiac output and low total peripheral vascular resistance. Diagnosis is made by echocardiography, and treatment is by surgical binding of the AV fistula to restrict blood flow.

Uremic cardiomyopathy is a diagnosis of exclusion when all other causes of CHF have been ruled out. In most uremic patients, left ventricular (LV) dysfunction is related to ischemic heart disease, hypertension, and hypoalbuminemia rather than to a uremic toxin. Dialysis rarely improves LV function in uremic patients with CHF. [6] However, parathyroid hormone has been linked to decreased LV function in uremia by studies showing marked improvement of LV function after parathryoidectomy.

Fluid overload in ESRD is a common cause of CHF but not always a requirement for pulmonary edema. Acute myocardial ischemia can cause depressed LV function to the point of causing pulmonary edema even in patients at or below their postdialysis ("dry") weight. In addition, pulmonary edema has been reported in ESRD patients in the absence of high pulmonary artery pressures, seemingly the result of increased pulmonary capillary permeability. Invasive hemodynamic monitoring in ESRD patients with pulmonary edema may be required to guide therapy.

Management of pulmonary edema in ESRD patients is usually similar to treatment in non-ESRD patients. Cornerstones of therapy in both types of patients include oxygen, nitrates, ACE inhibitors, and morphine. Diuretics, such as furosemide, are still effective in treating CHF in ESRD patients even with minimal urine output. [7] In pulmonary edema, intravenous furosemide in doses of 60 to 100 mg provides pulmonary vasodilatation, improving oxygenation. Preload reduction in ESRD patients can also be accomplished by inducing diarrhea with sorbitol and by phlebotomy. Phlebotomy of as little as 150 mL of blood is safe and effective in treating pulmonary edema.[8] For example, phlebotomy of 150 mL in a patient with a hematocrit of 20 percent results in the loss of 120 mL of plasma and 30 mL of packed red blood cells (10 g of hemoglobin). The improved oxygenation by phlebotomy will more than offset the decrease in oxygen-carrying capacity due to the decrease on hemoglobin. Phlebotomized blood should be collected in transfusion bags, enabling plasma to be extracted by the blood bank and transfusion of red blood cells later during dialysis. HD is the ultimate treatment for fluid overload in ESRD patients. PD does not remove volume fast enough to have a significant impact on pulmonary edema.

PERICARDITIS   Do not assume that all cases of pericarditis in ESRD patients are due to uremia; patients should be evaluated carefully for other causes. Pericarditis in ESRD can occur both before initiation of dialysis and during dialysis, so-called uremic and dialysis-related pericarditis, respectively. Uremic pericarditis occurs in approximately 16 percent of patients. Uremic pericarditis is most common when the other symptoms of uremia are most severe. The etiology of uremic pericarditis has

been linked to fluid overload, abnormal platelet function, and increased fibrinolytic activity. Most cases of uremic pericarditis improve with RRT.

Dialysis-related pericarditis also seems related to the general uremic milieu. This form of pericarditis is most common during periods of increased catabolism (trauma and sepsis) or inadequate dialysis due to missed sessions or vascular access problems. The pathophysiology of dialysis-related pericarditis has been linked to the buildup of middle molecules and hyperparathyroidism.

The clinical features and evaluation of pericarditis in patients with ESRD are similar to those for non-ESRD patients. The classic findings of chest pain, fever, and pericardial friction are more commonly found in dialysis-related than in uremic pericarditis. Mortality rates for ESRD patients with pericarditis are as high as 8 percent.

Management of both uremic and dialysis-related pericarditis in hemodynamically stable patients is by intensive dialysis therapy. HD is preferred over PD because of its higher clearance rates, but the risks of heparin and rapid fluid shifts precipitating tamponade must be taken into account. This therapy is effective in over 55 percent of cases of dialysis-related pericarditis usually after 10 to 14 days. Indomethacin and steroids are of questionable value for ESRD pericarditis. If pericardial effusion persists for more than 10 to 14 days with intensive dialysis, the treatment is considered a failure. Most centers now recommend anterior pericardectomy as the treatment of choice in this condition. Total pericardectomy is reserved for constrictive pericarditis.

Symptoms of pericardial tamponade are often quite subtle in ESRD patients, rarely presenting with the typical Beck's triad. Increased interdialysis weight gain, increased edema, and intradialysis hypotension suggest the early diagnosis of tamponade. Because of the slow accumulation of pericardial fluid, pulsus paradoxus and a pericardial friction rule are absent, and the only clinical suggestions may be weakness, moderate hypotension, and an increasing heart size on x-ray. Ultrasonography is needed to make the diagnosis. Hemodynamically significant pericardial effusions require pericardiocentesis under fluoroscopic or ultrasonographic guidance. Pericardiocentesis, because of its high complication rate, should be used only in hemodynamically unstable patients with pericardial tamponade.

Hematologic Complications

ANEMIA   Anemia in ESRD patients is of multifactorial origin, secondary to decreased erythropoietin, blood loss from dialysis, and decreased red blood cell survival times. In addition, wide fluctuations in plasma blood volume seen in dialysis patients often cause factitious anemia. Without treatment, the hematocrit in ESRD patients will usually stabilize at 15 to 20 percent, with normocytic and normochromic red blood cells. Bone marrow will show erythroid hypoplasia with little effect on leukopoiesis or megakaryocytopoiesis. Management of anemia is by the infusion of human recombinant erythropoietin on a regular basis. Erythropoietin replacement therapy has markedly improved the quality of life for ESRD patients by increasing exercise capacity and tolerance. An increase in blood pressure has been reported in approximately 30 to 35 percent of patients receiving erythropoietin.

BLEEDING DYSCRASIA   Abnormalities in hemostasis expose ESRD patients to increased risks of GI tract bleeding, subdural hematomas, subcapsular liver hematomas, and intraocular bleeding. The abnormal hemostasis in ESRD is characterized by decreased platelet function and von Willebrand factor defects. [9] Anemia has been determined to be the major etiologic defect causing abnormal hemostasis in ESRD patients. The skin bleeding test is the best predictor of clinically important defects in hemostasis. Improvements in bleeding times can be obtained by infusion of desmopressin, conjugated estrogens, and erythropoietin.

NEUTROPHIL DYSFUNCTION   Immunologic deficiency in ESRD patients produces a high mortality rate from infectious diseases. Both leukocyte chemotaxis and phagocytosis are depressed in uremic patients. Abnormal T-cell activation has also been noted in ESRD patients secondary to reduction in interleukin 2 production. Dialysis therapy does not appear to improve the immune function of leukocytes or T cells. In fact, HD may even exacerbate immunodeficiency by complement activation after exposure to the HD filter membrane.

Gastrointestinal Complications

UPPER GASTROINTESTINAL BLEEDING   Anorexia, nausea, and vomiting are common symptoms of uremia and are often used as an indication to initiate dialysis and to follow the adequacy of RRT. In the upper GI tract, there is an increased incidence of gastritis and bleeding in ESRD patients, but, it is interesting to note, the incidence of gastric and duodenal ulcers is similar in ESRD patients and the general population. The increased incidence of GI bleeding and rebleeding and the higher mortality rates from GI hemorrhage in ESRD patients are functions more of the bleeding dyscrasia than of a primary GI disease. In addition, ESRD patients are at increased risk from bleeding from angiodysplasias. Successful prevention of recurrent bleeding from GI angiodysplasias has been obtained by use of tranexamic acid and conjugated estrogens, which decrease bleeding time.

DIVERTICULOSIS AND DIVERTICULITIS   Chronic constipation is common among ESRD patients secondary to decreased fluid intake and the use of phosphate-bonding gels. ESRD patients have an increased incidence of diverticular disease and colonic perforation, especially patients with polycystic kidney disease.

ASCITES   Dialysis-related ascites is an idiopathic form of ascites secondary to fluid overload, portal hypertension from polycystic liver disease, and osmotic disequilibrium. Treatment of refractory ascites is possible with peritoneovenous shunts.

Renal Bone Disease

CALCIPHYLAXIS   As the GFR falls, phosphate excretion also falls, resulting in increased serum phosphate levels. When the calcium-phosphate product [Ca (mg/dL) × PO_4 (mg/dL)] is greater than 70 to 80, metastatic calcification can ensue. Clinically these patients present with complaints of pseudogout secondary to metastatic calcification of synovial joints. Metastatic calcification in small vessels results in skin and finger necrosis. Life-threatening calcifications can occur in the cardiac and pulmonary systems. An increased mortality rate has been observed in ESRD patients with a product greater than 72. [10] Treatment consists of the use of low-calcium dialysate and phosphate-binding gels.

HYPERPARATHRYOIDISM (OSTEITIS FIBROSA CYSTICA)   As ESRD progresses, the combination of calciphylaxis and vitamin D_3 deficiency results in depressed ionized calcium levels and stimulation of the parathyroid gland. The increased production of PTH results in high bone turnover. These patients present with weakened bones highly susceptible to fracture. In addition, patients with osteitis fibrosa cystica often complain of bone pain and muscle weakness. High alkaline phosphatase and PTH levels make the diagnosis. Treatment consists of control of serum phosphate with binding gels, vitamin D_3 replacement, and, if necessary, subtotal parathryoidectomy.

VITAMIN D_3 DEFICIENCY AND ALUMINUM INTOXICATION (OSTEOMALACIA)   Subsets of ESRD patients present with osteomalacia, a defect in bone calcification. Once vitamin D_3 replacement became universally available, aluminum intoxication became the major cause of osteomalacia in ESRD patients. Sources of aluminum are dialysate diluent and phosphate-binding gels. The signs and symptoms are weakened bones, bone pain, and muscle weakness, similar to those for hyperparathyroidism. Differentiation is made by finding low-to-normal alkaline phosphatase levels and low PTH levels in osteomalacia. Elevated serum aluminum and bone aluminum levels are useful for confirming the diagnosis. Treatment with desferroxamine has been shown to be effective in aluminum bone disease.

b_2-MICROGLOBULIN AMYLOIDOSIS   Dialysis-related amyloidosis, or b_2-microglobulin amyloidosis, is seen commonly in dialysis patients over 50 years of age and on dialysis for more than 10 years. Amyloid deposits have been found in the GI tract, bones, and joints. Complications include GI perforations, bone cysts with pathologic fractures, and arthropathies, including carpal tunnel syndrome and rotator cuff tears. Patients with amyloidosis have significantly higher mortality rates than those without this disorder. The etiology of b_2-microglobulin amyloidosis may be related to both decreased clearance and increased synthesis from immunologic reaction to hemodialyzer filters. Switching to more biocompatible filters that have higher clearance of b_2 microglobulin has markedly reduced the incidence of amyloidosis.

TREATMENT

Hemodialysis

HD in humans was first made possible by the invention of the rotating-drum artificial kidney by Kolff et al in 1943. Access to the patient's bloodstream was not

practical until the development of the external AV shunt by Scribner in 1960. Brescia and Cimino in 1966 developed the subcutaneous AV fistula, which made HD safer and more acceptable. RRT became universally available after Congress passed the Medicare entitlement for the treatment of ESRD in 1973.

TECHNICAL ASPECTS   The nephron removes toxins and maintains internal homeostasis through an elegant combination of glomerular filtration followed by selective reabsorption and secretion of water and solutes. HD uses the brute force techniques of ultrafiltration and clearance to replace the functions of the nephron. HD substitutes a hemodialyzer filter for the glomerulus to produce a ultrafiltrate of plasma. Adjustment of the pressure gradient across the hemodialyzer filter during HD controls the amount of fluid removal (ultrafiltration). Solute removal (clearance) during HD is dependent on the filter pore size, the amount of ultrafiltration (solute drag), and the concentration gradient across the filter (diffusion). Solute diffusion down chemical gradients from the blood to the dialysis fluid (dialysate) determines their final blood concentration. Since hemodialyzer pore size prevents the filtration of proteins, dialysate consists only of electrolytes (Na$^+$, K$^+$, Cl$^-$, HCO$_3^-$, Ca^{++}, and Mg^{++}) and glucose, whose concentrations are varied to control their clearance. [11] During HD, blood is removed from the vascular access site by large-bore needles (typically 15 g), circulated through the dialysis machine at rates of 300 to 500 mL/min, and returned to the patient. The dialysate usually flows at a rate of 500 to 800 mL/min through the dialysis filter in the direction opposite to blood flow. Small amounts of heparin, 1000 to 2000 IU, are typically used to prevent thrombosis at the vascular access site. HD sessions typically take 3 to 4 h.

Ultrafiltration and clearance usually occur simultaneously during dialysis but can be separated by adjusting the HD settings. In fluid-overloaded patients, adding suction to the dialysate side of the hemodialyzer filter augments ultrafiltration. Dialysate flow can be lowered, minimizing clearance to prevent hypotension during dialysis. When fluid loss is not desired during dialysis (for patients below their dry weight) balancing dialysate and blood pressures across the filter limits fluid removal. Decreasing the dialysate concentration of the desired solute can augment clearance of specific electrolytes (e.g., potassium).

Long-term successful hemodialysis is dependent on reliable access to the patient's circulation. [12] The external Scribner AV shunt provided adequate vascular access but only lasted on average 1 year. The Brescia-Cimino AV fistula formed by the anastomosis of a native artery and vein in the forearm has a much greater longevity. In cases where a native artery or vein are not suitable for fistula creation, an interposing vascular graft made of an autologous vein, polytetrafluorethylene, or bovine carotid artery must be used for vascular access. These grafts generally have a higher complication rate and shorter functional life expectancies than do natural AV fistulas.

COMPLICATIONS OF THE VASCULAR ACCESS   Vascular access is the Achilles heel of HD, and complications of the vascular access account for more inpatient hospital days than any other complication of HD.

Vascular Access Stenosis and Thrombosis   Thrombosis and stenosis of the vascular access are the most common complications. Grafts generally have a higher rate of stenosis, secondary to endothelial hyperplasia, than do fistulas. Stenosis or thrombosis presents with loss of bruit and thrill over the access. Stenosis and even thrombosis are not emergencies and can be treated within 24 h by either angiographic clot removal or angioplasty.

Vascular Access Infection   The vascular access provides the most common portal of entry for infection in dialysis patients. Vascular grafts have a higher incidence of infection than do AV fistulas. Patients with an infected access often present with only signs of systemic sepsis, such as fever, hypotension, or an elevated white blood cell count. Classic signs of pain, erythema, swelling, and discharge from an infected vascular access are often missing. The most common organism is *Staphylococcus aureus,* followed by gram-negative bacteria.[13] Patients with access infections usually require hospital admission. Vancomycin is the drug of choice (1 g intravenously) because of its effectiveness in methicillin-resistant organisms and long half-life (5 to 7 days) in dialysis patients. An aminoglycoside (gentamicin 100 mg intravenously initially and after each dialysis) is usually added empirically to cover gram-negative organisms.

Vascular Access Hemorrhage   Hemorrhage from a vascular access can produce life-threatening blood loss. Hemorrhage can result from aneurysms, anastomosis rupture, or overanticoagulation. Bleeding that requires the patient to come to the emergency department should immediately be controlled with digital pressure at the puncture sites for 5 to 10 min, and the patient should be observed for 1 to 2 h afterward. Continued or life-threatening hemorrhage may require the placement of a tourniquet proximal to the access. A vascular surgeon should be consulted if bleeding cannot quickly be brought under control. If overanticoagulation is a concern, the effects of heparin can be reversed by protamine given at a dose of 0.01 mg/IU heparin dispensed during dialysis. If the dose of heparin is unknown, 10 to 20 mg protamine will be sufficient to reverse 1000 to 2000 IU heparin. If bleeding stops, the patient should be observed for 1 to 2 h for rebleeding or thrombosis. Occasionally a newly inserted vascular access will continue to ooze at the insertion despite pressure. DDAVP can be administered as an adjunct to direct pressure. If the emergency physician is unfamiliar with the use of DDAVP in this situation, the nephrologist should be consulted.

Vascular Access Aneurysm   Vascular access aneurysms result from repeated puncturing, leading to bulging of the wall. True aneurysms are very rare, occurring in less than 4 percent of fistulas or grafts. Most aneurysms are asymptomatic, with patients occasionally complaining of pain or an associated peripheral impingement neuropathy. Aneurysms rarely rupture, causing hemorrhage.

Vascular Access Pseudoaneurysm   Pseudoaneurysms result from subcutaneous extravasation of blood from puncture sites. Patients commonly present with bleeding and infections at access sites. Bleeding from the puncture site is usually controlled by digital pressure or a subcutaneous suture carefully placed at the puncture site. Vascular surgery may be required for continued bleeding or infection.

Vascular Insufficiency   Vascular insufficiency of the extremity distal to the vascular access occurs in approximately 1 percent of all patients. The so-called steal syndrome is the result of preferential shunting of arterial blood away from nutrient arteries to the low-pressure venous side of the access. Patients present with exercise pain, nonhealing ulcers, and cool, pulseless digits. Steal syndrome is diagnosed by Doppler ultrasound or angiography and is repaired surgically.

High-Output Heart Failure   High-output heart failure can occur when greater than 20 percent of the cardiac output is diverted through the access. Branham's sign, a drop in heart rate after temporary access occlusion, is useful for detecting this complication. Doppler ultrasound can accurately measure access flow rate and establish the diagnosis. Surgical banding of the access is the treatment of choice to decrease flow and treat heart failure.

COMPLICATIONS DURING HEMODIALYSIS TREATMENT   **Intradialysis Hypotension** Hypotension is the most frequent complication of HD, occurring during 10 to 30 percent of treatments (Table 89-2). Excessive ultrafiltration from underestimation of the patient's ideal blood volume (dry weight) is the most common cause of intradialysis hypotension. [14] In fact, dry weight is often clinically defined when hypotension prevents further fluid removal. Dry weight is often underestimated because of changes in the ratio of muscle mass to blood volume over time.

Excessive ultrafiltration

Clearance simultaneous with ultrafiltration

Predialytic volume loss (GI losses, decreased oral intake)

Intradialytic volume loss (tube and hemodialyzer blood losses)

Postdialytic volume loss (vascular access blood loss)

Autonomic neuropathy

Medication effects (antihypertensives, narcotics)

Decreased vascular tone (sepsis, food, dialysate temperature >37°C or 98.6°F)

Cardiac dysfunction (LV hypertrophy, ischemia, hypoxia, arrhythmia)

Pericardial disease (effusion, tamponade)

TABLE 89-2   Differential Diagnosis of Intradialysis Hypotension

Predialysis volume deficiency is an important contributing factor to intradialysis hypotension. Predialysis losses can be suspected when the patient is below dry weight and are usually due to GI bleeding, vomiting, diarrhea, or decreased intake of salt and water. Intradialysis volume loss can occur from blood tubing or hemodialyzer filter leaks.

Factors other than the patient's predialysis volume may cause intradialysis hypotension. Fluid removal during HD averages 1 to 2 L over a 4-h session but removal of up to 2 L/h hour is possible. Maintenance of normal blood pressure during ultrafiltration is dependent on fluid movement from the interstitial space replenishing the intravascular volume. These fluid shifts are direct consequences of the decrease in intravascular hydrostatic pressure and the increase in serum osmolality caused by ultrafiltration. Blood pressure stability during ultrafiltration is also dependent on increased systemic vascular resistance, heart rate, and contractility caused by increased autonomic tone.

Defenses against intradialysis hypotension can be defeated by a large number of factors. Hypotension often occurs when ultrafiltration and clearance are carried out simultaneously. During clearance, serum osmolality decreases, limiting interstitial fluid refilling of the intravascular space. Autonomic dysfunction, especially common in diabetic patients, may result in failure to increase cardiac output and peripheral resistance during ultrafiltration. Decreased sympathetic tone also increases nitric oxide production, potentiating hypotension. Hypotension is also caused by increased nitric oxide generated in platelets and endothelial cells by an as yet unidentified uremic toxin. Antihypertensive medications and narcotics can both block sympathetic reflexes, resulting in hypotension. Decreases in vascular tone during hemodialysis occur in patients with sepsis, after eating, and when dialysate temperatures are greater than 37°C. Cardiac dysfunction during hemodialysis secondary to dysrhythmias, LV hypertrophy, hypoxia, and myocardial ischemia can prevent reflex increases in heart rate and contractility. Finally, pericardial effusion and tamponade decrease cardiac preload, thus potentiating intradialysis hypotension.

Often, the timing of hypotension is helpful in the differential diagnosis. Hypotension early in the dialysis session usually occurs with patients who are below dry weight from preexisting hypovolemia. Hypotension near the end of dialysis is usually the result of excessive ultrafiltration, but pericardial or cardiac disease is still a possibility.

Intradialysis hypotension produces nausea, vomiting, and anxiety. Orthostatic hypotension, tachycardia, dizziness, and even syncope may occur.

Treatment of intradialysis hypotension includes placing the patient in the Trendelenburg position and stopping HD. If hypotension persists, the patient is given salt by mouth (broth) or normal saline solution 100 to 200 mL intravenously. If these conservative measures fail, excessive ultrafiltration is very unlikely, and a more extensive evaluation is justified. These patients are commonly transferred to the emergency department for further evaluation.

The emergency physician should conduct a detailed investigation of volume status, cardiac function, pericardial disease, infection, and GI bleeding that may be producing or contributing to hypotension. Remember that estimation of this patient's blood volume by clinical criteria has already failed in the dialysis unit. The decision to undertake further volume expansion or administer vasopressors to support blood pressure may require invasive hemodynamic monitoring in an intensive care setting.

Dialysis Disequilibrium   Dialysis disequilibrium is a clinical syndrome occurring at the end of dialysis characterized by nausea, vomiting, and hypertension, which can progress to seizure, coma, and death. This syndrome should be distinguished from other neurologic disorders, such as subdural hematoma, stroke, hypertensive crisis, hypoxia, and seizures. Dialysis disequilibrium is produced when large solute clearances occur during HD, as during the patient's first dialysis session or in hypercatabolic patients. The cause of dialysis disequilibrium is believed to be cerebral edema from an osmolar imbalance between the brain and the blood. During high solute removal, the blood has a transiently lower osmolality than the brain, favoring water movement into the brain and causing cerebral edema. This condition can be prevented by limiting solute clearance when initiating HD. Treatment consists of stopping dialysis and administering mannitol intravenously to increase serum osmolality.

Air Embolism   Air embolism is always a risk when blood is pumped through an extracorporeal circuit. The clinical presentation depends on the patient's body habitus at the time of the air embolism. If the patient was sitting, air will pass retrograde through the internal jugular vein to the cerebral circulation, causing symptoms of increased intracranial pressure. In a recumbent position, air will go into the right ventricle and pulmonary circulation, causing pulmonary hypertension and systemic hypotension. The passage of air through a right-to-left (e.g., patent foramen ovale) creates an arterial air embolism, which can lodge in the coronary or cerebral circulation, causing myocardial infarction or stoke.

Patients with an air embolism typically present with symptoms of acute dyspnea, chest tightness, and unconsciousness, sometimes progressing to full cardiac arrest. Physical examination may show cyanosis and a churning sound in the heart from air bubbles in the blood.

Treatment consists of clamping the venous bloodline and placing the patient supine. Traditional recommendations have often included the Trendelenburg position with the left side down, presumably to favor air trapping in the right ventricle. However, experimental and anecdotal clinical evidence does not indicate any special benefit of this position. Other suggested therapies for vascular air embolism include percutaneous aspiration of air from the right ventricle, intravenous steroids, full heparinization, and a hyperbaric chamber to reduce bubble size and promote resorption.

Hemolysis and Electrolyte Shifts   In the United States, dialysate is prepared by proportionally mixing a dialysate concentrate with water. Errors in proportional mixing can produce severe electrolyte abnormalities, resulting in rapid osmolar shifts and hemolysis.

Hypercalcemia and Hypermagnesemia   In some communities, water contains high concentrations of calcium and magnesium and produces a final dialysate high in these minerals. This dialysate can result in the "hard water syndrome," characterized by clinically significant hypercalcemia and hypermagnesemia in HD patients. These patients present with nausea, vomiting, headaches, burning skin, muscle weakness, lethargy, and hypertension. Treatment consists of properly filtering the dialysis water to lower calcium and magnesium concentrations.

EVALUATION OF HEMODIALYSIS PATIENTS   Patients on HD may present to the emergency department for complications related to their ESRD or HD, or these conditions may be incidental to the reason for the visit. The past medical history is very important in HD patients, since many of the same diseases that caused ESRD (e.g., hypertension, diabetes, etc.) persist after the patient's kidneys have failed. Questions should be asked about the patient's ESRD and HD (Table 89-3). Repeated episodes of intradialysis hypotension may provide important early clues to pericardial tamponade or myocardial ischemia. Repeated access infections may represent a worsening immunologic status.

Etiology of ESRD

Recent complications of HD

Dialysis schedule

Any missed dialysis sessions

Dry weight, baseline laboratory values and vital signs

Average interdialysis weight gain

Does patient usually make dry weight by end of HD?

Does patient experience intradialysis hypotension? (Timing of hypotension?)

Which vascular access is currently functioning?

Symptoms of uremia

Retention of native kidneys?

TABLE 89-3   Key Historical Elements for Hemodialysis Patients

Patients should be asked about their HD schedule. The majority of HD patients in the United States are on an every-other-day schedule (Monday, Wednesday, and Friday or Tuesday, Thursday, and Saturday), each session lasting approximately 4 h. Certain centers have begun using high-flux HD machines with higher blood flows, allowing shorter HD sessions. The physician should document all recent missed sessions and the patient's explanations for missing them. Such history taking may provide important clues concerning worsening medical or social issues that need to be addressed outside of the patient's chief complaint.

Dialysis patients are often quite knowledgeable concerning their dry weights and baseline laboratory test results. If the patient is not forthcoming with this data, the emergency physician can contact the HD center and ask about the dry weight, average interdialysis weight gains, and any recent HD complications. In addition, the

dialysis nurses and technicians are very devoted to their patients can provide a great deal of "soft data" concerning the patient. Query the patient in detail concerning uremic symptoms as markers of inadequate HD. Finally, ask patients whether they retain their native kidneys, which can be continued sources of hypertension, infection, and nephrolithiasis.

The physical examination of HD patients should always include a careful examination of the vascular access (Table 89-4). Remember, the vascular access is both the patient's lifeline and the Achilles' heel, complications of which are responsible for the majority of ESRD inpatient days. Flow through the access can be established by the presence of a bruit and thrill over the access site. The classic signs of infection—erythema, swelling, tenderness, and purulent discharge—are commonly limited until the infection is far advanced. The bedside Branham's sign may detect patients with CHF due to high-output fistula-related heart failure. The cardiac examination of HD patients deserves some special attention. Signs of CHF, such as peripheral edema, HJR, and JVD, may misleadingly suggest the diagnosis of fluid overload when pericardial tamponade is present. A loud cardiac murmur in HD patients may just represent increased flow secondary to anemia or the AV access. Neurologic dysfunction in HD patients is generally diffuse and nonfocal. Any findings suggestive of a focal neurologic deficit should be investigated for structural, vascular, and infectious causes. Rectal examination to detect GI bleeding is always needed.

Vital signs

    Asterixis

TABLE 89-4 Key Elements of Physical Examination of Hemodialysis Patients

Peritoneal Dialysis

Ganter accomplished the first PD in 1923. Practical long-term RRT with PD did not become available until 1976, when Popovich and Moncrief worked out the basic concepts of continuous ambulatory peritoneal dialysis (CAPD). Their work was significantly aided by the development of a practical silicon rubber catheter by Tenckhoff in 1968, which is still in use today. Because of its simplicity, PD is the most common form of RRT used outside the United States and Canada.

TECHNICAL ASPECTS   PD can be accomplished in either an acute setting or chronically via exchanges of solution throughout the day (CAPD) or through multiple exchanges at night while the patient sleeps [continuous cyclic peritoneal dialysis (CCPD)]. [11,15]

Similarly to HD, PD relies on the separate processes of clearance (solute removal) and ultrafiltration (fluid removal) to replace the functions of the nephron. In PD, the peritoneal membrane serves as the blood-dialysate interface. Most solute removal occurs via diffusion down chemical gradients established by altering dialysate electrolyte concentrations. The amount of ultrafiltration is determined by osmotic pressure differences between the blood and dialysate, which are manipulated by varying the dialysate glucose concentration. Dialysate is supplied in either a 1.5 or 4.25% glucose formulation, which can be alternated to increase or decrease ultrafiltration.

Typical CAPD regimens utilize four exchanges daily, with 2 L of dialysate infused and left in place for several hours before draining. During the day, approximately 8 L is infused and about 10 L is drained, for a removal of approximately 2 L/day of fluid. Recent concerns that this type of regimen may be inadequate for patients weighing more than 60 kg has prompted the use of automated PD exchanges during the night in addition to one or two daytime exchanges.

COMPLICATIONS   **Peritonitis**   Peritonitis is the most common complication of PD. The incidence of peritonitis is about one episode every 15 patient-months. [16] Mortality rates with peritonitis have been reported between 2.5 and 12.5 percent, depending on the center studied. Symptoms and signs of peritonitis in PD patients are no different than those for other patients with peritonitis: fever, abdominal pain, and rebound tenderness. Abdominal tenderness and cloudy effluent suggest the diagnosis of peritonitis. Patients will often bring in a sample of the cloudy dialysate fluid, which should be sent for cell count, Gram stain, and culture. The cell count in PD-related peritonitis is usually more than 100 leukocytes, with more than 50 percent neutrophils. Results of the Gram stain are positive in only 10 to 40 percent of cases of culture-proven PD-related peritonitis. Organisms isolated in PD-related peritonitis are *Staphylococcus epidermidis* (about 40 percent), *S. aureus* (10 percent), *Streptococcus* species (15 to 20 percent), gram-negative bacteria (15 to 20 percent), anaerobic bacteria (5 percent), and fungi (5 percent).

Empiric therapy should begin with a few rapid exchanges of fluid lavaged quickly in and out to decrease the number of inflammatory cells in the peritoneum. The addition of heparin (500 to 1000 IU/L dialysate) will decrease fibrin clot formation. Empiric antibiotics are selected to treat the expected gram-positive and gram-negative organisms. PD-related peritonitis can be treated with antibiotics added to the dialysate; parenteral administration is not required. A first-generation cephalosporin (e.g., cephalothin) can be mixed with the dialysate, 500 mg/L with the first exchange and 200 mg/L with subsequent exchanges. In penicillin-allergic patients, vancomycin can be substituted, with an initial dose of 500 mg/L and maintenance doses of 50 mg/L per exchange. Gentamicin can be added with a loading dose of 100 mg/L and maintenance doses of 4 to 8 mg/L per exchange. Most protocols recommend treating for 7 days after the first negative culture results, usually for a total of 10 days. The decision to admit these patients or treat them as outpatients is a clinical decision based on how ill the patient appears.

Catheter Infections (Exit Site and Tunnel Infections)   Infections around a PD catheter are much less well defined than peritonitis. Patients present with pain, erythema, swelling, and discharge around the catheter exit site. The most common bacteria are *S. aureus* and *Pseudomonas aeruginosa.* Empiric therapy consists of a first-generation cephalosporin or ciprofloxacillin, for outpatient therapy. [17] Patients should be referred back to their CAPD centers for follow-up the next day.

Hernias   The prevalence of abdominal-wall hernias in PD patients has been estimated to be between 10 and 15 percent. The literature recommends immediate surgical repair of pericatheter hernias, which have the highest risk of developing an incarceration.

EVALUATION OF PERITONEAL DIALYSIS PATIENTS   When a PD patient arrives in the emergency department, certain historical elements are important (Table 89-5). As with HD patients, the disease that caused the renal failure frequently persists. The type of PD and the person who performs the daily care may provide information about the risks of infection. Try to obtain the date of the patient's last episode of peritonitis; frequent relapses may signify a fungal etiology or tunnel infection. Ask the patient about baseline weight and laboratory values; PD patients are selected for their knowledge about their condition and their ability to perform the procedure and monitor their care away from professional supervision. Weight gain may signal heart failure from ischemia or pericardial effusion. Weight gain may also be from ultrafiltration failure, a late sign of peritonitis.

Etiology of ESRD

Type of peritoneal dialysis (CAPD vs CCPD)

90 URINARY TRACT INFECTIONS

David S. Howes
William F. Young

Urinary tract infection (UTI) is defined as significant bacteriuria in the presence of symptoms. It affects an estimated 20 percent of women at some point in their lifetime, and accounts for a significant number of emergency department visits. In the elderly, UTI is a major cause of nosocomial gram-negative sepsis with a significant mortality.

EPIDEMIOLOGY

The epidemiology of UTI varies with age and sex. There are four groups at risk for infection: neonates, girls, young women, and older men (Fig. 90-1). In neonates, a UTI occurs more often in males (1.5:1 M:F ratio) and is often part of the syndrome of gram-negative sepsis. The incidence of UTI in preschool children is approximately 2 percent, with the incidence in girls at least 10 times greater than the incidence in boys. In schoolage children, the incidence rises to 5 percent, almost exclusively girls.
FIG. 90-1. Natural history of urinary tract infections.

Bacteriuria is rare in males under the age of 50 and symptoms of dysuria or urinary frequency are usually due to a sexually transmitted disease-related infection of the urethra or prostate. However, in men older than 50 years, the incidence of UTI rises dramatically because of prostatic obstruction or subsequent instrumentation.

Dysuria in females is a common symptom usually due to infection. UTIs are common in otherwise healthy young women, often due to sexual contact. The incidence of infection in postmenopausal women increases with age; the prevalence of bacteriuria among elderly women in nursing homes exceeds 40 percent.

The infecting organisms are generally those found colonizing the perineum, and in women with a traditional "positive" culture of 10^5 colony-forming units (CFU) per mL of urine, *Escherichia coli* is responsible for approximately 80 to 90 percent of infections. However, up to one-half of cases of dysuria in young women are characterized by low bacterial colony count culture results (10^2 to 10^4/mL), which was termed the "acute urethral syndrome." It is now believed that these patients have low-grade or early urinary tract infection due to *E. coli, Staphylococcus saprophyticus,* or *Chlamydia trachomatis.* The definition of UTI based on early studies that reported only upper tract disease established that a colony count of at least 10^5/mL was necessary to indicate the presence of "significant bacteriuria." Recent research suggests that with regard to lower UTI in the presence of symptoms, a colony count of 100/mL or greater may represent significant bacteriuria and merit treatment.[1]

Asymptomatic bacteriuria (ABU) is defined by the presence of more than 10^5/mL of a single bacterial species on two sucessive urine cultures in a patient without symptoms. The requirement for two positive cultures is to eliminate those individuals with transient colonization of the urinary tract. ABU occurs in up to 30 percent of pregnant women and in up to 40 percent of female nursing-home residents. ABU is also common in patients with indwelling urinary catheters and disorders that prevent complete emptying of the bladder.

UTIs in women recur either because of relapse or reinfection. Relapse is caused by the same organism, and symptoms recurring in less than one month represents treatment failure. When symptoms recur in one to six months, it is generally due to reinfection. Reinfection is usually from a different enteric organism or a different serotype of the same organism, and may represent a defect in the defense mechanisms of the host. If a patient has a cluster of infections with more than three recurrences in one year, a more complete workup may be warranted to look for the presence of structural abnormalities, tumor, renal calculi, or associated systemic illness such as diabetes mellitus.

A UTI during pregnancy poses special problems. If untreated, ABU may progress to symptomatic UTI or pyelonephritis, especially in the third trimester, and may lead to preeclampsia, sepsis, or miscarriage. This is the single setting in which treatment of ABU is definitely indicated.

PATHOPHYSIOLOGY

UTI should be thought of as either complicated, that is, occurring in patients with underlying renal or neurologic disease; or uncomplicated, occurring in patients in which no defect can be demonstrated.[2,3 and 4] The most common urinary pathogen is *E. coli*, which causes greater than 80 percent of uncomplicated UTIs (Table 90-1). Uropathogenic organisms often have adhesins, fibriae, or pili that allow for bacterial adherence to the uroepithelium. Anaerobic organisms do not grow well in urine and are rarely pathogenic. While complicated UTIs can be caused by *E. coli,* they are more likely to be caused by unusual pathogens, such as *Pseudomonas spp* or enterococcus.

Organism	Incidence
Escherichia coli	>80%
Klebsiella sp	
Proteus sp	
Enterobacter sp	5–20%
Pseudomonas sp	
Group D streptococci	
*Chlamydia trachomatis**	<5%
*Staphylococcus saprophyticus**	

*Much more common in the "dysuria-pyuria" syndrome where sterile or low colony count culture results are obtained.

TABLE 90-1 Etiologic Agents in Uncomplicated Urinary Tract Infection

Depending on its pH and chemical constituents, urine is generally a good culture medium. Factors unfavorable to bacterial growth are a low pH (5.5 or less); a high concentration of urea; and the presence of organic acids derived from a diet including fruit juice and methionine, a breakdown product of ingested protein that enhances acidification of the urine. A thin film of urine remains in the bladder after voiding. An intact bladder mucosa removes organisms from the film, probably by the production of organic acids by the mucosal cells and not by antibody formation or phagocytosis. Incomplete bladder emptying renders this mechanism ineffective and is responsible for the increased frequency of infection in patients with a neurogenic bladder, and in postmenopausal women with bladder or uterine prolapse. The latter group also has marked changes in vaginal microflora due to lack of estrogen, with loss of lactobacilli and increased colonization by *E. coli.*

Frequent and complete voiding has been associated with the reduction in recurrence of UTI. [5] Studies have found that the concentration of bacteria in the bladder may increase tenfold after sexual intercourse due to a "milking action" of the female urethra during intercourse. The use of a diaphragm and spermicide is also associated with recurrence in some patients, probably because the spermicide enhances vaginal colonization with *E. coli.*[6] It is recommended, although unproven, that prompt voiding after intercourse may lessen the frequency of UTI. An increased urinary flow also dilutes the bacterial inoculum that occasionally occurs from sexual intercourse.[5,6]

Susceptibility to UTIs may have a genetic basis, that is, women who do not secrete blood group antigens (nonsecretors) have a high incidence of recurrent infection. This appears to be due to the presence of specific uroepithelial cell *E. col*-binding glycolipids that promote fecal coliform colonization of the vagina.

The majority of uncomplicated UTIs remain in the bladder; the ureteral valves prevent ascent of the bacteria into the kidneys. If these mechanisms fail and ascending infection of the urinary tract occurs, renal defense mechanisms are called into play. Local antibodies are produced in the kidney and kill bacteria in the presence of complement. Local leukocytosis and phagocytosis also help eradicate bacteria.

Urinary infections are categorized into three clinical syndromes. The simplest and most common UTI is acute cystitis, where infection is isolated to the bladder. Subclinical pyelonephritis is characterized by bacterial infection in the upper urinary tract and detected by bladder washout techniques, selective ureteral catheterization, or the presence of antibody-coated bacteria in the urine. However, subclinical pyelonephritis is clinically indistinguishable from acute cystitis and it has been estimated about 25 to 30 percent of patients with the acute cystitis syndrome have subclinical pyelonephritis. Several epidemiologic factors correlate with increased risk for subclinical pyelonephritis: lower socioeconomic status; pregnancy; structural urinary tract abnormality; urinary stone; history of relapse after treatment for a UTI; prior history of acute pyelonephritis; frequent UTIs; symptoms for more than seven days; or diabetes or other immunosuppressing conditions. [2] Acute pyelonephritis is characterized by the presence of bacteria in the kidney with localized pain and tenderness and systemic symptoms of infection (fever, chills, nausea, vomiting, and prostration).

The infective process of acute pyelonephritis can progress into three patterns of renal infection not commonly considered part of the UTI spectrum: acute bacterial nephritis, renal abscess, and emphysematous pyelonephritis. [7,8] These tend to be diagnoses made on imaging studies performed on patients who have an inadequate or atypical response to treatment for presumed acute pyelonephritis. On ultrasound or CT imaging studies, acute pyelonephritis is seen as a diffusely enlarged kidney without focal abnormalities. Acute bacterial nephritis produces ill-defined focal areas, sometimes striated or wedge-shaped, of decreased density. [7] Renal abscesses appear as well-defined areas of decreased density. [7] Emphysematous pyelonephritis is a rare gas-forming infection within the kidney, nearly always in diabetics (70 to 90 percent of the time). These patients usually have symptoms and signs of a severe infection, often with dehydration and pyelonephritis. [8]

CLINICAL FEATURES

The clinical symptoms of UTI in an adult are dysuria, frequency, and lower abdominal pain. However, the correlation between symptoms and the presence of infection is inexact as only 50 to 60 percent of women with dysuria have significant bacteriuria. [2,4] Internal dysuria, a burning suprapubic pain during urination associated with bladder tenderness, is more associated with UTIs as compared to external dysuria, the burning sensation as urine passes over inflamed perineal tissue. In females, external dysuria or a history of vaginal discharge is more associated with vaginitis, cervicitis, or pelvic inflammatory disease than with a UTI.

Flank pain, costovertebral angle tenderness, or specific renal tenderness to deep palpation can be associated with cystitis because of referred pain. However, when these are found in association with fever, chills, nausea, vomiting, and prostration, the clinical diagnosis is acute pyelonephritis.

In the male, dysuria with a urethral discharge indicates urethritis. [3] A Gram's stain of the discharge may reveal gram-negative intracellular diplococci, which is virtually diagnostic of gonococcal urethritis. If the Gram's stain is inconclusive, the diagnosis is most likely nonspecific urethritis (NSU), which is mainly chlamydial or another sexually transmitted infection. In either case, laboratory tests for gonorrhea and chlamydia should be obtained, and possibly a serologic test for syphilis. It should be emphasized to the emergency department triage personnel that UTI in young adult males is extremely rare; therefore, a urine specimen should not be obtained until after examination by a physician. Witholding urination may enhance the likelihood of a positive urethral swab in the male patient with minimal discharge. On the other hand, several authors have demonstrated that the presence of urinary leukocytes was more sensitive than urethral Gram's stain in detecting patients who were later found to have chlamydial infection as confirmed by culture. Finally, if bacteriuria is present and is not clinically associated with urethritis or prostatitis, then treatment, followed by urologic referral, is indicated.

DIAGNOSIS

Factors that are independent predictors of a UTI in a patient with dysuria are advanced age, history of a UTI, back pain, pyuria, hematuria, and bacteriuria. [2,3 and 4] Among sexually active women, the incidence of symptomatic UTIs is high, and the risk is independently associated with recent sexual intercourse, recent use of a diaphragm with spermicide, and history of a UTI.[5,6]

If UTI is suspected, the first step in establishing the diagnosis is the careful collection of urine for a urinalysis and potentially for culture. The midstream voiding specimen is as accurate as urine obtained by catheterization if the patient is given and follows careful instructions. Instruct the woman to remove her underwear, sit facing the back of the toilet, spread the labia with one hand, cleanse from front to back with povidone-iodine swabs or liquid soap, pass a small amount of urine into the toilet, and then urinate into a sterile cup. Instruct the man to carefully cleanse the urethral meatus, retracting the foreskin if uncircumcised, and obtain a midsteam specimen as described above.

If the sample is properly collected, it should contain no or few epithelial cells. The many sources of contamination include material in the collection bottle, menses, vaginal discharge, urethral or periurethral tissue, and organisms multiplying in the urine after collection. Bacteria in urine double each hour at room temperature; therefore urine should be refrigerated if not sent directly to the laboratory. In addition to special care in cleansing, the use of a tampon also helps women to obtain a clean-catch specimen if menstruation or profuse discharge is present.

Catheterization is indicated if the patient cannot void spontaneously, is too ill or immobilized, or is extremely obese. It may also be performed as part of a urologic evaluation and to relieve obstruction. Many authors promote the ease and accuracy of "minicath"-obtained urine in women, especially with a vaginal discharge or bleeding. However, unnecessary catheterization should be avoided because 1 to 2 percent of patients develop UTI after a single catheter insertion. This seems to be a problem especially if the catheter insertion is done just prior to delivery.

Although blood or bile may be detected by gross examination of the urine, visual inspection or the smell of the urine is generally not helpful in determining infection. Cloudiness is usually not due to white blood cells (WBC) or bacteria, but to large amounts of protein or amorphous phosphate crystals. Malodorous urine may be caused by diet or medications and is not a reliable sign of infection.

Current emphasis is on the detection of pyuria and bacteriuria in the initial examination of the urine to confirm the diagnosis of a UTI. However, the assessment of pyuria is imperfect. Variables include the specific gravity of the urine, method of centrifuging the specimen, the amount of supernatant in which the sediment is

resuspended, and the final volume of urine under the coverslip that is examined. Laboratories that use a WBC counting chamber diminish some of this variability and increase accuracy in assessing both centrifuged and uncentrifuged urine. Using a WBC counting chamber, abnormal pyuria can be defined as the presence of 8 leukocytes or more per mL of uncentrifuged urine. This figure roughly corresponds to 2 to 5 leukocytes per high-power field (hpf or 400×) from a centrifuged specimen.

While some authors feel that low-level pyuria (<10 WBC/hpf) is clinically important, others have suggested that pyuria in women is significant only if there are more than 10 WBC/hpf, and only if bacteria is also present on the microscopic examination. Though the combination of pyuria and bacteriuria is likely to be true with typical coliform infection, lower degrees of pyuria with or without bacteriuria may be significant, especially with regard to infection with *Chlamydia.*

As knowledge of UTI in adult women evolves, it is clear that women with symptoms and low-level pyuria (<10 WBC/hpf) do have significant infection that will symptomatically and bacteriologically respond to antimicrobial therapy. In the past, these women were not treated initially and their cultures often did not contain more than 10^5 CFU/mL. Sensitivity to causes of lower UTI other than typical coliforms has brought the designation of the dysuria-pyuria syndrome (also referred to as the acute urethral syndrome), which almost always benefits from treatment.[1] It is in this subgroup of women that the urinalysis may well be more useful than the urine culture. In addition, a positive urinalysis would dictate more immediate management interventions than would awaiting a urine culture.

In men, more than 1 to 2 WBC/hpf can be significant in the presence of bacteria.[3] Again, it must be remembered that urethritis and prostatitis are far more likely causes of pyuria in young males who are sexually active and complain of dysuria, whether or not a urethral discharge is present.

Bacteriuria is also felt to be a sensitive tool for detection of UTI in the symptomatic patient. The presence of any bacteria on a Gram stain of uncentrifuged urine (>1 bacteria per oil-power field or 1000×) is significant and highly correlates with culture results of >10 ^{5}/mL. For Gram-stained centrifuged specimens, more than 15 bacteria per oil-powered field (1000×) is significant. Both of these methods fail to detect low colony count UTI or infection caused by *Chlamydia.* False-positives can occur when vaginal or fecal contamination is present.

Several studies have evaluated urinary dipstick nitrite and leukocyte esterase tests in the diagnosis of UTIs, correlating the results with urinalysis.[9] The urine nitrite reaction has a very high specificity (>90 percent) and a positive result is very useful in confirming the diagnosis of a UTI. However, the urine nitrite sensitivity is low (about 50 percent), rendering it much less useful as a screening examination and a negative result does not exclude the diagnosis of a UTI. The urine leukocyte esterase has been evaluated as an indicator of the presence of pyuria, one marker of UTI. As noted above, there is an inexact correlation between clinical symptoms, results of urine culture, and pyuria as detected by microscopic examination. Initial reports of high sensitivity (near 88 percent) supported use of leukocyte esterase as a screening tool for pyuria. However, these studies were done on symptomatic women with high levels of pyuria. Studies from the emergency department have found a low sensitivity (48 percent) for leukocyte esterase with more common levels of pyuria (6 to 20 WBC/hpf).[9] When the clinical presentation suggests UTI, a positive leukocyte esterase test supports the diagnosis, and treatment should be initiated without the need for microscopic examination. If the leukocyte esterase test is negative, a microscopic examination should be performed to detect lower levels of clinically significant pyuria.

Unfortunately, the clinician is sometimes faced with women who complain of dysuria, have no pyuria or demonstrable pathogen on culture, and who do not respond to antimicrobial treatment. The absence of pyuria in these patients is useful because it indicates that antimicrobial treatment is probably unnecessary. Presuming that vulvovaginitis or cervicitis (gonorrhea, chlamydia, and herpes) has been excluded, causes of dysuria may include inflammation of the urethra from physical trauma or due to the use of chemical agents, such as spermicides, cleansing douches, or other feminine hygiene products.

In a symptomatic patient who has fewer than 2 to 5 WBC/hpf, other causes of false-negative pyuria should be considered. These include ingestion of large amounts of fluids, which wash out the bladder and produce a dilute urine, and, more likely, old or leftover medication, or a drug belonging to another person, being taken by the patient on a self-directed basis, or systemic leukopenia. It should be remembered that, in the case of an infected and obstructed kidney, pyuria may be intermittent or absent.

For the patient with typical symptoms of an uncomplicated UTI and a "positive" urinalysis (pyuria on microscopic examination, positive leukocyte esterase test, bacteriuria on Gram's stain, and/or positive urine nitrite test), urine culture is not required. The vast majority of these patients respond to empiric therapy. Most authors agree that a urine culture should be obtained in these settings: acute pyelonephritis; patients with epidemiologic risk factors for subclinical pyelonephritis; any patient who needs to be hospitalized; those patients who have a chronic indwelling catheter; and all pregnant women, children, and adult males.[2,3 and 4] If the patient is symptomatic, a single positive culture is significant. For ABU, two or three positive cultures are necessary before treatment is undertaken, with the exception that treatment for ABU is always indicated in pregnancy.

It is commonly recommended to obtain blood cultures in cases of acute pyelopnephritis, and while they are positive in about 30 percent of patients, the results rarely change management.[10,11] Renal imaging studies are not indicated in otherwise healthy patients with acute pyelonephritis that can be managed as an outpatient. Elderly, diabetic, or severely ill patients with acute pyelonephritis should be considered for imaging, particularly if there is a poor initial response to antibiotic therapy. The kidneys can be imaged with portable ultrasound at the bedside, evaluating for obstruction and focal parenchymal abnormalities.[7] Plain film radiology and ultrasound have poor sensitivity for detection of intrarenal gas formation in emphysematous pyelonephritis; CT is the best imaging modality.[8]

TREATMENT

Acute Cystitis

The selection of antibiotics depends on the suspected bacteriology of the infection, the patient's compliance, potential drug toxicity, and cost.[12] In uncomplicated UTIs, *E. coli* is the offending microorganism in the vast majority of cases, and this and other typical coliform pathogens remain susceptible to a variety of agents: trimethoprim, co-trimoxazole, nitrofurantoin macrocrystals, and the fluoroquinolones (Table 90-2).

TABLE 90-2   Guidelines to Outpatient Management of Uncomplicated UTI

Trimethoprim alone or in combination with sulfamethoxazole (cotrimoxazole or TMP/SMX) is generally recommended because these are cheap and effective (Table 90-3). Nitrofurantoin is also effective though compliance with frequent dosing is a problem and nitrofurantoin is not effective against *S. saprophyticus.* Because of increased bacterial resistance, extended-spectrum penicillins (e.g., amoxicillin) and cephalosporins have become less-acceptable alternatives. In cases of treatment failure, or in the host with a structural or immunologic defect, use of amoxicillin with clavulanic acid or one of the fluoroquinolones may be considered. Concern about the emergence of resistant organisms and expense preclude indiscriminate use of the latter agents. In uncomplicated UTIs, the urine should be bacteria-free in 24 to 48 h with substantial relief of symptoms within the same time period. The offer of one to two days of an oral bladder analgesic, such as phenazopyridine, is considerate when urination is painful for the patient.

Generic Name	Cost, $*	Brand Name	Cost, $*
Trimethoprim (TMP)	14.39	Proloprim	36.39
Sulfamethoxazole (SMX)	NA	Gantanol	17.49
Co-trimoxazole (TMP/SMX) DS	11.59	Bactrim DS	54.49
Doxycycline	16.79	Vibramycin	81.79
Nitrofurantoin macrocrystals	23.49	Macrodantin	38.39
Amoxicillin with clavulanate	NA	Augmentin	77.89
Ciprofloxacin	NA	Cipro	62.49
Ofloxacin	NA	Floxin	82.99

TABLE 90-3   Cost Comparison of Urinary Antimicrobial Agents: 10-Day Course

Until the last decade, the duration of antibiotic treatment for a UTI was 7 to 10 days. Multiple studies of shorter treatment regimens for uncomplicated infections in nonpregnant adult women have been published and three days has become the recommended standard. [2,3 and 4,13] Short-course treatment appears to offer a number of advantages: cost and side effects are substantially reduced, compliance improves, and the development of resistant strains of bacteria is less likely. However, 20 to 30 percent of patients given short-course therapy fail treatment and/or quickly relapse. In addition, three-day regimens are not adequate for all patients and a seven-day course is recommended for pregnant women, those with symptoms over a week, patients with diabetes, individuals who had a previous recent UTI, those who are older than 65 years, and women who use a diaphragm. [4]

These recommendations for 3-day treatment courses has also generated concern regarding the entity of subclinical pyelonephritis, which has become increasingly apparent during studies of what was felt to be uncomplicated lower UTI. [2,4] Detection of this entity requires sophisticated differentiation based on analysis of immunofluorescent antibody results or analysis for b-glucuronidase and lactate dehydrogenase isoenzymes, principally research tools not available for routine clinical use. In several series, a number of patients with apparent simple cystitis exhibited tissue invasion as demonstrated by the presence of antibody-coated bacteria (ACB), that is, unsuspected or subclinical pyelonephritis. This group had a poor response to short-term therapy when compared to patients with ACB who received 10- to 14-day treatment. [4]

On the other hand, it has been suggested that short-course treatment may reliably identify patients with subclinical pyelonephritis as available diagnostic tests. This is because a short-course of antibiotics is less likely to eradicate bacteriuria in the patient with tissue invasion. In practice, women with the diagnosis of uncomplicated acute cystitis would be given a three-day course of co-trimoxazole with the expectation of cure in the vast majority. Those patients with recurrence of symptoms, pyuria, and bacteriuria will be promptly identified as having subclinical renal infection necessitating 14 days of therapy.

In certain emergency department settings, especially those serving indigent populations where there is delay in seeking care, the incidence of subclinical pyelonephritis may approach 70 percent of patients. In this circumstance, short-course therapy is difficult to justify. Before the emergency department physician decides to use a three-day course of treatment, the patient's ability to follow up within one week or return if symptoms persist must be assessed. If follow-up compliance is not expected, or the epidemiologic risk of subclinical pyelonephritis is great, then the patient should be placed on a 10- to 14-day regimen.

One should be suspicious that *Chlamydia* is responsible for symptoms in these settings: a woman with a recent, new sexual partner; a partner with urethritis; examination findings of cervicitis; or when there is low-grade pyuria with no bacteria seen on urinalysis. A seven-day course of doxycycline or a single dose of azthromycin is the preferred treatment.

For recurrent infection, culture and sensitivity tests are essential. [2,3 and 4] The infection is often due to a new serotype of *E. coli,* or it may be due to newly resistant organisms that develop as a result of antibiotics excreted into the gastrointestinal tract. Empirical therapy for recurrent infections includes co-trimoxazole, nitrofurantoin macrocrystals, or the fluoroquinolones. However, successful management depends on sensitivity testing. Again, it must be emphasized that these patients need referral when identified as having recurrent infections. In addition to evaluation of the urinary tract, chronic suppressive therapy is usually instituted.

Aggressive therapy is warranted for pregnant women with pyuria or bacteriuria, whether or not associated symptoms are present. Most clinicians prefer a cephalosporin for outpatient treatment. Co-trimoxazole may be considered except within two weeks of the estimated delivery date and in those with glucose-6-phosphate dehydrogenase deficiency. All regimens should be continued for seven days. Inpatient management is stressed for suspected pyelonephritis because the incidence is higher in pregnancy, and maternal and fetal morbidity is substantial.

Adjunctive therapy should include plenty of fluids to enhance diuresis, fruit juices containing vitamin C to acidify the urine, a proper diet, and frequent voiding (at least every two hours) to diminish tissue contact with bacteria. [14] Women should be reminded that postintercourse voiding may be helpful in reducing recurrent infection.

Once the infection is eradicated, management should be directed toward prevention of reinfection; up to 80 percent of women who have had one UTI develop another one at a later time. Because many factors are involved in reinfection and some of these are correctable, appropriate referral is essential.

Acute Pyelonephritis

Classically, acute pyelonephritis is characterized by shaking chills and fever, flank pain, and costovertebral angle tenderness following several days of dysuria and frequency. [2,4] The urine often demonstrates WBC casts and clumps, as well as bacteria. Sometimes the presentation may not be dramatic, and it might be difficult to distinguish lower from upper UTI.

Factors associated with an increased risk for pyelonephritis include pregnancy, prolonged symptoms prior to seeking care, three or more infections in the past year, immunocompromised state, and diabetes mellitus. [2,4] Less often, the patient may have a congenital or acquired anatomic urinary tract abnormality, neurogenic problems that result in incomplete bladder emptying, recent urinary tract instrumentation, renal calculi and nephrocalcinosis, prostatic hypertrophy, or prostatitis as precipitating factors for acute pyelonephritis.

Young, otherwise healthy females with uncomplicated acute pyelonephritis may be candidates for outpatient management. [15] Conversely, oral outpatient treatment cannot be recommended for patients who are immunocompromised, pregnant, diabetic, or chronically ill. Although unproven, a popular regimen at many institutions is to treat the patient with antipyretics, intravenous fluids, and the first dose of antibiotic (either oral or parenteral) while undergoing a brief period of observation in the emergency department to ensure that further oral therapy will be kept down, which is assessed by having the patient drink water. [16] Outpatient therapy for selected patients (young, otherwise healthy, able to keep down fluids and antibiotics) is as safe and effective, and considerably less expensive, than comparable patients treated on an inpatient basis. Acceptable antibiotics include the fluoroquinolones, amoxicillin/clavulanate, or co-trimoxazole, although *E. coli* are demonstrating increasing resistance to co-trimoxazole in some regions. [12] Outpatient treatment should be continued for 10 to 14 days. Patients should be instructed to return if increasing pain, fever, or vomiting. Overall, 80 to 90 percent of selected patients with acute pyelonephritis respond to outpatient oral therapy. [15,16]

The decision to admit a patient with acute pyelonephritis is based on age, host factors, and response to initial emergency department interventions. Fluid replacement and parenteral antibiotics are necessary if the patient is vomiting or dehydrated. Unremitting fever and/or loss of vasomotor tone mandate inpatient therapy. In an otherwise healthy host with no prior or recent history of UTI, the typical offending bacteria would often be *E. coli,* or another coliform bacteria. Acceptable intravenous antibiotic regimens include a fluoroquinolone (ciprofloxacin, levofloxacin, or ofloxacin), ampicillin plus gentamicin, a third-generation cephalosporin (cefotaxime, ceftazidine, or ceftriaxone), or extended spectrum penicillin plus b-lactamase inhibitor (ticarcillin/clavulanate or ampicillin/sulbactam). [12] The selection of which drugs to use depends on cost considerations and on local sensitivity patterns.

Younger patients without complicating factors have the least morbidity or mortality. Overall, about 1 to 3 percent of patients with acute pyelonephritis die from the infection. Factors associated with an unfavorable prognosis are old age and general debility, renal calculi or obstruction, a recent history of hospitalization or instrumentation, diabetes mellitus, evidence of chronic nephropathy, sickle cell anemia, underlying carcinoma, or intercurrent cancer chemotherapy. In patients with

these factors, it is imperative that broad-spectrum antibiotic coverage to include *Pseudomonas sp* be provided. A urologic or infectious disease consultation should be considered as part of the initial management of such patients.

Complications of acute pyelonephritis include acute papillary necrosis with possible ureteric obstruction, septic shock, and perinephric abscesses. Imaging studies to detect ureteral obstruction are essential in the management of these complications. Adequate fluid resuscitation must be emphasized.

91 MALE GENITAL PROBLEMS

Robert E. Schneider

One of the most anxiety-provoking problems presenting to an emergency department is the male with acute genital pain. The extensive sensory innervation of this area produces severe symptoms, and the close relationships of the abdominal and genital sensory afferent pathways in the male account for the common association of abdominal pain with some acute genitourinary disorders.

ANATOMY

Penis

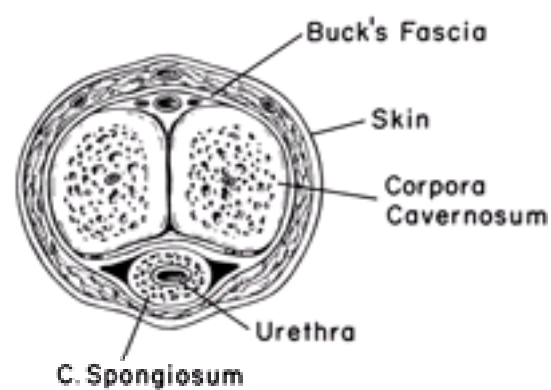
The penis is composed of three cylindrical bodies: the two corpora cavernosa, which form the main bulk of the penis, and the corpus spongiosum, which surrounds the urethra (Fig. 91-1). The corpora cavernosa are the major erectile bodies, extending distally from the pubic rami and capped by the glans penis. These two cylindrical structures are encased in a thick tunic of dense connective tissue, the tunica albuginea. All three cylinders are collectively covered by a thinner Buck's fascia, which fuses with Colles's fascia at the level of the urogenital diaphragm.


FIG. 91-1. Cross section of the penis.

The blood supply is primarily from the internal pudendal artery, which branches to form the deep and superficial penile arteries. Lymphatic drainage is into the deep and superficial inguinal nodes.

Scrotum

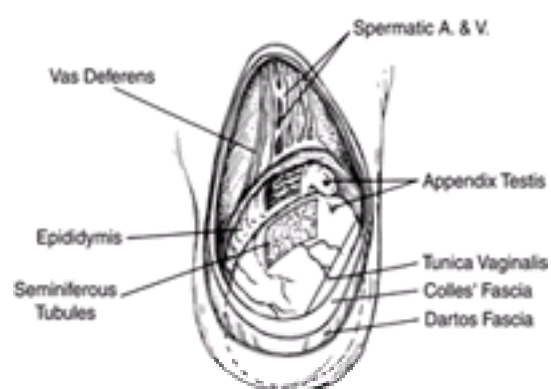
The prepubertal scrotal skin is thin and thickens with subsequent hormonal stimulation. Immediately beneath the skin are the smooth muscle and elastic tissue layers of the Dartos fascia, similar to the superficial fatty layer (Camper's fascia) of the abdominal wall. The deep membranous layer (Scarpa's fascia) of the abdominal wall extends into the perineum, where it is referred to as Colles' fascia and forms part of the scrotal wall (Fig. 91-2). The blood supply is primarily derived from branches of the femoral and internal pudendal arteries. Lymphatics from the scrotum drain into the inguinal and femoral nodes.


FIG. 91-2. Anatomy of the scrotum and the testis.

Testes

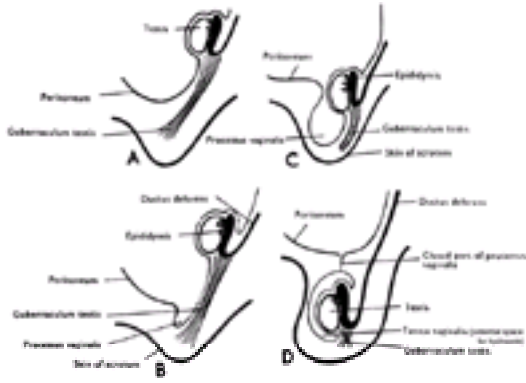
The testes usually lie in an upright position with the superior portion tipped slightly forward and outward. The average size is between 4 and 5 cm in length, and approximately 3 cm in width and depth. The overall volume is about 25 mL. Each testis is encased in a thick fibrous tunica albuginea except posterolaterally, where it is in tight apposition with the epididymis. The enveloping tunica vaginalis anchors each testis and epididymis to the posterior scrotal wall. Inferiorly, the testis is anchored to the scrotum by the scrotal ligament (gubernaculum). A lack of firm posterior fixation leaves both the testes and epididymis at risk for torsion. The posterior (visceral) leaf of tunica vaginalis is contiguous with the tunica albuginea testis. A potential space exists between this visceral leaf and the anterior (parietal) tunica vaginalis. Any traumatic or inflammatory event will impede the normal parietal tunica vaginalis from absorbing viscerally secreted fluid, resulting in a hydrocele (Fig. 91-3).


FIG. 91-3. Embryonic retroperitoneal testis descends into the scrotum and invaginates into the tunica vaginalis, which anchors it to the posterior scrotal wall. Note the potential space in the tunica vaginalis for development of a hydrocele.

The blood supply is by the internal spermatic and external spermatic arteries, which travel together in the spermatic cord. Venous return is primarily by the internal spermatic, epigastric, internal circumflex, and scrotal veins. The lymphatics drain toward the external, common iliac, and periaortic nodes.

The epididymis is a single, fine, tubular structure approximately 4 to 5 m long compressed into an area of about 5 cm. The function the epididymis is to promote sperm maturation and motility. Vestigial embryonic structures, the appendix epididymis and the appendix testis, which have no known physiologic function, are often associated with the testes and epididymis. The appendix epididymis, a remnant of the epigenitales, is found attached to the head of the epididymis, or globus major. The appendix testis, a pear-shaped structure of müllerian duct origin, is usually situated on the uppermost portion of the testis at the junction of the testis and the globus major of the epididymis.

The vas deferens, a prominent part of the adnexa of the scrotal contents, is a distinct muscular tube that is easily palpable within the scrotal sac. It extends cephalad in the spermatic cord from the tail of the epididymis (globus minor) traversing the inguinal canal and crossing medially behind the bladder over the ureters to form the ampullae of the vas, where it joins with the seminal vesicles to form the paired ejaculatory ducts in the prostatic urethra.

Prostate

The prostate originates from the urogenital sinus at approximately the third month of embryonic life. It is continually enlarging and in the young male is approximately 10 to 15 g, often not definable on rectal examination. As a man matures, the prostate may enlarge dramatically, resulting in significant bladder outlet obstruction. The prostate is divided into five lobes: anterior, median, posterior, and two lateral lobes.

PHYSICAL EXAMINATION

Physical examination should be carried out with the patient in both the supine and upright positions in a well-illuminated, warm room. If the scrotum is contracted despite proper room temperature, a warm towel placed over the genitalia permits the scrotum to relax and the testes to descend and be comfortably examined.

Examination should always begin with visual inspection. In uncircumcised males, the foreskin should be fully retracted to inspect the glans, coronal sulcus, and preputial areas for ulceration or malignant lesions. The location of the urethral meatus and presence of discharge should be noted. The penile shaft should be carefully palpated for plaques, cysts, or early abscesses.

The supine or modified lithotomy (frogleg) position is more comfortable for both the patient and the examiner and allows a more thorough examination of each testis, epididymis, the prostate, seminal vesicles, and rectal ampulla. During the critical evaluation of a scrotal mass, patient relaxation and cooperation in the supine position are paramount. Testicular nodularity or firmness should be considered carcinoma until proven otherwise. The epididymis usually lies on the posterolateral aspect of the testis and, if not inflamed or involved with other pathologic entities, has a soft, fleshy feel similar to that of the earlobe. Many males experience pain and tenderness with palpation of a normal globus major (head), body, and globus minor (tail) of the epididymis. All males experience some discomfort during palpation of a normal prostate. The supine position helps prevent an infrequent vasovagal response to the scrotal or prostate examination. The prostate has a heart-shaped contour with its apex located more distally, abutting the urogenital diaphragm (anatomic soft spot). The consistency of the normal prostate has the same resiliency as the cartilaginous tip of the nose, while suspicious carcinogenic areas feel more like the bony prominence of the chin. The posterior lobe is small and thin, allowing palpation of the median raphe that distinguishes the two lateral lobes. A normal rectal examination does not exclude bladder outlet obstruction secondary to an obstructing median bar or large intravesical prostate. The seminal vesicles, lying just superior to the prostate, cannot normally be distinguished unless there is inflammation, induration, or enlargement.

Examination of the inguinal canals for hernias and the scrotal spermatic cords for varicoceles is best done in the upright position, with the patient straining at the designated time. When the patient is upright, it should be determined whether the testes are aligned along a vertical or horizontal axis. Horizontally aligned testes are at greater risk for torsion.

Some genital disorders may require urine collection and analysis. The uncircumcised male should retract his foreskin and wash the glans penis with cleansing towels before collecting a midstream specimen. Failure to do so will result in preputial contamination. The often-described three-cup specimen used to localize male lower urinary tract infections is time-consuming and requires patient compliance, factors that tend to limit its usefulness in the emergency department.

COMMON GENITOURINARY DISORDERS

Scrotum

Because the scrotal skin is loose and elastic, dramatic enlargement of the scrotum may occur secondary to either scrotal or testicular pathologic conditions.

SCROTAL EDEMA   Simple, isolated scrotal edema is uncommon. It usually occurs secondary to insect or human bites, contact dermatitis, or, in young boys, to idiopathic scrotal edema. Contiguous scrotal and penile edema occurs in older men in conjunction with lower extremity edema in fluid overload states (congestive heart failure), hypoalbuminemia, and generalized anasarca.

SCROTAL ABSCESS   The important distinction with a scrotal abscess is whether the phlegmon is localized to the scrotal wall, i.e., simple hair follicle abscess, or involves, and even perhaps originates from, infection in one of the primary intrascrotal organs, i.e., testis, epididymis, bulbous urethra. This distinction can be very difficult late in the course of the disease process when a scrotal mass may be the only discernible finding.

A simple hair-follicle scrotal-wall abscess can be managed by incision and drainage. Oftentimes wound care can be simplified by circumferential excision of the entire roof of the abscess. This allows access for wound care and sitz baths and assures healing from the base outward. Antibiotics are rarely needed in an immunocompetent male.

Contiguous involvement of the scrotal skin by an inflammatory mass in the testis or epididymis is best evaluated by ultrasound. A retrograde urethrogram will delineate the integrity of the urethra. Definitive care of any complex abscesses should be directed by a urologist.

FOURNIER'S GANGRENE   Fournier's gangrene is a polymicrobial, synergistic infection of the subcutaneous tissues that originates from one of three sites: skin, urethra, or rectum. This infectious process typically begins as a benign infection or simple abscess that quickly becomes virulent, especially in an immunocompromised host, and leads to end-artery thrombosis in the subcutaneous tissue that promotes widespread necrosis of previously healthy tissue (Fig. 91-4).

FIG. 91-4. A patient with Fournier's gangrene of the scrotum. Note the sharp demarcation of gangrenous changes and the marked edema of the scrotum and the penis.

The diabetic male seems to be most at risk. Prompt recognition of Fournier's gangrene in its early stages should prevent extensive tissue loss that accompanies delayed diagnosis. Aggressive fluid resuscitation; gram-positive, gram-negative, and anaerobic antibiotic coverage; and wide surgical debridement sometimes in conjunction with pre- and postoperative hyperbaric oxygen therapy are the mainstays of treatment. Urologic consultation is often required when periurethral abscess is the inciting event, or when other etiologies have secondarily invaded the urinary tract and supravesical urinary drainage is needed. It is imperative that emergency physicians maintain a very high index of suspicion for this entity in immunocompromised patients who present complaining of scrotal, rectal, or any genitalia pain out of proportion to their physical examination findings. Surgical consultation is strongly recommended in all such patients, rather than deciding on symptomatic treatment and discharge from the emergency department.

Penis

BALANOPOSTHITIS   Balanitis is inflammation of the glans penis. Posthitis is inflammation of the foreskin. Balanoposthitis is inflammation of both the glans and foreskin. When foreskin retraction is attempted, the glans and apposing prepuce appear purulent, excoriated, malodorous, and tender. When recurrent, it can be the sole presenting sign of diabetes. Treatment consists of cleansing the area with mild soap, assuring adequate dryness, application of antifugal creams (nystatin or clotrimazole), and possibly circumcision. If secondary bacterial infection is present, a broad-spectrum antibiotic, usually a cephalosporin, should be prescribed.

PHIMOSIS   Phimosis is the inability to retract the foreskin proximally and posterior to the glans penis (Fig. 91-5). Causes include infection, poor hygiene, or previous preputial injury with scarring. Scarring at the tip of the foreskin can occlude the preputial meatus, infrequently causing urinary retention. Hemostatic dilation of the preputial ostium relieves the urinary retention until definitive dorsal slit or circumcision can be done.

FIG. 91-5. Phimosis and paraphimosis. (The lower figure depicts the method of reduction.)

PARAPHIMOSIS   Paraphimosis is the inability to reduce the proximal edematous foreskin distally over the glans penis into its naturally occurring position (Fig. 91-5). The resulting glans edema and venous engorgement can progress to arterial compromise and gangrene.

Paraphimosis is a true urologic emergency. Paraphimosis can often be reduced by compression of the glans for several minutes to reduce edema and allow for successful reduction of the foreskin back over the now smaller glans. Tightly wrapping the glans with a ×2-inch elastic bandage for 5 min is one method to reduce edema. Infrequently, several puncture wounds with a small needle (22 to 25 g) can help edema fluid be expressed out the glans. A local anesthetic block of the penis is also helpful if the patient cannot tolerate the pain of compression. If these methods are unsuccessful, local infiltration of the constricting band with 1% plain lidocaine followed by superficial vertical incision of the band will decompress the glans and allow foreskin reduction. This procedure should be done by an emergency physician unless a urologist is immediately available.

ENTRAPMENT INJURIES   Various objects can be placed around the penis, initially occluding the venous, and subsequently the arterial, blood supply. String, metal rings, and wire have been wrapped around the penis for sexual, experimental, or accidental reasons. One of the most insidious objects that can become entrapped behind the coronal ridge is human hair, usually found in young circumcised boys aged two to five years (Fig. 91-6). The child presents with swelling of the glans. The offending hair may be invisible within the edematous coronal sulcus. If the hair has been chronically occluding, the urethra and dorsal nerve supply of the penis may be partially or completely involved. Removal of the offending object requires ingenuity and care. Urethral integrity (retrograde urethrogram) and distal penile arterial blood supply (Doppler) must be assured prior to emergency department discharge.

FIG. 91-6. Hair is entrapped behind the coronal sulcus (*arrow*), constricting and progressively amputating the glans.

FRACTURE OF THE PENIS   An acute tear or rupture of the corpus cavernosa tunica albuginea is rare but easily diagnosed. The penis is acutely swollen, discolored, and tender. The history is of trauma during intercourse or other sexual activity, when a sudden "snapping sound" occurs. Even though the urethra is infrequently injured, a retrograde urethrogram may be necessary to assure urethral integrity. Surgical treatment consists of hematoma evacuation and suture apposition of the

disrupted tunica albuginea.

PEYRONIE'S DISEASE   The patient complains of gradual onset of dorsal penile curvature with erections; it is painful and may preclude successful vaginal penetration during intercourse. Examination of the dorsal penile shaft will disclose a thickened plaque involving the tunica albuginea of the corpora bodies without urethral involvement. Reassurance and urologic referral are warranted. Peyronie's disease of the penis has been noted in association with Dupuytren's contractures of the hand.

PRIAPISM   Priapism is a urologic emergency that presents as a painful, hard, pathologic erection in which both corpora cavernosa are engorged with stagnant blood. Even though the glans penis and the corpus spongiosum are characteristically soft and uninvolved, urinary retention may develop. Impotence has been reported to occur in 35 percent of cases who have sustained erections for prolonged periods of time; thus, expedient treatment and early urologic consultation is required. The potential for medical-legal liability mandates meticulous documentation in these cases.

A large number of cases of priapism in adults are pharmacologically related, either to intracavernosal injection for impotence or oral agents for hypertension or mental disorders. Most cases of priapism in children are due to hematologic disorders, usually sickle cell disease. Case reports have attempted to relate a variety of other drugs, metabolic conditions, and trauma to priapism, although the pathophysiologic mechanisms are speculative in most cases.

Priapism is classified into high-flow (nonischemic) priapism and low-flow (ischemic) priapism. The former is rare, most often nonpainful, and usually results from traumatic fistulae between the cavernosal artery and the corpus cavernosum. The latter is more common, is usually quite painful, and is diagnosed by the aspiration of dark acidic intracavernosal blood from the corpus cavernosum.

Low-flow priapism is further categorized as reversible or nonreversible depending upon etiology and the response to medical treatment (Table 91-1). Regardless of specific etiology, initial therapy with terbutaline, 0.25 to 0.5 mg subcutaneously in the deltoid area, repeated in 20 min as needed, is the most effective therapy. Traditional therapies of sedation or ice water enemas are ineffective. Pseudoephedrine 60 to 120 mg orally has been reported effective in some cases that present early (less than 4h). Priapism due to sickle cell disease is most consistently reversed by simple or exchange transfusion. Corporal aspiration followed by irrigation (either with plain saline or with a-adrenergic agonists, i.e., phenylephine (neosynephrine)) is the primary treatment method for persistent priapism. The urologic consultant usually performs this procedure, but if one is not readily available, the emergency physician may need to intervene. Reversible priapism may respond to these treatments, while nonreversible priapism usually does not respond and requires surgery.

Reversible Causes
A. Sickle cell anemia
    Treatment: Terbutaline, 0.25–0.5 mg subcutaneously in the deltoid muscle; packed red blood cell transfusion; hydration and alkalization may be beneficial
B. Iatrogenic injection of PGE1, papaverine, or phentolamine for impotence
    Treatment: Terbutaline, 0.25–0.5 mg subcutaneously in the deltoid muscle; aspirate 30–70 mL corporal blood, then inject 30–70 mL phenylephrine 20 µg/mL (10 mg in 500 mL normal saline), maximum dose = 1500 µg
C. Leukemic infiltration
    Treatment: Terbutaline, 0.25–0.5 mg subcutaneously in the deltoid muscle; specific chemotherapy
Nonreversible Causes
A. Idiopathic
B. High spinal cord lesion
C. Medications (phenothiazines, hydralazine, prazosin)
    Treatment of all nonreversible causes: Terbutaline, 0.25–0.5 mg subcutaneously in the deltoid muscle; corporal aspiration, phenylephrine instillation; heparin irrigation; shunt surgery

TABLE 91-1   Causes and Treatment of Low-Flow Ischemic Priapism

CARCINOMA   Carcinoma of the penis is a rare disease occurring in about 1 of every 100,000 malignancies reported, usually appearing in the fifth or sixth decade in an uncircumcised male. Carcinoma may appear as a nontender ulcer or warty growth beneath the foreskin in the area of the coronal sulcus or glans penis. It is often hidden by an inflamed phimotic foreskin.

Testes and Epididymis

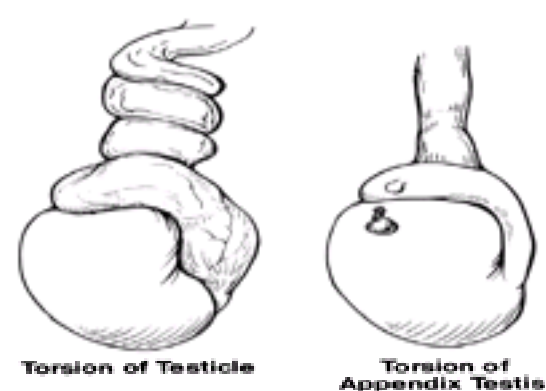
TESTICULAR TORSION   The differential diagnosis of acute scrotal pain includes testicular torsion, torsion of the appendix testis, appendix epididymis, and epididymitis. Testicular torsion must be the primary consideration (Fig. 91-7). While the peak incidence of intravaginal torsion occurs at puberty in conjunction with maximal hormonal stimulation, it may occur at any age.


FIG. 91-7. Diagrams of testicular torsion and torsion of the appendix testis.

Torsion of the testis or spermatic cord results from bilateral maldevelopment of fixation between the enveloping tunica vaginalis and the posterior scrotal wall. Characteristically, the at-risk testis is aligned along a horizontal rather than a vertical axis. The axis of alignment can be determined only with the patient in an upright position, and even then the determination may be difficult.

Frequently there is a history of an athletic event, strenuous physical activity, or trauma just prior to the onset of scrotal pain. However, a fair number occur during sleep. Unilateral cremaster muscle contraction results in testicular torsion. The pain usually occurs suddenly, is severe, and is usually felt in either lower abdominal quadrant, the inguinal canal, or the testis. While the pain may be constant or intermittent, it is not positional in nature as testicular torsion is primarily an ischemic event that becomes inflammatory only after the testis has infarcted.

In obvious cases of testicular torsion, emergent urologic consultation and surgical exploration are recommended. The often quoted 4-h warm-ischemia time for testicular salvage comes from controlled animal studies and cannot be extrapolated to clinical medicine. There are no readily available clinical or laboratory parameters to judge either the degree or the duration of testicular ischemia. Therefore, no matter how long the patient has been symptomatic and no matter what the presenting physical examination suggests, if testicular torsion cannot be excluded by history and physical examination, emergency scrotal exploration is the definitive diagnostic test and procedure of choice.

Color-flow duplex Doppler ultrasound and radionuclide scintigraphy are two imaging modalities used to evaluate patients with indeterminate clinical presentations. Both may be useful, but their routine clinical use is limited by timely availability and operator experience in interpreting the images. These studies are considered "positive" for testicular torsion when they demonstrate absent or clearly reduced blood flow to the painful side when compared to the opposite testicle, and "negative" when flow is normal or increased. Both studies have nearly identical reported sensitivity (80 to 90 percent) and specificity (75 to 95 percent) for testicular torsion.

Ultrasound has the advantage of demonstrating scrotal anatomy (which may indicate alternate diagnosis) but has the disadvantage of the greater number of indeterminate results when compared to scintigraphy. Within these limitations, both modalities may be useful when promptly available for patients with unclear clinical presentations but should never delay attempted manual detorsion and scrotal exploration.

While awaiting transportation of the patient to the operating room, the emergency physician should attempt manual detorsion of the affected testis. Most testes torse in a lateral to medial fashion. Therefore, detorsion should initially be done in a medial to lateral motion. It must be explained to the patient that detorsion is a painful procedure and while local anesthesia of the affected spermatic cord can initially make the patient more comfortable, it also removes an important endpoint of the detorsion maneuver, i.e., relief of pain. Detorsion is done in a manner similar to opening a book (Fig. 91-8). If one were to stand at the patient's feet, the patient's right testis would be rotated in a counterclockwise fashion (Fig. 91-9); the patient's left testis in a clockwise fashion (Fig. 91-10). Any relief of pain is a positive endpoint. A worsening of the patient's pain would dictate that detorsion be done in the opposite direction. Successful detorsion converts an emergent procedure to an elective one, but one that must be done to correct a potential bilateral anatomic disaster. The timing of the elective surgical correction should depend on the patient's compliance and responsibility.
FIG. 91-8. Testicular detorsion. This procedure is best done standing at the foot of or on the right side of the patient's bed. The torsed testis is detorsed in a fashion similar to opening a book (Fig. 91-8). That is, the patient's right testis is rotated counterclockwise (Fig. 91-9), the left testis is roated clockwise (Fig. 91-10).

FIG. 91-9. Testicular detorsion. This procedure is best done standing at the foot of or on the right side of the patient's bed. The torsed testis is detorsed in a fashion similar to opening a book (Fig. 91-8). That is, the patient's right testis is rotated counterclockwise (Fig. 91-9), the left testis is roated clockwise (Fig. 91-10).

FIG. 91-10. Testicular detorsion. This procedure is best done standing at the foot of or on the right side of the patient's bed. The torsed testis is detorsed in a fashion similar to opening a book (Fig. 91-8). That is, the patient's right testis is rotated counterclockwise (Fig. 91-9), the left testis is roated clockwise (Fig. 91-10).

Young boys may present to the emergency department with nonspecific abdominal pain suggestive of gastroenteritis only to return one to two days later with testicular torsion. Whether these patients had undisclosed testicular torsion at their initial evaluation is not known, but emergency physicians must think about testicular torsion in the differential diagnosis of any male presenting with a complaint of abdominal pain!

TORSION OF THE APPENDAGES   The appendages of the epididymis and testis have no known physiologic function. These pedunculated structures are, however, capable of torsion, and in prepubertal boys probably torse more often than the testes. If the patient is seen early, the pain is more intense near the head of the epididymis or testis, and an isolated tender nodule can often be palpated. When the involved infarcted appendage is brought close to the thin, prepubertal nonhormonally stimulated scrotal skin, a blue reflection may be seen when light shines upon it. This "blue dot sign" is pathognomonic of torsion of the appendix testis or epididymis. If the diagnosis can be absolutely assured and confirmed by color Doppler ultrasound showing normal intratesticular blood flow to the involved testis, immediate surgery is not necessary, because most appendages will calcify or degenerate over 10 to 14 days and cause no harm. If late in the process and testicular swelling is present, or if the color Doppler ultrasound is equivocal, then urologic consultation and surgical exploration may be necessary to exclude testicular torsion.

EPIDIDYMITIS   The onset of pain in epididymitis or epididymo-orchitis is usually more gradual than that of testicular torsion because of its inflammatory etiology. Bacterial infection is the most common cause and tends to be age-dependent. In young boys with documented epididymitis or epididymo-orchitis, congenital anomalies of the lower urinary tract in addition to chemical epididymitis secondary to retrograde reflux of sterile urine into the globus minor (tail of the epididymis) must be considered. In patients less than 40 years of age, epididymitis is primarily due to sexually transmitted diseases (STDs) or their complications, i.e., urethral stricture. In gay men with epididymitis or epididymo-orchitis, fungal infection of the lower urinary tract in addition to the more common STD organisms must be considered. In patients over 40 years of age, epididymitis is caused by common urinary pathogens such as *Escherichia coli* and *Klebsiella.* These patients will most often have pyuria on urinalysis, but the absence of white cells or bacteria does not exclude the diagnosis. Older men with epididymitis due to infected urine must be evaluated for the cause of their lower urinary tract infection, i.e., benign prostatic hypertrophy (BPH) or urethral stricture disease. Oftentimes the answer may be found by passing a 14F or 16F Foley or Coudé catheter into the bladder. Easy passage precludes a stricture. A large residual urine should alert the physician to outlet obstruction as the cause of the patient's infection.

Epididymitis causes lower abdominal, inguinal canal, scrotal, or testicular pain alone or in combination. The retrograde progression of infection from the prostatic urethra to the epididymis explains the location and progression of pain. Patients with epididymitis are more prone to lower urinary tract irritative voiding symptoms and may note transient relief of their pain in the recumbent position with scrotal elevation, due to the inflammatory nature of the disease. Initially, isolated firmness and nodularity of the affected globus minor is noted on examination. As the disease progresses, the sulcus between the epididymis and testis becomes obliterated, and

the inflammatory epididymal mass may become contiguous with the testis, producing a large, tender scrotal mass (epididymo-orchitis) that cannot be differentiated from testicular torsion or carcinoma. At this stage the patient may appear toxic and require admission for IV antibiotic therapy (see Table 91-2). Adjunctive diagnostic modalities such as color-flow duplex Doppler sonography or radionuclide scintigraphy will demonstrate increased or preserved blood flow to the testes.

TABLE 91-2 Etiology and Treatment of Epididymitis and Epididymo-orchitis

Admission criteria for epididymitis include fever with elevated white blood cell count and subjective toxicity, all of which can be indicative of epididymal or testicular abscess formation. A urologist will dictate inpatient management, which should include: (1) absolute bedrest for the first 24 to 48 h, with scrotal elevation and ice application (10 to 15 min every 4 to 6 h) to the involved testis/epididymis; (2) nonsteroidal anti-inflammatory drugs (NSAIDs); (3) intravenous antibiotics based on etiology (Table 91-2); and (4) narcotics for pain control, with concomitant stool softeners. These measures will prevent further progression of the inflammatory process. Once the bedridden patient is pain-free, he should begin ambulation with a scrotal supporter, being careful not to lift heavy objects or strain when having a bowel movement, both of which will increase intraabdominal pressure and exacerbate the inflammatory cycle. Any significant deviation from this plan will prolong the recovery period. Outpatient management is identical to inpatient management except that oral antibiotics are prescribed initially for 10 to 14 days. A urologist will need to reevaluate the patient in five to seven days and then ultimately decide when the patient may return to work based on his job description, i.e., a sedentary worker would be able to return sooner than a laborer.

ORCHITIS   Isolated orchitis, or inflammation of the testicle, is quite rare. It usually occurs in conjunction with other systemic diseases, such as mumps, other viral illnesses, or syphilis. Orchitis usually presents as bilateral testicular tenderness and swelling over a few days' duration. Treatment is symptomatic and disease-specific with urologic follow-up.

TESTICULAR MALIGNANCY   Any asymptomatic testicular mass, firmness, or induration is the hallmark of testicular carcinoma. Ten percent of tumors will present with pain secondary to acute hemorrhage within the tumor. Metastatic testicular tumors can be insidious and must be suspected in any male with unexplained supraclavicular lymphadenopathy, abdominal mass, or chronic nonproductive cough that appears resistant to antibiotic or other supportive therapy. Testicular examination may be diagnostic. While not a urologic emergency, any unexplained testicular mass must be approached as a tumor, with urgent urologic referral.

Urethra

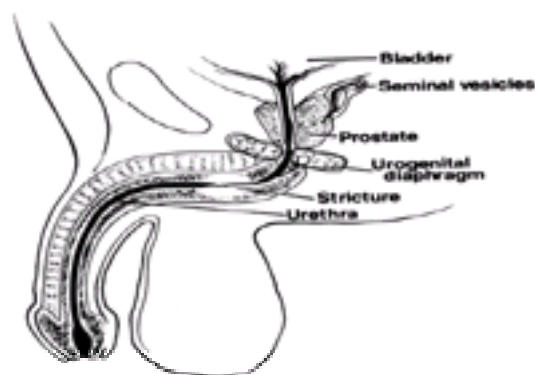
URETHRAL STRICTURE   Urethral strictures are becoming more prevalent secondary to the rising incidence of STDs. Increasingly, in teenagers and young adults, gonococcal and chlamydial infections have resulted in bulbous urethral obstruction (Fig. 91-11), while trauma and urethral instrumentation are less common and tend to be localized to areas where a traumatic event has occurred. In the older population, postendoscopy meatal stenosis or localized urethral strictures are more common.


FIG. 91-11. Stricture of the bulbous urethra.

If a patient requires measurement of his residual urine, has difficulty voiding, or is in urinary retention, and a 14F or 16F Foley or Coudé catheter cannot be easily placed into the bladder, the differential diagnostic possibilities include urethral stricture, voluntary external sphincter spasm, bladder neck contracture, or BPH. If time permits, retrograde urethrography can be done, which will define the location and extent of a urethral stricture. Only endoscopy can confirm a bladder neck contracture or the extent of an obstructing prostate gland. Suspected voluntary external sphincter spasm can be overcome by holding the penis upright and encouraging the patient to relax his perineum and breathe slowly during the procedure (Fig. 91-12).
FIG. 91-12. Foley catheter placement. Holding the penis upright will help eliminate urethral folding and reduce external sphincter spasm, both of which can impede catheter placement.

When a urethral stricture is encountered, copious anesthetic lubrication is placed intraurethrally after the foreskin has been controlled with a folded 4 × 4. This latter maneuver is especially important in uncircumcised patients (Fig. 91-13). A 12F or 14F Coudé catheter may negotiate the strictured area, since this catheter has an angled bend near its tip (Fig. 91-14). If there are previous false passages from attempts at dilation or unsuccessful instrumentation, passage of the Coudé catheter

may be difficult. Further urethral manipulation may create new false passages, leading to unnecessary hemorrhage and possible gram-negative bacteremia. If two or three gentle attempts to pass the catheter fail, urologic consultation is indicated. Under no circumstance should a catheter guide or urethral sound be used by anyone other than a urologist (Fig. 91-15).
FIG. 91-13. Foley catheter placement. Improper foreskin retraction and immobilization leads to difficulty with catheterization. The uncircumsized patient's foreskin should be fully retracted and immobilized with a folded 4 × 4.
FIG. 91-14. Goudé (top) and straight-tipped (bottom) catheters.
FIG. 91-15. Catheter guides and urethral sounds should be used only by a urologist.

In an emergency situation, suprapubic cystostomy, utilizing the Seldinger technique, can be performed with the least amount of morbidity. The infraumbilical and suprapubic area is prepped with povidone-iodine solution. A 25- to 27-g spinal needle is used to locate the bladder (Fig. 91-16). This step is especially important in cases of previous lower abdominal surgery where normal anatomic relationships may be distorted. Commercially available introducer cystostomy kits are readily available and utilize the Seldinger technique, which allows easy access to the bladder with a balloon catheter for temporary drainage. After the bladder has been accessed with a syringe and needle, the syringe is removed and a guidewire is passed through the needle into the bladder. The needle is then removed and the fascial dilator with an overlying 14F to 18F peel away sheath is passed over the wire into the bladder. The wire and dilator are then removed leaving the hollow peel-away sheath. An appropriate-sized Foley balloon catheter is passed through the peel-away sheath into the bladder, urine is aspirated from the catheter to assure proper placement, and the balloon is inflated with water. The sheath is then removed from the bladder and peeled away leaving the indwelling catheter, which should be withdrawn until it snugly approximates the cystostomy site. Appropriate urologic follow-up is necessary in two to three days.
FIG. 91-16. Suprapubic cystostomy. Bladder position is verified with a syringe and needle.

URETHRAL FOREIGN BODIES   Patients of all ages, but especially young children, may be victims of innocent urethral exploration or attempts to heighten sexual experiences utilizing a variety of foreign bodies such as bobby pins; long, thin paint brushes; or ball point pens. Bloody urine combined with infection and slow, painful urination should suggest a possible foreign body in the lower urinary tract. An x-ray of the bladder and urethral areas may disclose the presence of a foreign body.

Foreign bodies often require endoscopic removal or even open cystotomy. Occasionally a gentle milking action of the proximal end of the urethral foreign body by an experienced examiner will allow its retrieval from the distal urethral meatus. Even then, retrograde urethrography or endoscopic confirmation of an intact, nontraumatized urethra is indicated.

Urinary Retention

Obstructive uropathy causes a wide expanse of signs and symptoms. Overt urinary retention represents one end of the spectrum, while symptoms of insidious overflow incontinence will often fool an unsuspecting examiner. Prior to acquiring a detailed genitourinary history, questions regarding chronic systemic medical illnesses or carcinomas that have as sequelae sensory or motor neurogenic side effects or complications must be addressed. A detailed medication history, including over-the-counter cold and dietary medications, will often reveal the ingestion of a sympathomimetic agonist that has secondarily caused outlet obstruction due to its muscle-constricting effect on the abundant a-agonistic fibers in the bladder neck. Inconvenient, and therefore infrequent, voiding during a prolonged car trip by a vacationing patient with borderline obstructive symptoms may be just enough to result in urinary retention.

A thorough voiding history begins with questions regarding problems holding or initiating the urinary stream, voiding completely with one continuous stream rather than starting and stopping of the stream, a feeling of complete bladder emptying as opposed to incomplete emptying and postvoid residual, and the relative frequency of nocturia. Ultrasonography is a noninvasive, accurate way to determine the postvoid residual. Most men do not void as well or completely empty their bladders when sitting down to urinate, which happens most often during the night. Infrequent ejaculation may lead to secondary prostatic congestion and subsequent spurious symptoms of irritation and outlet obstruction. Unless specific questions are asked about the latter circumstances, these easily treatable causes of obstructive symptoms can be missed.

The most difficult evaluation involves the patient with silent prostatism. Historically, voiding symptoms have gradually worsened over the years, but at such a pace that the patient often makes adjustments and then perceives each worsening state as "normal" for him. The ultimate result is retention, with a large palpable bladder and often 1600 to 2000 mL residual urine. An intact sensory examination, anal sphincter, and bulbocavernosus reflex differentiate chronic outlet obstruction from the sensory or motor neurogenic bladder and spinal cord compression.

Intraurethral causes of urinary retention are the same as those of outlet obstruction (Table 91-3). Appropriate physical examination requires inspection of the meatus for stenosis; palpation of the entire urethral length for masses or fistulas consistent with urethral stricture disease or abscess formation; lower abdominal examination for palpation of a suprapubic mass; and rectal examination to evaluate anal sphincter tone and the size and consistency of the prostate. Outlet obstruction due to a large intravesical prostate can result in a palpably normal prostate on rectal examination. Similarly, rectal examination in a patient in urinary retention may initially reveal a spuriously enlarged, nodular prostate that will shrink considerably once bladder decompression is achieved.

Meatal stenosis

Urethral stricture

Bladder neck contracture

Benign prostatic hyperplasia

TABLE 91-3 Etiology of Outlet Obstruction

Most patients with bladder outlet obstruction are in distress, and passage of a urethral catheter alleviates both their pain and their urinary retention. Copious intraurethral lubrication must be used, and if attempts at passage of a straight 16F Foley catheter fail, a 16F Coudé catheter should be passed. Be certain to pass either catheter to its fullest extent, obtaining a free flow of urine, and only then inflate the catheter balloon. This will prevent balloon inflation in the prostatic urethra. If the catheter drainage holes become obstructed with lubricating jelly, gentle irrigation with sterile saline or water will quickly establish urinary drainage. Spontaneous, complete drainage of a distended bladder can be accomplished rapidly without the need for repeated clamping of the catheter. Occasionally, when a bladder has been chronically distended, bladder mucosal edema develops. Rapid decompression following catheter placement may result in transient gross hematuria. The transient hematuria is usually self-limited, of little consequence, and responds to orally induced diuresis. Postmicturitional or bladder decompression syncope is rare and should be treated symptomatically.

The catheter should be left indwelling and connected to a portable leg drainage bag. The patient or his family must be instructed in the care and drainage of this simple device. The initiation of antibiotic therapy depends on the presence or absence of infected urine and on the length of time catheter will be left indwelling. The patient or a family member should be instructed on Foley balloon deflation, should it become necessary to remove the catheter because of bladder spasms that are not responsive to oral anticholinergic medication.

If urinary retention has been chronic or insidious, postobstructive diuresis may occur secondary to osmotic diuresis or interstitial tubular dysfunction. Postobstructive diuresis may occur in the presence of normal BUN and creatinine levels and may become an emergency if the patient suddenly becomes hypovolemic or hypotensive without warning. Thus, close monitoring of urine output is essential, with appropriate fluid replacement. For these reasons, all patients with chronic or insidious obstructive voiding symptoms and urinary retention should either be observed for 4 to 6 h or be admitted, with particular attention paid to hourly intake, urinary output, vital signs, and urine and serum electrolytes. Osmotic diuresis will dissipate or the dysfunctional tubules will recover within 24 to 48 h. In all cases of urinary retention, consultation and follow-up with a urologist for a complete genitourinary evaluation are necessary.

92 UROLOGIC STONE DISEASE

Joel Moll
W. F. Peacock IV

Stones form throughout the urinary tract; however, the most frequent presentation to the emergency department occurs when renal stones migrate down the ureter. This acutely painful condition is called *renal colic.* While bladder stones do occur, they are much less common.

RENAL AND URETERAL STONES

Epidemiology

Urologic stone disease is a common condition with an incidence estimated as high as 12 percent.[1] Stones occur three times more often in males, usually in the third to fifth decades of life.[2] There is a genetic predisposition to stone development, and some hereditary diseases (e.g., renal tubular acidosis, hyperparathyroidism, and cystinuria) increase the frequency of kidney stones.[2]

Lifestyle factors may also augment stone growth. Patients in mountainous, desert, or tropical regions and those in sedentary jobs suffer a higher frequency of stone disease.[2] There is also an increased incidence during the warmest 3 months of the year for any geographic location.[2] In the United States the southeast region has a higher incidence than the remainder of the country.[3] Finally, increased water intake is associated with a decreased incidence of calculi.[4]

Some medications predispose to stone disease. Most recently, the protease inhibitor indinavir sulfate, used to treat HIV infection, has been associated with a 4 percent incidence of symptomatic urolithiasis. Diuretic use has also been shown to increase the prevalence of renal stones.[3]

Children under 16 years of age constitute approximately 7 percent of all cases of renal stones.[2] Unique to this age group is a 1:1 sex distribution.[2,5] The most common causes in this age group involve metabolic abnormalities (50 percent), urologic anomalies (20 percent), infection (15 percent), and immobilization syndrome (5 percent).[2] The remainder are diagnosed as idiopathic.

In patients with a history of a kidney stone, up to a third suffer recurrence within 1 year, with the recurrence rate at 5 years near 50 percent.[2] This is probably because the underlying abnormality that created the first stone is still present.

Pathophysiology

The precise cause of urinary stones is unknown. Theories regarding urinary calculi formation include urinary supersaturation of solute followed by crystal precipitation, or a decrease in the normal urinary proteins that inhibit crystal growth. Urinary stasis from physical anomaly, neurogenic bladder, or catheter placement, and the presence of foreign bodies (e.g., surgical suture) may provide the environment for stone growth.

Approximately 75 percent of calculi are composed of calcium, occurring in conjunction with oxalate, phosphate, or a combination of both.[2] These stones may develop as a result of increased urinary excretion of a given solute. Calcium excretion is elevated in conditions such as high dietary calcium intake, immobilization syndrome, or hyperparathyroidism. Oxalate excretion is enhanced in patients with bowel disease (e.g., Crohn's disease or ulcerative colitis) and as a result of small-bowel bypass surgery. Ten percent of stones are magnesium-ammonium-phosphate (struvite).[2] These stones are often associated with infection by urea-splitting bacteria and are the most common cause of staghorn calculi. Staghorn calculi are large stones that form a cast of the renal pelvis. Antibiotics are ineffective, since there is poor penetration into the calculus. Uric acid causes 10 percent of uroliths.[2] Cystine and other uncommon minerals comprise the remainder.[2]

Passage of stones through the urinary tract may be slowed or halted by areas of anatomic narrowing or bending. Progressing proximally to distally, common areas of impaction include the renal calyx, ureteropelvic junction (where the ureter passes over the pelvic brim and arches over the iliac vessels), and the ureterovesical junction (UVJ). The UVJ has the smallest diameter of the urinary tract and is a common location for impacted stones. The posterior pelvis in women, especially where the ureter is crossed anteriorly by the pelvic blood vessels and broad ligament, may slow the passage of a calculus.

If a stone causes acute ureteral obstruction, after an initial rise of renal blood flow and intraureteral pressure, both parameters decline. Concurrently, there is a proportional increase in renal blood flow to the contralateral kidney. These effects are reversible in acute unilateral obstruction if the obstruction is relieved. However, after prolonged obstruction (several weeks), irreversible renal damage occurs.[2] The contralateral kidney is usually able to maintain excretory requirements throughout the course. Therefore, blood urea nitrogen and creatinine levels do not rise even though there is only one functional kidney.

The probability of spontaneous passage of stones is determined by multiple factors, including size, shape, location, and degree of ureteral obstruction. Stones with diameters less than 4 mm will pass in approximately 90 percent of cases, while 50 percent of stones 4 to 6 mm in diameter pass, and only 10 percent of stones exceeding 6 mm pass spontaneously.[2] Bizarrely shaped or irregular stones with spicules and sharp edges will have a lower passage rate. Rates of passage based on the location of the stone at first diagnosis are approximately 20, 50, and 70 percent for the proximal, middle, and distal ureter, respectively.[6] Finally, with complete obstruction there is a lower rate of spontaneous passage than if the blockage is partial.

Clinical Features

Uroliths may be asymptomatic until there is at least partial obstruction of the urinary tract. The usual episode occurs while the patient is sedentary or at rest. Patients describe the acute onset of severe pain. Although subacute presentations occur, the usual rapidity of symptom onset is in contradistinction to many other diagnoses that may be considered.

Typically the pain originates in either flank, radiates anteroinferiorly around the abdomen, and progresses toward the ipsilateral testicle or labia majora. The discomfort can be extreme in intensity and may be associated with nausea, vomiting, or diaphoresis. Patients may be unable to find a comfortable position to relieve their symptoms. Consequently, they are sometimes anxious, pacing, and reluctant to lie still on the examining table. The "writhing of renal colic" is a useful point in the construction of a differential diagnosis.

The characteristic radiating pattern of renal colic pain results from autonomic nerve fibers serving both the kidney and respective gonad. However, atypical presentations with pain referral patterns to the hip, thigh, or knee are rarely reported.[2] As a stone progresses to the mid-ureter, anterior abdominal pain may radiate back toward the flank. With passage near the bladder, the patient may develop urinary frequency and urgency. Symptoms can be remarkably episodic due to intermittent obstruction of the urinary tract. If the stone passes or the obstruction is temporarily relieved, the patient will have immediate relief of symptoms.

Patients are frequently cool and diaphoretic, and a history of fever is unusual. Its presence should prompt a thorough investigation for urinary tract infection or other

causes of febrile illness.

In children, symptoms can vary with age. Older children are more likely to present in similar fashion to the adult. Younger children may have a more nonspecific presentation, such as abdominal or pelvic pain. Although renal colic is rare in infants, symptoms may be mistakenly attributed to intestinal colic. [5] Overall, 20 to 30 percent of children may have only painless hematuria. [2]

Patients with known stone disease may present after treatment with extracorporeal shock wave lithotripsy (ESWL). ESWL fractures stones into small particles using focused sound waves. The resulting "sludge" is passed in the urine. When there are large fragments, an acute episode of renal colic occurs. The presentation is identical to "de novo" episodes of renal colic.

Diagnosis

PHYSICAL EXAMINATION   Special attention should be given to the abdominal and cardiovascular portions so that potential catastrophes mimicking acute renal colic are excluded. The vital signs should be carefully noted. There may be elevations of blood pressure and pulse secondary to extreme discomfort. The presence of fever or hypotension should suggest the possibility of concurrent infection or a diagnosis other than renal colic.

The abdominal examination is extremely important. It should specifically include a search for the presence of bruit or a pulsatile mass to ensure that a rupturing or dissecting aortic aneurysm is not missed. Likewise, the pulses in the distal extremities should be carefully examined. If they are diminished, absent, or asymmetric, this suggests a potential vascular catastrophe.

Mild tenderness may be noted over the site of an impacted stone. However, true peritoneal findings (e.g., guarding or rebound) are not a component of acute renal colic. If peritoneal signs are found, the differential diagnosis should be expanded to include those pathologic conditions known to result in discomfort at that anatomic region. Similarly, abdominal distention is not a feature of renal colic. If present, it suggests an alternative explanation of the patient's presentation.

Of equal importance during the physical examination is the genitourinary examination. Costovertebral angle tenderness is not unusual, but, when present with fever or other signs of urinary tract infection, it may suggest pyelonephritis. Pyelonephritis can occur simultaneously with stone disease. In addition, since the radiating pattern of discomfort in renal colic includes the testicle or labia majora, these areas should be evaluated for a potential incarcerated hernia. In a male patient, the testicles should be inspected and palpated to exclude torsion or infection. A pelvic examination should be performed in females when the diagnosis is not clear to assess for ovarian cyst, torsion, infection, or, of importance in pregnant patients, ectopic pregnancy.

Other portions of the physical examination should address the cardiac, respiratory, musculoskeletal, and dermatologic systems. An abnormal cardiopulmonary examination may suggest an alternative diagnosis, such as lobar pneumonia or pulmonary embolus. Musculoskeletal complaints may result in flank pain similar to that caused by renal stones; however, comprehensive extremity and neurologic examinations are usually sufficient to exclude these conditions. Finally, the presence of a vesicular rash overlying a flank dermatome may suggest the onset of herpes zoster.

LABORATORY TESTS   All patients with suspected renal colic require a urinalysis. The presence of blood in the urine supports the diagnosis of renal colic. However, there is no correlation between the amount of hematuria and the degree of urinary tract obstruction. [7] Some patients demonstrate gross hematuria, but in up to 15 percent microscopic hematuria is absent. [8] A urine dipstick is an expedient method to aid in the initial diagnosis. The dipstick has excellent sensitivity for detecting red blood cells; however, hemoglobin and myoglobin will also test positively for blood. Therefore, a microscopic analysis should be performed on all dipstick-positive urines. A urinalysis may also help in excluding other alternative or associated conditions, such as infection. Patients with fever, pyuria, or a history of fever and chills should also have a urine culture obtained. Blood cultures, although not routinely required in uncomplicated pyelonephritis, [9,10] should be considered with concurrent obstruction, underlying comorbidity, or systemic toxicity. Urinary crystals, usually oxalate or rarely urate, may indicate the etiology of the present attack and the composition of the stone. However, because such crystals may be seen without association with renal stones, their presence is not diagnostic and should be interpreted cautiously. An elevated urine pH (>7.6) associated with infection may indicate the presence of a urea-splitting organism. An alkaline urine is also seen in renal tubular acidosis or following ingestion of large amounts of alkali. Urine should be collected and strained for the identification of any passed stones. All collected stones should be retained for pathologic analysis.

A pregnancy test specific for the b-HCG subunit should be performed on women of childbearing age. A positive b-HCG test result may indicate an important alternative cause of the patient's complaints, such as ectopic pregnancy. In addition, a positive test result will affect the choice of imaging study to confirm the diagnosis of renal colic.

A complete blood count is indicated if the history or physical examination suggests the possibility of anemia or infection. In straightforward cases of renal colic, a complete blood count is not indicated. If obtained, a complete blood count may demonstrate mild leukocytosis. This indicates white blood cell demargination from stress. A very high white blood cell count may represent infection.

Other laboratory evaluations can be individualized. Serologic testing of renal function (e.g., determination of blood urea nitrogen and creatinine levels) may be required in patients at risk for nephrotoxicity (elderly patients, those with renal insufficiency, diabetic patients, and hypovolemic patients) if a radiocontrast dye study is planned. In addition, diabetic patients should have a glucose level determination to ensure the stress of renal colic has not caused significant hyperglycemia. Diabetics with significant nausea and vomiting may be at risk for hypoglycemia.

DIAGNOSTIC IMAGING   The choice of an imaging modality to confirm the diagnosis of urolithiasis should be made with an understanding of the strengths and limitations of each test in conjunction with the characteristics of the patient and the capabilities of the institution. Historically, the standard for diagnosis of renal colic has been the intravenous pyelogram (IVP). With the advent of newer-generation computed tomography (CT) scanners, the use of noncontrast helical CT scanning in the evaluation of flank pain has dramatically increased. In some institutions helical CT has replaced IVP as the initial diagnostic imaging study. Helical CT is generally the emergency department procedure of choice except with pregnant patients, for whom ultrasound is preferred to minimize radiation exposure. Other modalities that may assist in the diagnosis include ultrasound, radionuclide renal scan, and plain abdominal radiographs.

It is controversial whether all patients require emergency department imaging for suspected renal colic. For young, healthy patients in whom the diagnosis is not in question, it may be appropriate to delay the workup, which can be conducted later on an outpatient basis. [11] For older patients, especially those in whom the differential diagnosis includes aortic abdominal aneurysm (AAA), the diagnosis should be confirmed by some imaging modality.

COMPUTED TOMOGRAPHY   The noncontrast helical CT scan has been shown to be both sensitive (95 to 97 percent) and specific (96 to 98 percent) in the detection of renal stones. [12,13] Its accuracy is comparable or superior to that of the IVP. [14] Images are obtained from the top of the kidney to the base of the bladder. Refocused images can be obtained in smaller increments through levels of suspicious calcifications and areas of ureteral caliber change. Secondary signs of ureteral obstruction, such as ureteral dilatation, stranding of perinephric fat, dilation of the collecting system, and renal enlargement, can also be helpful in making the diagnosis. In combination, unilateral ureteral dilatation and perinephric stranding have a positive predictive value of 96 percent for stone disease. [13,15] When both are absent, the negative predictive value is 93 to 97 percent. [13,15]

Noncontrast helical CT has several advantages over other imaging modalities, including the avoidance of exposure to radiocontrast agent, greater potential for identifying causes other than stone disease, and superior speed. However, because oral and intravenous radiocontrast agents are not used, the specificity and sensitivity for other diseases, such as AAA or gastrointestinal disorders, are not as great as with imaging protocols employing contrast. Interpretation of a "negative" noncontrast CT scan, when obtained to evaluate the possibility of urologic stone disease, should be done cautiously and with consideration of the limitations of the study. Most newer-generation CT scanners can complete the study within 5 min. [13]

Several disadvantages exist in the use of CT. Helical CT does not evaluate renal function or provide physiologic information about the degree of obstruction. Furthermore, its diagnostic ability relies on a newer-generation CT scanner with a radiologist skilled in using this modality to evaluate stone disease. At some institutions the cost of CT may be greater than that of other imaging modalities.

Abdominal CT scanning is the modality of choice if suspicion of a perinephric abscess exists. However, the use of radiocontrast agents may be required for adequate

detection of a potential abscess.

INTRAVENOUS PYELOGRAM   The IVP yields information regarding both renal function and anatomic morphology. Its ability to detect renal calculi has been found to be less than that of CT, with a sensitivity of 64 to 90 percent and specificity of 94 to 100 percent. [16,17]

When performing the IVP, intravenous fluid is administered to ensure that the patient is hydrated and will sustain adequate urinary flow throughout the procedure. Maintaining adequate urine output by the administration of intravenous fluids prior to radiocontrast media may decrease the risk of renal injury from radiocontrast dye. After radiocontrast media is administered, an initial scout radiograph is obtained, followed by repeat films at 5, 10, and 20 min. The first and most reliable indication of the presence of obstruction is a delay in the appearance of the nephrogram. Since the ureter is a peristaltic structure, it is usually not completely seen on any one radiograph. Visualization of the entire ureter is suggestive of obstruction.

The location of a radiolucent obstructing stone can often be determined by a ureteral dye-column cutoff. Adjuncts to the diagnosis of renal colic include the presence of a prolonged nephrogram, renal enlargement, dilatation of the collecting system or ureter, and dye extravasation. [18] If extravasation of dye is noted, it should be considered evidence of an obstruction that has decompressed into the perinephric tissue. Extraurinary collections of urine (urinoma) have the potential for infection and abscess formation.

A postvoid film is useful for identifying stones at the UVJ or distal ureter that are otherwise obscured by a full bladder. Multiple delayed films may be required to precisely determine the level of obstruction.

The main advantage of the IVP over other imaging modalities is its ability to give information on both renal function and anatomy. In addition, IVP may be more widely available than CT, depending on the institution. It may also be valuable as an adjunct to CT when functional information and knowledge of the degree of obstruction are required.

The most important potential disadvantage of the IVP is use of radiocontrast dye. Side effects of radiocontrast dye, allergic reaction and nephrotoxicity, must always be considered when ordering an IVP. Prior to obtaining an IVP, the patient should be closely questioned regarding the presence of allergy to radiocontrast media. Appropriate material for managing acute anaphylaxis should be immediately available for unexpected allergic reactions. A history of dye allergy should prompt the selection of an alternative diagnostic modality.

Radiocontrast-agent nephrotoxicity is most likely to occur in patients with preexisting renal insufficiency or diabetes mellitus. [18] These patients have a 9 percent risk of nephrotoxicity attributable to radiocontrast dye. [18] Other predisposing factors include dehydration, hypovolemia, hypotension, advanced age (over 70 years), multiple myeloma, hyperuricemia, hypertension, a history of intravenous radiocontrast media within 72 h, and the use of diuretics to treat cardiovascular disease. In patients at risk for nephrotoxicity when the administration of a radiocontrast agent is not otherwise contraindicated, the dye administration should be deferred until normal blood urea nitrogen and creatinine levels are documented. Although they are also nephrotoxic, nonionic contrast agents may result in a lower frequency of kidney damage. Finally, radiocontrast media should be used with caution in patients taking metformin, which has been associated with severe lactic acidosis and nephropathy in combination with radiocontrast material. Other imaging modalities, such as noncontrast CT or ultrasound, may be preferred for these patients.

Another disadvantage of the IVP is the potential time required to complete the study. If evidence of obstruction exists, serial delayed films are often obtained to delineate the level of obstruction. This may require several hours and multiple repeat radiographs and may delay the final diagnosis. Also affecting the quality of the IVP is the state of the bowel. Since emergency department practice does not allow for a bowel preparation, the IVP can be adversely affected by obstipation or ileus.

A false-negative IVP infrequently occurs when there is a small or radiolucent, partially obstructing stone. The IVP will also be "negative" if the ureteral stone passes into the bladder before radiocontrast dye is excreted by the kidneys. If this happens, the patient usually experiences nearly complete relief of pain. The IVP may also show evidence of ureteral spasm after passage of a stone.

ULTRASOUND   With patients who are not candidates for IVP or CT due to concerns of exposure to radiocontrast media (e.g., allergy) or radiation (e.g., with pregnant patients or children), ultrasound may assist in the diagnosis of urolithiasis. It is useful in the detection of larger stones; however, it may miss smaller (less than 5 mm in diameter) ureteral stones.[18] Ultrasound is helpful in diagnosing stones in the proximal and distal ureter. However, it does a poor job of visualizing mid-ureteral stones. Overall it has been shown to be 63 to 85 percent sensitive and 79 to 100 percent specific in diagnosing renal stones. [16,17] Ultrasound is very sensitive (98 percent) in detecting hydronephrosis, which may be a result of a renal calculus; however, the presence of hydronephrosis has a much lower specificity (78 percent).[18] Up to 22 percent of apparent cases of hydronephrosis by ultrasound do not represent obstruction. [18] Causes of false-positive results include normal variations, an extrarenal pelvis, a full bladder, an intravenous fluid bolus, and renal cysts. [18] Ultrasound studies can also obtain information on renal size and, with Doppler scanning, renal blood and urine flow. Limited information may also be obtained regarding other pathologic conditions mimicking urologic stone disease.

Ultrasound has many advantages: it is noninvasive, utilizes no radiocontrast dye or radiation, and has no known side effects. [18] It may also be superior to an IVP in detecting stones at the UVJ.[20] Ultrasound is, however, limited to anatomic findings only. It yields no information on renal function. In addition, the accuracy of ultrasound studies is operator and equipment dependent, body habitus (e.g., obesity) may interfere with obtaining good-quality scans, and ultrasound may miss obstructive signs in the early phase of renal colic. In addition, the rapid bolus infusion of crystalloid can result in a false-positive finding of hydroureter on ultrasound examination.

RENAL SCAN   With the increased utilization of CT and ultrasound and the reduced availability of renal scanning, the use of the latter is limited as an initial imaging modality in renal colic.[18]

PLAIN ABDOMINAL RADIOGRAPHS   The composition of most urinary calculi makes them sufficiently dense that the majority (90 percent) are radiopaque. [2] Calcium phosphate and calcium oxalate stones have a density similar to that of bone. Magnesium-ammonium-phosphate (struvite) calculi are slightly less radiodense, followed by cystine, which is only partially radiodense. Uric acid and matrix stones are essentially radiolucent. Most stones associated with medications are radiolucent as well, including those associated with the protease inhibitor indinavir. [21] However, because of their small size and the overlapping soft-tissue and bone shadows seen on abdominal radiographs, urinary stones are visible much less frequently on plain films. Plain abdominal radiographs alone have a low sensitivity (29 to 58 percent) and specificity (69 to 74 percent) compared to other imaging modalities. [17,22,23] In addition, a low negative predictive value (23 percent) makes a "negative" radiograph of little value in ruling out stone disease. [22] While a plain abdominal radiograph can assist in localizing some large radiopaque stones, its greatest utility is in the exclusion of other pathologic conditions. However, a plain abdominal radiograph may be helpful in patients with dye allergy, when other imaging modalities are unavailable, or in follow-up of known radiopaque stones. In patients for whom the diagnosis is already established (recent IVP, CT, or ESWL), a plain abdominal radiograph may suffice in localizing a migrating stone.

Differential Diagnosis

A number of diagnoses can be confused with renal colic. The history and physical examination can help to narrow the differential. However, this may be difficult, since the patient's discomfort can interfere with the usual history and physical examination. Crucial to the evaluation of these patients is to ensure that a catastrophe mimicking renal colic is not missed.

The most critical alternative diagnosis to consider is an aortic dissection or ruptured AAA. Renal colic and AAA may have a similar presentation. Focal abdominal tenderness, abdominal distention, pulse disparity, and hemodynamic instability are not found in renal colic. These findings suggest a leaking or ruptured AAA. If a dissection or rupture is suspected, an emergency vascular surgical consultation should be obtained. If an AAA has not been excluded from the differential diagnosis, appropriate monitoring equipment, intravenous access, and professional staff should be sent from the emergency department with the patient for an imaging study.

Pyelonephritis may also cause flank pain; however the prodrome is less acute and the discomfort usually not as severe as renal colic. Fever is not a finding with kidney stones, and the urinalysis of renal colic does not demonstrate bacteriuria or pyuria in the absence of a concurrent infection. If renal obstruction is suspected concurrently with pyelonephritis, obstruction must be excluded by IVP, CT, or ultrasound. Antibiotics have poor penetration into an obstructed kidney. If infection in the presence of obstruction is confirmed, emergency urologic consultation for prompt obstruction relief should be obtained.

Papillary necrosis presents much as renal stones do. It is most frequently seen in patients with sickle cell disease, diabetes, nonsteroidal analgesic abuse, or

infection. The urinalysis may appear to represent infection, with hematuria and pyuria. An IVP or CT can demonstrate sloughed renal papillae as a lucency within the renal pelvis. Urologic consultation and hospitalization are usually required.

Renal infarction, resulting from vascular dissection or arterial embolus, may present with acute flank pain. Urinalysis can demonstrate hematuria, and imaging will show decreased or absent function of the affected kidney. Emergency angiography is indicated. In renal vein thrombosis, there may be increased kidney size with decreased function. Urinalysis shows proteinuria and microscopic hematuria. All of these conditions require emergency urologic consultation.

Other pathologic conditions may cause compression or obstruction of the ureter, producing symptoms similar to those of renal colic. Any intrabdominal mass, including neoplasm or vascular structure, can potentially cause external compression of the ureter. A mass located within the urinary system may also cause obstruction and/or pain due to expanding size or in association with hemorrhage or necrosis. Therefore, a neoplasm is always within the differential diagnosis of renal colic.

Patients with severe abdominal pain out of proportion to the findings upon physical examination (especially if elderly or if the pain is in association with atrial fibrillation, congestive heart failure, liver disease, or low-flow vascular states) should raise suspicion of intestinal ischemia.

Gallstone pain can be very similar to that of renal colic and should generally be considered in all patients with any right upper quadrant abdominal tenderness. Unlike the symptoms of renal colic, biliary colic symptoms are often associated with oral intake, last for several hours before remitting, and include vomiting. Pancreatitis is suggested by left upper quadrant or midepigastric pain, especially in the presence of risk factors (e.g., alcohol consumption or cholelithiasis). A perforated peptic ulcer may present with severe pain in the midepigastrum or either upper quadrant. However, these patients have marked tenderness on examination and develop peritoneal signs over time. Appendicitis shares the unilateral presentation with renal colic, but the subacute prodrome usually excludes urolithiasis. Ventral hernias should also be considered in the differential diagnosis and sought on physical examination. Diverticulitis usually causes pain in lower quadrants, more commonly the left, and is associated with abdominal tenderness, fever, diarrhea, possibly hematochezia, but a more insidious prodrome than renal colic.

In women, gynecologic disorders can mimic renal colic. Ruptured ectopic pregnancy can present with acute pelvic and flank pain. A history of amenorrhea, tenderness on pelvic examination, and a positive pregnancy test result suggest this diagnosis rather than renal colic. Hemoperitoneum from a ruptured ectopic pregnancy may cause radiation of pain similar to that of renal colic as blood tracks along the abdominal cavity. Salpingitis usually has a more insidious onset, with cervical motion and uterine tenderness, and purulent discharge on pelvic examination. A tuboovarian abscess usually presents as salpingitis does, along with adnexal tenderness and mass on pelvic examination. An enlarging or ruptured ovarian cyst or ovarian or pelvic mass torsion should also be considered.

In men, other etiologies involving the genitourinary system must also be considered. Although renal colic can often cause pain radiating to the testicle, the findings on physical examination of the affected testicle should be normal. The presence of pain, redness, or swelling on examination should indicate another cause. Testicular torsion can present with the same sudden onset as renal colic; however, physical examination localizes the pathology to the testicle. Other entities, including infections such as epididymitis, prostatitis, and Fournier's gangrene, may have a more insidious onset, and the physical examination will differentiate them from renal colic. Finally, an incarcerated or strangulated hernia should be excluded by examination of the inguinal canals and scrotum.

Drug seekers may present with factitious episodes of renal colic. They can be remarkably inventive in the complexity of their ruse, and there is no specific method of detecting them. A history of multiple medical allergies to nonnarcotic analgesics and radiocontrast media is frequently given. Such patients may report having a known radiolucent stone and may simulate hematuria by placing blood in their urine. The vital signs may suggest this behavior if changes in blood pressure and heart rate do not match the extreme discomfort demonstrated. When the clinician is unsure, it is better to give analgesia than to deprive a patient suffering from true renal colic.

Treatment

The mainstay of emergency department treatment is pain control. Because in most cases the diagnosis is clinical, a rapid urine dipstick test for heme may provide sufficient information, coupled with clinical findings, to initiate analgesic therapy. Pain medication should not be delayed pending test results. Adequate analgesia frequently requires multiple doses of intravenous narcotics, titrated to the patient's level of discomfort. Narcotics may be accompanied by nonsteroidal anti-inflammatory drugs (NSAIDs) but NSAIDs should not be used in place of narcotics. The time of onset of NSAIDs is slower than that of intravenous narcotics. NSAIDs should be used with caution in patients with suspected compromise in overall renal function (elderly patients, diabetics, those with known renal insufficiency, and hypovolemic patients) so as not to precipitate or accelerate a decline in renal function. An antiemetic is an appropriate adjunct when emesis accompanies the symptoms or when nausea accompanies narcotic use. Intravenous fluids, usually normal saline solution, should be administered. For patients with evidence of associated infection, parenteral antibiotics should be administered promptly in the emergency department, and emergency urologic consultation should be obtained.

Disposition

Admission to the hospital is indicated if there is (1) infection with concurrent obstruction, (2) a solitary kidney and complete obstruction, (3) uncontrolled pain, or (4) intractable emesis.[2] Patients with an infection and concurrent obstruction have the potential for severe systemic toxicity and represent a urologic emergency. Patients with renal impairment are candidates for consideration of a drainage procedure, since they have little functional renal reserve. Because of lower rates of spontaneous passage, patients with large (>5 mm), irregular, or proximal stones should be considered for admission. If there is severe concurrent underlying disease (e.g., angina or chronic obstructive pulmonary disease) or in the fragile elderly, when the patient may be unable to tolerate the stress of renal colic, a lower admission threshold is indicated. When the IVP or CT scan demonstrates complete obstruction, or dye extravasation, the admission decision requires individualization and discussion with a urologist. Patients who have previously been diagnosed and managed as outpatients are more likely to require admission if they return with continued pain. A careful history and physical examination are indicated to ensure that the diagnosis is correct, but repeat imaging is probably unnecessary.

In most situations, unilateral renal obstruction has minimal acute or permanent effects. Discharge is appropriate in patients with smaller, rounded stones, in the absence of infection, and when pain is controlled by oral analgesics. Patients should be given a urinary strainer with instructions to save any stones that are passed for pathologic evaluation. Patients should be counseled to return promptly for fever, vomiting, or uncontrolled pain, and they require a prescription for an oral narcotic. Follow-up with a urologist should be arranged within 7 days.[24] Patients whose stone passes in the emergency department require no further treatment. Elective urologic consultation should be arranged so that the etiology of the stone can be determined and a prophylactic strategy arranged. Patients with hematuria, negative imaging study findings, and no other attributable source require urologic follow-up to determine the etiology of their hematuria.

The management of patients with protease-inhibitor-induced urolithiasis is similar to the management of other causes of stone disease; however, adequate hydration is particularly important.[21] In addition, discontinuation of the offending agent for a short period of time may be necessary. Such a decision should be made in consultation with a urologist and an infectious disease specialist. Disposition should be discussed with a urologist if there is (1) renal insufficiency, (2) severe underlying disease, (3) an IVP showing extravasation or complete obstruction, (4) multiple visits, (5) a large stone, or (6) sloughed renal papillae. [2]

BLADDER (VESICAL) STONES

Vesical calculi may occur at any age and are endemic in some developing countries.[25] In endemic areas and historically, the vast majority occur in males and develop in early childhood. In western, industrialized countries, 90 percent occur in males, and 80 percent occur in patients over 50 years of age. Calculi are associated with outflow obstruction or neuropathic bladder disease in 70 percent of cases. Urinary tract infection, vesical diverticuli, and the presence of foreign bodies (e.g., sutures, catheters, or implants) also predispose to bladder calculi. Bladder calculi have been reported in children and adults as a complication of urologic surgery. Calcium oxalate is the most common constituent of bladder stones, but urate and struvite stones also occur. Stones are usually solitary, but multiple stones occur in 25 to 30 percent of cases.[26]

Bladder calculi may be asymptomatic, especially in patients with underlying prostatic obstruction. Typical symptoms are intermittent dysuria and terminal hematuria. The greatest discomfort usually occurs at the end of micturition as the stone impinges upon the bladder neck. In bladder outlet obstruction, there is interruption of the urinary stream, with frequency and urgency commonly reported. There may be associated dull, aching low abdominal pain, unrelated to urination, that is exacerbated by exercise and abrupt movement. Pain is usually referred to the penile tip or scrotum by the second and third sacral nerves. Occasionally pain is referred to the low back or heel. With passage of the calculus, urethral obstruction can occur. Pain is referred to the rectum, the perineal area, or the site of urethral impaction. Patients report interruption of urinary flow followed by pain and urgency.

Physical examination is of little help in diagnosing a bladder calculus. Rarely, exceptionally large stones may be palpated during the rectal, vaginal, or abdominal examination. Urinalysis may demonstrate hematuria, pyuria, or bacteriuria. If there is coexistent infection, a complete blood count may show leukocytosis. Plain radiographs reveal vesical stones in approximately 50 percent of cases. While ultrasound may demonstrate bladder stones, cystoscopic examination is the most accurate method of detection.

Other cystic pathologic conditions can mimic vesical stones, including a foreign body, carcinoma, neurogenic bladder, bladder diverticula, or fistula. Complications include chronic bladder irritation, fistula formation, and urethral obstruction. Pericystitis may develop in chronic cases, and this can result in adherence of the bladder to the adjacent pelvic fat. Bladder perforation is a rare complication.

Bladder calculi require emergency therapy when they result in urinary obstruction or there is associated infection. Acute urethral obstruction requires either the successful removal of the stone or the placement of a catheter. Very distal stones may be able to be gently milked from the penis or removed by forceps. More proximal stones require emergency urologic consultation. If there is coexistent infection, antibiotics should be administered in the emergency department. Most patients with vesical calculi require cystoscopic stone removal. Any patient demonstrating signs of sepsis, urinary infection, or uretheral obstruction requires emergency hospitalization. Patients with symptomatic but nonobstructing bladder stones may be discharged with referral to a urologist.

93 HEMATURIA AND HEMATOSPERMIA

David S. Howes
Mark P. Bogner

HEMATURIA

Normal urine contains a small number of red blood cells (RBCs), usually too small to be detected by routine chemical dipstick testing or microscopic urinalysis. Hematuria—blood detected by routine methods—may be visible to the eye (gross or frank hematuria) or invisible (microscopic hematuria). The appearance of blood in a patient's urine often motivates the patient to come to the emergency department with a presenting symptom of gross hematuria. Microscopic hematuria is usually detected in the course of evaluating other symptoms. Hematuria may be associated with pain during urination and often accompanies urinary tract infections. Painless hematuria is more often due to neoplastic, hyperplastic, and vascular causes. Gross or microscopic hematuria warrants an attempt at definitive diagnosis, since underlying disease can be found in a substantial percentage of cases. The emergency physician's task is to rule out a life-threatening cause, make a diagnosis if possible, initiate treatment, educate the patient, and ensure continued appropriate treatment, disposition, follow-up, and referral.

Epidemiology

Gross hematuria is easy to define: the urine is colored red. However, other pigments, particularly myoglobin, may discolor the urine, or the urine may be contaminated by bleeding from a nonurinary source. It takes approximately 1 mL of whole blood per liter of urine to result in grossly visible hematuria. Gross hematuria may also result in false proteinuria, since 1 mL of whole blood equals about 5 billion RBCs or 50 mg of albumin. This must be taken into account when protein-losing diseases (e.g., nephritic or nephrotic syndromes) are considered in the differential diagnosis. About 3 percent of the general population has had an episode of gross hematuria.[1] The incidence is higher in women (due to urinary tract infections), older adults (due to neoplasia), and older men (due to prostatic hyperplasia).

Microscopic hematuria is more difficult to define. Approximately 1 million RBCs pass into the urine each day. This amount is detected as 1 to 3 RBCs/hpf (400 ×) in centrifuged urine sediment. While various definitions have been proposed, the most common (and arbitrary) definition of microscopic hematuria is more than 5 RBCs/hpf. Population-based studies of healthy young individuals have found at least one episode of transient microscopic hematuria in up to 40 percent of men and 13 percent of women.[2,3,4 and 5] The incidence of microscopic hematuria in children and adolescents is up to 6 percent for one specimen and 1 to 2 percent for two positive specimens.[6,7]

Pathophysiology

Any process that results in infection, inflammation, or injury to the kidneys, ureters, bladder, prostate, male genitalia, or urethra may result in hematuria (Table 93-1 and Table 93-2). In false hematuria, the urine appears bloody, but dipstick test results are negative for blood, and there are no RBCs on microscopic evaluation (Table 93-3). Free hemoglobin, myoglobin, or porphyrins in the urine result in a positive urine test strip reaction for blood but no RBCs on microscopic evaluation.

Etiology	Associated Age
Infections	Women, >15, men >45
Nephrolithiasis	Usually >20
Neoplasms	Typically >40 (except Wilms)
Benign prostatic hypertrophy	Males >40
Glomerulonephritis	Mostly young patients and children
Shistosomiasis	Any, most common cause worldwide

TABLE 93-1   Most Common Causes of Hematuria

TABLE 93-2   Differential Diagnosis of Hematuria

Munchausen syndrome, malingering, drug seeking: patients may add blood to voided urine

Medications: NSAIDs, phenytoin, phenothiazines, quinine, rifampin, nitrofurantoin, sulfasalazine

Foods and dyes: beets, berries, rhubarb

Serratia marcescens infection

Amorphous urates

Hemoglobinuria, myoglobinuria, porphyrins

Abbreviation: NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE 93-3   False Hematuria

Clinical Features

It is useful to identify when the blood appears during micturition. Initial hematuria is the appearance of blood at the beginning of micturition, with subsequent clearing, and suggests urethral disease. Hematuria occurring between voidings and noticed only as staining of underclothes with blood, while voided urine is clear, indicates lesions at the distal urethra or the meatus. Total hematuria is visible throughout micturition and corresponds to disease of the kidneys, ureters, or bladder. Terminal hematuria, occurring at the end of micturition after initially voiding clear urine, occurs with disease at the bladder neck or prostatic urethra.

Gross hematuria more often indicates a lower-tract cause, while microscopic hematuria tends to occur with kidney disease. Brown or smoky-colored urine along with RBC casts and proteinuria suggests a glomerular source. Red, clotted blood in the urine indicates a source below the kidneys. Hematuria that varies with menstruation and is associated with severe dysmenorrhea may indicate endometriosis involving the urinary tract.

In younger patients, microscopic hematuria is most often caused by nephrolithiasis or urinary tract infection. It is also important to consider such disorders as glomerulonephritis, immune complex disease, Goodpasture's syndrome, Henoch-Schönlein purpura and Wilms' tumor in children, and sickle cell anemia or trait. Poststreptococcal glomerulonephritis is more common in children and typically follows a throat or skin infection. Symptoms appear 7 to 14 days after the primary infection, and the subsequent findings can vary from isolated hematuria to severe nephritis. Unfortunately, treatment of the primary streptococcal infection with antibiotics does not prevent poststreptococcal glomerulonephritis. IgA nephropathy develops several days after a viral respiratory infection and is often accompanied by proteinuria secondary to glomerular damage from immune-complex deposition.

In older patients, infections and nephrolithiasis remain common causes of hematuria, but after age 40 any hematuria, even with a clear diagnosis of urinary tract infection or stone, warrants close follow-up and retesting of urine because renal, bladder, and prostate cancer increase in frequency and may coexist with urinary tract infection or kidney stone. Risk factors for uroepithelial cancer in addition to age over 40 include excessive analgesic use, tobacco use, occupational exposures (e.g., to dyes, benzenes, or aromatic amines), pelvic irradiation, and cyclophosphamide use. Similarly, hematuria in a patient on oral anticoagulants should not be attributed to the anticoagulant alone, since the incidence of underlying disease may be as high as 80 percent. [8] Expanding abdominal aortic aneurisms (AAAs) may erode into the urogenital tract or cause inflammation or obstruction from direct pressure. Signs and symptoms include back or flank pain, with or without hematuria.

Malignant hypertension, embolic renal infarction, and renal vein thrombosis (RVT) are other serious diagnoses that can cause hematuria. Pregnancy, dehydration, nephrotic syndrome, lymphoma, and renal cell or other types of carcinoma are all predisposing disorders for RVT. RVTs are commonly asymptomatic, with minimal or no pain. Children with RVT are typically volume depleted and have some other cause of a hypercoagulable state. In adults with RVT there is usually underlying nephropathy and obvious nephrotic syndrome. In pregnancy, hematuria can be associated with urinary tract infection, nephrolithiasis, or preeclampsia.

The reported incidence of hematuria in HIV-infected patients is 18 to 50 percent. [9] Causes include subclinical viral renal infection, early glomerulonephritis, urinary tract infection, chlamydial and gonococcal urethritis, chronic hepatitis B infection, neurogenic bladder, thrombocytopenia, subclinical uroepithelial Kaposi's sarcoma, and urethral trauma. However, up to 80 percent of HIV-positive patients with an episode of asymptomatic hematuria have no specific etiology found after complete urologic evaluation. [9]

Diagnosis

Consider the patient's age, gender, demographic characteristics, habits, potential risk factors, recent genitourinary instrumentation, and comorbidities. [3]

Is the hematuria traumatic or atraumatic, gross or microscopic, initial, terminal, or total? When did it start? Are there associated symptoms, such as menstruation; flank, back, or abdominal pain; dysuria; nausea; or fever? Is the patient pregnant? Are there risk factors for cancer or RVT? Has the patient had a recent respiratory or other infection that might predispose to IgA nephropathy or poststreptococcal glomerulonephritis? Has the patient recently traveled outside the United States, particularly to the Middle East or Africa, raising the risk of schistosomiasis? Was there recent instrumentation of the urinary tract or urinary or renal disease? Are there comorbid conditions, such as diabetes, hypertension, sickle cell disease, HIV, tuberculosis, cancers, lupus, or other diseases associated with vasculitis? A complete medication history is important to identify the use of anticoagulants or nephrotoxic agents. Strenuous exercise is a common cause of benign hematuria in healthy young individuals. [10,11]

The physical examination should note the vital signs and the patient's appearance. A younger and otherwise healthy patient without fever, writhing in pain on the cart, unable to find a comfortable position, exhibiting tachycardia and hypertension, and complaining of severe flank pain radiating to the perineum most likely has nephrolithiasis. Hypertension and edema imply nephrotic syndrome. A new heart murmur (endocarditis) or atrial fibrillation increase the likelihood of embolic disease and renal infarction. Dysuria and suprapubic pain and tenderness with or without fever suggest hemorrhagic cystitis. Perineal pain, dysuria, and a tender, boggy prostate in older men indicate prostatitis. A nodular prostate suggests the possibility of cancer. Flank or back pain with fever and costovertebral angle tenderness suggests pyelonephritis. Flank or back pain without fever suggests nephrolithiasis, asymptomatic AAA, renal infarction, or obstruction secondary to tumor. In an older patient, the examiner should palpate for a pulsatile abdominal mass and listen carefully for bruits. Hematuria with rash, arthritis, and abdominal pain may be the result of Henoch-Schönlein purpura in children. Polycystic kidney disease or renal malignancy may result in a large, palpable kidney. [12] External genitalia in males should be examined for obvious tumor or trauma. A pelvic examination should be performed to rule out a vulvar or vaginal source of hematuria.

A clean-catch midstream urine collection is appropriate for most patients. Catheter-collected specimens are recommended for women with a vaginal discharge, menstrual or vaginal bleeding, or perineal disease. While urethral catheterization may induce hematuria in about 15 percent of patients, the amount rarely exceeds 3 RBCs/hpf. [13]

Convenient, commercially available bedside urine dipstick and pregnancy tests provide useful initial screening examinations. A urine dipstick test for blood can detect as little as 150 μg/L of free hemoglobin, corresponding to 5 to 20 intact RBCs/μL on microscopic analysis. False-negative results may be obtained with urine dipstick tests for blood if the urine has a high concentration of ascorbic acid (more than 5 mg/dL) or a high specific gravity. False-positive results occur when oxidizing agents are present (e.g., household bleach used in cleaning containers) and in the presence of free hemoglobin, myoglobin, or porphyrins. Povidone-iodine may also result in a false-positive urine dipstick test result for blood. The urine dipstick test also provides useful information regarding infection (positive leukocyte esterase or nitrite test results), proteinuria, glycosuria, and ketonuria.

When results of the initial urine dipstick screening examination are positive or unavailable, or the clinical picture is highly suspicious for a urinary tract cause, a formal urinalysis is indicated. Abnormal RBC morphologic characteristics, RBC casts, and proteinuria suggest a glomerular source and the need for further nephrologic or hematologic workup. [14] Such patients typically do not require emergent renal imaging. The finding of normal RBCs on microscopic examination of the urine together with bacteriuria and leukocytes in a young healthy patient supports urinary tract infection as the probable cause of hematuria. If leukocytes are plentiful (more than 20 WBCs/hpf) and clumped, and the patient also has back pain and fever, then pyelonephritis is likely. The presence of normal RBCs without evidence of infection should prompt further urologic evaluation to determine the site of bleeding.

Strenuous exercise is a frequent cause of hematuria and follow-up is recommended even in cases of prompt resolution. [1,10,11,16] Patients taking anticoagulants must have appropriate hematologic studies performed in the ED with imaging studies indicated in follow-up for most older patients in order to exclude malignancy. [8]

A minority of patients (5 to 15 percent) with acute symptomatic urinary lithiasis have no hematuria, as measured by a urine dipstick test or formal urinalysis. [15] Thus, those with a clinical picture indicative of nephrolithiasis still require further evaluation. Further laboratory examination depends on the results of the history, physical examination, and presumptive differential diagnosis.

Renal imaging is done with one of three complementary studies: [16] intravenous pyelography (IVP), [17] helical computed tomography (CT) scanning, [18] or renal ultrasound. [19,20] IVP often clearly delineates renal tumor, obstruction, or stones and their precise location. [17] Renal function studies should be obtained first in older

patients, diabetics, and those with preexisting renal disease. The IVP does not directly assess the aorta, retroperitoneum, and pelvis.

Helical (ultrafast) CT scanning without contrast material is highly sensitive and specific in identifying nephrolithiasis. [18] In cases where no stone is identified, intravenous contrast infusion may also be performed and other structures evaluated at the same time.

Renal ultrasound is useful when screening for obstruction, hydronephrosis, or AAA. It is the study of choice in pregnant patients with suspected nephrolithiasis. [19,20] The presence of two kidneys can be confirmed, and they can be measured and screened for tumors or cysts. The pelvis, abdomen, and retroperitoneum can be scanned for free fluid, mass, or aneurysm. However, renal ultrasound rarely identifies or locates stones in the ureters that are not large enough to give findings of obstruction.

Gross hematuria in patients with blunt or penetrating trauma to the abdomen, flank, or back warrants an aggressive approach to identify the source of bleeding and to guide management.[21,22] For detailed discussion, see Chap. 252, Chap. 253, and Chap. 254. The incidence of significant urinary injury after blunt trauma is much lower, and imaging may not be required in all patients. Some trauma centers use the degree of hematuria, quantified as the number of red blood cells per high-power field, to decide which patients to image. While such an approach is not universally accepted, the studies indicate that patients with relatively minor blunt trauma to the back or flank (e.g., punched, kicked, fall of less than 10 ft) with low levels of microscopic hematuria (less than 20 RBCs/hpf) rarely have significant urinary injury. If they are stable, such patients can be discharged with careful return instructions and referred for repeat urinalysis.

Treatment and Disposition

Treatment of hematuria is directed at the cause. Urinary tract infections should be treated with appropriate antibiotics. Nephrolithiasis should be treated with hydration and analgesics. Systemic diseases should be appropriately treated. Outpatient management and referral for follow-up are appropriate in hemodynamically stable patients without an apparently life-threatening cause. Patients who are discharged should have no or minimal symptoms; be able to tolerate oral fluids, antibiotics, and analgesics as indicated; and have no significant comorbid conditions. Patients should not have significant anemia or acute renal insufficiency.

Patients under 40 years of age should be referred to a primary care physician for repeat urinalysis 1 to 2 weeks after treatment. Persistent hematuria warrants urologic evaluation. Stable patients over 40 otherwise fitting the low-risk profile outlined above can also be evaluated as outpatients, but in these cases cancer is higher on the differential diagnosis list, and referral to a urologist for more immediate outpatient workup is indicated. Children should have pediatric consultation or referral. HIV-positive patients with asymptomatic microscopic hematuria who have a benign urologic history and normal renal function can be safely referred for outpatient follow-up and repeat urinalysis.

Patients with intractable pain, intolerance of oral fluids and medications, significant comorbid illness, evidence of hemodynamic instability, or possibly life-threatening causes of hematuria should be admitted. Patients with suspected or newly diagnosed glomerulonephritis are at high risk of developing complications, such as pulmonary edema, volume overload, azotemia, or hypertensive emergency, and should be admitted with immediate consultation. In pregnant women, hematuria can accompany preeclampsia, pyelonephritis, or obstructing nephrolithiasis, and consultation and admission are indicated.

HEMATOSPERMIA

Hemospermia, or hematospermia, is a disturbing symptom that produces extreme anxiety in sexually active males. Most seek medical attention after one or two occurrences. Any process that results in trauma or other injury (e.g., tumor with erosion), inflammation, or infection of the male ejaculatory system may result in bloody semen.[23] The most common cause of hematospermia is iatrogenic trauma from instrumentation of the urinary tract or radiation therapy. Patients over 40 in particular may have tumors of the prostate or elsewhere in the ejaculatory system. Benign prostatic hypertrophy can cause hematospermia. In patients under 40, common causes are infections and inflammatory conditions, including prostatitis, seminal vesiculitis, urethritis, sexually transmitted diseases, epididymo-orchitis, calculi with inflammation, and tuberculosis. Testicular tumors occur in the younger population. Vascular abnormalities and cysts causing ductal obstruction are less common causes. As with hematuria, systemic factors may cause hematospermia, including hemophilia, other coagulopathy, oral anticoagulation, severe hypertension, leukemia or other hematologic disease, lymphoma, and scurvy.

A careful history, including sexual history, recent urologic procedures, medications, and HIV and tuberculosis risk factors, should be taken in the emergency department. The patient's general health and condition, vital signs, abdomen, external genitalia, and prostate should be examined. Because hematospermia may be the initial and only presenting complaint in underlying urologic disease, a urinalysis is generally warranted, and treatment and disposition are directed by the urinalysis findings (see "Diagnosis," under "Hematuria," above).

Hematospermia has long been considered a benign condition and is usually diagnosed as idiopathic even after a complete urologic workup. It is not uncommon after vigorous sexual activity. Infection, including sexually transmitted disease, should be considered and treated appropriately in the emergency department. In the absence of other reasons for an expedited workup or admission, patients should be referred to a urologist for follow-up and further outpatient evaluation. Patients under 40 can be reassured that the vast majority of cases of hematospermia in their age group are benign, self-limited, and idiopathic. While all patients with hematospermia should be referred to a urologist, those over 40 are at higher risk for cancer and should be strongly advised to seek further evaluation by a urologist even when there is spontaneous resolution of hematospermia.

94 COMPLICATIONS OF UROLOGIC PROCEDURES

Elaine B. Josephson
Anthony Gomez

Urologic surgical procedures are being more commonly performed with outpatients or with inpatients who are discharged from the hospital earlier in their postoperative course. Thus, patients often come to the emergency department with complications common to these urologic surgeries: urinary tract infection (UTI), acute renal failure (ARF), wound infection, urinary retention, pain, and fever. Whenever possible, the urologist who performed the original operation should be contacted when one of their patients comes to the emergency department with a complication from the procedure.

Although various problems in the postoperative phase are common to many procedures, the specific complications of surgery involving the prostate, renal/ureteral system, and vasectomies warrant special attention.

PROSTATE SURGICAL PROCEDURES

Prostate surgery is usually performed for either benign prostatic hyperplasia (BPH) or prostate cancer. Common surgical techniques employed include transurethral resection of prostate (TURP), transurethral incision of prostate (TUIP), transurethral laser/vaporization, and transurethral microwave thermotherapy.

Surgical procedures of the prostate typically involve direct manipulation of the urinary outflow tract. Therefore, common complications include hematuria, clots with subsequent urinary retention, urethral strictures, and urinary tract infections. Some patients experience obstructive or irritative voiding symptoms that may include incontinence, hesitancy, dribbling, urgency, and frequency. [1,2,3 and 4]

The overall rate of serious complications is low. [1,2,3 and 4] If bleeding is significant, however, patients should be evaluated for hemodynamic stability, intravenous fluids administered, and appropriate laboratory studies ordered [complete blood cell count (CBC), renal function (BUN/creatinine), and urinalysis (U/A)]. Outflow obstruction should be relieved by placing a triple-lumen urethral catheter and irrigating with saline to remove clots. If infection is present, antibiotics should be administered. An urologist should be consulted.

RENAL/URETERAL SURGICAL PROCEDURES

Lithotripsy (ESWL)

Extracorporeal shock wave lithotripsy (ESWL) involves the use of high-intensity sound waves to break up calculi within the genitourinary system. The main advantage with this technique in dealing with nephrolithiasis is its noninvasive nature. Overall morbidity with ESWL is quite low. Typically, patients with post-ESWL complications may come to the emergency department with the following signs and symptoms: nausea, vomiting (especially 48 h after the procedure), skin ecchymosis, pain, or ureteral colic and fever. [5,6,7 and 8]

Steinstrasse ("street of stone") refers to the post-ESWL dispersal of calculi usually located within the ureters. It is when an accumulation of these calculi, or a single large fragment becomes lodged that subsequent groin pain, urinary obstruction, and superimposed infection can ensue. [6,7] Steinstrasse is usually visible on a plain abdominal radiograph.

A potentially more serious post-ESWL entity, although rare, is a perirenal hematoma, usually secondary to subcapsular renal hemorrhage. Perirenal hematoma is suspected when there is significant and severe flank pain and evidence of hemorrhage (flank hematoma or fall in hematocrit). The diagnosis is made with computed tomography (CT) or ultrasound. Patients require close monitoring of hemodynamic status and laboratory studies to assess for decreasing hematocrit and renal function. [5,6,8]

In managing postprocedural complications of ESWL patients, supportive therapy is important: intravenous fluid hydration, antiemetics (if needed), and pain management, as well as antibiotic therapy, if indicated. An urologist should be contacted early on for possible surgical intervention if there is a concern regarding complicated Steinstrasse or a perirenal hematoma.

VASECTOMIES

Vasectomies are often done in an outpatient setting. Acute complications that may present to the emergency department include local wound infection (cellulitis or abscess), scrotal hematoma, and epididymitis. [9] Some patients may present months to years later with chronic testicular pain. [10]

Patients should receive appropriate pain management and antibiotics, when indicated, especially in cases of immunosuppression. When there is no evidence of bleeding or wound infection, treatment options for postvasectomy epididymitis include ice packs, scrotal support and analgesia with nonsteroidal anti-inflammatory medications. For patients with suspicion of testicular abscess (diffuse pain and swelling, often with fever), scrotal ultrasound should be used. An urologist should be consulted for testicular abscess, and scrotal hematoma in case surgery is needed to control bleeding.

95 COMPLICATIONS OF UROLOGIC DEVICES

C. Richard Ross
Edward Lee

Urologic devices are frequently encountered in the emergency department; these range from a Foley catheter to an artificial urinary sphincter. Complications of these devices are not uncommon and as they can occur in a relatively dramatic manner (e.g., urinary retention) or produce intense pain in a very sensitive region (e.g., unremovable penile ring). Patients typically present in an emergent manner and often are very distraught. Early recognition of the complication, along with timely treatment and consultation, are the goals of emergency physicians.

COMPLICATIONS OF URINARY CATHETERS

Infection

Urinary tract infection (UTI) is the most common nosocomial infection, accounting for 40 percent of hospital-acquired infections. As many as 25 percent of patients admitted to academic hospitals have a catheter placed during their stay and, of these, between 10 and 30 percent will develop bacteriuria. Nearly all patients catheterized for longer than 30 days will develop a bacteriuria. [1]

The bacteriuria appears to be as a result of direct inoculation along the inner and outer surfaces of the catheter. Women tend to be infected via the periurethral route, with approximately 70 percent of UTIs being caused by rectal flora, whereas the majority of UTIs in men occur through the intraluminal route. Prevention of bacteriuria in the setting of indwelling catheterization is best accomplished through routine cleaning of the urethral meatus and use of closed drainage systems.

A large number of patients are catheterized while hospitalized, and a portion of those will develop a UTI after discharge and may return to the emergency department with symptoms. The most common pathogens associated with short-term catheter-related UTIs are well known (Table 95-1). Although more than 70 percent of patients will clear a bacteriuria after catheter removal, symptomatic patients should receive antimicrobial treatment.

Escherichia coli
Enterococci
Pseudomonas aeruginosa
Klebsiella pneumoniae
Proteus mirabilis
Enterobacter sp.
Staphylococcus epidermidis
Staphylococcus aureus

TABLE 95-1   Common Bacterial Pathogens in Short-Term Catheter-Associated Urinary Tract Infection

Most catheter-related UTIs experienced in the emergency department setting are seen in patients with long-term indwelling catheters. It has been estimated that as many as 100,000 patients in nursing homes in the United States are catheterized at any given time. The prevalence of bacteriuria in this population is 100 percent, with as many as 95 percent of patients growing two or more strains of bacteria. Pathogens present in long-term catheterized patients are similar to those present in the short-term catheterization population, with the addition of *Providencia stuartii, Morganella morganii, Pseudomonas* sp., and *Candida* sp.

Most patients requiring long-term catheterization have underlying illnesses and, as such, are subject to increased morbidity and mortality as a result of catheter-related complications. In elderly catheterized patients, as many as two-thirds of febrile illnesses are a result of UTI. [2] Despite this, little has been shown to reduce bacteriuria and its complications significantly in patients with indwelling catheters. Routine antibiotic prophylaxis has been shown to postpone bacteriuria but does not prevent it in long-term catheterized patients and can result in infection with resistant organisms. Similarly, treatment of asymptomatic bacteriuria is not indicated. Chronic intermittent catheterization has a lower rate of bacteriuria and, as such, is an alternative to long-term catheterization in select patients.

Traumatic Complications

Trauma to the urethra can occur during catheterization. A false lumen can be created if excessive force is applied during insertion, especially in patients with underlying urethral stricture or prostatic enlargement. This usually occurs at the level of the proximal bulbous urethra. Signs of false lumen include bleeding, pain, and lack of urine output. This complication can be avoided by using either a large catheter (20 French or larger) or a Coudé-tipped catheter in order to pass an obstruction while using less force. Prolonged suprapubic or transurethral drainage can correct most false lumens, but surgical intervention may be required.

The urethra can also be damaged by inflation of the retention balloon within the urethra. Pain or resistance encountered during balloon inflation may indicate that the balloon is located within the urethra. Forceful removal of the catheter with the balloon fully or partially inflated will also cause urethral damage and edema. Prompt recatheterization is indicated in this situation to avoid subsequent urethral obstruction.

The erosion of the glans penis and necrosis of the urethra that can develop in patients with long-term catheterization can be avoided by properly anchoring the catheter so as to lessen any tension that is exerted on the meatus or urethra. Patients with penile prostheses are at particular risk for urethral necrosis and erosion as a result of urethral compression. Scarring at the site of urethral necrosis can lead to stricture formation. This is much more common in male patients and often presents as difficulty in catheterization. Diagnosis is made by retrograde urethrogram, and treatment frequently requires cystoscopic repair.

Damage to the bladder as a result of catheterization can range from mild bladder wall irritation to bladder perforation. Chronic indwelling catheters produce histologic changes to the bladder wall. Polypoid cystitis, a benign inflammatory reaction, develops after approximately 30 days but is readily reversible upon catheter removal. Squamous cell carcinoma can also develop as a result of long-term catheterization, however, and should be considered in patients who have hematuria with long-term indwelling catheters.

Perforation of the bladder can also result from catheterization. Long-term indwelling catheters can erode through the bladder wall and perforate the bladder. Catheters may also be passed through the bladder wall during catheterization. Although this is uncommon, its risk is increased if the bladder wall is distended or inflamed. Patients with bladder perforations typically have decreased urine output, pyuria, hematuria, and peritoneal signs. Diagnosis is best made by cystogram, and urologic consultation is required for definitive treatment. Many patients respond well to conservative treatment consisting of bladder drainage and decompression, but operative repair is often required.

Nondraining Catheter

Patients with nondraining catheters can present with incontinent leakage around the catheter or with abdominal distention and pain as a result of acute urinary retention. Although acute retention is direct evidence for obstruction, pericatheter leakage as a result of catheter blockage must be differentiated from either decreased urethral tone or spontaneous detrusor contractions. This can be accomplished by flushing the catheter with sterile water. Obstruction is suggested if the catheter does not easily flush or if there is no return of the irrigant.

Obstruction of the catheter by blood clots often creates a situation in which the catheter is easily flushed, but little or no irrigant is returned. If this occurs, the catheter can be replaced with a triple-lumen catheter so that the bladder can be easily irrigated. If, after clearing the bladder of all clots, evidence of continued bleeding is present, urologic consultation is recommended for possible cystoscopy. Some physicians advocate the use of single-lumen catheters to lavage the bladder, as its larger lumen may aid in the evacuation of larger clots.

Obstruction in long-term indwelling catheters can be caused by encrustation of the areas of the catheter exposed to urine. Ammonium magnesium phosphate (struvite), calcium phosphate, Tamm-Horsfall protein, and bacteria can all be components of encrustation.[3] *Proteus mirabilis* and other urea-splitting organisms contribute to obstruction by promoting struvite crystal formation. Routine catheter changes continue to be the mainstay of prevention, although multiple bladder irrigation solutions are currently in use to extend catheter-change intervals.

Non-Deflating Retention Balloon

A number of factors can lead to a frustrating inability to deflate the retention balloon on a Foley catheter. Mechanical obstruction, which is the most common cause of a non-deflating balloon, can occur as a result of clamping or crushing the inflation channel or can be due to a faulty balloon port valve. Also, filling of the balloon with a fluid other than water can lead to crystal formation with resultant blockage of the inflation channel.

Several techniques have been advanced to deflate retained balloons. If the obstruction is distal, the result of a crush or defective valve, the catheter can be cut proximal to the defect. If this does not deflate the balloon, a lubricated guidewire can be introduced into the cut inflation channel in an attempt to clear the obstruction. If this still fails to deflate the balloon, more invasive techniques can be employed. The balloon can be ruptured within the bladder by a number of techniques. The balloon can be overinflated with sterile water, often requiring 10 to 20 times the normal balloon volume. Chemical disruption can be accomplished by injecting ether, acetone, or mineral oil into the balloon port, or the balloon may be ruptured via a percutaneous suprapubic or transvaginal approach using a 25-gauge spinal needle with or without ultrasound guidance. Catheters should be examined closely for missing balloon fragments, which will often need to be removed by cystoscopy. Prior to attempting any of these techniques, the bladder should be filled with 150 to 200 mL normal saline to minimize injury from balloon fragments and chemical irritation.

Other Complications

Other less common complications of long-term catheterization include urethral fistulae, epididymitis, scrotal abscess, prostatitis, and prostatic abscess.

ALTERNATIVES TO LONG-TERM CATHETERIZATION

As has been previously mentioned, one alternative to long-term catheterization is intermittent catheterization. Another option is the placement of a suprapubic catheter. This type of bladder decompression reduces the incidence of certain complications associated with urethral catheterization. Because the suprapubic catheter does not exert pressure on the urethra or external genitalia, erosion and necrosis of these structures are eliminated. Damage to the urethra during insertion is similarly reduced, although injuries from suprapubic catheter insertion can include perforation of intraabdominal structures, as well as urinoma or abscess formation. Rates of bacteriuria from suprapubic catheters are lower as a result of the lower density of organisms at the catheter's abdominal insertion site.[4]

External urinary drainage devices (condom catheters) are also used for the long-term management of incontinence in men. By virtue of the noninvasive nature of these devices, urethral damage is minimized and introduction of external pathogens is greatly reduced. These devices do not, however, decompress the bladder and are therefore most useful in patients with either a hyperreflexic neurogenic bladder or with incontinence not due to neurogenic causes. Use of the condom catheter is also limited by the ability of the catheter to fit securely to the penis. Complications from these devices most commonly result from pressure necrosis at the area of the roller ring of the condom. These complications can range from nonhealing ulcers to distal penile necrosis.

COMPLICATIONS OF URETERAL STENTS

The common use of ureteral stents has greatly increased since the 19th century, when Gustav Simon first placed a tube into the ureteral opening during an open cystostomy. Ureteral stents are primarily used to support internal upper urinary tract drainage, especially in cases where healing is required. Such uses for stents occur in cases of urinary obstruction from nephrolithiasis, as well as obstruction from external malignancies. Stents can also be placed after surgery involving the urinary tract, as adjunctive therapy to extracorporeal shock-wave lithotripsy (ESWL), or in cases involving trauma to the ureter. Ureteral stents have radiopaque markers and are constructed from polymers, such as polyethylene, C-flex and polyurethane, and silicone, which are flexible and resist encrustation with mineral deposits to varying degrees. Stents employ various shapes at one or both ends to help anchor the stent in the renal pelvis and/or bladder, and prevent migration. The shapes most commonly used are "J" curves or pigtail loops.[5]
